Ketorolac has been evaluated as a perioperative analgesic, as it appears to have greater potency (similar to opioids) than other NSAIDs and an opioid-sparing effect. El-Tahan et al. studied the effect of preoperative ketorolac for CD, randomly assigning 90 patients to receive either IV ketorolac bolus at 15 mg prior to induction followed by infusion at 7.5 mg/h, or saline placebo.[142] The results showed, in part, that 15.6% of patients in the ketorolac group requested postoperative tramadol for analgesia, compared with 31.1% in the control group. The conclusion was that prophylactic ketorolac improved analgesia after CD. A randomized, controlled trial by Lowder et al. compared ketorolac with placebo after CD in 44 patients.[143] The ketorolac group was found to have significantly reduced morphine IV PCA requirements at 24 hours compared to the control group. It was concluded that ketorolac reduced opioid usage and postoperative pain. Another study was performed by Tzeng and Mok to determine the analgesic effect from a combination of ketorolac and low-dose epidural morphine after CD.[144] Ninety patients were enrolled in the study and randomized to three groups to receive postoperatively either (a) epidural morphine 2 mg and IV placebo, (b) epidural morphine 2 mg and IM ketorolac 30 mg, or (c) epidural saline placebo and IM ketorolac 30 mg. Group (b) had significant superior pain relief compared to the other two groups. The addition of ketorolac was thought to enhance the analgesic effect of low-dose epidural morphine.

## Cyclooxygenase-2 inhibitors

These drugs work by selectively inhibiting the COX-2 enzyme, which is involved in prostaglandin synthesis as part of the inflammatory response pathway. COX-2-specific inhibition both reduces the risk of gastrointestinal adverse events and lacks effect on platelet aggregation, in comparison to non-selective COX inhibitors (that block both the COX-1 and COX-2 enzyme), such as naproxen or ibuprofen. A number of COX-2 inhibitors have been withdrawn from the market because of concerns over serious cardiovascular events including valdecoxib and parecoxib.[145] Carvalho et al. randomized patients undergoing CD under spinal anaesthesia with intrathecal morphine 0.1 mg into two groups to receive either valdecoxib 20 mg or placebo. They were unable to demonstrate any significant analgesic effect of this COX-2 inhibitor.[146]

Celecoxib is a COX-2 inhibitor that is still available but it carries a FDA black box warning for possible increased risk of serious cardiovascular and gastrointestinal adverse events.

It is supplied as 50 mg, 100 mg, 200 mg, and 400 mg capsules and is metabolized hepatically, thus dosage adjustments must be made in those with impairment in hepatic function. It should be used with great caution in those with renal insufficiency, as NSAIDs may decrease renal perfusion. Celecoxib has been used in the perioperative period as an adjuvant analgesic and a Cochrane review evaluated the efficacy of a single dose of oral celecoxib for postoperative pain.[147] Eight trials were included. A 200 mg dose of celecoxib was as effective as 600/650 mg of aspirin and 1000 mg of paracetamol for relieving postoperative pain. A dose of 400 mg was as effective as 400 mg of ibuprofen. Adverse event rates were similar with celecoxib and placebo. The conclusion of the study was that a single dose of celecoxib was effective for postoperative pain relief. A 400 mg dose was recommended for acute pain. However, in the obstetric population there is little published work. Lee et al. evaluated a 200 mg oral dose compared to placebo and demonstrated no analgesic benefit whilst Fong et al. reported some analgesic benefit after CD with a 400 mg dose.[148,149] Because of concerns about the cardiovascular side effects of these drugs, currently there is very little evidence to support their use for post-CD pain relief.

## Patient-controlled oral analgesia

One of the disadvantages of IV PCA is that once the opioid PCA is discontinued, patients are no longer in charge of their own analgesia and must traditionally rely on nursing staff to administer medication. This has led to increased interest in patient-controlled oral analgesia (PCOA) programmes using short-acting oral medications for postoperative pain relief. This is gaining particular interest in the United Kingdom as part of enhanced recovery pathways in both obstetric and non-obstetric surgery. CD patients are often given a supply of three types of oral analgesia—paracetamol, ibuprofen, and a opioid-based oral analgesic in hospital with written instructions discussing how and when to take the medication and reinforcing the importance of regular administration to prevent breakthrough pain. Early PCOA studies suggest the benefits of PCOA are similar to IV PCA—that of improved pain control and increased patient satisfaction.[150,151] It is also a simple, low-cost system of analgesia delivery that teaches patients how and when to take pain medication before they are sent home. Further research and controlled trials are necessary to validate its role in the obstetric population.

## Conclusion

Failure to treat acute postoperative pain after CD can have adverse physical and psychological consequences for the patient and the potential to progress to a persistent, chronic pain state. The mainstay of postoperative analgesia for CD encompasses a multimodal regimen based on neuraxial opioids. This provides excellent postoperative analgesia with a decrease in total dose of parenteral opioid, low level of sedation, early ambulation, early return of bowel function, and better maternal–infant bonding with minimal accumulation of the drug in breast milk. However, neuraxial opioids may have side effects and complications; the most serious of which is delayed respiratory depression and these patients must be monitored appropriately postoperatively. Oral analgesia continues to have an important role in the subsequent step-down management of post-CD pain.

CHAPTER 25

# Persistent pain after caesarean delivery and vaginal birth

Patricia Lavand'homme and Fabienne Roelants

## Introduction

Acute pain following surgical intervention is one of the most frequent reasons for patients to seek medical care with some suffering chronic pain and long-lasting disabilities. Among the 20% of the US and European population who report chronic non-cancer pain, the majority are female.[1] Studies on sex-gender differences show that females have a higher incidence of severe pain, which is more anatomically diffuse and longer lasting compared to males[2] with the prevalence of visceral pain being more frequent in females. The abdomen (47%) and the perineal region (38%) are often mentioned as sites for persistent postsurgical pain (PPSP) by patients attending pain clinics.[3]

Few studies have examined long-term health outcomes for women after pregnancy.[4] Although childbirth may be considered a natural process, some deliveries need instrumentation and/or surgical intervention. Since caesarean delivery is one of the most common surgical procedures performed, the assessment of persistent pain after childbirth is therefore of significant interest[5] especially since the majority of women will not spontaneously consult a health professional about their chronic pain.[6] Furthermore, the prevention of chronic pain post surgery is currently a challenge for clinicians as an indicator of the quality of healthcare.

This chapter will review the different persistent pain symptoms, which are seen after vaginal and caesarean delivery, their prevalence, and nature. The possible risk factors as well as some preventive and therapeutic measures will also be discussed

## The definition of persistent pain after childbirth

If we superimpose the definition of persistent pain after childbirth on that of PPSP,[7] persistent pain after childbirth (vaginal delivery or caesarean delivery) is defined as:

- new pain that has developed after childbirth
- pain that lasts at least 2 months after delivery
- other causes for the pain having been excluded (e.g. infection, malignancy) as well as pain from a condition pre-existing to *or* developing during the pregnancy.

There are some limitations to the application of the definition of PPSP to persistent pain after childbirth. Firstly, so far, few studies designed to find the prevalence of persistent pain after childbirth have met this definition because the majority of them did not exclude pre-existing pain. Secondly, the time frame of 2 months usually considered for PPSP has been strongly debated because the exact duration of the inflammatory process caused by tissue injury still remains undetermined. Actually, some authors consider persistent pain as pain still present beyond 3–6 months (often > 6 months) after tissue damage.[8] Finally, as observed in the context of PPSP, the prevalence of persistent pain after childbirth shows some variability caused by the differences in study design including the criteria used to define patients suffering chronic pain, for example, pain intensity, frequency, and impact on the quality of life.

## Outcome of common pain syndromes reported during pregnancy

Chronic pain conditions may exist before pregnancy, as it is not uncommon for women of childbearing age to suffer from chronic pelvic pain, backache, and headaches.

### Pelvic pain of visceral origin

Epidemiological data show that 15% of women of reproductive age report chronic pelvic pain defined as non-cyclic pelvic pain of at least 6 months' duration, of sufficient severity to cause functional disability or to lead to medical care.[9] Chronic pelvic pain before pregnancy, that is, pain at ovulation, dysmenorrhea, or level of cramps during a menstrual period, and suspicion of endometriosis or interstitial cystitis can predispose to preterm delivery[10] and often persists after delivery.[11]

### Pelvic girdle pain and back pain

Pain may also develop during pregnancy and then persist after delivery. Sacroiliac joint and pelvic girdle pain are frequently reported as well as back pain.[12,13] However, symptoms may greatly vary and individuals are affected to different degrees. The prevalence of low back pain episodes may reach 72–77% during pregnancy.[14] Pelvic girdle pain is also common with an incidence rate of 18–56%. The most frequent complaints are located around the sacroiliac joints (76.6%) and the pubic symphysis (57.2%).[13] The pain usually starts in the first trimester of the first pregnancy and worsens with subsequent pregnancies. As with low back pain, the cause of pelvic girdle pain during pregnancy remains unclear. A large cohort follow-up study in Norway reported the presence of

pelvic girdle pain in more than 55% of women during pregnancy with the onset of pain around 17 weeks of gestation.[15] Within 6 months after delivery, 78% of these women had recovered, while 18.5% reported persistent pain at one or two pelvic locations with severe persistent pelvic girdle pain syndrome affecting 0.5% of the women.[15] The recovery rates were lower if women experienced a high level of pain severity at 30 weeks of gestation and 'emotional distress' (as defined in the original paper) during pregnancy.[15] A recent study among women continuing to work during their pregnancy has shown a 43% prevalence of pelvic girdle pain at 12 weeks postpartum.[17] Although the occurrence of back pain or pelvic girdle pain does not affect the outcome of pregnancy, their persistence is often associated with postpartum absence from work, which represents an important socioeconomic problem. Finally, results from a prospective observational cohort have highlighted an incidence of 21% of persistent low back pain developed during pregnancy 2 years after delivery. Patients with persistent low back pain were older, had an earlier onset of severe low back pain symptoms during their pregnancy, and had a higher weight gain, that is, a lower weight loss (inability to reduce weight to their pre-pregnant level) after delivery.[18]

New postdelivery backache is a very frequent complaint expressed by 28–49% of women at 6 months postpartum and by 10–15% at 12 months and later.[19,20] In a prospective study regarding health outcome after delivery, primigravida women who had a caesarean delivery were more likely to report back pain at 6 and 12 months postpartum than women who had a spontaneous vaginal delivery.[20] That finding, however, was not observed in another prospective study showing a prevalence of 11% of back pain at 2 years whatever the mode of delivery.[21] A possible relationship between the use of epidural analgesia during labour and postpartum backache has been questioned but numerous studies do not confirm an increased risk of low back pain after epidural use.[22] According to Breen et al.,[19] the incidence of back pain at 2 months postpartum was unrelated to the use of epidural analgesia and unrelated to the mode of delivery. Predictive factors for back pain included pain during the pregnancy and higher body mass index. Thompson et al.[23] found no statistically significant difference between the use of epidurals or not during labour and backache at 8, 16, and 24 weeks after delivery.

### Headaches

Headaches, either primary (migraine, tension headache) or secondary (postdural puncture headache, pregnancy-related hypertensive disorders, intracranial pathology), are frequently reported in the peripartum period making headache one of the most common reason for seeking medical care during the puerperium.[24,25] Primary headaches represent 75% of the postpartum headaches and are 20 times more frequent than postdural puncture headaches. While migraine headaches generally improve during the pregnancy due to a rapid increase of oestrogens, a high rate of migraine recurrence occurs after delivery.

Approximately 30% of mothers experience severe headaches within the first week of delivery.[25] In a large survey questioning women's health after delivery, the incidence increased from 5.7% up to 25.4% between hospital stay and 18 months postpartum.[20] Interestingly, breastfeeding until 6 months postpartum seems to be a protective factor as it significantly reduces migraine recurrence. In a prospective study dedicated to persistent pain after childbirth, Eisenach et al.[26] reported a headache incidence at 6 months of 18% after vaginal delivery and 0% after caesarean delivery. A history of headaches prior to pregnancy seemed to be the most relevant risk factor to present with headaches during the pregnancy and at 8 weeks postpartum.[25] Other risk factors for postpartum headaches include analgesic use surrounding pregnancy, multiparity, shorter pushing during the second stage of labour, and increasing maternal age.[25] Patients who have headaches during their pregnancy are nearly four times more likely to report headaches shortly after delivery and are three times more likely to experience headaches if they receive needle-based neuraxial anaesthesia for delivery pain treatment. However, the presence of headaches during pregnancy or shortly after delivery does not predict persistent headaches at 8 weeks after childbirth.[25]

### Key points

- Pelvic pain of visceral origin before pregnancy might predispose to preterm delivery and often persists after childbirth.
- Pelvic girdle pain can start around 17 weeks of pregnancy; its prevalence is 18–56% during pregnancy with an incidence of 18.5% of persistent pain at 6 months postdelivery. Low back pain: 72–75% during pregnancy and 21% persisting 2 years after delivery. Predictive risk factors include older patients, large weight gain, and early onset of severe low back pain during pregnancy.
- Postpartum headaches: primary headaches in 75% of the cases. Usually, migraine headaches improve during the pregnancy but with a high rate of recurrence after delivery (30% within the first week).

## Prevalence and characteristics of persistent perineal pain after vaginal delivery

In a large prospective multicentre study, severe acute perineal pain within 36 hours postpartum was present in 10.9% of the women after vaginal delivery while persistent pain at 8 weeks postpartum affected 10% of the women.[27] Patients experiencing severe acute pain after childbirth had a 2.5-fold increased risk of persistent pain and 3.0-fold risk of postpartum depression at 8 weeks postpartum compared with women having mild pain after delivery. In another prospective study, the degree of perineal trauma was responsible for the immediate intensity of pain (from 24 hours until day 7 postpartum), but by 6 weeks postpartum the incidence of perineal pain (around 9%) did not differ among the patients.[28] Therefore, the degree of tissue injury after vaginal birth appears to be independent of the risk to develop persistent pain.[27,28] Studies assessing persistent pain after vaginal delivery have found 2–10% of women with pain at 6 months and later after delivery, almost exclusively in mothers who had an assisted vaginal birth.[21,29,30] The prospective Pain After Delivery (PAD) study reported a much lower prevalence with less than 1% of persistent pain at 1 year.[26]

Two observations, however, need mentioning. First, the nature of persistent pain after vaginal delivery is poorly characterized perhaps because pain complaints localized to perineal areas that are related to sexual function, defaecation, and urination are often considered taboo.[9,31] A survey aimed to determine the prevalence and characteristics of postpartum-onset genital or pelvic

pain found 9% of women continuing to experience pain triggered by both sexual and non-sexual activities at 12 months after delivery, with none receiving treatment.[31] Among these women, 90% reported genital pain and 50% pelvic pain, which began at delivery. A survey assessing postpartum sexual dysfunction after delivery demonstrated that 27.6% of women present with late dyspareunia defined as pain during intercourse at 1 year after childbirth.[32] There was no relation between late postpartum dyspareunia and the mode of vaginal delivery, that is, spontaneous versus instrumental delivery, perineal lacerations or episiotomy. Recent publications suggest that women consult specialists in urology or pain medicine because of severe perineal pain and the interval between birth and the consultation is often long (mean interval from genital tract trauma (i.e. childbirth or surgery) to consultation for pain: 8 months, range 3 months to 20 years).[33,34] Difficult labour with a prolonged second stage and assisted vaginal delivery with/without episiotomy are frequently mentioned as the triggering event. Prospective studies also report the presence of deep abdominal, pelvic, and even buttock/leg pain associated with pain in the genital area.[21,26] Secondly, persistent pain after vaginal delivery might be worse than PPSP after caesarean delivery. Slowly resolving inflammatory reaction and scar tissue formation in the perineum, sometimes associated with deep pelvic pain, causes chronic lower genital tract pain, which may have a major impact on daily life. Indeed, around 11–15% of women complain that such persistent pain interferes significantly with their daily life.[35,36] Women not only mention dyspareunia but also complain when walking or sitting. Genital pain is often described as severe pain (i.e. visual analogue scale score ≥6 out of 10) in both intensity (5.6 ± 1.6) and unpleasantness (5.9 ± 1.9).[31] Retrospective data report intense, unbearable pain in 30% of women after vaginal delivery versus similar pain severity in 10% of women at 1 year after caesarean delivery.[30] In the PAD study, persistent pain at 2 months after childbirth is described as constant daily pain in 60% of women who had a vaginal delivery versus 36% of women who experienced caesarean delivery.[27] At 6 months, average worst pain severity was significantly higher after vaginal delivery (pain scores of 4.5 ± 2.7 out of 10 with 73% of these women taking analgesics) than after caesarean delivery (pain scores of 1.8 ± 1.0 out of 10 with 0% analgesics intake).[26] Finally, although the incidence of pain at 12 months was extremely low, it is worth noting that all the women who had pain underwent a vaginal delivery.[26]

### Key points

- Incidence of perineal pain after vaginal delivery: 10.9% at 24–48 hours; 1–10% at 2–6 months; less than 1% at 1 year
- The degree of perineal trauma:
  - is responsible for the immediate intensity of the pain (from 24 hours to 7 days after delivery)
  - does not seem to be associated with persistent pain (at 2 months and later)
- Dyspareunia (incidence: 9–27% at 12 months after delivery) is not associated with:
  - mode of vaginal delivery (spontaneous, instrumental delivery)
  - presence of lacerations or episiotomy.

## Prevalence and characteristics of persistent pain after caesarean delivery

A majority of studies investigating chronic pain after caesarean delivery are retrospective, including the small original study from Nikolajsen et al.[37] and the large survey 'Listening to Mother II'.[29] These studies report a prevalence after 6 months of approximately 18% of women who complain of pain following their caesarean delivery.[29,30,37] However, the prevalence of disabling pain with a negative impact on the mother's quality of life and on the mother–child relationship is consistently approximately 6% among retrospective studies.[38] Prospective studies are scarce but include a large cohort of patients. Their strength relies on the fact that they focus on 'new' pain related to the surgery and have excluded pre-existing pain. A Canadian study following 917 women with a breech presentation found a persistent pain incidence of 20% at 2 years after caesarean delivery, which reduced to 10% when the pain was restricted to the abdominal wall and within the abdominal cavity but, excluding backache and headache.[21] An Australian cohort survey examining long-term health outcomes after childbirth among 1507 nulliparae reported a similar prevalence of persistent pain in the long term, that is, 8% at 18 months including 1.8% scar pain.[20] Questioning 1228 women, the US PAD study from Eisenach et al.[26] shows an even lower incidence of persistent pain after delivery, as low as 1.8% (95% confidence interval (CI) 1.4–5.3%) at 6 months and 0.3% (95% CI 0.3–1.2%) at 12 months. This study only considered pain that began at delivery and that was not already present before pregnancy nor developed during pregnancy, such as back pain or pelvic girdle pain. Finally, a prospective Australian cohort study including 426 women reports persistent pain at the abdominal wound in 4.2% of women at 12 months after caesarean delivery, with only 1.1% of patients reporting mild constant daily pain.[39] By comparison, the first large study aimed to assess the prevalence of chronic postsurgical pain in a general population reported a prevalence of 18.3% moderate to severe pain in the area of surgery 3–36 months after the procedure.[40] In this survey, 62% of patients had local pain in the area of surgery before surgery. When excluding all these patients from the analysis, 6.2% of patients were left with chronic postsurgical pain. According to a recent meta-analysis, the incidence of persistent pain after gynaecologic surgery (hysterectomy for benign causes) is around 13.7%.[41] By contrast, the very low prevalence of persistent pain observed after childbirth in Eisenach et al.'s[26] and Liu et al.'s studies[39] is intriguing. However, only those subjects who reported pain at 2 months after delivery were followed-up at 6 months, and similarly, only those who reported pain at 6 months were contacted at 12 months.[5] Such follow-up assumes that chronic postsurgical pain is a continuum from acute postoperative pain, an assumption which may be far from the reality. Indeed, other surgical procedures suggest that persistent postsurgical pain may develop later, that is, within the first months as found after inguinal hernia repair and thoracotomy.[42] A recent study assessing persistent pain and sensory disturbances after surgery for breast cancer demonstrated that persistent pain is not static but seems to fluctuate considerably over time.[43] Therefore, the PAD study might have missed some patients who developed neuropathic pain later than within the first 2 months after surgery. Similarly, very little is known about the evolution of visceral pain and deep abdominal pain resulting from a uterine scar or pelvic adherences should not be excluded (Table 25.1).

**Table 25.1** Prevalence of pain after caesarean delivery compared with other surgical procedures

| | Severe acute pain (<36 hours) | Sub-acute pain (at 2 months) | Persistent pain (>6 months) | Neuropathic component in persistent pain |
|---|---|---|---|---|
| Caesarean delivery | 17% | 9% (9–16%) | 0.3–1.8% (4–10%) | 53–60% |
| Hysterectomy (non-malignant) | – | – | 4.8% (13.7%) | 19% |
| Inguinal hernia | – | 14% | 7% (2.5–19%) | 31–45% |
| All procedures (general adult population) | 30% | – | 6.2% (18.3%) | 24.5% |

Percentages in brackets are found in retrospective studies; other percentages were determined in prospective studies and/or concern new pain directly related to the surgical procedure.

References are in the text.

The nature of persistent postsurgical pain is still unclear in many cases because inflammatory mechanisms play an important role even in the development of neuropathic pain.[8] Recent arguments are in favour of a predominant neuropathic origin as there is a strong association between sensory disturbances such as hypoesthesia and hyperesthesia and the presence and the intensity of chronic postsurgical pain;[40] some surgical procedures appear to carry a higher risk than others.[41] After caesarean delivery, pain may result from nerve entrapment, caesarean scar problems, or pelvic adhesions.[44] In other words, scar pain (i.e. neuropathic pain) and deep intra-abdominal pain (i.e. visceral pain) may develop and even coexist. Retrospective studies usually mention pain as located at the site of (or very close to) the surgical incision.[29,30,37] In the prospective studies, deep intra-abdominal pain and pelvic pain are also reported although pain in the area of incision seems to dominate.[21,26] A Pfannenstiel incision is commonly used for caesarean delivery; its advantages include a low incidence of incisional hernia and an aesthetic scar. However, the risk of ilio-inguinal and ilio-hypogastric nerve entrapment related to the technique is real; up to 32% of women who have undergone obstetric or gynaecologic procedures with a Pfannenstiel incision report PPSP at incision site up to 2 years after surgery (7% suffering severe pain).[45] Few studies have used adequate screening tools to characterize abdominal pain after caesarean delivery. Bollag et al.[46] have found persistent pain as predominantly neuropathic in 56%, 50%, and 26% of the patients at 3, 6, and 12 months after caesarean delivery, respectively. The French study 'EDONIS',[47,48] a prospective epidemiological study, aimed to assess the prevalence and possible neuropathic character of postsurgical pain mentions a 6-month cumulative incidence of persistent pain after caesarean delivery of approximately 20%, with an established neuropathic origin in 61% of the cases. It is interesting to note that the reported pain intensity was generally low (pain score > 3/10 in only 2% of the patients). The low intensity of neuropathic pain diagnosed after caesarean delivery is intriguing. According to the EDONIS results, neuropathic pain following other procedures (e.g. breast surgery, thoracotomy, and varicose vein surgery) is perceived as much more painful.[47,48] Furthermore, in the literature, chronic pain of neuropathic origin is usually associated with higher pain intensity (average pain scores of approximately 7–8/10) than non-neuropathic chronic pain.[49] In other published studies as well, more than 85% of patients with persistent pain at 6 months after caesarean delivery rated their pain as low (average pain score of 2/10),[21,26,30,39] including the affective descriptors associated with the pain experience.[46]

As previously highlighted, childbirth may cause persistent pain located in the pelvic area and/or the deep abdomen. Chronic pelvic pain is a common gynaecological problem which concerns 15–24% of women of reproductive age.[9,50] Chronic pelvic pain is defined by the American College of Obstetricians and Gynecologists as non-cyclic pelvic pain localized in the lower abdomen, anatomical pelvis, lumbosacral back, or buttocks, present for at least 6 months, and which is of sufficient severity to cause functional disability or lead to medical care.[9] According to the prospective studies published to date, persistent pelvic pain and deep abdominal pain may occur independent of the type of delivery, that is, vaginal or caesarean delivery. In the PAD study, among the few women reporting persistent pain at 6 months after childbirth, 53% mention a pelvic pain location and 24% a deep intra-abdominal pain, whatever the type of delivery.[26] Two other large surveys which have examined persistent health problems after childbirth report a 6–10% incidence of persistent pelvic and deep intra-abdominal pain at 12 months and later after either vaginal or caesarean delivery.[20,21] Not surprisingly, in women undergoing a laparoscopy for diagnostic investigation of chronic pelvic pain, among risk factors like pelvic inflammatory diseases and endometriosis, a history of caesarean delivery may be found as the aetiology in 67% of the cases (odds ratio (OR) 3.7).[51] Otherwise, previous caesarean delivery is also an established risk factor for PPSP after hysterectomy for a benign indication (OR 1.5).[50]

### Key points

- Persistent pain after caesarean delivery is uncommon (incidence at 6 months and later, 0.3–1.8%) compared to the rate of PPSP observed after other surgical procedures in a general adult population (average incidence 6.2–18%).
- Although visceral pain, that is, pelvic pain and deep intra-abdominal pain, is also reported after caesarean delivery, the nature of persistent pain is neuropathic (abdominal wall pain) in more than 50% of the cases with a very low intensity which contrasts with the severity of neuropathic pain usually reported by the patients after other surgical procedures.
- A history of caesarean delivery is a risk factor for the development of chronic pelvic pain as well as for PPSP after hysterectomy for non-malignant indication.

## Risk factors for persistent pain after childbirth

Predictive factors for PPSP can be surgery specific, that is, related to tissue trauma, or patient specific.[8] Some studies have tried to predict the risk factors for severe acute pain after delivery, either by vaginal or caesarean delivery. Principal predictors for severe acute postdelivery pain revealed in the PAD study were history

**Table 25.2** Risk factors involved in the development of acute and persistent pain after childbirth

| | Incidence (%) | Risk factors |
|---|---|---|
| Severe acute pain (< 36h postpartum) | CD: 17<br>VD: 10 | History of pain during pregnancy<br>Intensity of menstruation pain<br>Tissue damage caused by delivery<br>Presence of mechanical hyperalgesia surrounding the scar (central sensitization caused by a previous CD) |
| Pain at 8 weeks | CD: 9.2<br>VD: 10 | Severity of acute postpartum pain, i.e. individual pain response to injury |
| Pain at 6 months | CD and VD: 1.8 | Not identified (small sample size) |
| Pain at 12 months | CD and VD: 0.3 | Not identified (small sample size) |

CD, caesarean delivery; VD, vaginal delivery.

Data from Eisenach JC *et al.*, Severity of acute pain after childbirth, but not type of delivery, predicts persistent pain and postpartum depression, *Pain*, Volume 140, pp. 87–94, Copyright © 2008 Elsevier and Bollag L *et al.*, Effect of transversus abdominis plane block with and without clonidine on post-cesarean delivery wound hyperalgesia and pain, *Regional Anesthesia and Pain Medicine*, volume 37, pp. 508–514, Copyright © 2012 Wolters Kluwer Health.

of pain during the pregnancy (relative risk 0.70), pain during menstruation (relative risk 0.44), and giving birth by caesarean delivery (relative risk 1.08).[27] Regarding chronic pain, the low incidence of persistent pain found in prospective studies make further analysis of the potential risk factors difficult (Table 25.2).[26]

## Surgery- and tissue damage-specific risk factors

### Mode of delivery: caesarean versus vaginal delivery, spontaneous versus assisted vaginal delivery

As the rate of caesarean delivery is increasing worldwide for both medical indications and maternal choice, an important debate is now arising over the relationship of the method of delivery to maternal postpartum physical health.[29,44] Three large prospective studies published to date did not find differences in maternal pain outcomes at 12 months and beyond postpartum between caesarean and vaginal delivery.[20,21,26] In the context of vaginal childbirth, the degree of tissue injury appears to be independent of the risk of persistent pain as the extent of perineal trauma was responsible for the immediate intensity of pain (from 24 hours until day 7 postpartum), but by 6–8 weeks postpartum, the incidence of perineal pain did not differ among the patients.[27,28] Finally, retrospective studies indicate no correlation between the mode of birth and persistent pain including late dyspareunia at 12 months after delivery.[31,32,35]

### Elective versus emergency caesarean delivery

One might hypothesize that having an unplanned caesarean delivery could increase the risk of reporting persistent pain as the risk of abdominal wall nerve injury may be higher during emergency procedures.[45] Furthermore, the depth of anaesthesia provided by either general anaesthesia or epidural anaesthesia, two techniques commonly used in cases of non-elective caesarean delivery, might be less effective to prevent nociceptive inputs to reach and to sensitize the central nervous system than spinal anaesthesia usually used in elective procedures.[52] Although an earlier study by Nikolajsen et al.[37] found that patients with persistent pain had more often undergone the procedure under general anaesthesia than spinal anaesthesia (37% versus 17.1% persistent pain at 10 months), a recent prospective study did not find an apparent increase in incidence of persistent pain associated with general versus neuraxial anaesthesia.[39] Furthermore, no published study so far either retrospective[35,36] or prospective[39] mentions emergency caesarean delivery as a significant risk factor for persistent pain by comparison with an elective procedure. Interestingly a trial of vaginal birth has not been associated with an increased risk of developing persistent pain after previous caesarean delivery.[35,36]

### Extent of tissue damage during caesarean delivery

Surgical factors such as operative technique have also been investigated. Closure of the parietal peritoneum is currently debated as this technique not only seems to increase acute postpartum pain but also to enhance the risk of persistent discomfort at 8 months after surgery.[53] The type of incision (i.e. vertical or Pfannenstiel incision) only has an impact on acute pain and does not affect persistent pain.[35,36] Most of the procedures are performed via a Pfannenstiel incision which carries a risk of injury of the lower abdominal wall nerves, with a risk of developing chronic neuropathic pain.[45] Neuropathic pain is frequently involved in persistent pain after caesarean delivery but the reported pain intensity is surprisingly low by comparison with that of neuropathic pain observed in other PPSP. It is worth noting that, not all lesions in the somatosensory system lead to neuropathic pain.[42] Persistent sensory dysfunction can be highlighted in pain-free postsurgical patients (e.g. 20% after hernia repair[54]). Individual related co-factors such as poor capacity of nerve regeneration, decreased pain tolerance related to altered endogenous pain processes, and particular psychological profile play a major role in the development of persistent neuropathic pain after a peripheral nerve lesion.[55]

## Patient-specific risk factors for persistent pain after childbirth

The fact that the degree of tissue trauma by itself (e.g. caesarean delivery versus vaginal delivery, and peripheral nerve damage) is not a risk factor to develop persistent pain suggests that some individuals may be predisposed to the development of persistent pain. To support this, the recent literature on PPSP, specifically the research on the transition from acute to chronic postsurgical pain, has moved from general risk factors such as gender, age, obesity, and so on to more individualized risk factors.[42,56–58] This view is confirmed by recent studies aiming to develop a risk index for the prediction of chronic postsurgical pain.[59]

### Severe early postpartum pain as an individual risk factor

Poorly relieved acute pain is commonly mentioned as a striking risk factor for PPSP and severe acute pain is involved in the transition from acute to chronic pain.[4,8] It is still unclear why acute pain

severity may increase the risk for PPSP: the risk may be due either to an increased individual susceptibility to develop both acute and chronic pain condition or to the fact that inadequately managed postoperative pain itself enhances the risk to develop persistent pain. Whatever the mode of delivery, several retrospective studies mention that patients with persistent pain recalled severe acute postpartum pain.[35,37,60] However, all of these studies may suffer major recall bias. Otherwise, the conclusions of two prospective studies, the PAD study and the study from Liu et al.,[39] do not support that finding. Severe acute postpartum pain concerns 17% and 13% of women within the first 36 hours of caesarean and vaginal delivery respectively, and caesarean delivery is associated with a 32.5% increase in acute pain scores by comparison with vaginal delivery.[27] However, acute pain severity, independent of the type of delivery, only predicted an 2.5-fold increase in the risk of persistent pain at 2 months (incidence 10%) but not later (incidence 0.3–1.8%).[26,27]

## Pre-existing chronic pain condition as an individual risk factor

Preoperative pain found in more than 50% of patients undergoing surgery,[40,61] either at the operative site or elsewhere, is one of the most consistent patient-related factors for both severe postoperative pain and PPSP.[4,58,59] Both the presence of a chronic pain condition and the potential regular intake of analgesics may contribute to sensitize the central nervous system and so may favour pain chronicity after tissue injury.[62] All the retrospective studies on chronic pain after childbirth mention the presence of pain elsewhere as a major risk factor for the development of persistent pain after delivery with an OR even superior to that related to the recall of intense acute postdelivery pain (OR 2.5 vs 1.3).[60] In the initial study from Nikolajsen et al.,[37] the occurrence of pain problems elsewhere was reported by 63% of the patients with persistent pain (versus 19% in patients without pain). Kainu et al.[35] also mention chronic pain after childbirth as significantly more common in women with previous pain or any chronic disease (22% versus 12%). In the study by Paterson et al.,[31] only a history of non-genital chronic pain was significantly correlated with persistent postpartum-onset genital pain. The large prospective study, the PAD study,[26] mentions pain history predictors such as pain during pregnancy and pain ratings during menstruation as risk factors for postpartum pain at 24 hours but not later. It is noteworthy that the very low incidence of pain at 6 months later precluded further statistical analysis. Beyond the aforementioned findings, clinical observations show that patients reporting pelvic pain often suffer from more than one pain, that raises the question of potential alterations of endogenous pain modulatory mechanisms rather than only local organ-based mechanisms.[9]

## Hyperalgesia, central sensitization, and altered endogenous pain processing as individual risk factors

Nociceptive inputs from injured tissues trigger a prolonged and usually reversible increased state of nervous system hyperexcitability referred to as central sensitization.[63] This amplification of neural signalling within the central nervous system elicits pain hypersensitivity, which translates into clinical hyperalgesia, mainly evoked by mechanical stimuli. Sustained central sensitization is thought to be one of the mechanisms underlying the development of persistent pain after injury. Secondary hyperalgesia (i.e. mechanical hypersensitivity in uninjured tissues surrounding the wound) has caught particular attention as a surrogate measure of central sensitization after surgery.[64,65] The extent of secondary hyperalgesia may correlate with the risk for PPSP as demonstrated after major abdominal surgery. However, all individuals presenting with secondary mechanical hyperalgesia at 24–48 hours after surgery will not develop PPSP.[42] In humans, clinical data on the incidence, extent, and duration of postoperative secondary hyperalgesia are scarce as this objective parameter is rarely assessed.[62] Moreover, the correlation between postoperative secondary hyperalgesia and the risk of persistent pain is even less frequently investigated. After caesarean delivery with a Pfannenstiel incision, 10–30% of the patients presented with secondary mechanical hyperalgesia surrounding the wound within the first 48 hours[46,66] while less than 15% of the patients reported persistent pain at 3 months and later. In a different study, at 6 weeks postdelivery, the incidence of persistent pain was 16% but that of secondary mechanical hyperalgesia was only 8%.[67] The prospective study from Liu et al.[39] shows that a history of previous caesarean delivery is not a risk factor for persistent pain. Ortner et al.[68] were the first to assess the presence of hyperalgesia surrounding the scar of a previous caesarean delivery in women who came to undergo repeat caesarean delivery. Scar hyperalgesia was present in 41% of the women, at 22 months and later after a previous caesarean section. These women had overall higher acute postoperative pain scores for both somatic pain and visceral cramping pain. Although the later study did not examine the development of persistent pain, it demonstrates that pre-existing hyperalgesia (i.e. a sign of central sensitization) correlated with enhanced acute postoperative pain. Similar findings also exist with hysterectomy where preoperative pain sensitization as reflected by cutaneous and vaginal hypersensitivity was associated with acute pain severity but less predictive to persistent pain.[69]

The preoperative assessment of pain sensitivity may predict to some extent the degree of postoperative pain and the probability to develop persistent pain.[70] Nociceptive signals from damaged tissues undergo a central modulation leading to either attenuation or enhancement of pain. Recent interesting developments have focused on dynamic test paradigms—in contrast with static tests like pain threshold—designed to measure endogenous pain processing and to depict individuals' pain modulation capacity.[57,71] Inter-individual differences in the modulation of endogenous pain perception and modulation place patients at more or less risk to present with severe acute pain or chronic pain.[56] As a consequence, the mechanisms involved in central sensitization, which result from the balance between endogenous inhibitory and excitatory processes, may differ among patients. Although human studies are still scarce, they seem to indicate that patients who display central hyperexcitability or impaired endogenous modulation would be more prone to have a poor outcome after a surgical procedure as found after thoracotomy[72] or major abdominal surgery.[73] Hyperexcitability of endogenous pain processes can be assessed by temporal summation, a surrogate measure of wind-up pain, defined as increased pain from repetitive tactile stimulation.[74] The presence of a positive temporal summation is highly suggestive of an altered central nociceptive processing. As a matter of fact, the presence of a preoperative temporal summation has been associated with enhanced postoperative pain after thoracotomy,[75]

abdominal surgery,[76] and also caesarean delivery.[68] In the later study, the authors also found a positive correlation between the presence of a preoperative scar hyperalgesia and a preoperative positive mechanical temporal summation in women undergoing a repeat caesarean delivery.[68] It is important to note that, beyond its association with postoperative pain intensity, temporal summation might also be predictive of a risk for persistent pain after surgery or trauma as it predicted a poor outcome after spine injury.[77] Also, after herniorrhaphy, mechanical temporal summation was found in 51% of PPSP patients but only in 15% (and at low intensity) in pain-free patients.[54,78] Studies aiming to assess the function of endogenous pain processes during pregnancy and in the immediate postpartum period are currently ongoing.[79]

### Psychosocial vulnerability as individual risk factors

Mental health has an important impact on the patient's willingness to recover. Psychological mechanisms of pain processing (emotion and when pain is perceived as a threat) already known to play a role in chronic pain conditions have recently attracted interest in trauma and perioperative conditions.[42] Obviously, there is a vulnerable population who present with a reduced ability to cope with pain, to anticipate pain, and to control pain when confronted with it. Pain hypervigilance[80] and catastrophization are currently investigated as important mental states to predict both severe postoperative pain and PPSP. In the context of childbirth, their impact may extend beyond the trauma period as, for example, catastrophization not only plays a role in the experience of pain during labour and delivery but also compromises social functioning and recovery after delivery.[81,82] A novel emergent concept is the relation between persistent pain and post-traumatic stress symptoms, and emotional numbing, observed after some trauma or surgical procedures.[42,58] Traumatic birth experiences may be associated with postpartum psychological impairment that could favour persistent pain. As an example, late postpartum dyspareunia seems to be linked more with the mother's experience of childbirth (low satisfaction with delivery) than with perineal trauma.[32]

### Genetic predisposition as an individual risk factor

Over the last few years, major developments in genomic research have shown how genetic variability may affect not only the response to medications including analgesics but also may account for the side effects of the medication. An actual challenge would be to find 'pain genes' allowing to identify individuals with an increased vulnerability to pain and genes which confer an increased risk of developing intense acute pain and chronic pain after tissue injury.[42,58,83] To date, a few reports have identified polymorphisms in human genes associated with some chronic pain conditions. However, none of these genes have been identified as specific markers for the generation of persistent pain after surgery or tissue trauma related to childbirth.[84] Persistent pain after childbirth like PPSP is multifaceted, characterized by multiple sensory-discriminative, affective-emotive, and cognitive variables. By consequence, translating pharmacogenetics into clinical practice is and will remain particularly challenging.[42,58] Nevertheless, several investigators are currently assessing pain modulation tests in combination with genetics to predict an individual's risk of developing persistent pain after tissue trauma.[79,83]

### Key points

- The extent of tissue damage, that is, mode of delivery, influences intensity of acute postpartum pain within the first week but not later.
- Other risk factors such as elective versus emergency caesarean delivery, trial of vaginal birth, or history of previous caesarean delivery have not been associated with an increased risk of developing persistent pain.
- An individual's pain response seems to be the most relevant factor in the development of persistent pain.
- In retrospective studies, patient-specific risk factors, for example, pre-existing chronic pain conditions or pain elsewhere as well as severity of immediate postpartum pain, were predictive of an increased risk of persistent pain after childbirth.
- Psychosocial vulnerability and genetic factors might be involved but further studies are needed.

## Does childbirth have a protective mechanism against pain?

Lower incidence of persistent pain after delivery, independent of the degree of tissue injury, by comparison with common surgical procedures, questions whether it might not be due to protective biological or psychosocial factors occurring during the puerperium.[26] Some experimental data support that hypothesis by demonstrating a reversal of hypersensitivity induced by peripheral nerve injury in rats during the postpartum period but not during the pregnancy itself.[85] First, endogenous oxytocin might exert protective effects by spinal inhibitory modulation of pain transmission and/or central modulation of the negative emotional experience related to pain at the supraspinal level (i.e. in the amygdale).[85] Increased postpartum oxytocin levels have been associated with elevated mood and decreased anxiety.[86] Second, the puerperium also seems to alter endogenous pain processes in favour of an inhibitory balance as the density of spinal noradrenergic inhibitory fibres increases following nerve injury in the postpartum period.[87]

## Prevention and management of persistent pain after childbirth

Although the prevalence of persistent pain after childbirth seems to be low, for the women who suffer persistent pain, this significantly affects their quality of life and also interferes with the mother–child bonding relationship. It is interesting to point out that a majority of women do not consult a health professional even if they feel that they need advice.[6] Furthermore, there is still a lack of education regarding pain relief in the postpartum period. There may be inadequate analgesic intake during the breastfeeding period for which both the caregivers and the mothers must take responsibility.

As 'prevention is better than cure', the evidence favours a preventive approach. However, very few studies have been designed to examine the possibility that PPSP can be prevented or attenuated.[58] In the context of obstetrics, peripartum administration of intravenous magnesium sulphate,[67] ketamine,[88] oral

gabapentin,[89] and spinal clonidine[66] have failed to prevent the development of persistent pain after caesarean delivery. It is worth noting that these preventive treatments have been administered to all the women without any attempt of individualization which might explain the lack of effect observed.[42]

In a more practical way, the extent of tissue injury during childbirth (e.g. a nerve injury) accounts for the intensity of acute postpartum pain and might cause persistent pain in predisposed patients. Consequently, as a first-line preventive measure, the obstetrician should ensure the least traumatic delivery possible. More importantly, obstetricians and all care providers should offer any patient the opportunity to contact them in case of any postpartum problem. If dealing with pain postpartum, the patients might be directed as soon as possible to an obstetric anaesthetist in the first instance, then if pain persists, to a pain specialist.[90] After tissue injury, the subacute pain period remains a grey zone which however might play an important role in the chronicity of the pain.[42] Finally, it should be pointed out that the use of systemic analgesics is restricted in breastfeeding women due to the concerns about the excretion of drugs in the breast milk and hence the potential toxicity for the infant. Therefore, if indicated, local analgesic treatments will be preferable, for example, scar infiltration of the abdominal wall,[91] intravaginal injection,[33] or pudendal block,[92] using a combination of corticosteroids and local anaesthetics. Beyond their diagnostic value, these nerve blocks may provide long-term pain relief in some patients. In case of intractable persistent pain caused by a nerve entrapment, the surgical neurectomy may represent an effective solution.[90,91]

## Conclusion

Excluding pre-existing pain or pain which developed during pregnancy, prospective studies show a surprisingly low prevalence of persistent pain after childbirth, much lower than the prevalence reported in retrospective studies and that of PPSP in a general population for similar procedures. The nature of persistent pain itself remains poorly characterized, particularly after vaginal delivery, and seems predominantly neuropathic after caesarean delivery but with a lower intensity than usually reported for chronic neuropathic pain. Finally, the fact that the type of delivery and the degree of tissue trauma do not seem to impact on the risk to develop persistent pain seems to suggest that individual factors may place people at risk for persistent pain, and furthermore, that protective mechanisms may occur during the peripartum as demonstrated in experimental studies.

PART 7

# Anaesthetic complications

# CHAPTER 26

# Management of the difficult airway

Mary C. Mushambi and Rajesh Pandey

## Introduction

Over the past four decades, mortality primarily due to anaesthesia has declined from 1/2500 to 1/5000,[1] but the causes of death during anaesthesia have remained the same. Inadequate airway management is one of the four leading causes of anaesthetic-related deaths and the factors contributing to this are human error, inadequate communication, substandard care, lack of supervision and organizational issues.[2,3]

In the United Kingdom, the Confidential Enquiry into Maternal Deaths (CEMD) has been publishing reports continuously for the last six decades. The numbers of direct deaths from anaesthesia have declined from 30–50 deaths in each triennium until 1981 to seven deaths in the 2006–2008 triennium. Mortality is usually associated with general anaesthesia (GA) and only a minority of deaths are associated with neuraxial anaesthesia. The major causes of death from GA are either failure to oxygenate the lungs at the time of intubation or aspiration of gastric contents.[4] The rates of caesarean delivery (CD) in the United Kingdom have increased over the last four decades (3.4% to 21% of all maternities) but the rate of direct deaths due to anaesthesia for CD has declined from 36 (1964–1966) to 1 (2000–2002) per 100,000 CDs. There has been a significant decrease in the rate of GA for CD from 77% in 1982 to 44% in1992 to 10% in 2001.[5,6] According to the National Obstetric Anaesthetic Database (NOAD), 91% of all CDs are performed under neuraxial anaesthesia[7] and the Royal College of Anaesthetists' audit recipe suggests that greater than 95% of elective CDs should be performed under neuraxial anaesthesia.[8] In the latest Centre for Maternal and Child Enquiries (CMACE) report, two of seven anaesthetic deaths were a result of failure to ventilate and the recommendation was that effective management of failed tracheal intubation is a core anaesthetic skill which should be taught and rehearsed regularly [4] and the use of simulation for teaching and rehearsing failed intubation drills is strongly recommended.

The four obstetric cases reported to the 4th National Audit Project (NAP4) were associated with failed tracheal intubation during emergency CD.[9] The learning points and recommendations of the audit are summarized in Box 26.1.

## Definitions

Several attempts have been made to define the difficult airway. The practice guidelines of the American Society of Anesthesiologists (ASA) define a *difficult airway* as the clinical situation in which a conventionally trained anaesthesiologist experiences difficulties with face mask ventilation of the lungs, difficulty with tracheal intubation and ventilation, or both.[10]

The two main objectives of airway management during GA are *maintaining oxygenation* and *ventilation of the lungs*, which can be achieved either by mask ventilation or by means of an airway device (supraglottic airway device (SAD) or tracheal tube). Therefore an alternative method of defining a difficult airway is based on the stage of airway management when difficulty is encountered.

The ASA defined *difficult mask ventilation* as a clinical situation that develops when it is not possible for the anaesthetist to provide adequate face mask ventilation as a result of one or more of the following problems: inadequate mask seal, excessive gas leak, or excessive resistance to ingress or egress of gas.[10] They described the signs of inadequate face mask ventilation as:

- absent or inadequate chest movement or breath sounds
- gastric air entry or dilatation
- decreasing or inadequate oxygen saturation
- decreasing or inadequate expired carbon dioxide
- haemodynamic changes associated with hypoxaemia or hypercapnia.

A four-point scale to grade difficulty in performing mask ventilation was proposed by Han and colleagues and modified by Kherterpal:[11,12]

- Grade 1—ventilation is possible with mask alone
- Grade 2—ventilation achieved with an oropharyngeal airway or muscle relaxant (neuromuscular blockade (NMB))
- Grade 3—difficult mask ventilation requiring additional manual assistance ± NMB
- Grade 4—ventilation is not possible with a mask.

**Box 26.1** Learning points and recommendations of the 4th National Audit Project (NAP4) on major complications of airway management in the United Kingdom

**Learning points**

1. Physiological changes in pregnancy, active labour, and isolated location increase the complexity of management of airway complications when they occur
2. All theatre personnel (obstetricians, midwives, and ODPs) should be aware of the considerable difficulty in managing airway complications in obstetric patients
3. Three of four parturients were obese and had complex obstetric, medical, and anaesthetic issues
4. While preparing failed intubation strategies, it should be recognized that it is not always possible to wake the patient
5. Decisions regarding management of complex patients require multidisciplinary collaboration when forming initial and back-up plans.

**Recommendations**

1. Obstetric anaesthetists should maintain airway skills which include management of difficult and failed tracheal intubation and CICV[a]
2. Obstetric anaesthetists should be competent in the use the second-generation SADs[b] which give better protection against aspiration and facilitate ventilation and/or intubation
3. Anaesthetic departments should ensure airway skills and equipment are available whenever awake fibreoptic intubation is indicated
4. Recovery staff including midwives should be trained and be competent to recover patients following an anaesthetic.

[a] Can't intubate, can't ventilate.
[b] Supraglottic airway devices.

Grades 3 and 4 are most likely to alter a future anaesthetic plan hence these should be documented in the patient's notes. However, the degree of difficult mask ventilation is also dependent on the skill and experience of the anaesthetist. The incidence of difficult mask ventilation is 1.4–5% and impossible mask ventilation is 0.07–0.16%.[12,13]

The laryngeal mask airway (LMA) has an established role as a routine airway device and also as a rescue device in a difficult airway. A *difficult LMA* is when the LMA is unable to provide adequate airway patency, oxygenation, and ventilation despite correct selection of the laryngeal mask size and provision of optimal airway opening manoeuvres when inserted. The signs of inadequate ventilation are similar to those with difficult mask ventilation.

*Difficult laryngoscopy* is the inability to visualize any portion of the vocal cords after multiple attempts at conventional laryngoscopy. A definition of difficult laryngoscopy was proposed by Cormack and Lehane (CL),[14] and this has been adopted by anaesthetists worldwide. They classified the view obtained at direct laryngoscopy using a Macintosh blade into four grades (Figure 26.1).

Subsequently, the CL classification has been modified to include a subdivided grade 2 (2a and 2b).[15] An easy grade 2a is where part of the vocal cords can be seen and a difficult grade 2b is where only the arytenoids are visible. In 2000, Cook proposed another more practical modification of the CL classification and graded the degree of difficulty into easy, restricted and difficult[16] (Table 26.1).

*Difficult tracheal intubation* is considered if more than three attempts are required or it takes longer than 10 minutes to intubate a patient in the presence or absence of tracheal pathology[10] and *failed intubation* occurs when placement of the endotracheal tube fails after multiple intubation attempts. A more appropriate definition reflecting events occurring in clinical practise is definition suggested by the Canadian Task Force[17] which is when an experienced laryngoscopist, using direct laryngoscopy (i) requires more than two attempts with same blade or a change in the blade, (ii) requires an adjunct to a direct laryngoscope such as a bougie, or (iii) uses an alternative device/technique following failed intubation with direct laryngoscopy. A UK national study aimed at estimating rate of failed intubation in obstetrics defined an *obstetric failed intubation* as failure to achieve tracheal intubation during a rapid sequence induction (RSI) for obstetric anaesthesia, thereby initiating a failed intubation drill.[18]

## Incidence of difficult tracheal intubation

Approximately 2.9 million GAs are administered in the United Kingdom every year with tracheal tubes being used in 38% of patients.[9] Of the airway deaths reported to the NAP4, 13% were associated with difficult tracheal intubation.[9] The incidence of failed tracheal intubation is quoted to be 1/300–800[19–21] for all types of emergency surgery (Table 26.2).

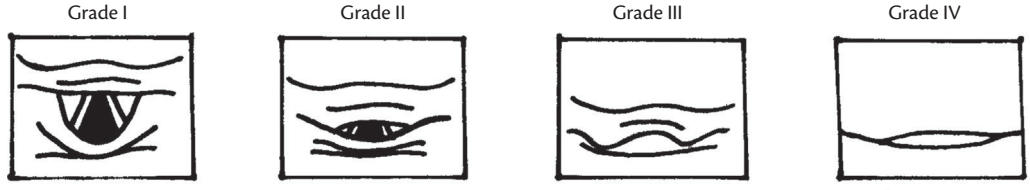

**Figure 26.1** Grading of laryngoscopic view. Grade I: vocal cords visible. Grade II: arytenoids and posterior part of vocal cords visible. Grade III: epiglottis visible. Grade IV: epiglottis not visible.

**Table 26.1** Classification of laryngeal grade: Cormack and Lehane classification and new classification of view at laryngoscopy

| **Cormack and Lehane classification** | **Grade 1** | **Grade 2** | | **Grade 3** | | **Grade 4** |
|---|---|---|---|---|---|---|
| **Modification** | **Grade 1** | **Grade 2A** | **Grade 2B** | **Grade 3A** | **Grade 3B** | **Grade 4** |
| Laryngeal views | Most of cords visible  | Posterior cord visible  | Only arytenoids visible  | Epiglottis visible and liftable  | Epiglottis adherent to pharynx  | No laryngeal structures seen  |
| Method of intubation | Direct | | Indirect | | Specialist | |
| New grading | Easy | | Restricted | | Difficult | |

Since 1985, the incidence of failed intubation in the obstetric patient has largely remained the same at 1/225–300.[18,19,22–27] These studies are summarized in Table 26.3. However, there is a wide variation in the sample size and the experience of anaesthetists in these studies. One study looked at the incidence of failed intubation over a 6-year period in the same maternity unit[22] and another study looked at a wider region including 13 maternity units over 1 year.[25] Despite this, all the studies have shown similar results. The exceptions to this are two studies, one by McKeen[27] (1/1300) and the second by Djabatey[26] (no case of failed intubation), who have shown improvement in the incidence of failed intubation. This improvement has been attributed to the fact that these studies took place in very busy maternity units where there was good antenatal anaesthetic consultation, anaesthetists who were experienced in GA for obstetrics, experienced anaesthetic assistance, and a high epidural rate (80% in the McKeen study[27]). Two studies have demonstrated a relationship between failed intubation and increasing age and obesity.[18,27] A UK national study conducted in 2008–2010 reflects obstetric practice in clinical environments with diverse settings.[18] The incidence of failed intubation in this study was 1/224. With an increase in the prevalence of obesity, rate of CD, and an ageing maternal population, providing safe obstetric anaesthetic care will no doubt continue to be challenging in the future.

## Assessment and prediction of the difficult airway

> Poor airway assessment contributes to poor outcome; this is either due to omission, incomplete assessment or failure to alter the airway management techniques in response to findings at the assessment. (NAP4[9])

Assessment is one of the first steps in managing an airway. However, failure to assess the obstetric airway correctly is a consistent finding in many studies.[9,26] Airway assessment allows the anaesthetist to choose the most appropriate and safest management technique (with backup plans) together with any extra equipment, and anaesthetic and surgical help that may be required.

### When to assess

The airway should be assessed as early as possible in the pregnancy. Ideally, every maternity healthcare professional should be able to identify and understand the consequences of a difficult airway. In the antenatal period, this is usually a midwife or obstetrician, but because of their lack of knowledge and experience, some patients with a difficult airway may not be identified.

**Table 26.2** Incidences of failed intubation[19–21]

Data from various sources (see references).

This can be addressed by ensuring that an anaesthetic referral system is in place. In the United Kingdom, only 30% of hospitals operate a formal anaesthetic clinic whereas the remainder have an ad hoc referral arrangement.[28] A referral checklist (Box 26.2) to identify diseases associated with difficult intubation may increase early identification by non-anaesthetists. Any patient with a body mass index (BMI) higher than 40 at booking should be assessed in the antenatal anaesthetic clinic.[29] Studies have shown an increase in the Mallampati scores with increasing gestation and at different stages of labour.[30–32] Another study demonstrated an increase in Mallampati score at the end of pregnancy but no further changes were noted during labour.[33] The authors attributed their findings to the difference in the amounts of fluids given during labour when compared with previous studies (554 vs 2500 mL in Kodali et al. study[31]) and they postulated that a low-fluid regimen policy might provide better Mallampati scores during labour probably by reducing neck oedema. It is recommended that the airway should be assessed as pregnancy progresses as well as during labour because of these changes in Mallampati scores.

**Box 26.2** Airway related pre-assessment checklist for referral to anaesthetists in the antenatal period in order to identify potential airway problems

1. Previous history of difficult or failed intubation
2. High body mass index > 40
3. Head and neck pathology:
   - Previous radiotherapy
   - Tumours
   - Trauma/burns
   - Previous surgery
4. Musculoskeletal diseases:
   - Rheumatoid arthritis
   - Ankylosing spondylitis
   - Kyphoscoliosis
   - Cervical spine abnormalities
5. History of obstructive sleep apnoea
6. Congenital abnormalities such as:
   - Pierre Robins
   - Treacher Collins
   - Downs
   - Goldenhar
   - Achondroplasia
   - Klippel–Feil
7. Endocrine disorders:
   - Acromegaly
   - Diabetes
8. Autoimmune disorders:
   - Scleroderma.

## How to assess

History, clinical examination, bedside tests, and investigations form the main components of assessing an airway. A good clinical history should include a review of the patient's notes with an emphasis on detecting previous airway difficulties. The presence of conditions such as morbid obesity, tumours of the neck, tumours or infection of the airway, cervical spine immobility, trauma, and congenital malformations of the upper airway are associated with potential airway difficulty. Risk factors for difficult mask ventilation include increased BMI, increased age, history of snoring, obstructive sleep apnoea, lack of teeth, Mallampati class III or IV, and airway tumours. Hence the history should also exclude symptoms suggesting airway pathology such as snoring, obstructive sleep apnoea, dyspnoea, dysphonia, dysphagia, and hoarseness of voice.

Several bedside tests have been described to predict a difficult airway. An ideal bedside test is one that is easy, quick to perform, has very low interobserver variability, and is highly sensitive (ability to detect difficult intubation) and specific (ability to detect easy intubations) with very low false-positive and false-negative values. Unfortunately all the bedside tests have high sensitivity, but low specificity values and moderate interobserver variability. Because of these limitations, when used individually, the tests have a poor positive predictive value (PPV).

Table 26.4 shows a list of simple bedside tests. A single abnormal finding should act as a cautionary sign for GA. However, it is recommended that an alternative anaesthetic plan including awake intubation should be considered if abnormal findings are present.

*Mouth opening* is assessed with the mouth maximally opened and measuring the inter-incisor gap. Normal adults are capable of inserting at least three fingers which corresponds to a mouth opening of between 4 and 6 cm.[34] An inter-incisor gap of greater than 3 cm allows insertion of a standard Macintosh blade. If mouth opening is less than 4 cm, it suggests an increased risk factor for difficult intubation and if it is less than 3 cm, it suggests significant temporomandibular joint dysfunction.[35]

*Mandibular subluxation* assesses the temporomandibular joint mobility. This is assessed by asking the patient to push the lower jaw in front of the upper jaw. If the lower incisors can be moved in front of the upper ones, the trachea is more likely to be easy to intubate but if they cannot, it is more likely to be difficult.[36] The classification is as follows:

- Class A: the lower incisors can be protruded in front of the upper incisors
- Class B: the lower incisors can be advanced to be in line with upper incisors only.
- Class C: the lower incisors cannot be protruded to reach the level of the upper incisors.

**Table 26.4** Suggested list of simple bedside tests to perform in the obstetric patient[18,19, 22–27]

| Airway component to be assessed | Normal findings |
|---|---|
| Mouth opening | Inter-incisor gap ≥ 4cm |
| | Or 3 finger breadths |
| Pharyngeal view | Uvula visible when tongue protruded, patient in sitting position (Mallampati ≤ II) |
| Temporomandibular joint movement | Protrusion of the lower jaw in front of upper jaw |
| Thyromental distance | >6.5 cm |
| Neck mobility | Flexion—can touch chin to chest |
| | Extension—can extend the neck |
| Weight | BMI < 30 or weight < 90 kg |
| (No snoring/obstructive sleep apnoea) | |
| Obvious airway compromise or pathology | |
| Upper airway tumours | |
| Stridor | |
| Voice changes | |
| Oedema (pregnancy-induced hypertension) | |

In 1983, Mallampati[37] evaluated a simple grading system of classifying the *pharyngeal view* obtained with patients sitting upright, head in the neutral position, and asking them to open the mouth and protrude the tongue out maximally. He hypothesized that an increase in the size of the tongue made laryngoscopy difficult. Depending on the visibility of the faucial pillars, soft palate, and the uvula, the view obtained was classified into three grades. This was modified in 1985 when class IV was added when the soft palate was not visible[38] (Figure 26.2). According to the authors, patients with a modified Mallampati score of class III or IV were at risk of a difficult intubation. In 1998, Ezri et al.[39] added a further class zero where the epiglottis is seen, the incidence of class zero was 1% and it was concluded that this was a good predictor of grade I laryngoscopy. However, anecdotal case reports have suggested that laryngoscopy may be difficult in patients with class zero view and this was attributed to a large epiglottis.[40]

A good range of *neck movements* is needed to achieve the optimum intubating position. The patient is asked to touch the chin to the chest and extend the neck maximally. A sternomental distance of less than 12.5 cm,[41] thyromental distance of 6.5 cm or less, and restricted neck movements caused by cervical spine immobility are associated with difficult laryngoscopy.

In spite of the use of several bedside predictors and their association with predicting airway difficulty it is hard to recommend a single test because of lack of good evidence. Although the Mallampati score is used commonly by anaesthetists, it has a low sensitivity and high interobserver variability.[42] A meta-analysis of

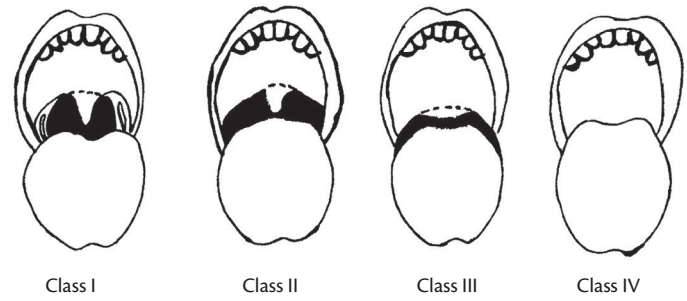

**Figure 26.2** Classification of the pharyngeal structures as seen when conducting the Mallampati test. Class 1: pharyngeal pillars, soft palate, uvula visible. Class II: soft palate and uvula visible. Class III: only soft palate visible. Class IV: soft palate not visible.

55 studies found only 35% of patients with Mallampati score III and IV had difficult intubation. As a stand-alone test of a difficult laryngoscopy or tracheal intubation, it has a low PPV but this is improved if it is combined with other tests such as the thyromental distance and jaw protrusion.[43–45] The ASA Task Force practice guidelines recommend the use of several airway features for prediction and management of difficult airway.[10] Therefore in summary, multiple abnormal tests predicting difficult intubation are better than any single test.

### Communication and documentation

Depending on the severity of the difficulty the anaesthetist should formulate an airway and anaesthetic management plan, discuss the risks and alternatives with the patient and their partners, and document them in the notes. There are many reports on poor documentation of preoperative airway assessment of pregnant women.[18,19,26] Good communication and documentation are extremely important to ensure details of the management plan are available to the team and anaesthetists involved in the final care of the patient. If airway problems are identified antenatally, these patients should be encouraged to have an early epidural which should be reviewed regularly when in labour to ensure that the epidural is functioning well to reduce the chances of requiring a GA. One of the key contributing factors for mortality from inadequate airway management is inadequate, or lack of, communication.[1,46]

## Causes of difficult tracheal intubation in obstetric practice

The reasons for difficult airway and intubation in obstetrics can be divided into anatomical and physiological changes, training, and situational factors and these are summarized in Box 26.3.

### Anatomical and physiological changes

#### Airway oedema

During pregnancy, there is an increase in total body water leading to engorgement and swelling of the nasal mucosa, tongue, pharynx, larynx, and trachea. An increased incidence of Mallampati

**Box 26.3** Causes of difficult airway and tracheal intubation in obstetric practice

**Anatomical and physiological changes**

- ↑ airway oedema and engorgement
- ↑ weight and breasts enlargement
- ↓ FRC
- ↑ oxygen requirements
- ↓ lower oesophageal pressure and ↑ risk of aspiration
- ↓ gastric emptying during labour.

**Training issues**

- ↓ clinical experience of trainees
- ↓ number of general anaesthetic cases for CD per trainee
- ↓ number of CD under general anaesthetic
- ↓ use of STP and suxamethonium for RSI in non-obstetric patients.

**Situational issues**

- Emergency situation and time pressure to deliver the baby
- Application of cricoid pressure on a tilted table
- Remote location of the delivery suite
- Lack of communication with senior staff and between the delivery suite team members.

CD, caesarean delivery; FRC, functional residual capacity; RSI, rapid sequence induction; STP, thiopentone.

score (class III/IV) has been demonstrated from the eighth month of pregnancy and these changes persist until 48 hours after delivery.[32,47] Laryngeal oedema especially in pre-eclamptic women presenting with hoarseness may compromise the airway, therefore a wide selection of tracheal tubes down to 5.5 mm internal diameter should be available when inducing GA in these patients.[48] Engorgement of blood vessels of the airway increases the risks of mucosal bleeding especially if the nasal route is used for fibreoptic intubation and the oral route is therefore the preferred choice.

### Increased weight gain and breast enlargement

Weight gain during pregnancy is due to the growing fetus, increase in maternal fluid volume, and soft tissue. On average, a pregnant woman gains 20 kg during pregnancy of which 3.5 kg is due to storage of fat.[49] Enlargement of the breasts make laryngoscopy difficult. Use of the short-handled laryngoscope or polio blade may overcome this difficulty.

Obesity in pregnancy is defined as a BMI of greater than 30 kg/m$^2$ at booking. The prevalence of maternal obesity in England has increased from 7% (1990) to 16% (2007).[50] One in 1000 pregnant women have a BMI of greater than 50 and have a higher CD rate of 50% compared with 22%. The incidence of failed intubation in obese patients is 15%[51] and for every 1 kg/m$^2$ there is a 7% increased risk of failed intubation.[18] Airway complications are attributed to difficult mask ventilation, short and thick neck, large tongue, and large breasts which make laryngoscopy and intubation difficult. Obesity increases the risk of regurgitation and aspiration because of hiatus hernia and increased gastric reflux and increased gastric volume.[52]

### Effect of the gravid uterus

Enlargement of the uterus displaces the diaphragm cephalad and affects the lung volumes and capacities. A decrease in functional residual capacity (FRC) and increase in oxygen demand decreases overall oxygen reserve. The FRC decreases by 20% in the sitting position and 25% in the recumbent position. As a result, the time taken to desaturate following apnoea is considerably faster in pregnant patients (173 seconds) compared with the non-pregnant patients (243 seconds) and is unaffected by change to a head-up position (pregnant 153 seconds vs non-pregnant 331 seconds).[53]

An increased risk of regurgitation and aspiration is caused by the displacement of the stomach by the gravid uterus and relaxation of the lower oesophageal sphincter. Labour is associated with delayed gastric emptying which is further exacerbated with the use of opioids. All patients should be considered at risk of aspiration during pregnancy.

## Training issues

There has been a considerable reduction in the sum total of all clinical experience gained by trainees because of the introduction of the European Working Time Directive (EWTD). The number of CD performed under GA has reduced over the past few decades[54] and as a result, the number of GAs for CD performed by trainees is decreasing. There is a perceived lack of skill (and especially self-confidence) in mask ventilation because trainees favour the use of SADs. Many trainees have received very little training in the classic RSI using thiopentone and suxamethonium as many senior anaesthetists are choosing to use modified RSI using alternate induction agents and muscle relaxants in non-obstetric patients.[55] The infrequency of difficult and failed intubation means that most trainees would never see a case during their obstetric module.

## Situational issues

The majority of cases of difficult or failed intubations in obstetrics occur during emergencies[9] and the risk of aspiration is further compounded if the mother has recently eaten. The added pressure of delivering the baby quickly means that a relatively inexperienced practitioner in a stressful environment may feel rushed with the preoperative assessment; this compounded with suboptimal positioning and inadequate preoxygenation contribute to increased risk of failure. Incorrect application of cricoid pressure on a tilted table may impair the view at laryngoscopy and make intubation difficult. Some delivery suites in the United Kingdom, are located in separate buildings or isolated from the main operating theatres. Due to the remote location, help in the form of senior anaesthetists and specialists (e.g. ear, nose, and throat (ENT) specialists), trained assistants, and equipment may not be easily accessible for anaesthetists in the delivery suite. Lack of awareness of difficulties faced during difficult intubation amongst non-anaesthetic staff in the delivery suite is of major concern.[9] In the United Kingdom where electronic patient records are not routine practice in all

hospitals, handheld notes are vital if patients are admitted as an emergency or at another hospital.

## Optimum airway management in the pregnant patient

Airway management and tracheal intubation in the pregnant patient require careful planning, preparation, and an optimal technique in order to reduce morbidity and mortality associated with the airway.

### Planning and preparation

#### Communication

Good communication between the members of the delivery suite team is essential to ensure patient safety. Anaesthetists are encouraged to attend ward rounds with the obstetricians in order to identify high-risk women. Team briefing should be carried out daily to identify problems and allow time to plan any airway strategies. Good communication must occur between anaesthetists and obstetricians if there is a patient in labour with a potentially difficult airway. If there is fetal distress, this should be identified and communicated early so that an epidural top-up or *de novo* spinal can be used, thereby avoiding the 'crash' GA. A World Health Organization checklist should be carried out on every patient.[56] Junior anaesthetic staff should have appropriate supervision for their level of experience and should know who and how to call for help if this is required urgently.

#### Training

Because trainees are undertaking fewer obstetric cases under GA,[57] all elective cases under GA should be used to teach RSI in the pregnant patient. The teaching of simulated failed intubation drills should involve obstetricians, midwives, and operating department practitioners (ODPs) in order to improve communication and non-technical skills between the team.[58,59] ODPs should be trained in the correct application of cricoid pressure. ODPs and recovery staff should also be trained to the same national standard as staff in the general theatres.

#### Anaesthetic equipment

The obstetric theatre should be equipped to the same standard as the general theatres and monitoring should comply with the Association of Anaesthetists of Great Britain and Ireland (AAGBI) standards.[60] Equipment should include basic airway equipment and equipment for the difficult airway (Box 26.4). The standardization of the contents of difficult intubation trolleys was a recommendation of NAP4.[9] The layout of the difficult intubation trolley in plans A, B, C, and D of the Difficult Airway Society (DAS) unanticipated difficult airway guidelines may help the anaesthetist and assistant to progress through the Failed intubation guidelines during an unanticipated difficult airway[61] and avoid fixation on one aspect of patient care to the detriment of other more clinically important areas.[62] Figure 26.3 is an example of a similarly designed difficult intubation trolley. The multiple use bougie with a coudé tip (gum elastic bougie) is traditionally the most commonly used adjunct to facilitate intubation in the United Kingdom.[63,64] With increasing concern regarding cross-infection,[65] single-use bougies are now widely used. However, studies have shown that single-use plastic bougies are associated with lower success rates[64] and more trauma.[66]

**Box 26.4** Airway equipment for the obstetric theatres

**Routine equipment**

1. Masks of various sizes
2. Oropharyngeal airways of different sizes
3. Wide selection of tracheal tubes (including size 7 or less)
4. Macintosh laryngoscopes with standard and long blades
5. Short handle Macintosh laryngoscopes
6. McCoy laryngoscope with sizes 3 and 4 blades
7. Bougies
8. Intubating stylet
9. A video laryngoscope
10. Magill forceps.

**Equipment for the unanticipated difficult airway**

1. Laryngeal mask airways (LMAs) including second-generation SADs (e.g. The LMA ProSeal™, Supreme™ LMA, or i-gel®)
2. Equipment for 'can't intubate can't oxygenate':
   - Narrow-bore kink-resistant cannulae and a high-pressure ventilating system such as the Manujet® (VBM)
   - Large-bore cannulae (Quicktrach® or Melker® cricothyroid cannulae)
   - Surgical cricothyroidotomy set and tracheostomy tube
3. Fibreoptic scope
4. Equipment for awake fibreoptic intubation:
   - Equipment to apply local anaesthetic to the upper airway such as the mucosal atomizer device (MAD®), or oxygen tubing, three-way tap, and cannula for the Mackenzie technique
   - Re-enforced or intubating LMA tracheal tubes
   - Epidural catheter
   - Berman airway or 'Safe Bite' to prevent the patient biting on the fibreoptic scope
   - Local anaesthetics such as 4% lignocaine, 2% lignocaine gel (Instillagel®), 5% lignocaine/0.5% phenylephrine mixture.

Video laryngoscopes have been shown to improve the grade of laryngoscopy at intubation compared with the standard Macintosh laryngoscope.[67–76] They should be available for the management of a difficult airway on the delivery suite. Figure 26.4 shows some examples of video laryngoscopes that are available. These can be classified into 'channelled video laryngoscopes' such as the Airtraq® and the Pentax Airway Scope® (AWS), and the 'non-channelled video laryngoscopes' such as the Glidescope®, C-Mac® and McGrath MAC®.

**Figure 26.3** An example of a difficult intubation trolley. The drawers are arranged according to layout plan A, B, C, and D of the DAS unanticipated difficult airway guidelines in order to help the anaesthetist and anaesthetic assistant to progress through the DAS guidelines during an unanticipated difficult airway.

The Airtraq® is a single-use laryngoscope with a guiding channel which acts as a conduit for the tracheal tube. The second channel has an optical system which transfers the image from the illuminated tip to the viewfinder. The laryngoscope has the option of a wireless video system.

The Pentax airway scope is a reusable, rigid, portable video laryngoscope that combines a camera, LCD screen, and a disposable blade. The blade has a side channel for tracheal tube placement.

The McGrath MAC® is a reusable laryngoscope with an integral display monitor mounted on the handle of the laryngoscope. It uses disposable blades.

The C-Mac® is a reusable laryngoscope which resembles a Macintosh laryngoscope but with an integral video camera. The camera projects

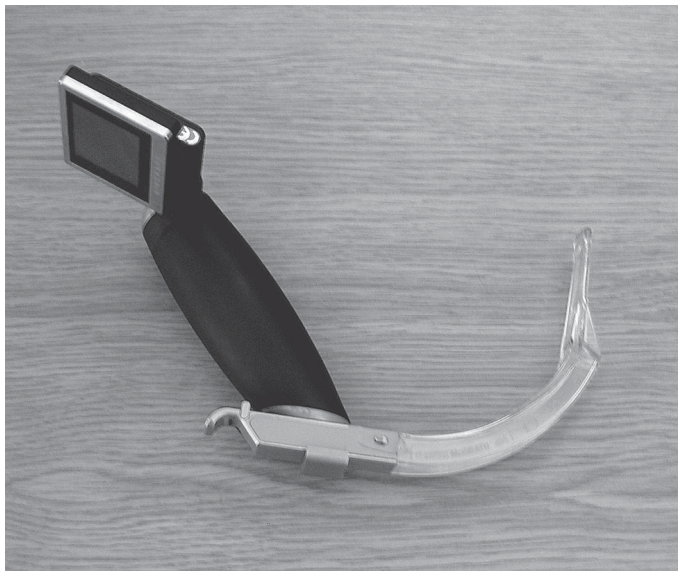
(D)



(E)

**Figure 26.4** Continued

the image onto a portable screen. It may be used with a D-blade for a difficult intubation and a bougie may be required for this.

The Glidescope® is a reusable video laryngoscope with a video camera at the tip of the reusable baton. The camera is connected by a cable to a separate display monitor. The baton fits into different sizes of single-use blades. A stylet or bougie is required to facilitate intubation.

The Venner AP Advance® video laryngoscope is a new laryngoscope which has two types of disposable blades, the conventional size 3 and 4 Macintosh for standard laryngoscopy and the difficult airway blade which is angulated and has a guiding channel.[77] King Vision® video laryngoscope is another new video laryngoscope which has two types of disposable blades depending on the preferred technique. It has a standard blade that requires a stylet to direct the endotracheal tube and a channelled blade where one can guide the tube with the blade.

Most video laryngoscopes have been shown to improve laryngoscopy grades but an adequate view of the glottis does not always translate into quick intubation. This is because a good view of the glottis on the screen does not guarantee easy passage of the tracheal tube into the larynx, as hand–eye coordination may be impaired by the indirect view.

At least one type of a SAD including a second-generation SAD such as the LMA ProSeal™, Supreme™ LMA, or i-gel® (Figure 26.5) should be available.

The LMA ProSeal™ is a reusable LMA with a better oropharyngeal seal (10 cm higher than the classic LMA (cLMA)) and a drain tube which forms a more effective seal with the gastrointestinal tract thereby decreasing aspiration risk. The drainage tube can be used to pass an orogastric tube for aspiration.[78]

The i-gel® has a gastric channel which allow early recognition of regurgitation of gastric contents and passage of a drainage tube, an epiglottic ridge, and a built-in bite block (a ridged flattened stem) which aids insertion and reduces the risk of axial rotation.

The Supreme™ LMA is a single-use second-generation LMA with the features of the LMA ProSeal™ and intubating LMA.

A fibreoptic scope should be readily available on the delivery suite.[9]

## Reducing the risk of aspiration

Fasting guidelines for women undergoing elective surgery should be the same as in the non-pregnant patient. However, fasting guidelines for women in labour is less uniform. Oral intake of a light diet during labour increases gastric contents, incidence of vomiting, and volume of vomit significantly compared with those taking only sips of water.[79] However, in 2007 the National Institute of Health and Clinical Excellence (now the National Institute of Health and Care Excellence (NICE)) published guidelines which classify women into low aspiration risk (LAR) for those with uncomplicated labour and high aspiration risk (HAR) for those who develop risks factors making GA more likely or who

**Figure 26.5** Second-generation laryngeal mask airways: (A) The LMA ProSeal™ (showing the optional Introducer), (B) i-gel®, and (C) Supreme™ LMA.

received opioids. It is recommended that women in the LAR group receive a light diet while women in the HAR receive liquids only.[80] However, recent evidence shows that prediction of those women who may require a GA is inaccurate.[81] Women who undergo GA for CD are at risk of aspiration at induction and at extubation. To reduce aspiration risk at tracheal extubation, an orogastric tube passed after induction of anaesthesia should be considered in any women with a history of recent food ingestion. This was highlighted in the only case of aspiration and death in the 2006–2008 CEMD report in which the patient aspirated at extubation and an orogastric tube had not been used.[82]

Pharmacological agents should be used routinely to neutralize acid in the stomach. A recent Cochrane review suggested that compared with no treatment or placebo, antacids, histamine 2 receptor ($H_2$) antagonists and proton pump antagonists reduced the risk of an intragastric pH of less than 2.5 at intubation.[83] However, for women in labour, proton pump antagonists are less effective compared with $H_2$ antagonists and antacids alone.[84]

Women undergoing elective surgery should receive an $H_2$ antagonist administered the night before and 2 hours prior to anaesthesia (with or without a prokinetic drug such as metoclopramide) followed by an antacid immediately prior to the GA. High-risk women in labour should receive 6-hourly oral $H_2$ antagonist and antacid immediately prior to GA. However, mothers who have not received an $H_2$ antagonist in labour should be given an antacid to cover induction and intravenous $H_2$ antagonists to cover tracheal extubation.

## General anaesthetic techniques

As well having correct equipment available and appropriate choice of induction agents and muscle relaxants, an optimum RSI requires (a) good position, (b) effective preoxygenation, (c) correct application of cricoid pressure, and (d) optimum laryngoscopy.

### Positioning

Good position is essential to optimize laryngoscopy views. Jackson described the method of laryngoscopy in which the head was elevated and neck extended [85] and in 1936, Magill suggested the term 'sniffing position'.[86] Bannister and colleague used X-rays to investigate which positions gave the best alignment of the mouth, pharyngeal and laryngeal axes and concluded that cervical flexion and atlanto-axial extension provided the best alignment.[87] However, Adnet questioned Bannister's conclusion and used magnetic resonance imaging to show that the sniffing position did not align the three axes in normal awake volunteers.[88,89] They also demonstrated that the 'sniffing position' did not provide a better view of the glottis than with simple extension except in patients with morbid obesity and reduced cervical mobility.[90] Therefore although the sniffing position is generally advocated for providing the best alignment of the three axes at laryngoscopy, there is evidence that this may not always be the case in all patients and other factors may need to be considered.[91]

Sitting patients in a 30° head-up position increases FRC and decreases the restriction caused by large breasts. Other methods which have been shown to improve laryngoscopic view especially in the obese patient is the 'ramped' position in which the patient's upper body and head are elevated to create a horizontal alignment between the external auditory meatus and the sternal notch. Collins and colleagues demonstrated that the 'ramped' position was superior to the standard 'sniffing position' for direct laryngoscopy in morbidly obese patients.[92] The ramped position can also be achieved using commercial devices such as the Oxford H.E.L.P (Head Elevating Laryngoscopy Pillow)[93,94] (see Figure 39.3 in Chapter 39). In patients with braided hair or knotted scarves, these should be undone or removed as they may limit neck extension.[95]

### Preoxygenation

An end-tidal $O_2$ of 0.9 is regarded as the gold standard[96] for optimal preoxygenation. As a result of reduced FRC and increased oxygen consumption, oxygen reserves in the pregnant woman are rapidly depleted following apnoea. A useful concept is the 'safe duration of apnoea' also termed duration of apnoea without desaturation (DAWD). This is defined as the interval between the onset of apnoea and the moment when $SpO_2$ reaches a value of less than 90%. In healthy non-pregnant adults, DAWD is typically 6.9 minutes after inhaling 100% oxygen.[97] The DAWD is shorter in pregnant women (2 minutes). In non-pregnant subjects, the efficacy of preoxygenation in obese and non-obese subjects is improved by positioning the subject in a head-up position compared with the supine position.[98–100] However, in contrast with obese patients, the head-up position has not been found to confer any advantages in the pregnant women probably because parturients and morbidly obese patients have different fat distributions, and the gravid uterus significantly impairs diaphragmatic excursion, irrespective of position.[101] Leaks around the face mask during preoxygenation which reduce the efficacy of preoxygenation, have been reported in up to 22% of preoxygenation sessions.[102] The effect of fresh gas flow rates on DAWD has also been investigated. Russell and colleagues showed that flow rates of 10 L/min or more for 3 minutes provided optimal preoxygenation in the pregnant patient but this optimization was not improved by increasing the flow from 10 to 15 L/min.[102] Thus a tight fit must be achieved between mask and the patient's face and sufficient gas flow of at least 10 L/min must be provided. Air in the lungs is replaced with oxygen at a rate that depends directly on alveolar minute ventilation and inversely on FRC. In normal adults, to obtain 95% gas exchange, that is $FEO_2$ greater than 90%, approximately five half times are required and this equates to 2.9 minutes.[101] Hence it is recommended that tidal volume breathing for a minimum of 3 minutes is the most reliable if time allows. However, in emergency situations where time is crucial, the 'fast technique' which involves asking the patient to take deep or vital capacity breaths has been proposed. It has been shown that 8 deep breaths are as effective as 3 minutes of tidal slow breaths and that 4 deep breaths are ineffective[103] although more recent work has recommended 12 deep breaths as being more effective than 8 deep breaths.[104] The use of 10 $cmH_2O$ of positive end-expiratory pressure (PEEP) has been advocated in obese subjects to prolong safe apnoea time.[105,106] However, this may not translate to the pregnant woman where the gravid uterus limits the ability of PEEP to increase FRC. Insufflation of 5L/min oxygen using nasal canulae has also been tried to improve safe apnoea time in obese patients[107] and may be used in obstetrics, particularly in the obese parturient. Apnoeic mass oxygen transfer can be used to delay the onset of desaturation provided the oxygen mask is kept on with a good seal and a patent airway.[108] Therefore, in summary, effective preoxygenation in pregnant patients should be as follows:

- Tidal breathing 10 L/min for 3 minutes with tightly fitting face mask
- In emergency situation with insufficient time for full preoxygenation, 8–12 deep breaths of 10 L/min with tightly fitting face mask.

### Cricoid pressure

Cricoid pressure which was first described by Sellick in 1961[109] is aimed at occluding the upper oesophageal sphincter by applying pressure on the cricoid cartilage to prevent regurgitation and aspiration of gastric contents. However, there is controversy regarding the benefit, the technique, the timing, and the method of applying cricoid pressure.[110–113] One prospective study demonstrated that cricoid pressure did not have an effect on preventing regurgitation or reducing mortality.[111] However, this study was not randomized and the possibility of bias could not be

excluded. In an editorial to accompany this paper, Vanner stated that cricoid pressure is probably effective in preventing regurgitation at induction of anaesthesia in patients at risk but randomized controlled trials are awaited to confirm this. Although cricoid pressure can improve laryngoscopy view, it can also make the view worse in some patients. Insertion of a laryngeal mask is made more difficult, and ventilation with a face mask is more likely to be obstructed the more cricoid force is applied. It is therefore important that cricoid pressure is released or reduced if intubation or ventilation with a mask is difficult. In the United Kingdom, there is universal agreement amongst anaesthetists to use cricoid pressure during RSI[114] whereas in France, cricoid pressure is used by only 66% of anaesthetists during GA for CD. [115] The amount of force applied is crucial. Too much force (e.g. >45 N) is associated with airway obstruction[116,117] and insufficient force may not protect the patient from regurgitation. In a study in cadavers, 20 N of cricoid force prevented regurgitation with oesophageal pressures of 25 mmHg and 30 N prevented regurgitation with oesophageal pressures of 40 mmHg.[118] Therefore 30 N of cricoid force may replace the function of the upper oesophageal sphincter (UOS) which has a normal functioning pressure of 40 mmHg.[119] Average gastric pressures are 11 mmHg at emergency CDs and below 25 mmHg in 99% of patients.[120] This suggests that the optimum cricoid force in anaesthetized patients should be 30 N.[121,122] The timing of cricoid pressure is important because too much force in the conscious patient will be uncomfortable and can cause retching and vomiting and increase the risk of oesophageal rupture.[123] Thiopentone causes a rapid reduction in the UOS pressure which starts before loss of consciousness.[119] Therefore ideally cricoid pressure should be applied in the awake patient before loss of consciousness as described originally by Sellick.[109] Awake subjects tolerate up to 20 N cricoid pressure without discomfort.[124]

Incorrectly applied cricoid pressure may lead to inability to ventilate the lungs or a poor view of the glottis at laryngoscopy[125] and females are at a higher risk of airway occlusion.[116] If cricoid pressure is applied correctly, it may improve the laryngoscopy grade and does not increase the rate of failed intubation in elective cases.[126,127] There is debate as which hand to use and on which side of the patient to stand while applying cricoid pressure. The force applied by the left hand (non-dominant hand) with the ODP standing on the left side of the patient tends to be lower than that applied by the right hand (dominant hand) and that inadequate or excessive force is more frequent with the left hand.[122] When prolonged cricoid pressure is required, for example, in a failed intubation scenario, incorrect cricoid force is applied more with the left hand than with the right hand.[122] There is no proven benefit in a two-handed technique[128–131] and there is no difference in the incidence of airway obstruction when cricoid pressure is applied in the supine or lateral tilt position.[132] The use of cricoid pressure did not affect the success or duration of intubation when using the Airtraq® video laryngoscope.[133] In a patient with a nasogastric tube, it is not necessary to remove the tube but it should be left open to atmospheric pressure.[134,135]

Therefore in summary, evidence supports:

- applying a force of less than 20 N (10 N should be adequate[135]) cricoid pressure in the conscious patient and 30 N after loss of consciousness
- using one hand and preferably the right hand (dominant hand), applied at 90° to the tilt of the table by a trained assistant[122]
- adjusting or releasing cricoid pressure during a difficult airway and/or intubation.

### Optimal laryngoscopy

With correct positioning, optimal preoxygenation, correct choice of drugs, correct application of cricoid pressure, and correct choice of laryngoscope, the first attempt at intubation should result in successful tracheal intubation in the majority of patients. A short-handle or Polio blades are helpful in patients with enlarged breasts. A size 3 Macintosh blade is the standard but size 4 should be selected if deemed necessary in larger women. A McCoy blade (size 3 or 4) may help to lift the epiglottis and should be considered early. If the glottis is partially visible, the tracheal introducer (bougie) is useful but should be used carefully to avoid causing trauma. External laryngeal manipulation consisting of applying backwards, upwards, and rightward pressure on the thyroid cartilage (BURP) and optimal external laryngeal manipulation (OELM) may be used to improve laryngeal view.[136,137] However, it is important to clarify that the two manoeuvres (BURP and OELM) differ from cricoid pressure and the need for cricoid pressure may preclude the use of these manoeuvres. There is now a large amount of data to show that the laryngeal views obtained using video laryngoscopes are significantly better than those using conventional Macintosh laryngoscopy. This has been shown in patients with normal airways, predicted difficult airways, and restricted cervical spine mobility.[67–77] Video laryngoscopes have been used with success in obstetrics.[133,138–140] As a result, video laryngoscopes are becoming accepted as a rescue strategy and should be considered early should the first attempt at intubation fail. Smaller endotracheal tubes (<7 mm internal diameter) should be used routinely especially in patients with airway oedema.

Table 26.5 summarizes the ideal technique in order to optimize airway management and reduce the chance of either a difficult airway or a failed intubation.

## Management of the anticipated difficult airway

Management of anticipated difficult airway and tracheal intubation in the pregnancy entails early recognition in the antenatal period and multidisciplinary discussion on the mode of delivery and an airway management strategy.

### Antenatal management

#### Assessment

Any pregnant woman with a suspected or known difficult airway should be referred in the antenatal period to the anaesthetic team. The time of referral to the anaesthetic team should allow sufficient time to obtain previous notes and investigations and carry out any further investigations. Depending on the severity of the difficult airway, an airway and anaesthetic management strategy should be identified and documented in the notes.

#### Plan

If a difficult airway is anticipated, the anaesthetist should liaise with the obstetrician to decide on the mode of delivery to ensure safe

**Table 26.5** Optimum GA to reduce the risks of difficult airway or failed intubation the obstetric patient

| | |
|---|---|
| Staff | Multidisciplinary team briefing/WHO check |
| | Trained ODP staff |
| Fasting | Nil by mouth for elective cases |
| | Oral fluids only for HAR and light diet for LAR in labour |
| Premedication | $H_2$ antagonist/antacid ± prokinetics |
| Equipment | Full AAGBI standard monitoring |
| | Electric operating table capable of taking >160 kg on a tilt |
| | Airway equipment (Box 26.3) |
| | Suction |
| Position | Slight head-up and optimize head and neck position |
| | Ramping in obese patient (external auditory meatus is aligned horizontally with the sternal notch) |
| | 15° left lateral tilt |
| Pre-oxygenation | End-tidal oxygen of >90% |
| | 3 minutes' tidal breathing or 8–12 vital capacity breaths of 100% oxygen, 10 L/min with tight-fitting mask |
| | Maintain mask on face and maintain a clear airway to allow apnoeic mass oxygen transfer |
| | +/– use of insufflation of 5L of oxygen via nasal canuale |
| Drugs | Correct doses of induction agent and muscle relaxant |
| Cricoid pressure | At 90° to the tilted table |
| | 10 N with induction agent and 30 N at loss of consciousness |
| Optimal laryngoscopy | Correct choice of laryngoscope |
| | Availability of an alternate laryngoscope |
| | Appropriate use of a bougie |
| Confirm intubation | Confirm correct placement of the tracheal tube (visual/chest movement/auscultation and end-tidal $CO_2$ measurement) |
| | Maintenance of a balanced anaesthetic technique with volatile agents, muscle relaxants, and analgesia |
| Extubation | Consider insertion and aspiration of orogastric tube where necessary |
| | Suction under direct vision and insert bite block |
| | Use of peripheral nerve stimulator |
| | Use of reversal agents |
| | Extubate awake |
| | Position—left lateral or head-up |
| Recovery | Monitoring and appropriately trained staff |

HAR, high aspiration risk; LAR, low aspiration risk.

outcome for both mother and baby. The decision for vaginal birth will mean that an unscheduled operative procedure may occur with all the potential for a failed intubation. Elective CD allows the opportunity for timed planned delivery. The risks and benefits of management options should be clearly explained to the patient and partner. Neuraxial anaesthesia should be strongly recommended.

### Communication

Communication with the multidisciplinary team regarding a management plan for the patient with a known difficult airway is essential in order to ensure a safe outcome for both mother and baby.[144] The theatre team should be given sufficient notice to ensure that appropriate equipment and trained staff are available. Backup plans are necessary to recruit additional senior anaesthetic staff when necessary.

## Management options

Airway management of a patient with anticipated difficult airway depends on whether the elected mode of delivery is a planned vaginal delivery or elective CD. A suggested algorithm in Figure 26.6 summarizes pathways that could be followed. These are not the only approaches as patient co-morbidity and different situations vary significantly and will influence the final decision.

### Planned vaginal delivery

When vaginal delivery is planned, the type of labour analgesia and anaesthetic management for unanticipated operative delivery should be documented in the notes. The best way to circumvent a difficult airway or a failed intubation is to avoid GA by siting an epidural early in labour and active management to ensure a good working epidural block which can be used confidently for any operative procedure. However, the risks of a failed regional, high or total spinal blockade, and inadvertent intravenous injection should be considered. It may be advisable therefore that regional block in such a patient should be carried out by a very experienced anaesthetist. Approximately 5% of women who have epidural analgesia for labour and require topping up for operative delivery need conversion to GA[141] and this should be anticipated. The patient should receive regular antacid prophylaxis during labour and oral intake should be restricted in case a GA is required. There should be a plan for the administration of a GA should this be required and this could entail either the use of awake fibreoptic intubation or awake intubation using other rigid airway devices.[142–146] An awake tracheostomy or cricothyroid cannula may be considered before inducing GA in patients with a severe difficult airway.

### Planned elective caesarean delivery

Ideally, an elective CD in a patient with known difficult airway should be carried out under neuraxial anaesthesia. The choice of anaesthesia can be either a single-shot spinal, epidural, combined spinal–epidural (CSE), or continuous spinal catheter[147] anaesthetic. Despite meticulous technique, these techniques may fail to produce adequate anaesthesia for surgery and plans should be in place if this should happen. For this reason, a CSE may be preferable to a single-shot spinal or epidural because of its added flexibility should a top-up be required. However, even a CSE may fail as reported in a woman who had both failed CSE and failed intubation.[148] A backup plan such as an awake intubation or the use of a SAD should be in place for when neuraxial anaesthesia fails or serious complications of regional block occur.

Awake intubation using the fibreoptic scope or other airway devices is an alternative plan for elective CD when regional block is contraindicated, when regional anaesthesia fails, or when serious complications occur.

**Figure 26.6** A suggested algorithm for the management of the anticipated difficult airway in the pregnant patient.
This article was published in *Chestnut's Obstetric Anesthesia, Principles and Practice*, Chestnut DH *et al.*, Copyright Elsevier (2014).

Local anaesthetic infiltration as the sole anaesthetic for CD is an option but this is seldom carried out in the United Kingdom because of lack of experience. The majority of obstetricians are neither familiar nor proficient with this technique. Large volumes of local anaesthetic are required with the possibility of toxicity especially when the maximum dose of local anaesthetic may already have been reached with previously attempted central neuraxial blockade.

## Awake intubation techniques

Intubation may be performed by awake fibreoptic intubation, awake intubation via a SAD such as an intubating LMA[143,144] or an LMA[142] or intubation using rigid laryngoscopes such as the Macintosh, a video laryngoscope[146] or the Bullard laryngoscope.[145] The classic and more conventional way for awake intubation is to use a flexible fibreoptic scope.

### *Awake fibreoptic intubation*

**Preparation**

*Consent*: the patient should be well informed of the need for the awake intubation. The procedure should be explained and informed consent obtained.

*Fasting*: for an elective procedure, the patient should be starved for 6 hours as normal practice.

*Premedication*: premedication should include an $H_2$ antagonist and 30 mL of 0.3 M sodium citrate immediately prior to starting sedation. An antisialogogue—glycopyrrolate 200 mcg intravenously—should be administered as soon as an intravenous cannula has been inserted.

*Team:* two experienced anaesthetists are required, one to perform the endoscopy and the other to monitor and administer sedation. An experienced ODP is essential. Neonatologists should be made aware in advance of the use of sedation and its potential effects on the neonate.

*Equipment*—the following equipment should be available:

- full monitoring
- fibreoptic scope with camera and monitor
- an airway adjunct to stop the patient biting and damaging the fibreoptic scope, such as the Berman airway (Figure 26.7)
- equipment to apply local anaesthetic to the upper airway, for example, mucosal atomizing device or cannula, oxygen tubing, and three-way tap for the Mackenzie technique[149] (Figure 26.8)
- epidural catheter fed through the working channel of the scope for administration of local anaesthetic
- tracheal tube size 6–7 mm (re-enforced or intubating LMA tracheal tube are recommended)
- syringe pump for administration of drugs by infusion.

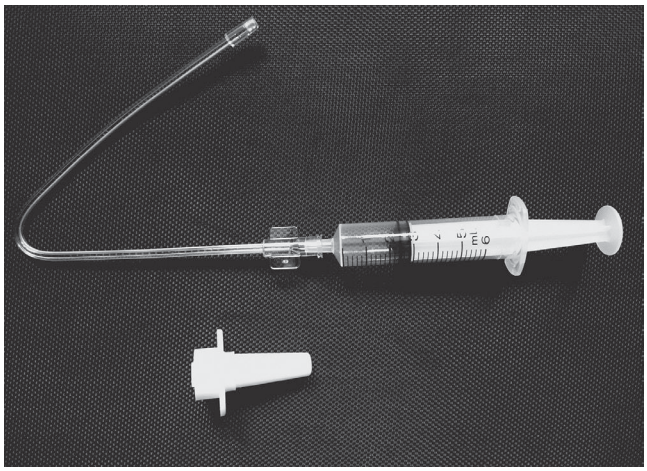
**Figure 26.7** The Berman airway used to protect the fibreoptic scope during awake fibreoptic intubation.

## Performance of intubation

### Conscious sedation

Although it is possible to carry out awake fibreoptic intubation with local anaesthetic alone,[150] it is more comfortable for the patient to receive some form of sedation/analgesia using midazolam, fentanyl, alfentanil, remifentanil, or propofol. Midazolam 0.5–1 mg is useful to ensure a degree of amnesia. Remifentanil is gaining popularity as it provides the best analgesia for the mother with conscious and cooperative sedation and suppression of the gag reflex which gives good intubating conditions. Infusion rates of 0.05–0.175 mcg/kg/min[151] or target-controlled infusion (TCI) of up to 3 ng/mL have been used in non-obstetric patients. TCI with propofol has been used for awake fibreoptic intubation in obstetrics when a target concentration of 0.8–1.2 mcg/mL was used successfully combined with midazolam 1 mg and topical anaesthesia.[152] A recent extensive review on conscious sedation for awake fibreoptic intubation by Johnston and Rai, recommended remifentanil TCI (effect-site concentration 3–5 ng/mL) in conjunction with midazolam 1–2 mg or with propofol TCI (effect-site concentration 0.5–0.8 mcg/mL).[153] Excessive sedation should be avoided as it makes the larynx incompetent and increases the likelihood of aspiration. Antagonists such as flumazenil and naloxone should be readily available. Oxygen should be administered. Dexmedetomidine, which has found favour for sedation in critical care, has been enthusiastically advocated for awake fibreoptic intubation on the grounds of its ability to

(A)



(B)

provide profound sedation without causing respiratory depression. However, experience of its use in the United Kingdom either in the general or the obstetric population is limited. There is some evidence in case reports of its use in obstetrics.[154,155]

### Topical anaesthesia

Concern has been raised in the use of topical airway anaesthesia in patients at risk of regurgitation and aspiration. However, Ovassapian et al. showed that provided sedation was not excessive, there was no evidence that there is increased risk of regurgitation and aspiration.[156]

The nose, mouth, and pharynx may be anaesthetized by direct spray using a device such as the commercially produced mucosal atomizing device (MAD®) (Figure 26.8A) or the Mackenzie technique which uses a size 18 or 20 G cannula attached by a three-way tap to oxygen tubing which is connected to 2 L/min oxygen supply[149] (Figure 26.8B). The patient may also be asked to gargle using 6 mL of 2% lignocaine gel (Instillagel®). The remainder of the airway can be anaesthetized using one of three techniques: spray as you go (SAYGO), nerve blocks, and nebulized lignocaine:

- SAYGO: this involves dripping local anaesthetic into the airway via an epidural catheter fed through the working channel of the fibreoptic scope. Aliquots of 1–2 mL of 4% lignocaine are injected into the supraglottic, glottis, and subglottic area.
- Nerve blocks: this is seldom carried out. It involves blocking the lingual branch of the glossopharyngeal nerve which supplies the base of the tongue. Injection is made into the base of the anterior tonsillar pillar with 2 mL of 1% lignocaine. The second nerve block is the internal branch of the superior laryngeal nerve which is performed by locating the greater cornu of the hyoid bone and injecting 2–3 mL of 1% lidocaine into the thyrohyoid membrane. This is followed by transtracheal injection of 2–3 mL of 2% lignocaine through the cricothyroid membrane using a cannula.
- Nebulized lignocaine: nebulized 4% lignocaine (4–6 mL) anaesthetizes the nose, mouth, pharynx, larynx, and trachea. However, when used alone, it is not fully effective and requires supplementation with the SAYGO technique.

In general, the total dose of lignocaine for awake fibreoptic intubation exceeds the normal recommended dose of 200 mg. This is because a large proportion is swallowed and because of the high first-pass metabolism, toxic blood concentrations are not reached when using doses up to 9 mg/kg in non-pregnant patients.[157,158] However, this may need to be reduced in the pregnant patient because of the increased vascularity of the upper airway.

### Route of intubation

The oral intubation is the preferred route of intubation because of the risks of nasal bleeding from the congested nasal and airway mucosa. Occasionally, this route is not possible due to oral or temporomandibular joint pathology or trismus and the nasal route must be used and if so, the type of vasoconstrictor should be considered carefully.[159] Cocaine is a very effective vasoconstrictor but it is associated with reduced placental blood flow and placental abruption and therefore is best avoided during pregnancy.[160,161] Phenylephrine 0.5%/lignocaine 5% combination and xylometazoline hydrochloride 0.1% spray are safer alternatives. Vasoconstrictors should be used with care in pre-eclamptic patients as they may cause hypertension.

### Position

It is important that aortocaval compression is avoided during the procedure by positioning the patient in either the sitting posture or with left lateral tilt.

### Intubation

A small size tracheal tube such as size 6–7 should be used to reduce the chance of impingement on the arytenoids. The design of the tip of the tube may also make a difference and the intubating LMA tracheal tube with a Huber tip is the least likely to impinge. When the trachea is intubated, the cuff should be inflated and the position of the tube confirmed before the patient is anaesthetized.

## Management of unanticipated difficult intubation

The unanticipated difficult intubation in the pregnant patient presents problems different from those in the non-pregnant patient (Box 26.5).

If tracheal intubation fails after the first attempt despite reducing or removing cricoid pressure, external laryngeal manipulation, adjustment of head and neck position and use of a bougie if appropriate, then gentle mask ventilation is recommended to oxygenate the lungs, assess the ease of ventilation and provide time to prepare equipment for the second intubation strategy.[162–165] However care should be taken to avoid insufflation of the stomach. A second attempt at intubation should be with an alternative laryngoscope with cricoid pressure removed. In order to avoid bleeding and airway oedema, the number of attempts to intubate should be limited to a maximum of two as excessive attempts at airway manipulation may convert a 'can't intubate, can oxygenate' scenario to a 'can't intubate, can't oxygenate' scenario. If

**Box 26.5** Factors to consider during unanticipated difficult intubation in the pregnant patient

1. Physiological changes which accelerate the onset of hypoxaemia—may need mask ventilation between attempts at intubation
2. Risk of upper airway oedema and bleeding—avoid excess multiple attempts, avoid the use of nasopharyngeal airway
3. Enlarged breasts which obstruct the insertion of the laryngoscope—use short-handle laryngoscope
4. Remote site which means that help make take a while to arrive—call for help earlier
5. The presence of a fetus which confounds the decision of when to wake the mother up or continue with the surgery—an advance multidisciplinary decision is recommended
6. Application of fundal pressure may exacerbate the risk of regurgitation and aspiration if anaesthesia is continued using a supraglottic airway device—ask obstetrician to avoid or minimize during delivery of baby
7. Choice of anaesthesia to minimize uterine relaxation—be prepared for postdelivery haemorrhage.

**Box 26.6** Proceed with surgery?

Criteria to be used in the decision to wake or proceed following failed tracheal intubation. In any individual patient, some factors may suggest waking and others proceeding. The final decision will depend on the anaesthetist's clinical judgement.
Reproduced from Mushambi MC, Kinsella SM, Popat M., et al. Obstetric Anaesthetists' Association and Difficult Airway Society guidelines for the management of difficult and failed intubation in obstetrics. *Anaesthesia* 2015; 70: 1286–1306, copyright © 2015 The authors. Anaesthesia published by John Wiley & Sons Ltd on behalf of Association of Anaesthetists of Great Britain and Ireland.

intubation fails after the second attempt, the anaesthetist should declare a failed intubation, communicate this to the obstetrician and theatre team and help urgently summoned. Help should be sought from senior anaesthetists including a consultant, a senior obstetrician and an additional ODP.

The decision needs to be made whether to proceed or to wake the patient. This decision is complicated because of the two lives at risk and ideally this decision should be made with the team prior to the administration of GA. The new OAA/DAS obstetric airway guidelines[166] propose a list of factors to be considered to help with this decision making and is shown in Box 26.6. The table demonstrates clearly that the decision to wake the mother or proceed with surgery is influenced by multiple factors relating to the woman, fetus, staff and clinical situation and this information is available prior to the induction of GA. Factors relating to the rescue device and airway patency are only available once failed intubation has occurred.

## Failed intubation algorithm

Traditionally, the teaching has been to awaken the woman if failed intubation occurs, in order to avoid continuing with an unprotected airway. However in a recent article, 8 anaesthetists describe continuing GA with cLMA for non-urgent cases (category 3 and 4)[18]. This is in contrast with previous publications in which anaesthetists tended to wake patients up during a failed intubation.[19,23] This change of practice may be as a result of increased experience in the use of SAD in the non-pregnant patients and publications of the use of supraglottic airway devices for elective Caesarean delivery.[167–169] Traditionally, SADs are used for elective surgery when the patient is considered at low risk of regurgitation

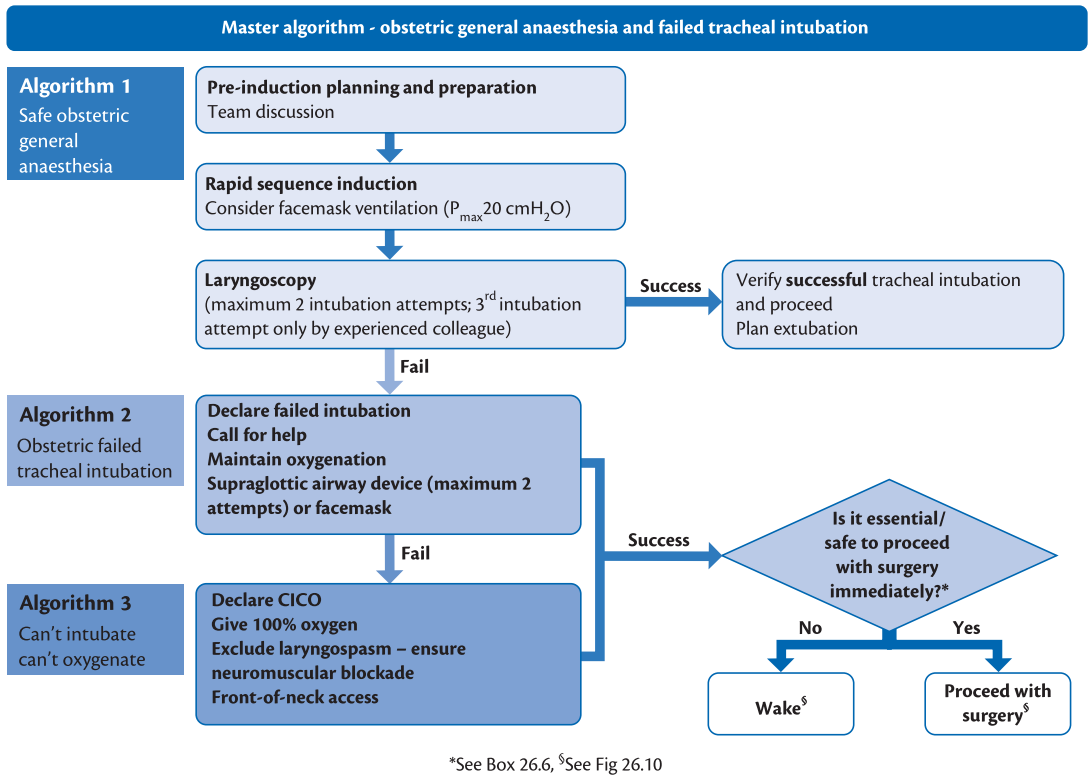

**Figure 26.9** Obstetric Anaesthetists' Association/Difficult Airway Society: Master algorithm—Obstetric general anaesthesia and failed tracheal intubation with permission from OAA.

Reproduced from Mushambi MC, Kinsella SM, Popat M., et al. Obstetric Anaesthetists' Association and Difficult Airway Society guidelines for the management of difficult and failed intubation in obstetrics. *Anaesthesia* 2015; 70: 1286–1306, copyright © 2015 The authors. *Anaesthesia* published by John Wiley & Sons Ltd on behalf of Association of Anaesthetists of Great Britain and Ireland.

and aspiration. As a result, the use of SADs for Caesarean deliveries had been limited to failed intubations.[170–176] In 2001, Han evaluated the use of classic LMAs in 1,067 elective Caesarean sections and recommended it for experienced users and selected patients.[168] However in an editorial following this publication, Preston argued that the use of SAD in selected patients in this study should not be accepted as safe for airway management in the pregnant patient who is at risk of aspiration.[177] The conclusion in this editorial was that the SAD is acceptable as an emergency rescue device for airway management in the parturient but not as the sole chosen airway device. The UKOSS survey showed that the commonest airway rescue device was the cLMA with 39 out of 57 cases using it.[18] The choice of the cLMA over other types of SADs such as the second generation SADs in this survey is likely to be related to experience and familiarity with the cLMA. The LMA ProSeal™ and Supreme LMA have also been evaluated in selected patients for elective Caesarean section with no adverse effects.[167,169]

In the past, several failed intubations algorithms for the pregnant patient have been described[166,180–185] and in 2004 DAS published guidelines for the management of unanticipated difficult intubation in the non-pregnant patient[186] and these have recently been updated.[187] However it is only recently that the OAA and DAS published the obstetric specific airway guidelines which are based around four algorithms and two tables.[166] The master algorithms Figure 26.9, gives a composite overview of three specific algorithms that deal with induction of general anaesthesia, failed intubation and can't intubate can't oxygenate situation.

Oxygenation of the patient following a failed intubation should be with the use of either a face mask with or without simple adjuncts such as an oropharyngeal airway or the use of a supraglottic airway device. A nasopharyngeal airway should be avoided because of the risk of epistaxis which may then worsen the situation. If an oropharyngeal airway fails, this is followed by two person mask ventilation technique and then a removal of cricoid pressure. If a supraglottic airway is used, a second generation supraglottic airway device such as LMA ProSeal™, LMA Supreme, i-gel® is recommended. It is necessary to remove cricoid pressure during insertion of the supraglottic device. If ventilation and oxygenation fails, the anaesthetist should declare a can't intubate, can't oxygenate situation and ensure muscle paralysis before proceeding to a front-of-the-neck access.

Front-of-neck access is a rescue technique which is used when there is increasing hypoxaemia and inability to ventilate the lungs and the three options for oxygenating the patient are:

(i) Cricothyroidotomy with a narrow bore non-kinking cannula and oxygenation with a high pressure system (eg. Manujet®)

(ii) Cricothyroidotomy with large bore cannula and ventilation of lungs using normal anaesthetic circuit.

(iii) Surgical cricothyrodotomy or tracheostomy with ventilation using normal anaesthetic circuit.

Narrow bore cricothyroidotomy has the advantage of being quick and simple to perform but has a high failure rate particularly in

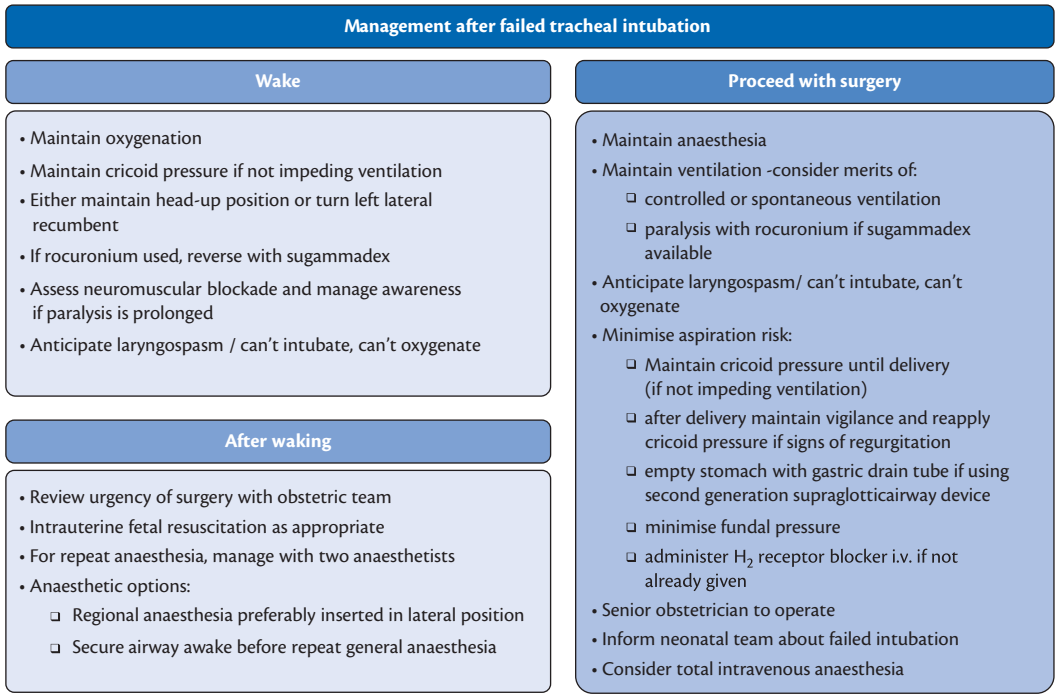

**Figure 26.10** OAA/DAS obstetric airway guidelines—Management after failed tracheal intubation.[166]
Reproduced from Mushambi MC, Kinsella SM, Popat M., et al. Obstetric Anaesthetists' Association and Difficult Airway Society guidelines for the management of difficult and failed intubation in obstetrics. *Anaesthesia* 2015; 70: 1286–1306, copyright © 2015 The authors. Anaesthesia published by John Wiley & Sons Ltd on behalf of Association of Anaesthetists of Great Britain and Ireland.

the obese patient.[9] It only provides a temporary airway and is associated with complications such as barotrauma from the high pressure ventilating system. Large bore cannulae have a higher success rate but are associated with more complications at insertion such as haemorrhage and damage to neck structures. These may be inserted using the Seldinger technique. The use of surgical cricothyroidotomy using a scalpel, bougie and tube technique is now recommended by the new 2015 DAS Unanticipated difficult airway guidelines.[187] Tracheostomy requires an ENT surgeon and may not be practical because most labour wards in the UK are sited remotely from the central operating department.

### How to proceed with general anaesthesia or awaken the patient

Should a decision be made to either continue with general anaesthesia to allow surgery to continue or awaken the patient, Table 2 of the OAA/DAS obstetric guidelines (Figure 26.10) provides information on positioning, mode of anaesthesia and ventilation and prevention of aspiration and awareness. The choice of airway will depend on what has already been used as a rescue airway strategy and this could be mask ± oropharyngeal airway (less preferable) or a SAD (preferably a second generation SAD). Further attempts to intubate the trachea are discouraged as this may lead to loss of airway from airway trauma and oedema. Intubation of the trachea in this situation should only be considered if the patient requires admission to the ITU for further ventilation of the lungs. In this situation, the SAD may be used to facilitate fibreoptic laryngoscopy to achieve tracheal intubation. However, only an anaesthetist skilled in fibreoptic intubation skills should undertake this task. A ventilation- exchange bougie such as the Aintree Intubating Catheter (AIC) may be used to facilitate intubation and removal of the SAD if prolonged intubation is anticipated.[188] The AIC is loaded onto the fibreoptic scope and placed into the trachea under direct vision. The SAD is then removed and an endotracheal tube is railroaded over the AIC and passed into the trachea using the AIC as a bougie. This task should again only be carried out by an anaesthetist who is trained and experienced in its use as its misuse has been associated with significant morbidity and mortality. A tracheostomy may be an alternative choice of airway. Uterine relaxation from the inevitable use of higher inspired concentrations of a volatile agent may cause postpartum haemorrhage. The choice of agent depends on the anaesthetist's experience, but sevoflurane offers an advantage in being less irritant to the airway. Measures should be taken to prevent postpartum haemorrhage such the use of an oxytocin infusion. At delivery, the surgeons should be warned about minimising fundal pressure to avoid reflux, regurgitation and the risk of aspiration.

## Tracheal extubation and recovery

In the NAP4 report, 28% of the reported cases were airway complications at emergence and in the recovery period emphasizing that both these periods are high risk for airway complications.[9] Some of the recommendations of NAP4 were that patients at high risk of airway problems at emergence require specific extubation and re-intubation plans; recovery staff should be trained to an agreed standard in all hospital sites and this must include prevention, early recognition, and management of airway obstruction; and the use of capnograph in the recovery area especially in high-risk cases. In the 2006–2008 CMACE report,[4] one mother died from aspiration of gastric contents on emergence from a GA following emergency CD. She had had a full meal shortly before

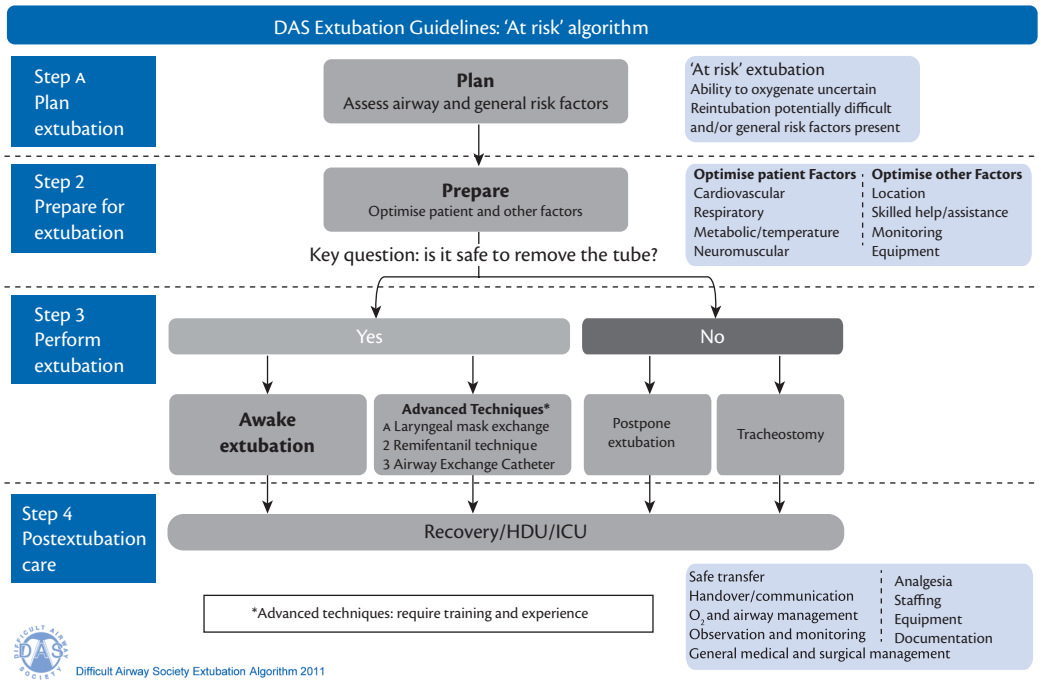

**Figure 26.11** The Difficult Airway Society extubation guidelines—'at-risk' patient.

Reproduced with permission from V. Mitchell *et al.* Difficult Airway Society Guidelines for the management of tracheal extubation, *Anaesthesia*, Volume 67, Issue 3, pp. 318–30, Copyright © 2012 John Wiley and Sons.

the decision for an emergency (category 1) CD and an orogastric tube was not used. In a series of anaesthesia-related deaths from Michigan, United States,[189] five of eight anaesthesia related deaths, occurred from obstruction or hypoventilation during emergence and recovery. Inadequate postoperative monitoring was recognized in five patients and in two of these continuous pulse oximetry was not used. In a paper by McDonnell and colleagues, regurgitation of gastric contents occurred in 8/1095 patients (0.7%); four episodes were at induction, five at extubation (one patient regurgitated at induction and extubation), and two of these cases were elective.[25]

DAS has recently published guidelines for the management of extubation[190] and these may be used for both the pregnant or recently pregnant patient (Figure 26.11).

The guidelines describe four steps of the extubation process:

1. *Planning extubation*: the risk factors such as known difficult airway, risk of aspiration, airway oedema, obesity, obstructive sleep apnoea, and any special medical conditions which may have an impact on the airway at extubation should be identified and included in the decision-making of how to extubate the trachea.
2. *Preparing for extubation*: this requires optimizing the patient and the environment for extubation. Equipment, monitoring, and skilled assistance should be available and the location for extubation should be chosen according to the patient's risk factors. In cases where there are concerns about airway oedema (e.g. in pre-eclampsia), tracheal extubation can be delayed until the swelling has subsided and a leak around the tracheal tube is present.
3. *Performing extubation*: because of the nature of increased aspiration risk, obstetric patients are in the 'at-risk' category of the algorithm. If the patient has a difficult airway, this should be taken into account whether the trachea is extubated awake, delayed, or a tracheostomy is required prior to extubation. The advanced techniques in the algorithm are unlikely to apply in the obstetric patient who is at high risk of aspiration. Oropharyngeal suction should occur under direct vision and with the patient in a deep plane of anaesthesia. The use of a bite block can prevent occlusion of the airway if the patient bites down on the tube. NMB should be checked with a peripheral nerve stimulator and antagonized and the patient's lungs pre-oxygenated. Traditionally, all obstetric patients underwent awake tracheal extubation and in the left lateral head-down position. There is a general trend towards extubating patients awake but in the head-up position, especially the obese patient.
4. *Post-extubation care:* after extubation, the patient should be given oxygen and safely transferred to the recovery ward where full monitoring should be used and the patient looked after by trained recovery staff.

## Post-failed intubation/difficult airway management plan

### The team

Difficult airway or failed intubation can be very stressful to the staff involved in the management of the patient. The psychological impact of a failed intubation and the aftermath on the staff should not be underestimated. It is vital that all members of staff are supported and a mentor assigned if necessary. Debriefing of the team at a time to suit all staff but preferably within a few hours of the incident is recommended as it may help allay anxiety and provide

reassurance to the staff. Another aim is to provide and record information and to gain feedback while the details are still fresh.[191]

### The patient

Following management of difficult airway or failed intubation, the patient should be followed up to inform the patient about the difficulties which were encountered and to carry out a clinical review to exclude morbidities arising from the difficult airway management process. Minor injuries to the airway may include dental damage, minor bruises to the lips, and sore throat. Serious morbidities include damage to the larynx (oedema or perforation) and perforation of the pharynx or oesophagus. Perforation might present with pyrexia, retrosternal pain, and surgical emphysema. This can be associated with high mortality and therefore if suspected, urgent review by the ENT specialist and early treatment with antibiotics and nil by mouth regimen is recommended.[192]

Reviewing the patient is a good opportunity to explain what happened, express regret, and provide apologies for any morbidities that may have been caused. The nature of the problem should be explained to the patient and it is paramount for the patient to understand the seriousness of the problem and that they should convey this to clinicians, especially anaesthetists, in the future. The possibility of awareness should be explored as there is an increased incidence in the obstetric patient with a difficult airway.[193]

### Documentation

The patient's case notes should have the full documentation of the incident and any discussions with the patient. A summary of airway management should be fully documented on the anaesthetic chart. The airway management information should state what the difficulty was (e.g. difficulty with mask ventilation), direct laryngoscopy or tracheal intubation, grade of laryngoscopy, how the airway was managed, airway equipment or adjuncts used, and any advice about management in the future if appropriate (e.g. recommend an awake fibreoptic intubation).

Communication regarding the airway problem should be in the form of a medical alert bracelet, documentation in the notes, a letter to the general practitioner, and a copy of the letter should be given to the patient to present to the clinicians at future. An example of a form which can be used is available on the DAS website.[194]

## Conclusion

Management of difficult airway in obstetrics still remains challenging. Over the past 6 decades, increasing use of neuraxial anaesthesia has helped to decrease the mortality and morbidity associated with anaesthesia. However, the incidence of difficult airway in obstetrics remains largely unchanged. This may be due to lack of training opportunities, and increase in maternal obesity and age with the associated comorbidities. Early referral to the anaesthetist for antenatal planning and preparation, involvement of multidisciplinary teams, use of skills drills and simulation, availability of advanced airway management devices, and the skills to use the devices can be helpful in managing both unanticipated and anticipated difficult intubation. During a failed or difficult intubation, the primary goal is to maintain maternal and fetal oxygenation and the decision-making whether to proceed or wake the patient during a failed intubation should involve the senior anaesthetist and obstetrician. Extubation remains a high-risk period and therefore requires careful planning and preparation. When a failed or difficult intubation has occurred, full documentation of the incident should be performed, the patient should be followed up, and documentation to inform future anaesthetists put into place.

CHAPTER 27

# Postdural puncture headache

Michael J. Paech and Patchareya Nivatpumin

## Introduction

In obstetric anaesthesia, postdural puncture headache (PDPH) is an important potential complication of neuraxial anaesthesia and analgesia or diagnostic lumbar puncture, and follows both spinal techniques and unintentional (also termed accidental or inadvertent) dura and arachnoid mater (hereafter 'dural') puncture during epidural needle or catheter insertion. Pregnant women appear a high-risk population for PDPH because of their gender, age, and, arguably, hormonal status. The headache and associated symptoms can cause considerable suffering and dissatisfaction, usually prolong hospital stay, and sometimes persist for weeks or months. This has implications for healthcare costs, subsequent loss of productivity, and litigation, making correct diagnosis and effective early management vital.

## Pathophysiology of postdural puncture headache

PDPH is initiated by loss of cerebrospinal fluid (CSF) and the subsequent changes in intracranial CSF volume when the head is elevated or the body erect.[1,2] Normal CSF formation, largely by ependymal cells of the choroid plexuses in the ventricles, is 450–500 mL/day (approximately 0.35 mL/min) in adults. A volume of 150 mL is located within the cerebral ventricles (~25 mL) and subarachnoid spaces (~125 mL). Absorption into the venous circulation occurs via cranial and spinal arachnoid villi, but if CSF efflux through a dural hole exceeds replacement, CSF pressure dynamics alter significantly with changes in body position. On assuming an upright position, redistribution causes low intracranial pressure (ICP) and this may precipitate headache, not only after dural puncture but also among patients with spontaneous intracranial hypotension, which follows spontaneous CSF leak.[2–4]

One possible explanation for pain (and some associated symptoms and complications) is loss of buoyancy when the head is elevated, leading to brain descent, traction on cranial nerves, meninges, and intracranial and meningeal veins. This pathology can be seen as pachymeningeal enhancement on cranial magnetic resonance imaging (MRI), although tonsillar descent or change in intracranial structure position is not necessarily evident.[1,5] Dilatation of the anterior internal vertebral venous plexus and spinal hygromas appears common.[5] A further plausible explanation for headache is the compensatory cerebral vasodilatation seen on imaging.[2,5] This is thought to be mediated by adenosine receptors in response to reduced ICP and the theory is supported by the changes that occur during induced hypercapnia or hypocapnia that maintain the intracranial volume; and by the immediate reduction in cerebral blood flow that follows an epidural blood patch (EBP).[6]

The individual's predisposition to headache varies, with several postulated explanations. CSF substance P concentrations have been implicated,[7,8] as have differences in CSF loss secondary to orifice occlusion by the intrinsic elastic recoil of the dura mater. The histological and anatomical characteristics of the dura mater vary, even within different areas of adjacent dura within an individual.[9] Differences in baseline ICP and cerebrovascular responses may also be relevant,[10,11] with patients having lower baseline ICP possibly more susceptible. Higher levels of oestrogen in women alter cerebral vessel tone responsiveness and possibly increase vascular distension in response to CSF hypotension.[11]

## Incidence of postdural puncture headache

The incidence of PDPH is largely determined by physical factors such as the size and configuration of the meningeal perforation, which influences the volume of CSF loss until the breach has healed; and patient factors that determine the subsequent response to changes in CSF compartment dynamics. *In vitro* studies of CSF loss associated with various needles and human observational or randomized trials show that the characteristics of the needle are critical determinants of risk, with higher rates of PDPH after use of larger gauge (G) spinal, and possibly also epidural, needles (Table 27.1).

A meta-analysis of obstetric studies found an incidence of PDPH of 1.5–11% from spinal needles and 52% after unintentional puncture by an epidural needle.[12] The incidence following use of small-gauge pencil-point needles is as low as 0.4–0.5%[13,14] compared with 80–100% after puncture by a 16–17 G Tuohy epidural needle.[15–17]

## Risk factors for postdural puncture headache

### Needle characteristics

For spinal-induced PDPH, the relevance of needle gauge and tip configuration is well recognized.[18,19] A larger-diameter needle with a traumatic tip results in more CSF loss and a cadaver study found a fivefold increase in the volume lost after puncture by the same-gauge Quincke versus Whitacre needle and a sixfold greater loss from a 22 G versus 25 G spinal needle of the same design.[18] Clinical observations confirm that the lowest risk is conferred by smaller-gauge needles of pencil-point or non-cutting bevel design (Whitacre, Sprotte, or other atraumatic needle tip).[13,14,20–23]

**Table 27.1** The incidence of PDPH associated with different needles used in obstetric anaesthesia

| Needle characteristics | Incidence (%) and references |
|---|---|
| **Spinal needle** | |
| 24 G Sprotte | 0.7–4[20–22] |
| 25 G Quincke | 7–9[20,21] |
| 25 G Whitacre | 2.5–3[13,21,23] |
| 26 G Atraucan | 5[21] |
| 27 G Quincke | 3.5–8[20] |
| 27 G Whitacre | 0–0.5[13,14] |
| 29 G Whitacre | 0[14] |
| **Epidural needle** | |
| 16–18 G Tuohy | 52–100[12,15–17,27,28] |
| 18 G Sprotte | 55[17] |

G, gauge.
Data from various sources (see references).

Meta-analysis shows a threefold reduction in the risk of severe PDPH (odds ratio (OR) 0.26; 95% confidence interval (CI) 0.11–0.62) compared with cutting needles.[19] The relative risk of developing PDPH from a 27 G pencil-point needle compared with a 27 G Quincke needle is 0.38 (95% CI 0.19–0.75).[24]

Despite the frequency of PDPH after epidural needle dura penetration (50–90%), the contribution of needle size and design (and thus the characteristics of the meningeal perforation) is unclear because of the absence of randomized trials. Low levels of evidence from studies in which PDPH was a secondary outcome suggest that smaller-gauge epidural needles reduce risk.[17,25–27] However, there was no difference in either the severity of PDPH or the need for repeat EBP after puncture by 16, 17, or 18 G Tuohy needles in a prospective trial with an open choice of needle gauge (unpublished data).[28] The incidence of PDPH from an 18 G Sprotte tip epidural needle is lower than that from a 17 G Tuohy needle.[17]

## Needle bevel orientation

Electron microscopy shows that the lumbar dura mater consists of collagen fibre bundles oriented in various directions, plus elastic fibres arranged mainly longitudinal to the long axis of the spine.[29] Consequently, inserting a cutting-edge spinal needle with the bevel parallel to the longitudinal axis is thought to decrease the tendency of a dural hole to remain open under tension when the patient is erect, reducing the PDPH risk (OR 0.29; 95% CI 0.17–0.50).[30] On this basis, some have advocated epidural needle insertion with the bevel facing laterally, but subsequent needle rotation to facilitate catheter placement has been condemned by others, because it could tear the dura mater, which can lie close to the ligamentum flava in the posterior epidural space.[31]

## Reinsertion of the needle stylet

Reinserting the stylet of a large (21 G) spinal needle prior to its withdrawal from the subarachnoid space may reduce the risk of PDPH, perhaps by avoiding strands of arachnoid mater being pulled into the dural defect and prolonging the duration of CSF leak.[32] This is of little relevance to obstetric practice, in which smaller-gauge needles should always be used.

## Direction of needle approach

It has been suggested that approaching the dura at an angle creates a tissue flap and valvular closure of the meningeal hole, reducing the risk of PDPH, but a cadaver study found no difference in CSF loss through holes made at a 30° versus 90° puncture angle[18] and clinical studies report no advantage from a paramedian approach.[33]

## Multiple needle insertions

Repeated needle passes during unsuccessful attempts to locate the subarachnoid space may result in multiple dural holes, increasing CSF loss, and the risk of PDPH.[34]

## Neuraxial technique: combined spinal–epidural versus epidural only

A needle-through-needle combined spinal–epidural (CSE) technique provides a secure conduit for spinal needle puncture. Although it might be anticipated that PDPH rates would be higher after CSE than epidural-only approaches, given a deliberate dural puncture, it has been suggested that the risk of unintentional puncture is lower because the operator is more cautious, using CSF efflux from the spinal needle to confirm correct epidural needle-tip location. A large obstetric observational study involving small-gauge needles and meta-analysis both indicate that CSE and epidural-only techniques are associated with similar rates of PDPH and EBP.[16,35]

## Operator experience

During epidural techniques, operator inexperience (and possibly fatigue) is associated with increased risk of unintentional dural puncture.[36]

## Epidural loss of resistance with air or saline

A loss-of-resistance technique using normal saline has been advocated on the basis that saline allows continuous advancement of the epidural needle and on entry into the epidural space, saline pushes the dura away from the needle tip. A large quasi-randomized non-obstetric study by a single operator found no difference in the rate of dural puncture between saline and air, but a higher incidence of PDPH due to subarachnoid injection of air. Intracranial pneumocephalus may be visible on brain computed tomography (CT) scans and the ensuing headache is of earlier onset but shorter duration than typical PDPH.[37] A meta-analysis of five trials found no difference in the risk of headache between use of saline or air.[38]

## Ultrasound-guided epidural insertion

Although the incidence of PDPH was a secondary outcome, randomized trials comparing an ultrasound-guided pre-scan to a conventional landmark-guided epidural insertion report no difference in PDPH risk.[38]

## Patient age

Observational studies indicate that patient age is an important risk factor, with young children and the geriatric population very resistant to PDPH.[39] Pregnant women appear at high risk, with

possible explanations being different dural elasticity, vascular responsiveness, and lower epidural space compliance (greater tamponade of CSF loss) compared with older populations.

### Patient gender

Non-pregnant females are at greater risk of PDPH than males (OR 0.55; 95% CI 0.44–0.67).[40] Possible explanations include oestrogen-influenced differences in cerebral vasodilatory responses and nociceptive processing; and in pregnancy the effects of further hormonal changes, although it is not known whether pregnancy per se confers an additional risk.

### Patient history

Patients with a history of previous PDPH appear at greater risk of developing PDPH following a subsequent spinal technique.[41] Those who suffer from migraine are also postulated to be at greater risk, because of their vascular responsiveness.

### Body habitus and anatomy

Although women with an epidural space located at the shallowest depth beneath the skin (2–3 cm) or those with abnormal ligamentous anatomy might be at increased risk, logistic regression of a large obstetric anaesthetic database identified only one significant factor, namely increasing depth to the epidural space.[42] Retrospective data suggest that parturients of body mass index (BMI) greater than 35 kg/m$^2$ are less likely to develop PDPH after unintentional dural puncture with a 17–18 G epidural needle, although conflicting data also exist.[43–45] A postulated explanation is that higher intra-abdominal pressure limits CSF loss from smaller breaches of the meninges.[43,46]

### Pushing during labour

Retrospective data suggest an increased incidence of PDPH and EBP among women who bear down in the second stage of labour after unintentional dural puncture with a 17 G epidural needle.[47] It was suggested this was due to increased CSF loss, but a prospective study after 22 G Quincke needle spinal anaesthesia did not confirm that bearing down was a risk.[48] There are no prospective studies associated with use of small-gauge pencil-point needles or after unintentional dural puncture.

## Features of postdural puncture headache

### Symptoms

The pathognomonic feature of PDPH is its postural or orthostatic component, such that it is precipitated or exacerbated by erect postures and relieved by recumbency, although paradoxical (reverse) postural headache can occur.[49] Pain is located in a bifrontal and/or occipital distribution, and in almost 50% of cases is accompanied by shoulder or neck stiffness.[25,50] The characteristics are a throbbing or dull headache of mild to excruciating intensity. Lybecker et al. graded the severity from mild to severe based on interference with activities and related symptoms,[50] defining PDPH as moderate if it confined the patient to bed at times. Severe PDPH rendered the patient incapable or reluctant to raise their head or to stand and was always associated with other symptoms. Paech et al. defined a severe PDPH as one which prevented normal ambulation and care of the neonate.[15] Approximately half the obstetric cases after unintentional dural puncture meet this latter definition.[15,25]

Most associated symptoms appear consequent to low ICP or nerve traction, with neck stiffness due to irritation of upper cervical nerves. Nausea is also common, whereas ocular symptoms such as diplopia and photophobia are rare.[50] Most case reports describe an abducens (sixth) cranial nerve palsy, due to its long intracranial route from the pons across the petrous bone.[51–53] Diplopia usually presents a few days after dural puncture but may outlast, by several weeks, the resolution of PDPH[51,53] and can be resolved by an EBP.[54,55]

Hearing loss is demonstrable after spinal anaesthesia with (inappropriately) large-gauge needles[56] and is due to reduced pressure transmitted to the cochlear aqueduct through the inner ear, causing an endolymphatic hydrops that affects hair cell position. Auditory symptoms or tinnitus are associated with PDPH in 10% of patients.[50]

A variety of other neurological complications may be caused by dural puncture, so imaging should always be considered as a means of excluding concurrent intracerebral pathology.[57]

## Diagnosis of postdural puncture headache

The International Headache Society introduced the International Classification of Headache Disorders. In its third edition (ICHD-3), diagnostic criteria for postdural (post-lumbar) puncture headache were provided[58] (Box 27.1).

The diagnostic key is headache or neck pain, occurring hours to days after dural puncture, and resolving when supine or exacerbated when upright. Supporting features of low ICP may or may not be present on MRI. A sitting epigastric pressure test to raise abdominal pressure and momentarily relieve headache has been

**Box 27.1** ICHD-3 diagnostic criteria for postdural puncture headache

**Description**

Headache occurring within 5 days of a lumbar puncture, caused by cerebrospinal fluid (CSF) leakage through the dural puncture. It is usually accompanied by neck stiffness and/or subjective hearing symptoms. It remits spontaneously after 2 weeks, or after sealing of the leak with autologous epidural lumbar patch.

**Diagnostic criteria**

A. Any headache fulfilling criterion C

B. Dural puncture has been performed

C. Headache has developed within 5 days of the dural puncture

D. Not better accounted for by another ICHD-3 diagnosis

ICHD-3, The International Headache Society's *International Classification of Headache* Disorders, 3rd edition, 2013.

described but has low sensitivity and is not widely used.[25] Given that PDPH is principally a clinical diagnosis and that it is associated with potentially life-threatening pathologies, the myriad of causes of postpartum headache need to be excluded from the differential diagnosis.[59,60] Atypical presentations of apparent PDPH warrant investigation,[57] by reviewing the patient's history, repeating a physical examination, especially neurological, and sometimes by blood tests and brain imaging. Symptoms can be mimicked by preeclampsia; tension, migraine, and sinus headache; muscular pain; sleep deprivation; and caffeine withdrawal. Rarely the differential includes meningitis,[61,62] cerebral tumour,[63] arteriovenous malformation,[64] neurocysticercosis,[65] or a number of complications directly related to dural puncture.

## Onset of postdural puncture headache

In approximately 85% of cases, PDPH begins within 48 hours of dural puncture.[15,50] Onset as early as 20 minutes after spinal anaesthesia with a 27 G Whitacre needle has been reported, [66] although immediate or rapid onset is typical following intrathecal injection of even only a few millilitres of air.[37,67] The ICHD-3 criterion is onset within 5 days, but delayed onset, 12 days after epidural analgesia for labour, has been described.[68]

## Duration of postdural puncture headache

The duration of PDPH varies considerably. Symptom severity and duration tends to be greater after epidural needle dural puncture, making interpretation of the literature, including about interventions such as EBP, more difficult. Post-spinal headache usually lasts 1–12 days (mean 5 days).[50] Pneumoencephalus may cause severe headache of shorter duration (lasting hours to a maximum of 3–5 days) compared with headache from CSF loss.[37] Post-epidural PDPH frequently lasts at least 4–6 days and at least 10% of women will remain symptomatic after a month.[16] Surveys suggest that women with PDPH are more likely to develop chronic headache (not necessarily postural), with reported incidences of almost 30% at 18 months [69] and almost 20% at 3–6 years.[70]

Low ICP headache is a rare condition (incidence 2–5/100,000) which is thought to be precipitated by a spontaneous dural tear and CSF leak somewhere in the neuraxis.[3,4,71] This type of headache can be of gradual onset and very persistent, such that it is often treated conservatively for 2–3 weeks after presentation and may persist for months, despite treatment with an EBP. Nevertheless the response to a non-targeted lumbar EBP is good, with two-thirds of patients experiencing relief. If repeatedly unsuccessful, blood patching or fibrin glue administration at the site of a leak located by radionucleotide cisternography may be required. Of note, an EBP can effectively resolve long-standing PDPH up to years later.[72]

## Serious complications associated with postdural puncture headache

Although individually very rare, many pathologies warrant consideration in the differential diagnosis of PDPH or occur concurrently with PDPH after dural puncture. Cranial nerves other than ocular nerves may be involved[73] and severe upper limb or back pain has been successfully treated by an EBP.[74,75] Due to traction on intracerebral vessels, especially cortical bridging veins, subdural haematoma appears to be the most frequently reported of the rare serious neurological complications.[76] Extremely rare but potentially fatal cerebral tonsillar[77] or uncal brain herniation has been described.[78]

Although a direct relationship is difficult to establish, some patients with PDPH present with other neurological events, such as cortical vein thrombosis,[53,79] posterior reversible leucoencephalopathy,[80] generalized tonic–clonic seizures,[81,82] subarachnoid or intracerebral haemorrhage,[83] ischaemic stroke,[84] and acute psychiatric illness.[85]

## Prevention of postdural puncture headache

No intervention is very effective in preventing PDPH after unintentional dural puncture and the evidence supporting some measures is too weak to permit firm recommendations (Figure 27.1).[86] The lack of efficacy of some widely advocated therapies has been demonstrated with high (e.g. hydration) or moderate (e.g. caffeine) levels of evidence. For others (e.g. oral opioids) there is no supporting evidence (Table 27.2).

### Bed rest, manipulation of posture, or abdominal binders

It was thought that bed rest for 24 hours might decrease CSF hydrostatic pressure and reduce CSF leak, this has proven ineffective for obstetric patients after spinal anaesthesia.[87] A Cochrane review of studies comparing bed rest with early ambulation found no significant difference in the incidence (OR 1.21; 95% CI 0.94–1.55) or severity (OR 1.10; 95% CI 0.79–1.53) of PDPH.[87] An abdominal binder increases intra-abdominal and epidural pressure, which theoretically might help tamponade CSF loss, but is unsupported and has been abandoned because of the impracticalities.

### Fluid intake

There is no apparent relationship between PDPH and the volume of oral fluid ingested.[88] Administering intravenous (IV) fluid or encouraging additional oral intake, with the hope of maximizing CSF production, does not prevent PDPH (OR 1.00; 95% CI 0.44–2.25)[87] and makes management more difficult.

### Intrathecal saline

A small non-randomized study[89] of patients who experienced an unintentional dural puncture suggested that either immediate injection of intrathecal saline 10 mL through the epidural needle, or later injection through an intrathecal catheter prior to removal, might decrease the incidence of PDPH and need for EBP. This has not been confirmed by larger series or randomized trials and severe radicular pain and paraesthesia have been reported,[90] so this approach cannot be recommended.

### Intrathecal insertion of an epidural catheter

Deliberate subarachnoid placement of the epidural catheter at the time of dural puncture is a useful analgesic management option and several case series suggest it lowers the risk of PDPH after catheter removal.[91–94] The rationale is that the presence of a catheter mechanically obstructs CSF loss when bearing down during childbirth and promotes an inflammatory response that aids puncture closure, although the latter supposition is based on an animal study involving weeks, not days, of catheterization. Initial opinions that the intrathecal catheter should be retained for more

than 24 hours have not been supported by larger case series.[92,93] An updated meta-analysis of nine studies found no significant reduction in PDPH (RR 0.82; 95% CI 0.067–1.01) but a significantly lower risk of EBP (RR 0.64; 95% CI 0.49–0.84)[94] (Figure 27.2). Since then, a retrospective analysis of accidental dural punctures with 18 G needles, followed by intrathecal catheterization for at least 24 hours and post-delivery intrathecal saline infusion, found a reduction in PDPH from 62% to 42% (OR 2.3; 95% CI 1.04–4.86) and a reduced need for EBPs.[95] If there is a benefit, it is probably modest, because the best quality but underpowered

Data from various sources (see references).

study, a quasi-randomized trial in obstetric patients,[27] found no reduction in PDPH or EBP associated with intrathecal catheter placement.

## Cerebral vasoconstrictors (caffeine and triptans)

Caffeine is a central adenosine receptor antagonist while the triptans are 5-hydroxytriptamine-$1_D$ and -$1_B$ agonists, and aminophylline a phosphodiesterase inhibitor and adenosine receptor antagonist. These drugs cause vasoconstriction of cranial and basilar arteries. Low-quality investigation of IV caffeine sodium benzoate 500 mg suggested PDPH after non-obstetric spinal anaesthesia was less severe,[96] but multidose oral caffeine 75–150 mg combined with paracetamol (acetaminophen) 500 mg, started prior to spinal anaesthesia and repeated regularly for 3 days after, is ineffective.[97] A review concluded that caffeine is insufficiently supported to warrant prophylaxis against PDPH.[98] Caffeine is often poorly tolerated due to insomnia and agitation and it may be a risk factor in postpartum seizures.[99]

IV aminophylline appears of no value.[100] Subcutaneous sumatriptan and oral frovatriptan, which has a longer half-life, are effective for migraine headache. A small open study indicates frovatriptan might have promise, but this has not been tested in a high-quality trial or an obstetric setting.[101]

## Neuraxial morphine

A small randomized trial found no effect of subarachnoid morphine,[102] but a blinded study among parturients suffering unintentional puncture with a 17 G epidural needle reported a significantly reduced incidence of PDPH and EBP if epidural morphine 3 mg was given after delivery and again 24 hours postpartum.[103] This therapy requires validation in larger trials and may not always be an appropriate strategy because of the potential side effects and monitoring requirements.

## Intravenous cosyntropin (tetracosactide) or dexamethasone

A single, small randomized trial in obstetric patients suffering an unintentional dural puncture found that IV cosyntropin 1 mg reduced the incidence of PDPH from 69% to 33% and the need for an EBP from 40% to 31%.[104] The authors postulated that cosyntropin, a synthetic derivative of adrenocorticotrophic hormone (ACTH) that retains full activity, increases CSF volume through unspecified mechanisms. While encouraging, this finding requires confirmation. Studies of IV dexamethasone are conflicting, with the largest randomized trial reporting that dexamethasone increased the incidence and severity of headache on the first postoperative day and had no effect thereafter.[105]

## Prophylactic epidural blood patch

Injection of 15–20 mL of blood into the epidural space markedly increases subarachnoid pressure for 15 minutes[106] and sustains this rise in CSF pressure compared to very transient increases after epidural saline or dextran.[107] Epidural injection of blood also induces cranial vasoconstriction, immediately returning the elevated cerebral blood flow that is associated with reduction of CSF volume to normal.[6] The mass effect of blood distributed along the epidural space is also thought to prevent CSF loss from, and promote healing of, the meningeal perforation.[108,109]

Prior to catheter removal, administration of autologous blood through a re-sited epidural catheter is a popular prophylactic approach in some countries but rarely used in others.[110,111] A number of low-quality studies with inadequate blinding describe good efficacy from a prophylactic epidural blood patch (PEBP) compared with no intervention, symptomatic expectant treatment (bed rest, oral fluid, and analgesics) or epidural saline. The two randomized trials, only one of which used a sham PEBP as the comparator, found conflicting results after accidental dural puncture. One found a clinically relevant reduction in the incidence and severity of PDPH after PEBP (from 80% to 18%).[112] The study including a sham PEBP to reduce bias found that the incidence of PDPH and therapeutic EBP did not differ between groups, although the duration of PDPH was shorter.[113] Prior to the positive study,[112] a meta-analysis of randomized trials[86] had shown no benefit (Figure 27.1) and both a Cochrane systematic and a focused review had concluded that there was insufficient evidence to recommend the routine use of a PEBP.[114,115]

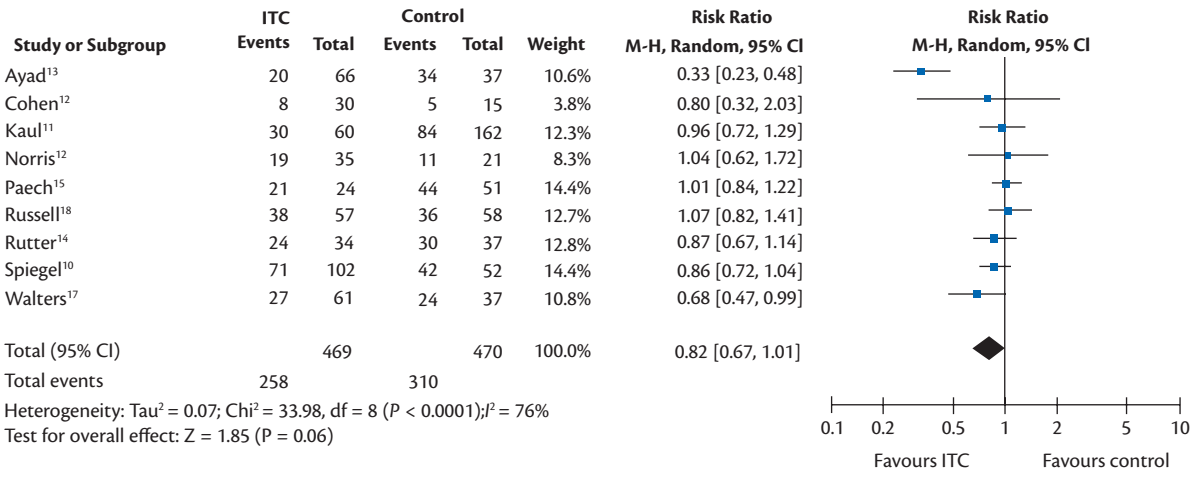

**Figure 27.2** Forest plot for risk ratio of PDPH after intrathecal catheter placement.

RR, relative risk. RR < 1 favours the intervention.

### Epidural saline or colloid

Infusing saline into the epidural space causes a very brief pressure increase of a few centimetres of water[116] and the possibility that this might translate to a clinical effect resulted in clinical studies investigating prophylaxis with either intermittent boluses of normal saline (40–60 mL) or a continuous infusion. Meta-analysis shows a non-significant relative risk reduction in PDPH (RR 0.65; 95% CI 0.40–1.05)[86] (Figure 27.1). Case reports describe severe interscapular or neck pain or intraocular haemorrhage during saline infusion.[116,117] Low-quality studies have evaluated Dextran 40 (20 mL) as an alternative injectate, but neither efficacy nor safety has been established.[118]

## Treatment of postdural puncture headache

### Symptomatic versus interventional management

Although headache usually resolves spontaneously within days to weeks, the high frequency of moderate to severe and functionally disabling headache[15,25] makes relief an imperative. Regular counselling and psychological support is an essential component of management irrespective of whether an expectant or interventional approach is planned. While awaiting spontaneous resolution, PDPH is traditionally managed with supine bed rest, fluid hydration, and analgesic drugs. This approach increases the length of hospital stay and number of emergency room visits post discharge,[119] and unfortunately symptomatic relief has proven very disappointing. Most drugs have either analgesic or cerebral vasoconstrictor properties, for example, non-opioid and opioid analgesics, caffeine, theophylline, triptans, ergot alkaloids, gabapentinoids, adrenocorticotrophic hormone, and steroids. The evidence base supporting these various drug therapies is very poor.[120,121]

The longest established and best supported therapy is an EBP.[114] Although an invasive procedure, EBP has withstood the test of time because it shows inconsistent but generally moderate to high efficacy[122,123] and symptoms resolve rapidly (Table 27.3).

### Pharmacological treatments

#### Oral non-opioid and opioid analgesics

Oral opioids presumably improve mood and provide sedation, but there are no data supporting relief of PDPH.

#### Epidural morphine

Case reports suggest that epidural morphine 3.5–4.5 mg can relieve PDPH after spinal anaesthesia[124] but there are no evaluations after unintentional dural puncture or clinical studies on which to base a positive recommendation.

**Table 27.3** Best levels of evidence[a] and grade of recommendation supporting various treatments of PDPH

| Treatment | Post-spinal | Recommendation | Post-epidural | Recommendation |
|---|---|---|---|---|
| Oral non-opioid and opioid analgesics | N/A | | N/A | |
| Epidural morphine | 4[124] | C | N/A | |
| Caffeine | 2b[125] | C | 2b[125] | C |

N/A, not available.

Data from various sources (see references).

### Caffeine

Caffeine 500 mg IV was proposed several decades ago as an appropriate treatment for post-spinal PDPH, but appears to have, at best, low efficacy.[38,121] For example, a randomized controlled trial of single-dose oral caffeine 300 mg versus placebo for parturients suffering from PDPH due to 26 G spinal or 17 G epidural needles found that pain was reduced 4 hours after treatment but that the effect was short-lived and EBP requirement unchanged.[125] Therapeutic doses cause problematic excitatory side effects, with case reports describing dizziness, flushing, jitteriness,[125] insomnia,[99] and an association with convulsions.[99] Adverse effects in the newborn are well documented[126] and maternal ingestion of large quantities when breastfeeding may contribute to irritability and poor sleeping patterns in the infant.[127]

### Theophylline

Theophylline is a methylxanthine causing cerebral vasoconstriction. A pilot study suggested that theophylline might be effective against post-spinal PDPH and IV theophylline 200 mg showed efficacy but it is not clear whether the study was randomized or blinded and there was no patient follow-up.[128] Until larger randomized trials are conducted there is insufficient evidence or safety data to support this treatment.

### Triptans

The triptans are serotonin agonists that are considered the most effective cerebral vasoconstrictors for treatment of acute migraine. Their side effects include injection site reactions, nausea, vomiting, pressure and heat sensations, flushing, fatigue, tingling, and coronary vasoconstriction (making coronary artery disease or co-administration with other vasoconstrictors a contraindication). A small case series suggested possible efficacy but the only randomized, double-blind trial for PDPH, while probably underpowered, found no improvement in severe PDPH after a single dose of subcutaneous sumatriptan 6 mg.[129]

### Ergot alkaloids

Methylergonovine maleate (methergine) is an ergot alkaloid derivative with activity at serotonin, dopamine and noradrenaline receptors. Side effects are nausea and vomiting, numbness and tingling of digits, muscle pain, coronary and peripheral vasoconstriction, hypertension, and rarely acute vasospasm. Despite some efficacy in treating migraine, there are several contraindications. A dose of 0.25 mg three times a day was reported to be effective for obstetric patients with spinal-induced PDPH, with only one of 25 patients requiring an EBP.[130] However the combination of oral ergotamine and caffeine is less effective than oral gabapentin,[131] so the ergot drugs are not recommended.

### Gabapentinoids

Gabapentin and pregabalin are analogues of gamma-aminobutyricacid (GABA) and are effective against acute, neuropathic and inflammatory pain. Small, non-obstetric, placebo-controlled randomized trials in patients with post-spinal PDPH found gabapentin 300 mg every 8 hours for 4 days significantly reduced headache intensity, with side effects such as somnolence, ataxia, light-headedness and visual disturbance;[132] or was more effective and less nauseating than oral ergotamine 1 mg and caffeine 100 mg.[131] Pregabalin may be effective in the same population based on a case report and a randomized, single-blinded study (150 mg/day for 3 days, then 300 mg/day for 2 days, versus placebo).[133] Its side effects are short-lived dizziness and somnolence.

One unit reported encouraging improvement in PDPH from obstetric epidural dural puncture when gabapentin was titrated against sedation[134] but currently the evidence-base is poor. Data on breast milk transfer is limited and potential effects on the developing brain have been raised based on adverse effects in rodent models. Thus gabapentinoids appear the most promising of the symptomatic treatments, but further evaluation is required.

### Adrenocorticotrophic hormone and cosyntropin

It has been postulated that ACTH or cosyntropin (1-24 corticotropin or tetracosactin) may reduce the severity of PDPH due to anti-inflammatory, salt and water retention and ß-endorphin enhancing properties.[135,136] Potential side effects include hypersensitivity reactions, flushing, malaise and dyspnoea; and postpartum seizures have occurred contemporaneously.[82] Open studies indicated successful relief of PDPH after single doses of intramuscular ACTH or cosyntropin (1.5 units/kg IV infusion over 30 minutes),[135] but a small, randomized, double-blind trial in obstetric patients found no effect of Synacthen® Depot 1 mg (equivalent to ACTH 100 units) intramuscularly on the severity of headache or requirement for EBP.[136] Based on this evidence, these agents cannot be supported.

### Intravenous hydrocortisone

Although beneficial actions are speculative, possibly through suppression of algogenic inflammatory mediators, steroids may be effective against low ICP headache. Efficacy against post-spinal PDPH has been found in obstetric and non-obstetric small, randomized, double-blind trials, with IV hydrocortisone 100 mg every 8 hours for 48 hours reducing headache severity within 6 hours compared with conventional symptomatic treatment.[137,138] There were no apparent side effects, but very low rates of blood patching indicate that external validity and efficacy after unintentional dural puncture need to be established.

## Non-pharmacological treatments

### Occipital nerve block

PDPH is often experienced in the frontal and occipital regions, where the scalp is supplied by the greater and lesser occipital nerves of C2 and C3 roots. Occipital nerve block is a minimally invasive treatment for occipital neuralgia, cluster, and migraine headache. For PDPH, it has been postulated that this block might reduce central sensitization, by transiently disrupting nociceptive input to the dorsal roots and trigeminal nucleus.[139] In addition to case reports of resolution of post-spinal and post-epidural PDPH, a randomized, single-blinded trial allocated a mixed group of obstetric and non-obstetric patients with post-spinal PDPH to either greater or lesser occipital nerve blocks with lignocaine, bupivacaine, fentanyl, and clonidine or conventional expectant treatment. Occipital block reduced pain, analgesic consumption, and provided complete relief for 68% versus 8% after 1 to 2 daily injections.[140] Potential risks such as subcutaneous haematoma, local pain, or alopecia are minor. Larger randomized studies in obstetric patients and with different injectates are required, but occipital nerve block may prove to be a relatively straightforward treatment for patients who refuse an EBP.

### Acupuncture

Case reports suggest acupuncture can reduce the severity of PDPH, sometimes with immediate effect,[141] but there is insufficient evidence to support this treatment.

### Epidural saline

After epidural injection of saline 10–30 mL, epidural and subarachnoid space pressures increase for 3–10 minutes. Whether this is of benefit in restoring ICP and reducing headache is uncertain, because although good success was reported in treating PDPH due to 25 G spinal needles, there was no benefit for post-epidural PDPH.[142]

Epidural normal saline infusions (15–30 mL/h for 24 hours) might sustain a rise in vertebral canal pressure more effectively and are claimed to have relieved PDPH following a failed EBP.[143] For patients with spinal deformity, caudal normal saline injection is an alternative. A small observational study of male and female patients with post-spinal PDPH used 80–220 mL of caudal saline infusion up to twice per day for 1–2 days and noted that 85% improved after 3–4 sessions, with only 7% requiring an EBP, but there was no control group.[144] In practice, epidural saline infusion is limited by pressure-related adverse effects such as back, neck or ocular pain, and retinal haemorrhage has been reported.[142–145] Given the poor evidence base, this approach should only be considered for women for whom an EBP is contraindicated or has repeatedly failed.

### Epidural colloids

Dextran, gelatins, and starch-based colloids show delayed reabsorption from the epidural space compared with normal saline. After lumbar puncture a small number of case reports describe the resolution of PDPH.[146,147] No immunohistochemical evidence of neurotoxic change was seen in experimental animals receiving intrathecal Dextran 40 or 3.5% colloidal solution of polygeline (Haemaccel®),[148] but some patients experience dysaesthesia or burning at the injection site. Given that the epidural colloids have not been adequately evaluated, they should only be considered when blood is contraindicated or refused; and specific informed consent would be essential.

### Epidural fibrin glue

Gel-like fibrin glue has high tensile strength and successfully closes dural defects in neurosurgical patients and after removal of intrathecal catheters in cancer patients. An effective seal of a 17 G epidural needle hole was obtained in a swine model[149] and a case report described a non-pregnant patient who was suffering a post-spinal PDPH that had not responded to an EBP, but which resolved after injection of epidural fibrin glue 3 mL.[150] This epidural medium has not been tested in obstetric patients or after unintentional dural puncture, but warrants investigation.

### Epidural blood patch

#### *Compared to conservative treatment*

A Cochrane review concluded that EBP is more effective than either conservative treatment or a sham procedure (OR for PDPH 0.18; 95% CI 0.04–0.76 and OR 0.04; 95% CI 0.00–0.39 respectively).[114] The best quality randomized study, involving 42 non-obstetric patients, found that EBP with 15–20 mL produced headache relief on the first and the seventh post-procedural day in 42% and 84% of participants respectively, compared with 10% and 14% of those receiving conservative treatment.[123] EBP is thought to resolve symptoms through an immediate and sustained tamponade, with the increase in intracranial CSF pressure leading to adenosine receptor inhibition, cerebral vasoconstriction, and fall in the elevated cerebral blood flow .[6,107] Animal studies show a sustained CSF pressure increase for up to 240 minutes after epidural injection of blood or fibrin glue, compared with only a few minutes after epidural saline or Dextran.[107] In humans, the increase in subarachnoid pressure is sustained for at least 15 minutes after EBP.[106] CSF accelerates coagulation and it is thought that relief is then sustained if the blood clots over the meningeal hole, preventing further CSF loss[108,151] and stimulating the fibroblastic proliferative response and collagen repair of the defect.

#### *Contraindications to an epidural blood patch*

Although relative contraindications, in a number of circumstances an EBP may present an unacceptable degree of risk. The injection of infected blood or tissue is inadvisable, precluding EBP in those with suspected or known systemic infection or skin infection at the puncture site. Injection of matched allogeneic blood into a febrile patient with severe PDPH has been described but is controversial, as the risk of creating suitable conditions for abscess formation still exists.[147,152] The risk of spinal canal haematoma may be unacceptable in those with defective haemostasis or on anticoagulant therapy. For example, patients on prophylactic low-molecular-weight heparin should not receive a neuraxial block for at least 12 hours and most consider a platelet count of less than $50{,}000 \times 10^9$/L a contraindication. Oncological seeding of the central nervous system has been raised as an issue for patients with haematological malignancy[147,153] but EBP is not contraindicated in HIV-positive patients.[154] Jehovah's Witness patients may find EBP acceptable if a continuous circuit from the venous circulation to the epidural space is used,[155] but alternative solutions are saline or colloid.

#### *Efficacy and success of an epidural blood patch*

The efficacy of an EBP is thought to depend on several factors, such as the diameter and shape of the meningeal perforation, the timing of the procedure, the technique and volume of blood used, patient response, and post-procedural management. An EBP for PDPH from 20–27 G spinal needles has a short-term success rate of 88–96%, but relief is complete in only 50–75%.[122,156] After dural puncture with a 16–18 G epidural needle in obstetric patients, partial relief from EBP occurs in more than 70% and complete relief in 30–50%.[28,157,158] After unintentional puncture in the obstetric population, recurrent headache occurs after initial success in approximately 30%, of whom 30–60% request another EBP.[157,158] The success rate of a second EBP is similar to the initial.[122,157] A third EBP is only very occasionally indicated and re-evaluation, with possibly further diagnostic investigation, should first be undertaken.[57] Back pain during injection may limit the volume of blood that can be administered .[28] Nevertheless successful EBP, performed years after dural puncture, is reported.[72,159]

A large observational study identified two risk factors for the failure of an EBP, namely penetration of the dura and arachnoid by a needle of size 20 G or less (OR 5.96: 95% CI 2.63–13.47) and performing the procedure within 4 days (OR 2.63; 95% CI 1.06–6.51).[122] The failure rate of EBP was noted to be higher in those patients who received an EBP less than 24 hours after dural puncture, compared with beyond 24 hours.[122] This finding is

supported by other observational studies, including in obstetrics, where success rates within 24 hours of dural puncture are extremely low[158,160] and both partial and complete success rates of EBP performed after 48 hours are higher.[28] The advantage of delaying an EBP is that the anticoagulant effect of local anaesthetic drugs in the epidural space will have waned[161] and closure of the meningeal perforation may have commenced. Although selection bias cannot be discounted, it appears that EBP should ideally be delayed for at least 24 hours and possibly 48 hours after unintentional dural puncture, keeping in mind that delay increases the period of suffering and hospitalization.[119]

#### *Technique and volume of blood in the epidural blood patch*

To minimize the risk of a repeat dural puncture, an EBP should be performed by experienced personnel after the patient has been informed about its efficacy and complications, found to be free of relative contraindications, and has given written informed consent. The procedure should be performed under standard monitoring, due to the possibility of bradycardia and syncope.[162] The lateral position is more comfortable for the patient but a short period of sitting is usually tolerated. A full aseptic technique is obligatory and is easier if an assistant deals with the sterile venepuncture. A warning about mild (and occasionally moderate to severe) back pain during the injection of blood is mandatory, because this is experienced by 30–50% of patients, usually after at least 10 mL of blood has been administered. The risk increases as more blood is injected.[28] Injection at an interspinous space at, or a space below, the level of the dural breach is common, but is not based on outcome data and only supported by imaging that demonstrates spread of blood across multiple segments, favouring cephalad distribution.[1,109,163] Use of EBP in patients with spontaneous intracranial hypotension shows that injection of blood remote to the location of the CSF leak can be effective,[3,4,71] so the level of insertion is probably not critical. A slow rate of injection is recommended because it limits the peak neuraxial pressure, which is thought to minimize nerve root pain. Intolerable back or leg pain may necessitate termination of the procedure—20% of women do not tolerate the injection of 20 mL and 50% do not tolerate 30 mL of autologous blood.[28]

The optimum volume of blood has been addressed in two randomized trials in obstetric patients who had post-epidural PDPH. There was no difference in clinical outcome between 7.5 and 15 mL.[164] A three-arm study (15, 20, or 30 mL) found that immediate and permanent relief was more likely after 20 mL than 15 mL (OR 4.49; 95% CI 1.31–15.42), although all volumes were of similar efficacy in achieving partial or permanent relief.[28] In addition to larger volumes of blood being more poorly tolerated, linear regression shows a direct relationship between increasing EBP volumes and worsening neurological compression syndromes.[165] On this basis, injecting at least 20 mL of blood is recommended when treating PDPH after unintentional dural puncture in obstetric patients.

#### *Post-epidural blood patch management*

The lumbar CSF pressure is increased in the semi-erect or erect position, which in theory might overcome the proposed 'dural plug' effect of an EBP. Although observations suggest that outcomes after EBP are not significantly affected by patient ambulation, a small randomized trial in non-obstetric patients recommended placing patients in a supine position for 2 hours after the procedure rather than a shorter period of recumbency, because the headache was then of lesser intensity.[166] Based on anecdotes of recurrent PDPH after EBP following heavy lifting, coughing, or abdominal straining, stool softeners may be advised. Occasional cases of fever[122] mandate early observation of vital signs including temperature. Patients must be reviewed after EBP and their general or family practitioner informed, so that rare complications such as an epidural haematoma or abscess are diagnosed. The patient should be given advice about potential back pain and who to contact with post-discharge concerns.

#### *Complications of epidural blood patch*

More than half of those having an EBP experience post-procedural back, buttock, or leg pain for several days. This is usually mild but can be moderate to severe in up to a quarter of cases.[28,122] Other complications include transient bradycardia,[162] nausea, neck pain, dizziness, auditory disturbance, and fever.[122,123] Serious neurological complications have not been quantified but appear very rare. These include radicular back pain, lumbovertebral syndrome (low back pain with neurological deficit in the lower extremities), cauda equina syndrome, arachnoiditis, seizures, and subdural haematoma.[165] Adverse outcomes have resulted from cerebral ischaemia[167] and VI and VIIth cranial nerve palsies are thought to be precipitated by changes in ICP that affect neural blood supply.[168] The duration of cranial nerve palsy associated with PDPH correlates with days delayed before EBP, so early treatment of cranial nerve palsy with EBP has been recommended.[168] Although imaging suggests there is rapid reabsorption of epidural blood,[163] and success rates of subsequent epidural techniques are unaffected,[169] it appears that rarely adhesions are formed, resulting in subsequent inadequate block, possible subdural block[170] or chronic back pain due to calcification.[171]

### Surgical closure of the dural tear

Surgery is the most invasive management of PDPH and may be required for the management of subdural haematoma, but meningeal repair is very rarely used and reserved for patients for whom all less invasive methods have failed to stop a chronic CSF fistula or persisting headache.

## Conclusion

There is still much to be learned about the pathophysiology, risk factors (needle, technical, and patient related), natural history, diagnosis, and management of PDPH. High-level evidence supports prevention by using small-gauge, non-cutting spinal needles, but other preventative strategies against either unintentional dural puncture or PDPH are poorly supported. The absent or poor efficacy of commonly applied measures such as bed rest, hydration, cerebral vasoconstrictor therapy, epidural or intrathecal saline injection, intrathecal catheter placement, or PEBP, is noted. Validation of stronger evidence supporting epidural morphine or IV cosyntropin (tetracosactide) is required. Symptomatic treatment of PDPH is also unreliable and the limited evidence that supports a modest benefit from caffeine, gabapentinoids, or IV hydrocortisone requires substantiation.

The intervention of an EBP is highly likely to relieve post-spinal PDPH, and is effective for PDPH after unintentional dural puncture, but in the latter situation a single blood patch only completely resolves headache in a minority of cases. The mechanism of action

and best methodology for EBP also requires further research, but delayed intervention and injection of approximately 20 mL of autologous blood appear appropriate.

CHAPTER 28

# Neurological complications of neuraxial blockade

Vibeke Moen

## Introduction

Neuraxial techniques for obstetric analgesia and anaesthesia are widespread, and serious complications are extremely rare. However, no medical procedure is completely without risks, and the symptoms of severe complications might present themselves after the woman has left the delivery suite. The knowledge of possible complications to central neuraxial blockade (CNB) is therefore essential not only to anaesthetists, obstetricians, and midwives, but also to general practitioners.[1] A recent meta-analysis of studies published after 1990 estimated the incidence of persistent neurological injury following obstetric CNB as 1/260,000.[2] The Third National Audit Project of the Royal College of Anaesthetists (NAP3) prospectively estimated complications of CNB and found that obstetric CNB accounted for more than 45% of all CNBs, but only 14% of all complications.[3] More than 80% of all complications followed adult perioperative CNB. Twelve serious complications occurred in 320,425 obstetric CNBs, and the risk of permanent neurological injury was 'optimistically' estimated as 0.3/100,000, 'pessimistically' as 1.2/100,000. These numbers indicate the safety of obstetric CNB, but it should also be remembered they apply to healthy parturients. Women with severe systemic disease, neurological and haematological disorders become pregnant, and may expect the same methods for pain relief during labour and delivery. Risk factors that explain higher incidence of complications in perioperative patients might be present in these women. Some smaller studies are published regarding outcome of CNB in pregnant women with spinal pathology or haemostatic disorders, but produce statistics that are not clinically useful, due to the extremely low incidence of complications in healthy women.[4–6] Previously healthy women may also develop haemostatic disorders during labour caused by major obstetric haemorrhage, severe pre-eclampsia, or the syndrome of haemolysis, elevated liver enzymes, and low platelets (HELLP). Intravertebral spinal haematoma (SH), an otherwise rare complication of obstetric CNB, is predominantly described in these patients (Table 28.1).[7–9]

The possible injuries caused by CNB include direct trauma, cranial or spinal haematomas, and infectious complications. Arachnoiditis is a rare condition that in recent years has received renewed attention. Although the incidence of each single possible complication is extremely low, one study indicates that the majority of women wish to be informed even of unlikely events; however, this may not be feasible in emergency situations.[10] Intrinsic obstetric neuropathies, on the other hand, are not infrequent as they are reported to occur in 0.6–92/10,000 labouring women.[11] Due to the widespread use of neuraxial techniques for labour analgesia, many of the women suffering from an intrinsic obstetric neuropathy will also have received CNB, and frequently obstetricians and midwives will assume the CNB to have caused the neuropathy. The anaesthetist must therefore be familiar even with these obstetric neuropathies, particularly as there is some inconclusive evidence that obstetric neuropathies could be more frequent in women receiving neuraxial labour analgesia.[11,12] The explanation could be that the pain from impending damage to peripheral nerves would also be alleviated by the CNB along with the labour pain. Positional nerve compression in a person without neuraxial anaesthesia will induce change of position, but profound neuraxial anaesthesia may mask the experience of pain, and cause the woman to remain in an unaltered position for longer periods of time.[11,13]

## Traumatic injuries

The last decades have seen an increase in the use of obstetric CNB, and this is also reflected in a related increase in insurance claims in different countries. Nerve injury has become the most frequent damaging event in obstetric anaesthesia reported in the American Society of Anesthesiologists Closed Claims Project, and a recent review of claims against the National Health Service in England revealed the same pattern.[14,15] Only surpassed by claims for intraoperative pain, nerve injury was the second most common cause for litigation in England. Fortunately, most of these nerve injuries are less severe and temporary.[15] A large prospective French study found 24 radiculopathies, accounting for an incidence of 4.7/10,000 procedures using spinal anaesthesia (SA) and 1.6/10,000 cases of epidural anaesthesia (EA). In most cases there was either paraesthesia or pain during performance of the CNB, and the symptoms of the following radiculopathy had the same topographic distribution.[16] The usual presentation of a radiculopathy was that of hypoaesthesia and in some cases also muscle weakness.[13] All were reversible, except one case following SA. The NAP3 reported permanent nerve injury following SA in two obstetric patients, accounting for an incidence of 1/67,000.[3]

More severe damage can occur when the conus medullaris or the medulla itself is damaged. Reynolds described seven cases of damage to the conus during SA in six obstetric and one female urological patient.[17] All cases of SA were believed to have been performed at the L2/3 interspace, whereas later magnetic resonance

The incidence of SH following SA, EA and CSE in three recent, large series. CSE was very rarely performed in Sweden during the actual period.

[a]Both obstetric patients in Sweden had severe coagulopathy due to HELLP. In one case, SA was performed for emergency caesarean delivery, and although the patient had severe haemostatic compromise, SA was preferred to GA. A small SH developed, but the patient recovered completely with conservative management. In the other case, the epidural catheter was withdrawn while the coagulopathy was deteriorating. Diagnosis was delayed, and although laminectomy was performed, the patient did not recover completely.

imaging (MRI) of the patients showed damage at levels varying from T10 to L2. None had spinal cords ending at exceptionally low levels and all had experienced pain during performance of the SA. There were three obstetric patients among the nine who experienced damage to the conus in a Swedish study and the anaesthetist thought that the block had been performed at L1/2 in only one case.[8] In all other cases, a lower level was assumed. EA was performed on eight of these patients and SA in one. Pain was experienced during performance of the CNB in all cases but one, and all patients were left with neurological deficit. A recent case of traumatic damage to the conus medullaris followed SA for caesarean delivery. The SA was reported to have been performed at the L2/3 interspace; however, the MRI accompanying the case report apparently indicates damage of the conus at the level of L1/2 (Box 28.1 and Figure 28.1).[18]

Direct trauma to the cord or conus medullaris evidently occurs even when the anaesthetist believes the CNB to be performed at a safe interspace.[17] This may be due to the spinal cord ending lower than usual, erroneous identification of the lumbar interspace, or an unfortunate combination of both these circumstances.

The cord usually terminates above the L1/2 interspace, but may extend further.[17] Results from two separate studies, one using MRI, the other in cadavers, indicate that the spinal cord terminates below L1 in 60–80% of adults, and below the lower part of L2 in 5–20% of adults.[19,20] The MRI study indicates that the conus may end as high up as the middle-third of the T12 vertebral body, or extend to the L3 vertebral body.[19] Moreover, the conus tends to end lower in women compared to men, and there are also racial differences, as the conus is reported to end at L2 or L2–3 in 32% of Africans compared to 20% of Europeans.[21,22]

The imaginary line joining the iliac crests, most often named Tuffier's line, is commonly used as an anatomical landmark for neuraxial anaesthesia.[17] When Tuffier's line is determined by palpation, it is considered to cross the spine at the L3/4 interspace (see Figure 20.4 in Chapter 20). However, Tuffier's line was originally a radiological landmark, and on imaging, Tuffier's line crosses

**Box 28.1** Traumatic injury to the conus medullaris during spinal anaesthesia

A 28-year-old healthy woman at 40 weeks' gestation was admitted for urgent caesarean delivery. A senior anaesthetist performed SA in the L2/3 'where the inter-space was best palpated' using a 26 G Atraucan needle. When the needle had been introduced approximately 85 mm, the patient experienced shooting pain radiating from the lumbar region to the back of the left leg and foot. When the spinal needle was withdrawn 2–3 mm, CSF flowed freely, and the local anaesthetic was injected without causing pain. The caesarean delivery was successfully completed with good anaesthesia. On the second postoperative day the patient complained of back pain, and severe pain radiating to the left leg. The left patellar and Achilles reflexes were weak, and there was also a sensorial deficit in the left L3 and L4 dermatomes. MRI showed a hyperintense lesion in the conus medullaris. The patient was treated with methylprednisolone for 24 hours. After 2 months she had recovered completely.

On the MRI, the lesion would appear to be at the L1/2 level, not the L2/3 level (Figure 28.1). This case therefore also illustrates the difficulty of correctly determining the interspace.

Data from Erk G, Taspinar V, Akay M, Gokcil Z., Spinal hematoma as a result of spinal anesthesia for cesarean section. *Neurosciences (Riyadh, Saudi Arabia)*, volume 14, Issue 2, pp. 182–3, Copyright 2009.

the spine at the spinal process of L4 or at the L4/5 interspace, and therefore some authors may refer to Tuffier's line as crossing the spine at this lower level.[17,23,24] It is of course not surprising that the intercristal line determined by palpation lies higher than when it is determined on imaging, and the inaccuracy may be increased in the pregnant patient.[25] In addition to hyperlordosis and weight gain, patient positioning may also lead to inaccuracy when determining Tuffier´s line in the obstetric patient when lying on her side. The width of the woman's hips compared to that of her shoulders will induce the imaginary intercristal line to cross the spine obliquely, and at a higher level.[25]

Two recent studies have assessed by ultrasound the level at which the intercristal line, determined by palpation, crossed the spine in pregnant women at term.[23,24] The results from these two studies show that Tuffier's line crossed the spine immediately above the L2–3 interspace in 27% and 35.5% respectively.

The inability even amongst experienced anaesthetists to correctly localize the interspace has been repeatedly documented.[26,27] Broadbent and colleagues found that the interspace identified was one to four interspaces higher than intended on 68% of all occasions. Similar results were found in a more recent study that used ultrasound 24–72 hours after delivery to determine the actual level of insertion of CNB in 99 obstetric patients who had received CNB during labour.[22] Ultrasound examination showed that the CNB had been performed higher than the level noted in the anaesthetic record in almost 50% of the patients, and at a lower level only in 15% of the patients. From these studies, it is apparent that SA is quite often performed at levels where many patients could still have underlying spinal cord.

A recent study found that in 29% of occasions even experienced anaesthetists perforated the dura with a 27 G Whitacre needle without experiencing the 'pop-sign' and the needle advanced further than intended.[28] The authors recommend that in addition to choosing a low interspace, anaesthetists should advance the spinal needle with an incremental rather than continuous technique. It should also be remembered that the tip of the modern atraumatic needles is also approximately 1 mm beyond the orifice compared to the older cutting edge Quincke needles, so insertion to obtain cerebrospinal fluid (CSF) is deeper and the potential for cord damage is greater.[17] Therefore, the practice of routinely performing SA in the L2/3 interspace exposes the patient to an unnecessary risk, and should be discouraged, as it is associated with a high probability of performing SA at an interspace with underlying conus.[20]

Ultrasound technology may prove a valuable tool for the safe placement of CNB, as this technique may correctly determine the midline and the interspace before performing CNB. Also, the ultrasound may predict the distance from the skin to the ligamentum flavum.[29] One study used ultrasound imaging of the spine to determine the depth of the epidural space in 61 patients requiring EA for labour analgesia.[30] The predicted depth of the epidural space correlated well with the actual needle depth, with a correlation coefficient of 0.881 (95% confidence interval (CI) 0.820–0.942). However, the use of ultrasound in an emergency situation would be difficult in all but experienced hands, and palpation of Tuffier's

line will continue to be the standard technique in the future. Therefore, knowledge of anatomical details and caution particularly when performing SA are of upmost importance. For further details, see Chapter 54.

## Spinal haematoma following central neuraxial blockade

The development of intravertebral SH following obstetric CNB is a very rare event. Scott and Hibbard reported one case of SH following 505,000 obstetric CNBs performed between 1982 and 1986.[31] A recent meta-analysis calculated the incidence of SH following obstetric EA as 1/562,628 in contrast to the incidence of 1/11,243 in the general surgical population.[32] Whereas the incidence of SH following SA is reported as 1/173,000 to 1/775,000 in non-obstetric patients, the rare case reports of SH following obstetric SA preclude any statistic calculation (Table 28.1).[8,13,33] Spontaneously occurring SH during pregnancy is also described.[34] The few reported cases of obstetric SH following CNB have mostly, but not exclusively, occurred in patients with compromised haemostasis due to major obstetric haemorrhage, severe pre-eclampsia, or HELLP (Table 28.1, Box 28.2, and Figure 28.2).[7,8,14,33] In rare cases, previously asymptomatic arteriovenous malformations may cause SH following CNB.[11]

The haematomas may be localized in the spinal, epidural, or in the subdural space.[35] With MRI this distinction is possible, and recent papers describe more accurately the localization. Most of the rare cases reported in the literature are reported simply as SH without further distinction of localization and are discussed as such in this section. Risk factors for the development of SH in the non-obstetric population are spinal pathology, vascular disease, anticoagulant therapy, and haemostatic disorders, including those caused by renal insufficiency.[8,32,36] The performance of CNB in women with spinal pathology or previous spinal surgery may be technically difficult or unsuccessful, and in one study neurological complications appeared to be more frequent.[4] If an obstetric patient has risk factors she should be informed of the increased risks of developing a SH but the actual quantifiable risk is difficult to define.[6] However, an individualized risk:benefit analysis should be performed in order to determine if a neuraxial block is justified.

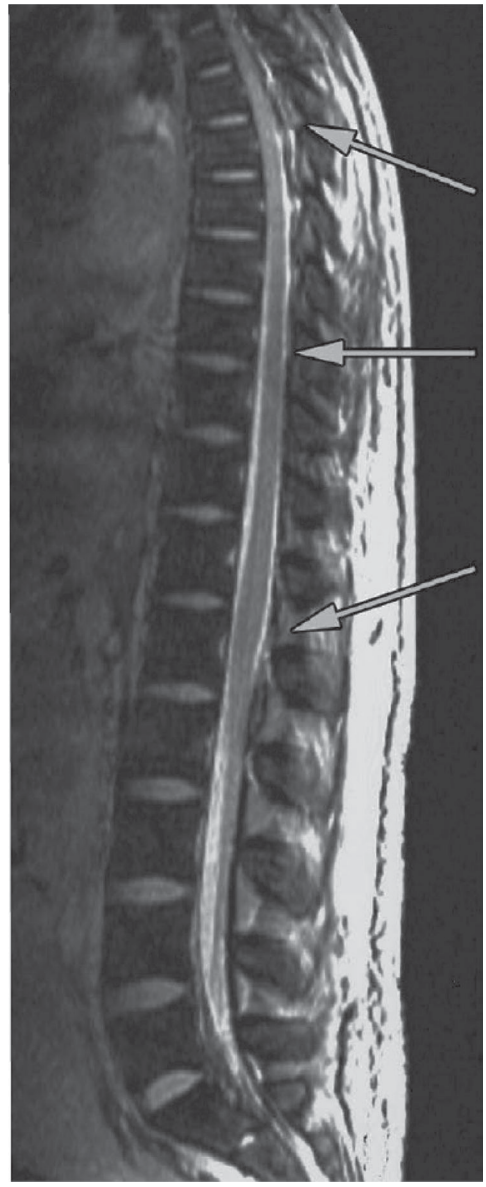

**Figure 28.2** Sagittal view at the dorso-lumbar level; The arrows indicate: Hyperdense epidural collection reaching from T3 to L5 (white) in relation to the medulla (recent blood: methemoglobin) and hypodense (black) corresponding to old blood, hemosiderine at the borders of the collection. Springer and the *Canadian Journal of Anesthesia*, volume 53, issue 3, 2006, pp. 252–7, Epidural hematoma after hemorrhagic shock in a parturient. Luc Nguyen. With kind permission from Springer Science and Business Media.

**Box 28.2** Spinal haematoma after large obstetric haemorrhage

During delivery of her first baby, a healthy 38-year-old woman had an epidural inserted for analgesia. Her coagulation status was normal, with a platelet count of 118 × $10^9$/L. The epidural catheterization was uneventful with no bloody tap, and the catheter was introduced 3 cm in the L4/5 interspace. She was delivered by ventouse extraction because of a non-reassuring fetal heart rate. The baby had an Apgar score of 0 at birth, and did not respond to resuscitation. Massive postpartum haemorrhage ensued, with severe coagulopathy. The lowest platelet count was 16 × $10^9$/L. Under general anaesthesia, ligation of the hypogastric arteries was performed, this being necessary to control haemorrhage. When the patient was extubated, 48 hours after delivery, she was paraplegic. An emergency MRI showed a haematoma extending from T3 to T5 (Figure 28.2). No surgical intervention was considered necessary, because the cord had minimal compression, and the patient recovered completely. The epidural catheter had accidentally been withdrawn during the transfers between operating theatre and intensive care units, while her coagulation was severely compromised. This manipulation of the epidural catheter was considered to have caused the haematoma.

Data from Nguyen L, Riu B, Minville V, Chassery C, Catalaa I, Samii K., Epidural hematoma after hemorrhagic shock in a parturient, *Canadian Journal of Anaesthesia*, volume 53, issue 3, pp. 252–7, copyright © 2006 Springer.

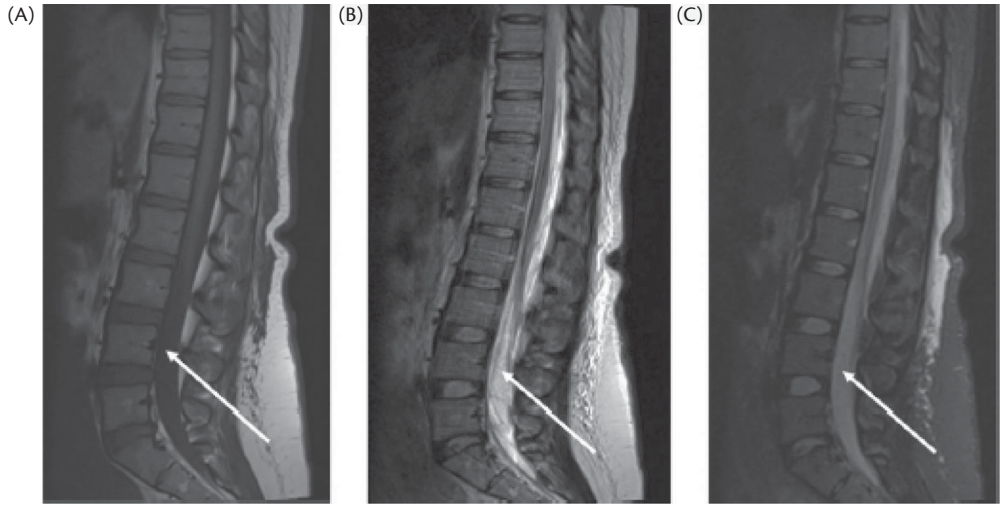

**Figure 28.3** MRI images 48 hours after CSE anaesthesia, approximately 44 hours after the onset of sensorimotor symptoms. (A) Lumbar spine sagittal T1-weighted image showing haematoma up to L2–3 (arrow) which is difficult to identify due to isointensity with spinal cord and CSF. (B) Lumbar spine sagittal T2-weighted inversion recovery image with fat saturation showing heterogenous collection between L3 and L5 (arrow) in the caudal sac with compression of the cauda equina and nerve root displacement. (C) Sagittal turbo inversion-recovery image with fat saturation showing a hypointense area of the dural sac from L3 to S1 (arrow), consistent with CSF contamination with blood.

Traumatic CNB insertion has also been considered a risk factor for the development of SH. European guidelines advise considering postponing non-obstetric surgery in the case of a bloody tap, particularly when intraoperative anticoagulation is planned.[32,37] However, in obstetrics, the luxury of postponing delivery is not possible, and the discrepancy between the low incidence of SH and the frequent bloody tap when performing obstetric EA is therefore of particular interest.[38] The incidence of bloody tap, reported as varying between 1% and 12%, is influenced by the positioning of the obstetric patient during performance of the CNB.[38] A study involving 900 women reported the incidence of bloody tap when performing EA in the sitting, lateral recumbent, or lateral recumbent head-down position (25–30°) as 10.7%, 6%, and 2% respectively. Women with a body mass index above 35 kg/m$^2$ were excluded from this study, and a subsequent study examined the influence of position in the morbidly obese.[39] The results from this study showed that bloody tap occurred in 1.3% patients in the lateral recumbent head-down position compared to 12.9% and 12.0% in the lateral recumbent and sitting position respectively.

The lack of serious consequences of a bloody tap in obstetric patients is obvious from clinical practice. The state of hypercoagulability in the pregnant woman could limit bleeding following a bloody tap. Also, the young spine is more forgiving if there is bleeding in the spinal canal, as demonstrated by a series of MRIs performed between 30 minutes and 18 hours after blood patches in five individuals, all younger than 45 years.[40] The MRI showed extensive leakage of blood into the subcutaneous tissue in all patients. In contrast, a case report showed that an epidural infusion of local anaesthetic at a rate of 5 mL/h caused compression of the medulla in an elderly woman with severe scoliosis.[41]

Removal of the epidural catheter is as critical to the formation of a SH as the insertion of the EA. This is indicated by the fact that 30–50% of all SHs reported have occurred following catheter removal.[8,36,42] The healthy obstetric patient can develop severe coagulopathy after placement of the epidural catheter, thus becoming a high-risk patient for SH.[42] Postpartum haemorrhages resulting in coagulopathy is a contraindication to removal of an epidural catheter. Coagulopathy must be reversed before removal of the catheter, and the epidural catheter should not be removed within 12 hours of administration of thromboprophylaxis. Similarly, administration of anticoagulant must be delayed for more than 4 hours after an epidural catheter is removed.[43,44] Midwives should be aware of this, and there should be written and established routines regarding management and withdrawal of the epidural catheter.

## Symptoms and diagnosis

Contrary to widespread belief, the first symptom of SH following CNB is usually not pain, but more often progressive motor blockade and sensory deficit. Bladder and bowel dysfunction may also be present.[3,7,8,11,32,36] The possibility of SH should therefore not be dismissed by the absence of pain. Interestingly, a recent review describes pain, often intense, as the presenting symptom in all 11 cases of spontaneous SH in pregnant women.[34] These differences could have pathophysiological explanations. In more slowly progressing compression, an impairment of the venous drainage reduces circulation in the medulla, with slow development of symptoms.[45,46] Abrupt interruption of circulation as caused by spontaneous SH may cause more dramatic symptoms.

Modern labour analgesia causes little or no motor impairment, therefore the greatest confounding factor in a newly delivered woman would be an obstetric neuropathy. Obstetric neuropathies, compared to SH, are common and usually unilateral. Postoperative pain relief by epidural infusion of local anaesthetics may, however, cause some motor block, thereby inducing the well-described mistake of attributing motor blockade to the local anaesthetic.

The presence of motor or sensory impairment in a newly delivered woman should generate prompt evaluation, and all anaesthetists involved in obstetric anaesthesia should be able to recognize an obstetric neuropathy.[11,47]

Computed tomography (CT) is usually more readily available, but may not provide the correct information, thus delaying diagnosis.[35] The definitive diagnosis of SH should be made by MRI, and as the MRI findings of a SH evolve over time, information regarding time perspective is important for the radiologist (Figure 28.3).[35] In the hyperacute phase (within 12 hours of haematoma formation), the oxyhaemoglobin present will produce an isointense signal on T1-weighted images, and it may also be difficult to visualize the SH on the T2-weighted images. Therefore, a negative MRI in a patient with symptoms should not definitively rule out the diagnosis of SH. Diagnostic delay caused by a negative CT scan and misinterpretation of MRI images led to permanent neurological damage described in a recent tragic case report.[35] Laminectomy is most often warranted, and the time at disposal for diagnosis and surgery is very short. For a prognosis of full restitution, a time frame of 8 hours from appearance of symptoms to definitive treatment is usually quoted.[36]

## Risk factors and prevention

Coagulopathies and haemostatic disorders are the most important risk factors for SH in obstetric CNB.[7,48] Guidelines regarding thromboprophylaxis and CNB are issued by government bodies and specialist subcommittees in many countries.[37,43,49–53] The most recent guidelines issued in the United Kingdom include specific recommendations for obstetric patients, and are easily accessible also in cases of emergency (Table 28.2).[44] These guidelines also grade their recommendations according to level of risk associated with CNB.

Guidelines may differ in their recommendations, reflecting the lack of robust data assessing specific risk. Consensus relies heavily on expert opinion, and concern has been expressed regarding medicolegal implications of the guidelines.[54] However, the lack of guidelines has also been recognized as a risk factor.[3] Patient safety should therefore be expected to benefit from adherence to guidelines, with the knowledge that recommendations never can guarantee absolute safety, and all treatment must be individualized.

## Thrombocytopenia and haemostatic disorders

Platelet count is not usually performed before placement of CNB in a healthy parturient, nor is it considered necessary without a history that indicates risk of abnormal bleeding.[11,44,53] Platelet count should be performed whenever coagulation abnormality is suspected, and in women receiving thromboprophylaxis, as well as in women with pre-eclampsia, placental abruption, or intrauterine fetal death.[44] Cholestasis may cause malabsorption of vitamin K, leading to coagulopathy due to a deficit in clotting factors.[44] However, thrombocytopenia may be accidentally discovered, and benign gestational thrombocytopenia accounts for 75% of thrombocytopenic cases encountered during pregnancy.[55]

Gestational thrombocytopenia typically appears in the third trimester and may be repeated in subsequent pregnancies. Platelet count can decrease up to 20% during normal pregnancy, but remains above $150 \times 10^9$/L in most of these women. However, 7% of pregnant women have platelet counts below $150 \times 10^9$/L; of these, 0.5–1% will have platelet counts below $100 \times 10^9$/L. The platelet count usually remains above $90 \times 10^9$/L, and platelet function is normal. Importantly, the fetus is not affected. The gestational thrombocytopenia is therefore usually without clinical significance, and does not preclude CNB.[56] A stable platelet count above $75 \times 10^9$/L is proposed as adequate level for CNB in healthy women in the recent UK guidelines (Table 28.2).[44,56]

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune disorder that accounts for 4% of the observed cases of thrombocytopenia in pregnancy.[55] Thrombocytopenia due to ITP may predate pregnancy, may worsen during pregnancy, and the platelet count may decrease below $50 \times 10^9$/L. One study found that detection of thrombocytopenia prior to 28 weeks of gestation and platelet levels lower than $50 \times 10^9$/L were highly sensitive indicators of ITP.[55] The maternal antibodies may be transferred to the fetus, leading to fetal platelet destruction, and caesarean delivery might be chosen to reduce fetal risk. The low platelet level associated with ITP has been considered a contraindication for CNB, but small studies report CNB performed without complications.[5] Douglas suggests that patients with ITP, and no history of bleeding at that count, can receive CNB at a platelet count above $50 \times 10^9$/L, and this view is supported by Abramovitz and Beilin.[56,57] The recent UK guidelines consider relative risk of CNB 'normal' in women with ITP and platelet count above $75 \times 10^9$/L, and 'increased risk' with platelets $50–75 \times 10^9$/L (Table 28.2).[44]

Platelet count may also decrease in pre-eclampsia and HELLP, and together with gestational thrombocytopenia and ITP these conditions account for 99% of all cases of thrombocytopenia in pregnancy.[57] Thrombocytopaenia may also be caused by treatment with heparin and low-molecular-weight heparin (LMWH).[44]

The platelet function is as important as the platelet number.[44,57] In gestational thrombocytopenia and ITP the platelet function is normal, whereas thrombocytopenia in association with decreased platelet function may be present in pre-eclampsia and HELLP.[57] HELLP is associated with a significantly increased risk of bleeding, including risk of SH following CNB, but the risk of SH in pre-eclamptic women is more difficult to evaluate.[7,48,58] One epidemiological study found a significant increase in postpartum bleeding in pre-eclamptic women compared to healthy women.[59] This population-based study did not find that bleeding was correlated to the severity of pre-eclampsia. However, Davis and collaborators found that while only women with HELLP had reduced clotting strength examined with thromboelastography, platelet function was decreased in all pre-eclamptic women when measured with a platelet function analyser.[60]

The safe level of platelet count has yet to be determined, and probably also varies according to the cause of thrombocytopenia, with stability and preserved function being more important issues.[57,61] In gestational thrombocytopenia and ITP, the number of platelets is more constant and the platelet function normal, whereas the platelet count might be rapidly diminishing in pre-eclampsia and HELLP.[57] Platelet count and evaluation of coagulation by activated partial thromboplastin time (aPTT) and prothrombin time (PT), usually measured by international normalized ratio (INR), should be performed in close temporal relationship to CNB in women affected by severe pre-eclampsia and HELLP. When considering the method of anaesthesia for caesarean delivery in these patients, the indefinable risk of SH following SA must be weighed against the documented risk of lethal

**Table 28.2** Relative risks related to neuraxial blocks in obstetric patients with abnormalities of coagulation

| Risk factor | Normal risk | Increased risk | High risk | Very high risk |
|---|---|---|---|---|
| LMWH–prophylactic dose | >12 h | 6–12 h | <6 h | <6 h |
| LMWH–therapeutic dose | >24 h | 12–24 h | 6–12 h | |
| UFH–infusion | Stopped > 4 h and APTTR ≤ 1.4 | | | APTTR above normal range |
| UFH–prophylactic bolus dose | Last given > 4 h | Last given < 4 h | | |
| NSAID + aspirin | Without LMWH | With LMWH dose 12–24 h | With LMWH dose < 12 h | |
| Warfarin | INR ≤ 1.4 | INR 1.4–1.7 | INR 1.7–2.0 | INR > 2.0 |
| General anaesthesia* | Starved, not in labour, antacids given | | Full stomach or in labour | |
| Pre-eclampsia | Platelets > $100 \times 10^9.1^{-1}$ within 6 h of block | Platelets 75–$100 \times 10^9.1^{-1}$ (stable) and normal coagulation tests | Platelets 75–$100 \times 10^9.1^{-1}$ (decreasing) and normal coagulation tests | Platelets < $75 \times 10^9.1^{-1}$ or abnormal coagulation tests with indices ≥ 1.5 or HELLP syndrome |
| Idiopathic thrombocytopenia | Platelets > $75 \times 10^9.1^{-1}$ within 24 h of block | Platelets 50–$75 \times 10^9.1^{-1}$ | Platelets 20–$50 \times 10^9.1^{-1}$ | Platelets < $20 \times 10^9.1^{-1}$ |
| Intra–uterine fetal death | FBC and coagulation tests normal within 6 h of block | No clinical problems but no investigation results available | | With abruption or overt sepsis |
| Cholestasis | INR ≤ 1.4 within 24 h | No other clinical problems but no investigation results available | | |

LMWH, low molecular weight heparin; UFH, unfractionated heparin; APTTR, activated partial thromboplastin time; NSAID, non-steroidal anti-inflammatory drug; INR, international normalised ratio.

*Although general anaesthesia is not a risk factor per se for coagulation complications, it is included in this Table to highlight that the alternatives to regional anaesthesia are not free of risk; thus a risk-benefit comparison is required when choosing one over the other.

intracerebral haemorrhage during intubation, in addition to the well-known risks of failed intubation in this group.[44,58]

Placental abruption and intrauterine fetal death may also be complicated by coagulopathy, therefore platelets, INR, and aPTT should be determined before performance of CNB.[44]

### Thromboprophylaxis

Pregnant women are at high risk of thromboembolic events, and a large number of women receive thromboprophylaxis or even therapeutic doses of anticoagulants, usually LMWH.[43] The guidelines issued by the Royal College of Obstetricians and Gynaecologists suggest that women receiving thromboprophylactic doses of LMWH discontinue their medication at the onset of labour or prior to planned delivery to allow administration of CNB during labour.[43] For women receiving high prophylactic or therapeutic doses of LMWH, the dose of heparin should be reduced to thromboprophylactic levels the day before induction of labour. CNB should not be used until at least 12 hours after the previous prophylactic dose of LMWH, and if a woman receives therapeutic doses of LMWH, CNB should not be administered for at least 24 hours after the last dose of LMWH (Table 28.2).[44] Likewise, the epidural catheter should not be removed within 12 hours of the most recent injection. Administration of LMWH should be delayed for 4 hours after SA or after an epidural catheter has been removed.[43,44] NICE guidelines also recommend aspirin 75 mg daily to women at high risk of pre-eclampsia, and some of these women may also receive LMWH. However, aspirin per se is not a contraindication to receiving neuraxial anaesthesia.[62] The recent UK guidelines recommend that CNB be delayed 12–24 hours after last dose of LMWH in these patients (Table 28.2).[44]

However, in the clinical setting, the anaesthetist will also have to consider the different risks and benefits related to EA for labour pain compared to SA for emergency caesarean delivery. Neuraxial anaesthesia is recommended for emergency caesarean delivery as it is considered safer than general anaesthesia.[44,48,63] Therefore, the lower risk of SH following SA could permit its use in patients with a degree of haemostatic disturbance that would be considered a contraindication to EA.[56] No case of SH is reported after CNB in obstetric patients receiving thromboprophylaxis with LMWH. As always, the final decision must rely on an individualized evaluation and risk:benefit analysis.

### Major obstetric haemorrhage

In the obstetric patient with deteriorating coagulation, most frequently due to large obstetric haemorrhage or HELLP, haemostatic function should be monitored and INR should be interpreted with great caution.[50]

The correlation between the actual levels of vitamin K-dependent coagulation factors (II, VII, IX, and X) and PT expressed as INR are reliable indicators of adequate haemostasis only in the stable patient. The PT is most sensitive to factors II and VII, less to factor X, and does not measure the activity of factor IX at all. The half-life of factor VII is 6–8 hours, factor II has a half-life of 50–80 hours, and the half-life of factor X lies in between, at 25–60 hours. Bleeding may occur if the level of any of the clotting factors is reduced to 20–40% of its baseline. In stable conditions, an INR of 1.5 is associated with a reduction of factor VII to 40% of baseline, and is therefore considered an indicator of adequate haemostasis. In unstable conditions, however, these correlations are unreliable. The patient recovering from coagulopathy due to large obstetric haemorrhage may have an INR of 1.4, but INR will mainly reflect the increase of factor VII, as factors II and X will recover more slowly. Therefore, in these situations, an INR of 1.4 might not be associated with good haemostasis.[50] Removal of an epidural catheter should not be considered before the INR has indicated adequate haemostasis for the time necessary for all coagulation factors to reach 40% of baseline. It would therefore seem prudent to wait until the INR has been stable at 1.4 or below for 24 hours before considering removal of an epidural catheter. One case report describes a SH that occurred following major obstetric haemorrhage, and it was later discovered that the epidural catheter had been inadvertently withdrawn when severe coagulopathy was present (Box 28.2 and Figure 28.2).[42]

In summary, available data suggest that platelet level, and eventual rate of decline of platelet level, should be considered as well as platelet function before performing CNB in a woman with thrombocytopenia. Additional tests of haemostasis such as INR and aPTT should be performed in these women, and also after large obstetric bleeding, and in cases of intrauterine fetal death or placental abruption.[44] Removal of the epidural catheter is as critical with respect to SH formation as the insertion of EA. SA performed with a small-gauge atraumatic needle carries a lower risk of SH than EA.[8,44,56] Adherence to guidelines may enhance patient safety.

## Cranial subdural haematoma

Cranial subdural haematoma (CSH) is a well-documented complication of accidental dural puncture as well as uncomplicated SA, and is usually considered extremely rare. Vos reported 45 cases of CSH before 1991 in the literature, and Errando and Perez-Caballero reported 57 cases from 1994 to 2010.[8,64,65] However, a Medline search discloses eight cases reported in 2012 alone, including five obstetric cases.[32,66–72] The incidence of CSH might be very low, but the large number of CNBs performed will most probably continue to cause this potentially life-threatening complication. The prevalence of obstetric patients amongst those suffering CSH after accidental dural puncture might reflect the larger proportion of obstetric EAs performed, but the presence of risk factors particular to the obstetric population cannot be ruled out.

A recent review described 25 cases of CSH following SA performed with needle sizes varying between 19 and 27 G.[73] The age of the patients varied between 20 and 88 years, and six of these patients were obstetric. The same review reported 21 patients with CSH after accidental dural puncture, of these 19 were obstetric patients. The earliest diagnosis of CSH following SA was made 6 hours after SA, the latest after 29 weeks. The time intervals were similar following accidental dural puncture. Surgery was performed in 35 patients, and of these six patients died.

Often the diagnosis was delayed, typically in a case of post-dural puncture headache (PDPH) that despite change in severity or characteristics was left without further investigation until severe neurological symptoms developed. These symptoms vary from confusion and disorientation, hemiparesis, and seizures and obviously will depend on the size and localization of the haematoma. Thus, the severity and diagnostic difficulties of CSH are not to be neglected, as illustrated by a case report published in 2011 (Box 28.3 and Figure 28.4).[74]

**Box 28.3** Cranial subdural haematoma following epidural analgesia

A 43-year-old healthy woman received an uncomplicated EA for pain relief during labour. Delivery was uneventful. In the following 3 weeks, the woman developed headache, which was worse on standing. She sought medical attention for her complaints, but as she had no other symptoms beside headache, no further investigations were made. Twenty-two days after delivery, she was taken to the emergency department with disorientation and altered mental status. The Glasgow Coma Scale score was 9/15. A CT brain scan showed large bilateral chronic subdural haematomas (Figure 28.4). She was immediately transferred to the neurosurgical department. On arrival she had fixed dilated pupils. The haematomas were evacuated, but the patient never recovered consciousness, and died 24 hours later.

This case report is very scant on details; however, it is also very illustrative. Most probably, an inadvertent dural perforation occurred during performance of the EA, and the headache was interpreted as PDPH, also when symptoms changed characteristics. The case report also highlights the necessity not only for anaesthetists, but also for general practitioners and obstetricians, to correctly diagnose intracranial pathology.

Data from Demetriades AK, Sheikh MF, Minhas PS., Fatal bilateral subdural haematoma after epidural anaesthesia for pregnancy, *Archives of Gynecology and Obstetrics*, volume 284, issue 6, pp. 1597–8, Copyright © 2011 Springer.

Leakage of CSF and the consequent low intracranial pressure (ICP) are considered the cause of both PDPH and CSH.[75] The downward displacement of the brain with traction of the bridging cerebral veins is believed to cause their rupture, leading to the formation of a subdural haematoma.[70]

However, based on data from experimental studies, Grände offers an alternative explanation to the mechanisms that cause PDPH, and in extension, also to the development of CSH.[76] The subdural draining veins just inside the dura are normally collapsed, as the ICP is higher than the venous pressure. These collapsed veins prevent retrograde transmission of systemic venous pressure variations, creating a venous gate protecting the brain. Lumbar puncture (LP) causes distal opening to the atmosphere of the normally closed dural space, thereby reducing ICP. Lowering of ICP will reverse the normal subdural venous collapse, leading to venous dilation which causes pain and an increase in intracranial blood volume. The effect of these changes in pressure gradients is most evident in the upright position, explaining the typical positional severity of PDPH.[76] One study showed that bearing down after accidental dural puncture increased the incidence of PDPH.[77] This could be explained by the loss of the protective venous gate as described by Grände, thereby permitting transmission of increased venous pressure, and could also favour the development of CSH in obstetric patients. Brain size decreases by approximately 2% during pregnancy, and the ventricles increase proportionally, returning to original size 24 weeks after delivery.[78] It is not known whether this physiological variation has any impact on the hydrostatic changes that follows perforation of the dura in the obstetric patient.

An epidural blood patch as treatment for PDPH has been proposed also to prevent the development of CSH, but in several case reports the CSH occurred in patients who already had received a blood patch.[65,70,73,79] However, the above-mentioned pathophysiological mechanisms support the use of a blood patch in patients suffering from PDPH.

The diagnosis of CSH is best performed with MRI, but if only a CT scan is available, this must be contrast enhanced. A CT scan performed without contrast may be unreliable 7–21 days after all forms of subdural haematoma, because the haematoma and brain tissue have the similar radiographic density.[70] For some patients with CSH, conservative treatment has been appropriate, but craniotomy has been necessary in many of the cases described.[65,70,74,79]

## Cranial nerve palsies

Focal neurological deficit due to isolated cranial nerve palsies may be present in patients who have received CNB.[12] It is believed that a dural puncture may cause low ICP leading to stretching of the cranial nerves as well as PDPH. Patients may complain of diplopia and hearing loss that may accompany or precede PDPH.[42] Diplopia is most frequently caused by stretching of the abducens nerve (cranial nerve VI). The oculomotor nerve (cranial nerve III) and the trochlear nerve (cranial nerve IV) may also be affected. The palsy is usually unilateral, but can be bilateral. Low ICP is also reflected in a decreased pressure in the perilymph within the cochlea that causes hearing impairment, typically in the low frequency area.[12] Smaller-gauge needles more rarely cause cranial nerve palsies, and blood patches may not always resolve the condition once it has become manifest.[42] Patients may suffer from chronic palsies despite a blood patch for PDPH.[8,42]

Bell's palsy is three times more common in the pregnant compared to the non-pregnant patient, and may occur even after delivery.[43] Facial nerve palsy is usually not related to CNB, but there are occasional reports of facial nerve palsy that have been considered associated with obstetric CNB.[12]

## Ischaemic injury to the spinal cord

Ischaemic injury to the spinal cord is most often described following aortic surgery, but rare cases are reported in obstetric patients.[13,45,80] Prolonged hypotension may cause cord ischaemia in obstetric patients, but also aortic compression, epidurally administered vasoconstrictors, as well as vasospasm elicited by the epidural catheter are believed to have caused cord ischaemia.[81,82] The anterior lumbar spinal cord is particularly sensitive to hypoperfusion, as its blood supply depends on a single unilateral artery, the artery of Adamkiewicz.[46] A secondary blood supply arising from the internal iliac artery is described in 15% of individuals. Compression of this artery by the fetal head could cause ischaemia even in the absence of systemic hypoperfusion.[83] The anterior spinal artery syndrome arises from ischaemic damage limited to the anterior part of the cord. The symptoms are therefore characteristic, with motor deficit and dissociated sensory loss, as pain and sensation of temperature is lost, but sensation of vibration and position is preserved. MRI is the method of choice for visualizing ischaemic damage to the cord.[80] Fluids and vasoactive drugs

should be used to restore mean arterial pressure to normal values following spinal injury, but there are no clear guidelines for specific pharmacological treatment of spinal strokes.[45] The outcome of spinal cord infarction following aortic surgery is worse than when ischaemia has other causes.[80] Some obstetric patients have recovered completely, whereas others have suffered severe damage.[13,81,82]

## Infectious complications

Meningitis and epidural abscess are severe infectious complications of CNB. Their incidences are difficult to quantify, but these complications are often preventable, potentially life-threatening, and therefore of major concern. Although infectious complications are considered rare, they accounted for 46% of neuraxial complications following obstetric CNB reported in the American Society of Anesthesiologists Closed Claims Project from 1990 to 2003.[14] The incidences reported in literature vary greatly, and whereas the lowest incidences are reported in large surveys and reviews of literature, smaller studies performed in a clinical setting report higher incidences, possibly as they identify cases that easily may be lost to follow-up.[2,3,8,84–86] EA and SA cause different complications, as epidural abscess is most often caused by EA, and meningitis is most frequently a complication of SA.[8,84,87]

Epidural abscess and deep tissue infections following obstetric CNB are reported to occur in 0.2–48/100,000 cases.[86] The incidence of bacterial meningitis following obstetric CNB calculated on cases reported in surveys varies between 1/3000 and 25.5/million.[84] The number of cases reported in the literature is not in proportion to the reporting countries' population, indicating a probable under-reporting, in addition to cases of meningitis, that although unrecognized as such, have been adequately treated with antibiotics.[87] The several clusters of iatrogenic meningitis described in the literature confirm the consequences of breaches in aseptic technique.[87–89]

### Bacterial meningitis

When meningitis occurs as a complication to CNB, it almost invariably follows a perforation of the dura, intended or accidental, and may therefore appropriately be renamed postdural puncture meningitis (PDPM).[87] Streptococci of the viridans group, also called α-haemolytic streptococci, are the most frequently encountered pathogens in cases of PDPM and accounted for 49% of all positive CSF cultures in Baer's comprehensive review.[87]

Viridans streptococci are part of the normal flora of the upper airways, gastrointestinal tract, and female genital tract, but are usually not found on the skin.[90] *Streptococcus salivarius* is the most frequent viridans pathogen of PDPM; other viridans streptococci encountered are *S. anginosus, S. mitis, S. mutans*, and *S. sanguinis*.[91] The viridans streptococci are facultative Gram-positive aerobic bacteria and their presence in saliva is in the magnitude of $10^9$ colony forming units per millilitre of saliva.[92] Several clusters of PDPM are reported in literature, and when the origin of the pathogen has been determined, it has been found in the oral flora of the LP operator.[87–89,93,94]

Viridans streptococci lack the virulence of the bacteria causing community-acquired meningitis, *Haemophilus influenzae, Neisseria meningitides*, and *Streptococcus pneumonia*. Therefore viridans streptococci only very rarely cause spontaneously occurring meningitis, but they do cause meningitis when inoculated directly into the CSF.[87] No patient predisposition has been found in patients suffering PDPM, nor is it necessary for the development of PDPM, as the breach of defences against infection are caused mechanically.

It is noteworthy, however, that almost all cases of obstetric PDPM have been in women who were or had been in labour when they received the CNB.[84] The occurrence of meningitis could possibly be caused by bacteraemia induced by labour or bladder catheterization, or indicate that the hygienic conditions in the delivery suite are less satisfactory. However, there are no cases of maternal meningitis reported without the use of CNB, indicating that labour itself is not a risk factor for meningitis.[90] Only in one case

published in 1989 was haematogenous spread of viridans streptococci considered to have caused postpartum meningitis following but unrelated to EA. *Streptococcus uberis* was found in the patient's CSF as well as in her blood, urine, and vaginal secretions.

Bacteraemia caused by brushing of teeth has also been proposed as important for the development of PDPM.[95] In one study, bacteraemia occurred following brushing of teeth in 23% of the study subjects, and the bacteraemia lasted for 60 minutes in 9% of these study participants.[96] Roughly half of the bacteria detected belonged to the viridans group. However, polymerase chain reaction (PCR) is not known to have linked any case of obstetric PDPM either to the woman's own oral flora or to her vaginal flora.

Other bacteria occasionally found in PDPM are *Staphylococcus aureus* (5%), *Pseudomonas aeruginosa* (4%), and *Enterococcus faecalis* (2%).[87] Two cases of PDPM caused by *Serratia marescens* have been described.[97] Investigation disclosed the presence of *Serratia* in multi-use bottles, once again illustrating the importance of investigation following any case of PDPM (and discouraging the use of multi-use bottles). The most recent case report of PDPM was caused by *Abiotrophia descens*.[98] *Abiotrophia* is also part of the oral flora, and the authors report that the anaesthetist might have omitted his/her mask during the performance of the blockade. One case of meningitis in an obstetric patient, reported in 2003, followed combined spinal–epidural anaesthesia (CSE), performed without the use of a mask.[99] *Neisseria meningitides* was identified as the pathogen in this case, and the meningitis was therefore considered as community-acquired meningitis, only temporarily linked with the CSE. However, symptomatic carriers of *N. meningitides* are not uncommon, indeed, they are believed to spread the infection.[100] *N. meningitides* might thus be contained in the same droplets as viridans streptococci. In this actual case, PCR was performed only for diagnosis, not for tracing bacterial origin, so no certain conclusions can be made regarding transmission. However, the case serves as a reminder of the considerable risks involved when performing CNB with inadequate aseptic technique.

In a large series of 27 cases of PDPM from India, 11 cases followed SA for caesarean delivery. The mortality was significantly higher amongst these obstetric patients, but the article does not disclose the exact number of obstetric deaths.[101] The pathogens were different from the series originating in Western countries, as 37% were diagnosed with chronic meningitis caused by tuberculosis. The authors considered that the SA might have caused rupture into the CSF of a central nervous tubercle, causing acute deterioration. There were also five cases of meningitis caused by *Aspergillus fumigatus*, and of the 22% with positive CSF culture, there were three cases of *Staphylococcus aureus*, and one case each of *Pseudomonas* and *Acinetobacter*.

The risk of PDPM also highlights one long-lasting controversy: should the dura routinely be breached during labour?[90,102] A 2012 Cochrane report did not find evidence of increased incidence of PDPM following CSE, but the low number of patients in the studies included would not be expected to reveal an increase of such a rare complication.[103] Interestingly, no case of PDPM has been reported from Scandinavian countries, where CSE is not routinely used for labour analgesia.

The oral flora of the performer of the CNB is often the most likely source of the pathogen in PDPM.[84,87] One important exception is the cluster of PDPM in Sri Lanka 2005, caused by *Aspergillus fumigatus* and responsible for the death of three women following caesarean delivery.[104] These deaths prompted a major epidemiological investigation and the most probable explanation found was *Aspergillus* contaminating syringes and needles used for SA, equipment that had been donated following the tsunami catastrophe and stored in a humid and hot environment. The onset time for *Aspergillus* to cause meningitis is long, 7–36 days in the series from Sri Lanka, making epidemiological research even more difficult.[104] *Aspergillus* is an ubiquitous fungus that will cause infection only in immunocompromised patients, and meningitis only if inoculated directly into the CSF. Meningitis from *Aspergillus* carries a high mortality rate, 50% was reported in the series from Sri Lanka. However, treatment before symptoms occur may prevent the development of meningitis, and in Sri Lanka no further deaths occurred after patients at risk were identified and treated.[104] The management of this tragedy should be a learning point, indicating the need for scrupulous investigation of hygienic procedures whenever a case of iatrogenic meningitis occurs.

### Lumbar puncture and bacteraemia

Performing a LP in the presence of bacteraemia has been proposed as a possible cause of iatrogenic meningitis.[105–107] The dural puncture could cause a breach in the blood–brain barrier, thus introducing bacteria into the CSF. Bacteria lacking the virulence necessary to breach the blood–brain barrier could by this mechanism also cause meningitis. This could be of concern to the obstetric patient, as bacteraemia may be present in 1–4% of women following uncomplicated delivery, and in 8% following bladder catheterization.[84,108,109] One study found bacteraemia in 8% of women affected by chorioamnionitis, but no infectious complications developed following CNB, and only a minority received antibiotics.[110] It can be assumed that bacteraemia is probably present in many of the obstetric patients who also receive CNB, but the bacteraemia may be completely asymptomatic, and the febrile patient is not necessarily bacteraemic.[111] However, it should also be taken into account that most of these are low-grade bacteraemias. The human and animal studies correlating LP to meningitis have had high bacterial blood counts.[109] Epidemiological studies found significantly higher mortality from *Staphylococcus aureus* infection in patients with high-grade bacteraemia compared to mortality in patients with low-grade bacteraemia.[112] Data presented in a review suggested that SA may be performed in patients at risk of low-grade bacteraemia.[113] This is supported by the low incidence of infectious complications to CNB despite the probable high prevalence of low-grade bacteraemia in obstetric patients. However, patients with signs of systemic infection should be treated with antibiotics prior to administration of CNB.[3,109]

### Symptoms, diagnosis, and treatment of bacterial meningitis

The symptoms of PDPM usually appear within 24 hours of the CNB, but may occur after only 8 hours, or after a delay of 8 days, probably caused by partially effective antibiotic treatment.[8,87] It is difficult to mistake the typical symptoms of bacterial meningitis when a patient presents with the classical triad of fever, altered mental status, and nuchal rigidity.[100] Intense headache and photophobia may be present together with other signs of meningeal irritation such as Kernig's sign (the inability to lift the leg without bending the knee) and Brudzinski's sign (spontaneous flexion of the hip during passive flexion of the neck). Severe meningitis will increase ICP causing altered levels of consciousness

and cause pupillary abnormalities as well as seizures and focal neurological signs.

The signs and symptoms of PDPM may, however, be more subtle, probably due to the lower virulence of the infective agent.[8,87,114] All patients in a large series presented with headache and fever, but in several cases the absence of more serious symptoms led to an initial diagnosis of PDPH, often with an additional diagnosis of infection such as urinary tract infection or endometritis.[8] Therefore, meningitis should be in the differential diagnosis whenever a woman who has received CNB for labour or delivery complains of headache and also presents with fever.

LP is usually performed when meningitis is suspected, but is no longer essential for aetiological diagnosis, as this can be provided by PCR long after live bacteria have disappeared from the CSF.[93,94] Moreover, LP is not completely without its own risks as it may precipitate herniation in patients with high ICP.[76,87,115] Neither CT scan nor ophthalmoscopy are reliable methods of determining acutely increased ICP.[76,116] CT scans were performed in an outcome study regarding active management of increased ICP in community-acquired bacterial meningitis.[115] Radiological signs of brain swelling were evident only in five out of the ten patients who all had increased ICP measured with invasive monitoring. A retrospective assessment of CT scans performed in 103 patients with bacterial meningitis found that all patients with radiological signs of cerebral oedema also had clinical signs of increased ICP.[116] These studies indicate that increased ICP may be present despite normal CT scans, and that clinical signs of increased ICP, when present, are reliable indicators of increased ICP.

When LP is performed, CSF may be cloudy with increased white cell count, protein, and lactate, together with glucose content lower than plasma glucose, typical findings of bacterial meningitis.[100] Increased white cell count or C-reactive protein in blood may be delayed. Gram stain of the CSF may be done, and when suspecting PDPM, culture in broth medium will favour growth of viridans streptococci.[84] In a large proportion of PDPM (36%), the CSF culture was negative, or was not reported.[87] This may have several explanations: Viridans streptococci are usually not pathogens, so their presence might have been considered as contamination or in any case not significant.[87,117] The failure to grow might erroneously lead to the diagnosis of chemical meningitis.[84] Often antibiotics are administered prior to LP, effectively clearing the CSF within hours.[100] Finally, viridans streptococci often do not grow well on agar, so broth culture is to be preferred.[84] However, PCR may identify the pathogen in the CSF even when LP is performed after antibiotics have been given.[94]

Empirical broad-spectrum antibiotics according to national guidelines for management of community-acquired bacterial meningitis should be administered.[87] Treatment should not be delayed by the performance of diagnostic LP or CT scans.

Most of the patients with PDPM are successfully treated, but several deaths have been reported in the literature.[84,87] At least seven previously fit obstetric patients have died following PDPM, reflecting the potentially lethal nature of this condition.[87,88,104] The latest obstetric death occurred in 2009 in Ohio, United States, when the anaesthetist, omitting the use of a mask, performed SA for pain relief during labour causing lethal meningitis in a previously healthy young woman. PCR was used in the epidemiological follow-up, and the origin of the pathogen (*Streptococcus salivarius*) was traced to the anaesthetist (Box 28.4).[88] Another issue, not to be dismissed, is the increasing resistance to antibiotics, also amongst the viridans streptococci.[118] As PDPM is such a serious complication, a root/cause analysis should be done to investigate the sequence of events leading to the infection so that lessons can be learnt and preventative measures put in place.[93,94,119]

**Box 28.4** Cluster of PDPM in Ohio 2009

Patient A: a 26-year-old healthy woman was admitted to the delivery suite in active labour. She received SA for labour analgesia, and delivered a healthy baby. Approximately 15 hours after receiving the SA, the patient developed fever, nausea, and severe headache, and she later became lethargic and unresponsive. She received treatment for meningitis, and recovered.

Patient B: a second healthy 30-year-old woman in active labour was admitted to the same hospital 3 hours after patient A. Patient B also received SA, performed by the same anaesthetist, and delivered a healthy baby. Approximately 13 hours after the SA she developed symptoms of meningitis. Despite adequate treatment she died 12 hours after debut of symptoms.

Blood and CSF cultures from both patients revealed *Streptococcus salivarius*.

The subsequent investigation included culture of medication vials and a review of the SA procedure protocols. Staff interviews disclosed that the anaesthetists in the hospital did not always wear masks while performing SA. Culture and analysis by PCR of medication vials revealed no evidence of contamination. Cultures performed on swabs obtained from oropharynx, buccal mucosa, and tongue from the anaesthetist that had performed the two SA resulted in no growth, as the anaesthetist had received post-exposure antibiotic prophylaxis for a presumed meningococcal meningitis. However, subsequent laboratory analysis enabled the identification of a strain of *S. salivarius* that was genetically indistinguishable from the *S. salivarius* of the two patients.

## Epidural abscess

Spontaneously occurring epidural abscess is reported with an incidence of 2/10,000 hospital admissions per year.[120] The reported incidence of deep epidural infection and epidural abscess following obstetric CNB varies between 0.2 and 48/100,000 with higher incidences reported in smaller series.[86] However, obstetric patients appear to develop epidural abscess after CNB less frequently than non-obstetric patients. The recent NAP3 reported 13 cases of epidural abscess in 312,450 perioperative CNBs, but only one case of epidural abscess occurring after 186,900 obstetric EAs (including 25,350 CSEs).[3]

The pathogens involved are most often *Staphylococcus* species both when epidural abscess occurs spontaneously or following CNB; therefore the microbial agent does not indicate route of transmission as in most cases of PDPM.[84,121] However, in one case report, genetic fingerprinting identified the anaesthetist's flora as the origin of the *S. aureus* responsible for the epidural abscess.[122] Another study could identify the origin of the *S. aureus* in the

patient's own skin flora.[123] The predominant microorganism of the skin flora is *S. epidermidis* (65–69%), whereas *S. aureus* (1–2% of skin flora) is the prevalent pathogen in cases of epidural abscess complicating CNB.[124] This discrepancy would indicate that disinfectants more effectively prevent further contamination from *S. epidermidis* compared to *S. aureus*.[124]

During spontaneous epidural abscess, the bacteria reach the epidural space by haematogenous spread, whereas the catheter is believed to facilitate the introduction of bacteria from the skin in cases of epidural abscess following CNB.[125] This is supported by the results from a carefully conducted prospective study involving 205 epidurals. The study results showed that a positive culture at the catheter tip following removal was significantly correlated to positive culture of the skin near the point of entry.[125]

The development of epidural abscesses is also related to the duration of catheterization, and it is well known that the risk of superficial infection increases with the duration of catheterization.[121] Loo and collaborators recommended that the indwelling time of epidural catheters on most occasions should be limited to 24 hours in obstetric patients.[13] Studies have reported 3–4 days as median time of catheterization in patients with catheter-related epidural abscesses, but epidural abscesses has also been described after only a few hours of catheterization.[126–128]

Risk factors for the development of epidural abscess also include immunosuppression of any origin and traumatic performance of blockade.[126] The pregnant woman is often considered immunosuppressed. However, while cell-mediated immunity is decreased during pregnancy, normal humoral immunity is maintained.[3,129] The pregnant woman is therefore only more susceptible to certain intracellular organisms, such as viruses, parasites, and intracellular bacteria. This may explain the increased number of infections during pregnancy from listeria and toxoplasmosis, and the increased severity of influenza in the pregnant patient, but at the same time less frequent epidural abscesses following CNB when compared to non-obstetric patients.[3] However, diabetes is often found as a risk factor in cases of epidural abscess and one review found that 46% of the patients were diabetic.[130] In a recent series from Australia, three out of the four obstetric patients who developed an epidural abscess or deep infection following EA were affected by gestational diabetes.[86] With the exception of possible traumatic insertions, other risk factors usually associated with the development of epidural abscesses are absent in the healthy obstetric patient, thus possibly decreasing the risk of epidural abscess formation in the obstetric population.[131]

### Symptoms, diagnosis, and treatment of an epidural abscess

The first symptoms of an epidural abscess usually appear 2–5 days following catheterization, but significant delay has been described in some cases.[86,126,127] A lapse of 6 weeks up to 4 months is reported.[8,121] The development of symptoms is classically described as evolving in four phases. Phase I is characterized by backache, usually at the level of the developing abscess. The symptoms progress over 2 or 3 days into phase II with the development of radicular pain. After another 3 or 4 days, sensory and motor deficits, as well as sphincter dysfunction develop, typical of phase III. The progression to the paralysis characteristic of phase IV may be rapid.[126,132] Fever and even severe signs of general infection might be present at any stage, confounding the picture. In a retrospective survey of 42 patients with catheter-related epidural abscesses, the correct diagnosis was considered initially only in 15 patients.[126]

**Box 28.5** Epidural abscess after epidural analgesia for labour and delivery

A healthy woman received an epidural for pain relief during labour. The skin was disinfected with chlorhexidine 0.5% in 70% alcohol, and the anaesthetist wore a mask and sterile gloves, but not a gown, and there is no mention of a cap. The epidural insertion was uneventful, the baby was delivered 3 hours after catheter placement, and the catheter was removed approximately 6 hours after placement.

During the following days, the patient complained of back pain of increasing intensity. She had no local or systemic signs of infection, and no neurological impairment. Five days after delivery, her back pain became unbearable. White blood cell count was $10.1 \times 10^9$/L, and C-reactive protein was 26 mg/dL. A contrast-enhanced lumbar CT scan was performed, but was inconclusive. However, a median, sagittal T2-weighted MRI showed an intraspinal, ellipsoid fluid collection in the dorsal epidural space at L2/3, with compression of the dural sac (Figure 28.5). Empirical antibiotic treatment was initiated. On the following day, the patient developed a sensory deficit in the left leg, necessitating a neurosurgical intervention, with decompression and drainage of the abscess. *Staphylococcus aureus* was cultured from the abscess fluid. The patient was treated with antibiotics for 4 weeks, and recovered completely.

Epidural abscess after obstetric EA is exceptionally rare, but this case reminds us of the need for scrupulous aseptic technique. It also illustrates the limitations of CT scan, and the fact that neurosurgical intervention often is necessary.

Data from Schroeder TH, Krueger WA, Neeser E, Hahn U, Unertl K., Spinal epidural abscess – a rare complication after epidural analgesia for labour and delivery., *British Journal of Anaesthesia*, volume 92, Issue 6, pp. 896–8, Copyright 2004.

Other studies confirm the diagnostic difficulties, and the low rate of initial accurate diagnosis.[128,130] The NAP3 reported 17 cases of epidural abscesses, and local signs of infection were present in the nine patients who made complete recovery, probably leading earlier to the correct diagnosis. In seven of the eight patients who did not attain full recovery, there were no local signs of infection.[3] The diagnostic difficulties of this rare condition may be even greater in an obstetric patient (Box 28.5 and Figure 28.5).[128]

The diagnosis of an epidural abscess should be performed by MRI, but when this is unavailable, a CT myelography may be performed. However, its invasiveness carries additional risks, and the CT scan may be falsely negative.[128] Surgical treatment in addition to long-lasting antibiotic treatment is often necessary. Unfortunately, complete recovery is less probable if diagnosis and treatment is delayed until the appearance of neurological deficit.[120]

## Aseptic technique for performance of central neuraxial blockade

Medical costs and patient morbidity and mortality from hospital-acquired infections are increasing. In many countries, subspecialty societies and official government bodies issue guidelines regarding the importance and methods of strict aseptic technique during performance of CNB.[133–135]

A recent observational study of residents performing EA found that their skills improved over 6 months but their breaches in aseptic technique did not diminish, despite formal education.[136] The authors concluded that their results reflected major gaps in teaching as well as understanding of aseptic technique. This conclusion is supported by another study that found that experienced physicians performed more breaches than their residents.[137]

A recent survey in the United Kingdom regarding prevention of infection in obstetric CNB revealed that although all anaesthetists used sterile gloves, and 99% wear a gown, only 91% use a mask, and 87% use a cap.[138]

The effectiveness of masks in preventing droplet spread of bacteria is well documented.[139,140] A good surgical mask has been shown to prevent the growth of oral flora on agar plates that were placed at a distance of 30 cm from the mouths of 25 speaking study participants. When the same subjects talked without the mask, bacterial growth was found on 50% of the agar plates.[139] However, until recently, the use of a mask as a preventive measure was much debated.[135] The use of masks has been questioned in the operating theatre, and one study addressing this issue found no increase in surgical wound infections when masks were omitted.[141] However, this study did not include patients undergoing orthopaedic or vascular prosthetic surgery, as viridans streptococci are well known to cause infection in these patients, the same viridans streptococci that may cause PDPM. Studies of infectious complications in surgical patients are therefore not directly applicable to the practice of neuraxial anaesthesia. The use of masks when performing CNB is now considered mandatory, and included in guidelines.[131,134,135] Nonetheless, the latest death caused by PDPM followed SA for labour analgesia, performed by an anaesthetist who omitted his/her mask, violating the previously issued guidelines.[94,133] The mask must be a good quality surgical mask, and should be changed between patients. The assistants present during preparation and performance of the CNB should also wear a mask.[90] The mask itself should never be touched.[84,124] Caps are important protective measures that should always be worn when performing CNB.[84,131] The hands should be disinfected with alcohol-based disinfectant before applying the gloves and, of course, after removal of watches and jewellery that ideally should not be worn at all during work hours.[124] The skin must be disinfected with an appropriate disinfectant and due to superior disinfectant qualities, chlorhexidine in alcohol is now considered the most appropriate agent, and is therefore widely recommended.[3,124,133,134]

Chlorhexidine is available in concentrations varying from 0.5% to 4%, but there are no substantial data in support of the use of a stronger solution than 0.5%.[143,144] The neurotoxic potential of chlorhexidine should also be considered.[109,144,145] The safety of chlorhexidine 2% is advocated by a retrospective analysis of 12,465 SAs performed in the same institution without detecting increase in neurological complications after the introduction of chlorhexidine gluconate 2% as disinfectant.[146] However, the statistical value of this study is hardly reassuring, as the result is compatible at the 95% confidence level with an incidence of one case of arachnoiditis following 4000 SAs.[144] Chlorhexidine 0.5% in alcohol is therefore the disinfectant of choice.[134] It is also advised that it should be applied twice, and left to dry after each application.[90,143] Malhotra and colleagues compared single versus repeated application of chlorhexidine gluconate 0.5% in 70% alcohol, and found no growth of bacteria following either methods.[147] These results would support the single application of chlorhexidine at least in emergency situations, when the risk of not allowing chlorhexidine to dry completely is apparent.[148]

The neurotoxic effects of chlorhexidine should also imply that great attention must be made never to contaminate any equipment that may come into contact with the central nervous system.[143] The use of chlorhexidine spray for disinfection, *before* opening the neuraxial anaesthesia pack, would appear to offer the smallest risk of contamination or risk of wrong route injection, and may also permit adequate disinfection without causing delay.[84] Reinsertion of the stylet in the spinal needle, before removing the needle from the patient, could be a critical moment both for the development of PDPM and contamination with chlorhexidine.[87] The removed stylet could have been exposed to contamination both from droplets as well as chlorhexidine, and therefore the practice of reinsertion of the stylet should be discouraged.

Chlorhexidine may also cause severe allergic reactions and these appear with increasing frequency as a large number of people are exposed to chlorhexidine in commercial products such as mouthwashes.[149] Anaphylactic reactions have been described to appear with 20–40 minutes' delay, and the condition can be of

great severity. Diagnostic difficulties are increased in the anaesthetized patient undergoing surgery.[150]

## Chemical meningitis and arachnoiditis

Chemical meningitis was described in older medical literature, and by 1947 more than 100 cases had been described.[151] The incidence decreased rapidly after studies had shown that chemical contamination, mainly detergents, caused chemical meningitis. Contrast media, and other substances injected into the CSF, may also cause chemical meningitis, but the complication has practically disappeared from modern anaesthetic practice, together with the disappearance of reusable needles. A wide range of systemic medications may also cause chemical meningitis.[151]

One study in neurosurgical patients, who may develop both types of meningitis, described the differences in chemical and bacterial meningitis.[152] Bacterial meningitis can be culture negative, therefore meningitis was defined as non-infectious only if the bacterial culture was negative, and the patient recovered without antibiotics. The study results showed that chemical meningitis could be excluded if the white cell count in the CSF exceeded $7500 \times 10^6$, and glucose levels were below 10 mg/dL. The clinical picture of chemical meningitis may resemble that of bacterial meningitis with high fever and meningeal irritation, but the patients recover without antibiotics, usually within a week. However, due to the improbability of aseptic meningitis following modern CNB, no patient with suspected meningitis can be left without antibiotic treatment.[84]

The term aseptic meningitis is sometimes used as synonym for chemical meningitis, but more often indicates meningitis of viral origin.[151] To add to the confusion, culture-negative bacterial meningitis may also be referred to as aseptic meningitis, although culture-negative bacterial meningitis is common.[100,152]

Infection or injection of neurotoxic chemical substances may lead to chronic adhesive arachnoiditis.[144,153] Two large surveys including a total of approximately 2.5 million CNB found one case of arachnoiditis each.[3,8] One patient in the United Kingdom received compensation in 2007 for a severe case of arachnoiditis considered to have been caused by chlorhexidine 0.5% in 70% alcohol contaminating the spinal needle during performance of SA for planned caesarean delivery.[144] The anaesthetic community initially questioned the causality, but when a patient in Australia received an admittedly erroneous injection of chlorhexidine into the epidural space there could be no doubt regarding the pathogenesis of the severe arachnoiditis that developed. Since then, several cases of arachnoiditis following CNB have been described, but the causality is not always apparent. However, the neurotoxic potential of chlorhexidine is recognized[144] and therefore, the anaesthetist must pay scrupulous attention not to contaminate equipment with disinfectant of any kind.

Chlorhexidine induces inflammation that transforms the pia-arachnoid into scar tissue. In severe cases, this can tether neural tissue and lead to atrophy. The MRI changes are typical and diagnostic, but presentation of symptoms in relationship to insult varies greatly, both in terms of severity and timing. Pain in the back and legs develop and sphincter dysfunction may also be present. In some of the most severe cases the patient may even become tetraplegic and develop obstructive hydrocephalus.

## Transient radicular irritation

Transient pain in the lower back or buttock, irradiating to the lower extremities, has been described, typically occurring 12 hours after the resolution of uncomplicated SA.[154] The condition is not associated with motor impairment, and disappears within 5 days. Neurological examination is normal, and no long-lasting consequences are reported. Analgesic treatment may be offered with non-steroidal anti-inflammatory drugs. A Cochrane report found the syndrome to occur seven times more frequently when lidocaine was used for SA compared to all other local anaesthetics, but the complication is also described following SA with bupivacaine.[155] The report could not draw conclusions regarding incidence in the obstetric population.

## Investigation and diagnosis of neurological deficits

Headache and backache are common following delivery, and urinary retention, incontinence, and fever may also result from normal labour.[11] The anaesthetist is often consulted to consider PDPH in a woman who has received CNB. The presence of fever, although possibly caused by the recent delivery, should cause a review of a possible alternative diagnosis. Meningitis will usually occur within 24 hours of CNB, and the symptoms of PDPM might not be of the severity usually seen in community-acquired meningitis.[8] Headache from meningitis is not expected to be positional as in PDPH, but the patient could suffer from the two conditions simultaneously. Nausea and vomiting may also be present in both conditions. Alterations of mental status might be difficult to appreciate, but opinions from relatives and midwives might be valuable. Signs of meningeal irritation such as nuchal rigidity and photophobia should be sought. Severe headache and visual disturbances may also be present in pre-eclampsia with impending eclampsia, and other symptoms of pre-eclampsia are not always present.[156] Migraine may also be accompanied by these symptoms, but the woman should be able to recognize the symptoms from earlier attacks. Cerebral venous thrombosis carries an incidence of 1/10,000 deliveries and may present itself with a vast variety of symptoms.[157] CSH usually presents with a delay of days or weeks following dural puncture, but may occur within 6 hours of dural puncture.[73] Headache is frequent in these two conditions, and any neurological symptom including seizures may be present. The first symptoms of an epidural abscess may be limited to fever and headache, therefore the anaesthetist should always perform inspection and palpation of the site of epidural catheterization when attending a woman with any type of complaint after CNB.[3] Backache can also be the first symptom of an epidural abscess, even preceding signs of infection.[128] An LP should be performed if PDPM is suspected, but could cause meningitis in the case of an epidural abscess. Antibiotic treatment should not be delayed by diagnostic procedures if the patient has symptoms of meningitis.

An obstetric patient who complains of focal neurology of any kind, including lower extremity motor impairment, sensorial deficit, or pain, should be examined without delay. The more severe conditions that may cause such symptoms are extremely rare, but must nonetheless be considered and excluded. The anaesthetist will often be consulted even in cases of obstetric palsies, due to the frequent administration of CNB during labour. Therefore, the

anaesthetist should be familiar with their signs and symptoms, and consult a neurologist or neurosurgeon if the diagnosis of the obstetric palsy is not straightforward. Particularly when an obstetric palsy is bilateral, which is possible, a reliable clinical diagnosis must be obtained if radiological investigation is to be avoided.[11] Peripheral neuropathies, for example, affecting the lateral cutaneous nerve of the thigh, and femoral nerve are described in Chapter 45.

Neurological examination should be performed to distinguish between central and radicular lesions, indicating complications possibly related to the CNB, and plexus and peripheral nerve lesions, indicating obstetric nerve palsies.[11] The clinical investigation alone may, however, be unable to give a precise diagnosis. Examination of the paraspinous muscles may differentiate between peripheral and central nerve root injury.[11,158] The paraspinous muscles and the skin over the lower back are innervated by the posterior rami of the spinal nerves. Intact paraspinous muscles and sensitivity of the lower back suggests more distal injury, whereas the opposite indicates more central damage.[11,158] Sacral numbness without any other neurological symptom has been reported after caesarean delivery with SA.[12,159] Local anaesthetic neurotoxicity has been proposed, but the condition has also been described after EA.[12] Pressure-related compression of sacral nerves has therefore been considered responsible. Attention to positioning is advocated, and the patient can be reassured, as the numbness wears off within 8 weeks. However, all neurological symptoms must be carefully evaluated, to avoid delay in diagnosis of the more severe complications.

The first symptoms of SH are usually motor and sensorial deficits, and SH may present itself without pain, but pain on the other hand is always absent in obstetric palsies, and if present, should raise suspicion of SH or epidural abscess.[7,8,11,36] Radicular pain is typical of epidural abscess.[126]

The patient history should include information regarding previous neurological or muscular impairment. Detailed information regarding the CNB should be documented. There may be relevant information indicating the probability of an obstetric palsy with regards to duration of second stage and mode of delivery. The onset of the symptoms should be described, as the neurological deficit of obstetric palsies usually are noted immediately following delivery, but the symptoms due to SH or epidural abscess occur with latency, and will be progressive in severity. The severity of obstetric nerve palsies will not be progressive and get better with time.[11] However, in case of femoral nerve palsy, the patient might not realize her nerve injury before her leg gives way when she bends her knee getting into the car to get home. Meralgia paraesthetica may have been present before delivery, but may have gone unnoticed or may have been aggravated during delivery, and therefore noted only afterwards. In serious cases there might be paraesthesia and hyperaesthesia, but otherwise intrinsic obstetric palsies are not associated with pain. Pubic symphysis separation may cause severe pain, irradiating to the back or the hips, and may also cause walking difficulties.[11]

Even the slightest suspicion of either SH, CSH, or epidural abscess should lead to radiological diagnostic intervention without delay, as patient outcome depends entirely upon speed of surgical intervention. MRI is necessary for the diagnosis of SH and CSH, as well as epidural abscess, as a CT scan may give false-negative results.[35,70,128] MRI techniques are also best for the diagnosis of cerebral venous thrombosis, but CT angiography may also be diagnostic.[157]

## Conclusion

Serious neurological complications following CNB do occur but are rare. Measures must be undertaken to prevent them at all costs. They require prompt diagnosis to prevent lasting patient harm and obstetric anaesthetists must therefore be competent in the examination of a patient presenting with neurological deficit and the ability to detect symptoms or signs of spinal/epidural space-occupying lesions and systemic infection. Appropriate consultation with medical experts from other specialities may be necessary to exclude other pathologies and urgent investigation is warranted.

# CHAPTER 29

# Medicolegal issues

Elizabeth Combeer, Rehana Iqbal, and Steve Yentis

## Introduction

Medical law covers a vast breadth of issues including individuals' rights to access healthcare, confidentiality, end-of-life decisions, and research. It also varies across different countries, though in general law is developed through two processes, legislative (Acts of Parliament) and judicial (case law, also known as common law or precedent).

Acts of Parliament (statutes) are developed following identification of a need to develop new statutory law to regulate a particular issue. Examples of such Acts that are important within the sphere of medical law are the Mental Capacity Act 2005 and the Human Tissue Act 2004.

In case law, decisions made in legal courts on a case-by-case basis set precedents in determining how future, similar cases should be decided ('similar' referring to the principles of a case, rather than the setting—for example, a case concerning the sale of defective non-medical products may inform cases concerning harm resulting from defective drugs or medical products). Prior judgements of higher (appeal) courts tend to be binding on lower courts within the same jurisdiction, and also offer guidance to cases in other common law jurisdictions. Where no case law exists that relates to a case being tried, the judiciary are, in essence, creating brand new law with their decisions.

Medical statutory and case law is reactive to the ever-changing technology and possibilities of medicine and also reflects the evolution in values held by society. The judiciary have attempted to use ethical reasoning in addition to legal principle in order to arbitrate in difficult cases that have presented brand new dilemmas to society and healthcare professionals.[1] The robustness of such ethical reasoning has been extensively debated[2] and yet has frequently been the basis on which a case has been decided, blurring the boundary between law and ethics. As previously explained, such decisions then form a precedent for future cases and so the evolution in law continues. It is for these reasons that there are no definitive answers in medical law, just an interpretation of the current position.

In this chapter we attempt to give a brief overview of some of the key areas of medical law that relate to obstetric anaesthesia and, where possible, to offer some guidance to the practising anaesthetist. The emphasis is on English law although we have attempted to be as broad as possible to allow extrapolation of the principles to other jurisdictions.

## Battery

If a doctor touches a patient without her consent then a case in battery may be brought against the doctor. Battery is a civil wrong (tort) that one person may do to another and, as such, the case would be heard in a civil court; if the judge finds in favour of the claimant then compensation would be awarded. Battery, legally defined, is any form of non-consensual contact and is therefore not restricted to contact between a doctor and patient. The patient does not even have to prove that harm has occurred in order to win her case. A claim in battery may also apply where consent has been taken but is irrelevant to the procedure that actually takes place, for example, wrong-sided surgery, or where a doctor operates beyond that which they have gained consent for (e.g. in *Bartley* v *Studd* where the patient had given consent for a hysterectomy but the surgeon performed an oophorectomy in addition[3]).

## Negligence

Negligence is also a tort, so a case would also be heard in a civil court. A case in negligence could be brought if a patient believes she has suffered harm during treatment as a result of substandard care. In order for a case in negligence to be successful, the patient must be able to demonstrate three things to the court. Firstly, that the doctor owed her a duty of care. In the majority of situations this is not a difficult issue to resolve: a doctor who has engaged in any form of assessment or treatment of a patient clearly has a duty of care to her. However, even when harm has occurred due to the absence of care, the duty of care is usually straightforward to prove. When a National Health Service (NHS) hospital accepts referral of a woman for obstetric care, there is the implicit undertaking that the hospital and its healthcare employees have accepted a duty of care for her. In the private healthcare setting, there is a contract between the doctor or hospital and the patient, which establishes a duty of care.

Secondly, the patient must prove that the care she received fell short of the standard that it should have been. The difficulty here is in establishing precisely what the standard for any given form of treatment or interaction between doctor and patient should be. The traditional stance is derived from the *Bolam* case: if a doctor acted in line with a 'responsible body of medical men' (even a minority), then their actions would be viewed as appropriate and legally they would not be found negligent.[4] However, case law has evolved since *Bolam*, the major change being signified in the case of *Bolitho*, in which it was ruled that a doctor's actions (and the view of said responsible body of medical men) must be 'capable of withstanding logical analysis'.[5] For example, in a case of harm resulting from failure to check an anaesthetic machine it is not enough to offer the defence that, say, 40% of anaesthetists as a whole would also not check it—the judge might reasonably conclude that whilst satisfying the *Bolam* principle, such a claim

fails the *Bolitho* test in that such practice is neither reasonable nor responsible.

Finally, the patient must prove to the court that this breach in the duty of care has resulted in harm to her.

## Gross negligence, manslaughter, and murder

Negligent care of a patient may rarely result in death. In such cases, a doctor may face a criminal prosecution for manslaughter if it is considered that the degree of negligence demonstrates 'such disregard for the life and safety of others as to amount to a crime … deserving of punishment'.[6] The borderline between 'ordinary' negligence and 'gross' negligence is the subject of considerable debate. There has been concern in recent years that criminal charges of manslaughter have been brought against doctors (including anaesthetists) too readily for cases involving simple (but admittedly catastrophic) mistakes rather than what the medical profession might consider 'gross negligence'.[7]

The key case describing gross negligence unfortunately involves an anaesthetist, Dr Adomako, who took over the care of an anaesthetized patient having ophthalmic surgery. He failed to notice when the breathing circuit became disconnected. When the patient became bradycardic and hypotensive, he administered atropine but failed to respond to other alarms warning of the disconnection. Approximately 9 minutes after disconnection was thought to have occurred, the patient suffered a cardiac arrest. The disconnection was discovered during the unsuccessful resuscitation attempt.[8]

The Corporate Manslaughter and Corporate Homicide Act 2007 enables charges of manslaughter to be brought against corporate entities, for example, companies and NHS trusts, that practise gross negligence resulting in death.[9] Only a small number of convictions have resulted (three up to the end of 2012[10]) but the number of cases being brought is increasing each year. Senior managers within trusts (including doctors) are theoretically vulnerable if they are deemed to have failed sufficiently in their duty so as to constitute gross negligence.

Manslaughter is distinguished from murder by a lack of intent. It is rare for anaesthetists—especially obstetric anaesthetists—to face a murder charge, but this may occur if they are involved in end-of-life decisions in which drugs are administered that are judged to have ended the life of a patient, and where this is found to have been the intended purpose. Most such cases have involved intensivists.

## Clinical guidelines

Recent years have seen a proliferation of written statements advising on or directing the delivery of healthcare. Terms used to describe these written statements include recommendations, protocols, guidance, policies, and guidelines. This is confusing and may suggest greater compliance is legally required with, for example, a protocol than a recommendation, although there is no objective support for this suggestion. The number and varying roles of agencies that are involved in the development and dissemination of guidance further compound this confusion.

A large number of agencies have developed guidelines that impact on both the provision of obstetric anaesthetic services[11] and the management of specific clinical conditions.[12] Advocates for guidelines would argue that their use minimizes unjustifiable variation in clinical practice thus improving patient safety and clinical outcomes. However, there is concern about the impact of guidelines on the use and development of clinical judgement, the quality and evidence base for their development and the legal and professional consequences of deviating from them. Although clinical practice is influenced by guidelines, there is a lack of data looking at outcomes following their introduction to support claims of improvements in quality of care.[13] Despite this, guidelines are often viewed as documented standards of care.

The courts have recognized the difficulties associated with determining the legal status of guidelines. In *Crawford* v *Board of Governors of Charing Cross Hospital*, Lord Denning stated that 'the time may come in a particular case when a new recommendation may be so well proved and so well known, and so well accepted that it should be adopted'.[14] It has been suggested that if a guideline fulfils the elements of this 'Denning Test' (i.e. that the guideline is proven, disseminated, accepted, and adopted by the profession) then there may be a greater legal requirement to comply with it.[15]

Adherence to guidelines has been used as a successful defence against negligence claims. In *Early* v *Newham* the claimant experienced a period of awareness following a failed intubation attempt. However, her claim was unsuccessful, as the anaesthetist had adhered to locally developed failed intubation guidelines.[16] The quality of the local guideline was unsuccessfully challenged as the claimant was unable to prove that the guideline was such that no responsible body of practitioners would have complied with it.[4]

It should not, however, be assumed that adherence to guidelines provides an impenetrable shield against litigation claims. In the case of *Wickline* v *The State of California*, a patient was discharged early from hospital, in accordance with guidelines, but subsequently came to harm. The court emphasized the importance of clinical judgement and the responsibilities of the physician. It recognized that clinical judgement may be contrary to guidelines and that rigid compliance with guidelines in these circumstances may not be legally defensible.[17] The importance of clinical judgement has also been emphasized in the English courts, for example, in an unsuccessful claim of negligence against clinicians for failure to follow clinical guidelines in the management of severe asthma in a pregnant patient. The courts supported the use of clinical judgement despite the existence of guidelines.[18]

There are a number of reasons why a clinician may choose to comply with or deviate from guidelines. These reasons may include a professional assessment of robustness of the evidence base for the guideline, its applicability to the current clinical situation, the existence of conflicting guidelines, and whether the particular circumstances dictate different management. Guideline compliance may also be limited by the cost of its implementation.

The precise hierarchy of authority of guidelines, where conflict exists between two guidelines advising on the management of the same issue, has yet to be tested. However, guidelines developed by national regulatory bodies such as the General Medical Council (GMC), the National Institute for Health and Care Excellence (NICE), and the Royal Colleges are likely to have greater authority than other sources. When choosing to manage patients contrary to guidelines, clear documentation of the reasons for departure from guidance, explicit consent, and an acceptable standard of care that promotes best interests would be necessary.

## Autonomy and informed consent

Autonomy refers to an individual's right to 'self-govern' and make one's own decisions. Respect for autonomy (along with justice, beneficence, and non-maleficence) is one of the moral principles underpinning medical ethics,[19] and medical paternalism has given way to an era of respect for the decision-making of the patient. Consent is the process by which a doctor recognizes a patient's autonomy. For consent to be valid, adequate information must be given to the patient, she must have the capacity to make a decision (see 'Capacity and the Mental Capacity Act'), there must be adequate time to do so, and there must be freedom from coercion.

A patient can bring a case in negligence against her doctor if she develops a complication from treatment, the possibility of which was not disclosed during the consent process. If no consent took place then the claim would be brought in battery, although this would be unusual. The usual principles of negligence apply to cases concerning inadequate consent: that a duty of care exists; that there was a breach in the duty of care (the level of information disclosure was inadequate); and that harm has occurred as a direct result of the breach because, if warned, the patient would not have given consent.

It can be difficult to judge precisely how much information is 'adequate', sufficient to enable an informed decision by a patient without overburdening her with an endless list of rare or trivial possible complications. GMC guidance advises doctors to try to understand the particular patient they are caring for and the adverse outcomes they may be most concerned about when deciding what risks to discuss.[20] Patients must be advised of serious adverse outcomes (those resulting in death, permanent or long-term disability, effect on employment, or social or personal life) 'even if the likelihood is very small'. Withholding information concerning adverse outcomes for fear that it may unduly scare the patient or lead her to decline an intervention is not permitted. Patients who do not wish to be told about potential risks should still be advised of the general nature of an intervention or treatment and should be informed about any serious risks. If a patient refuses to hear even this most basic information, then she should be advised that she can change her mind at any time and the discussion should be fully documented.

The GMC guidance can be difficult to apply in practice. Obstetric anaesthetists meet many of the patients they care for in emotionally charged, emergency situations when the patient may be suffering significant pain. Limited time for discussion makes it difficult to establish the individual wishes of each patient concerning information disclosure. The *Bolam* case established that an explanation that was in line with that of colleagues would be viewed as adequate from a legal perspective.[4] However, 40 years later, *Bolitho* determined that merely providing the same standard of explanation as some of one's peers is inadequate: that standard must be 'capable of withstanding logical analysis'.[5]

As previously discussed, guidelines from professional bodies may be viewed as standards of care. The Royal College of Anaesthetists (RCoA),[21] the Association of Anaesthetists of Great Britain and Ireland (AAGBI), and the Obstetric Anaesthetists' Association (OAA) have all produced patient information leaflets explaining the risks associated with anaesthesia. The OAA, for example, has produced an information card to facilitate discussion of risks with women during the consent process for labour epidural analgesia. The OAA clearly concurs with the GMC on the need to offer maximal information to patients: adverse consequences stated on the card include the possibility of paralysis of 1 in 250,000 women.[22] Application of such a guideline may be regarded as a standard that is capable of 'withstanding logical analysis' due to the authority of the professional body from which it originates. Furthermore, as the use of the OAA information card becomes more widespread, the 'Denning Test' may be seen to apply: deviation from such a guideline might therefore require documented evidence of justification.

The case of *Chester* v *Afshar* is an interesting reflection on how important the judiciary now believe a patient's right to information is.[23] Miss Chester was not warned of the risk of cauda equina syndrome following back surgery, and it was admitted by the defendant that she should have been. However, Miss Chester admitted to the Court that she would probably have gone ahead with the surgery anyhow, thus failing to prove causality, a key component of a negligence claim. Nonetheless, the Court was so keen to compensate Miss Chester for the breach to her right of autonomy that it found in her favour.

There is no definitive way to ensure that one's method of obtaining consent will provide immunity from claims of negligence. Ensuring that practice is in line with colleagues would seem to help. Applying the guidance on consent published by professional bodies will ensure that information disclosure achieves a documented standard that should be capable of withstanding logical analysis. Ensuring that information disclosure is of a level and quality to facilitate patient autonomy is an important focus.

## Capacity and the Mental Capacity Act

Testing capacity (competence) evolved through case law, as the courts were called upon to make decisions in situations where there was doubt as to whether individuals could reasonably be allowed to make up their own minds about proposed medical treatment. C[24] was a man with paranoid schizophrenia who developed a gangrenous leg. His doctors wanted to amputate his leg in his best interests, as they considered that he did not have the ability to decide for himself owing to his mental health problems. C did not want to have his leg amputated and sought an injunction against his doctors. The courts found C to be competent and a simple test of mental capacity was developed that has since been enshrined in statutory law in England and Wales in the form of the Mental Capacity Act 2005. The Act's starting point is that all persons over 16 years old should be assumed to have capacity unless shown otherwise. In order to demonstrate capacity, a patient must understand and retain the information given to her, use this information to make a decision, and then to be able to communicate that decision back to the doctor caring for her (Box 29.1).

A woman with capacity has the absolute right to determine what happens to her body in the context of agreeing to or refusing medical treatment. The right of a competent patient to refuse treatment, even if this will lead directly to her death, has been upheld in case law.[25]

The Mental Capacity Act regards capacity in the context of being situation or decision specific, rather than something one either has or has not. However, when considering the management of patients who lack capacity for a specific decision, it is useful to view them as falling into four broad categories: those who have yet

**Box 29.1** Capacity testing according to the Mental Capacity Act 2005

(a) To understand the information relevant to the decision

(b) To retain that information

(c) To use or weigh that information as part of the process of making the decision

(d) To communicate his decision (whether by talking, using sign language or any other means)

to develop capacity (children); those who have never had capacity and are never likely to; those who have previously had capacity but have permanently lost it; and those who usually have capacity but have temporarily lost it. Parturients who lack capacity are most likely to fall into this fourth group as temporary loss of capacity may result from factors associated with labour. (Management of this group is discussed later in 'Patients Who Temporarily Lack Capacity, Consent in Labour, and Birth Plans'.) However, obstetric anaesthetists may also be required to provide treatment for patients from the other three categories and so the legal approach to managing the care of such women will be described here.

## Children and capacity

The law concerning consent in children is important to obstetric anaesthetists because parturients may be under 16 years of age: the rate of pregnancy in girls aged 15–17 years in England and Wales is 35.5 per 1000.[26] The interpretation of law concerning children and consent has been made problematic by the fact that there is no clear statutory law that dictates a precise age at which a child assumes complete responsibility for giving or withholding consent for her own medical treatment. The Mental Capacity Act assumes competence for anyone over 16 years old, whilst the Family Law Reform Act 1969 has been interpreted as meaning that children are not able to *refuse* treatment if they are under 18 years old.[27] This interpretation has been reflected in subsequent case law.[28]

The *Gillick* case concerned the legitimacy of doctors providing sexual healthcare to girls less than 16 years without the knowledge or consent of their parents.[29] From this case stems the term 'Gillick competence', used to describe children who are under the age of 16 but who demonstrate the maturity and understanding required to give consent for their own treatment. Gillick competency is probably better referred to as Fraser competency after the judge who described the criteria for such circumstances. It is important to note that these guidelines require the doctor to decide that it is in the child's best interests, both in terms of her medical best interests and her social circumstances, to proceed with care in the absence of parental knowledge or permission. Lord Fraser stated that, occasionally, a situation might arise where 'a doctor is a better judge of the medical advice and treatment which will conduce to a girl's welfare than her parents'.[29] Thus the *Gillick* case empowers mature children to give assent to treatment thought to be in their best interests by their doctors or their parents, and it allows them to have medical treatment without their parents' knowledge or permission if that is thought by their doctor to be in their overall best interests. It does not, however, allow them to refuse treatment that is thought (by their parents or doctors) to be in their best interests and the courts have demonstrated themselves willing to compel underage children to have such treatment if they attempt to refuse.[30]

**Table 29.1** Summary of consent rights according to patient age

| | Child | Gillick competent child | 16–17 years | 18 years |
|---|---|---|---|---|
| Right to give consent? | No | Yes | Yes | Yes |
| Right to refuse treatment? | No | No | No | Yes |
| Parents (or those with parental responsibility) may give consent on child's behalf? | Yes | Yes | Yes | No |
| Doctors able to treat the patient in her best interests despite parental and patient refusal of consent? | Yes | Yes | Yes | No |

Cases tried subsequent to *Gillick* have continued to debate the precise meaning and application of its ruling. If the judiciary are unclear, then it is unsurprising that many clinicians have an indistinct grasp of how to manage consent in adolescents. The following is a summary of the current legal position (Table 29.1). Once a girl is 18 years old, she has the absolute right to accept or decline medical treatment offered to her. Over the age of 16 years, it should be assumed that a girl is competent to give consent for her own care unless there are factors that lead the clinician to decide that she lacks competence. Under the age of 16 years, the doctor must assess whether a girl is Gillick competent according to whether she displays the specifics of capacity laid down in the Mental Capacity Act (see Box 29.1). If the child appears to be competent, she may give consent for herself for medical treatment offered to her. It is good practice, where the competent child permits, to involve parents in supporting a teenager's decision-making.[31] However, there will be occasions where parents (or those with parental responsibility) may disagree with the consent given by a Gillick competent child or adolescent patient. In these situations, the parents are not legally permitted to overrule the consent of the patient. (NB Parental responsibility is held by all mothers, a father if he was married to the mother at the time of the birth, fathers who jointly registered the birth with the mother (from 1 December 2003), and fathers who have attained parental responsibility through agreement with the mother or through a court order. Parental responsibility may also be held by a legally appointed guardian, a local authority in whose care a child is or a local authority or person with an emergency protection order for a child.)

Although a Gillick competent child or girl over 16 years may give consent for her own treatment, she is not permitted to refuse treatment if this may lead to death or serious injury. A situation

might arise, therefore, where the parents and doctors of a Gillick competent child wish to proceed with treatment but the child refuses. Where time permits, legal assistance should be sought to assist in resolving such disputes. However, in an emergency situation, doctors should treat in accordance with the best interests of a child under 18 years, even if this is contrary to the child's and/or the parents' wishes.

Until a child is 16 or has developed capacity, the parents (or those with parental responsibility) are entitled to give consent for them. It is obvious that discussions and explanations should involve the child as much as possible, even if she is not legally in a position to sign a consent form for herself.[32] The child benefits from time spent with a doctor who is prepared to give explanations targeted to her level of maturity. This maximizes her autonomy and allows her to develop trust in her clinicians. It is important that children should develop a relationship based on trust with those treating them in order that healthcare experiences as a child do not deter them from seeking treatment in later life. Once again, if parents refuse to give consent for treatment that clinicians believe to be in the child's best interests, then an application must be made to the Court of Protection (through the hospital lawyers) for the resolution of the dispute. In an emergency, treatment should proceed whilst this is being undertaken.

The rights of a pregnant teenager concerning consent do not alter despite the fact that she is about to give birth to her own child. However, the potential for dispute between the girl, her parents, and the healthcare professionals should be anticipated where possible. It is of paramount importance to engage young pregnant girls early in antenatal care. They are statistically more likely to come from a background associated with deprivation, abuse, lack of parental involvement, and mental health and educational problems, and are more likely to be poor antenatal attendees.[33] Their babies are significantly more at risk of prematurity, perinatal death, or death in infancy than the babies of older mothers. Ideally, specialized, multidisciplinary antenatal care (often including social care professionals) targeted to the needs of teenage women should be offered. Discussions concerning possible outcomes and the potential need for medical treatment in labour should happen during the child's pregnancy in order to avoid conflict, rushed decisions and the need to act contrary to a girl's wishes in an emergency. It is important that obstetric anaesthetists are included in such discussions.

## Patients who no longer have capacity

Before the Mental Capacity Act 2005, no person could act as a proxy in giving consent to medical treatment on behalf of another adult. If treatment was considered necessary for a patient who lacked capacity, the medical team caring for her would act in her best interests. The Mental Capacity Act has sought to improve the method by which decisions are made for patients who lack capacity, to ensure that (where known) the patient's views can be included in decisions and to ensure that all people who lack capacity are represented by an advocate (whether friend, family member, or professional) when major decisions are being made on their behalf.[34] There are three ways in which this may be achieved:

1. The Mental Capacity Act requires doctors caring for a patient who lacks capacity to discuss the medical plans with family, carers, or friends who may hold key information about the patient's thoughts and beliefs before making a best interests judgement about how to proceed with treatment. In this manner, the patient's wider best interests may be respected rather than making a decision based purely on likely medical outcomes.
2. The Mental Capacity Act also reinforces the concept of Advance Decisions (previously known as Advance Directives) to detail an individual's wishes concerning future medical treatment. An Advance Decision may be made verbally or in writing. If made verbally, some form of record of the decision must be made, for example, in the hospital notes. If it is a written statement it does not need to be witnessed, unless it concerns refusal of life-sustaining treatment. However, it must be sufficiently detailed and specific to ensure that it clearly applies to the circumstances that eventuate. A patient cannot make advance requests for treatment that the clinicians do not believe to be appropriate.[35] An Advance Decision only comes in to force after the individual loses capacity and may be withdrawn at any time, verbally or in writing, until capacity is lost. Doctors are legally bound to follow the wishes laid out in an Advance Decision or they may find themselves liable for battery. However, situations may arise where there is doubt as to the validity of a decision: the circumstances in reality may differ from those described in the decision; there may have been a significant change in the individual's life; there may be doubt regarding the capacity of the individual at the time of making the decision; or a Lasting Power of Attorney (LPA; see below) might have been subsequently appointed who advises the medical team contrary to that which is stated in the decision.[36] The clinicians caring for the patient should continue to treat the patient according to her best interests until an assessment of the validity of such an Advance Decision is made. A form of Advance Decision commonly encountered in obstetric practice is a mother's birth plan, which is discussed later. Another relevant Advance Decision is that made by Jehovah's Witnesses concerning refusal of administration of blood products. Ideally, such a decision should be explored antenatally in an unhurried manner. However, it is feasible for an Advance Decision to be produced in an emergency situation when the woman herself is either unconscious or under general anaesthesia. Such circumstances are fortunately rare but should they occur, urgent consultation with the hospital lawyers is recommended; medical management should continue in the woman's best interests in the interim, with careful documentation of all aspects of her immediate care.
3. Individuals may also appoint a LPA to act as a proxy decision maker on their behalf once capacity has been lost. This appointment will be registered with the Public Guardian and may be a friend, relative, or professional adviser of the individual ('donor' of power). Unless the LPA has been given express, written permission by the donor, they may not make decisions regarding the continuation or cessation of life-sustaining treatment. Furthermore, they cannot request treatment that the medical team caring for the patient believes to be inappropriate. Before loss of capacity, the donor can revoke the decision to appoint an LPA at any time.

## Patients who have never had capacity

If a woman has never had capacity she will not have been able to appoint an LPA or make an Advance Decision. However, it is

still reasonable to involve her friends, carers, and relatives when decisions are made on her behalf as these people will be able to advise the clinicians about the woman's likes and dislikes.[37] In conjunction with the medical team caring for such a woman, the majority of medical decisions made on her behalf should be straightforward. However, there are situations where a woman who has never had capacity or who has permanently lost capacity (and has no Advance Decision or LPA) has no friends or relatives to support her in making appropriate medical decisions. For all but minor treatment decisions, the Mental Capacity Act requires that an Independent Mental Capacity Advocate (IMCA) be consulted. The IMCA is permitted access to the patient (and her records) in order to attempt to represent the patient's views in the decision-making process. Like family members and friends, an IMCA does not have the power to act as a proxy decision-maker.

The Court of Protection has the power to appoint a Court Appointed Deputy (CAD) to act as a proxy decision-maker for an individual who lacks capacity and who does not have an LPA (whether this is because she never had capacity to do so or because she did not exercise this right when capacitous). This may be done if there are particularly complex issues to address or if there is likely to be an ongoing requirement for decisions to be made. A member of the patient's family may be appointed as a CAD, for example, the parent of an adult with severe learning difficulties. Just like an LPA, a CAD must always act in the best interests of the individual whom they represent. The Court of Protection remains the ultimate arbiter in cases where there is dispute between family, friends, LPAs, IMCAs, CADs, and healthcare professionals about how best to proceed in medically treating an adult who lacks the capacity to make her own decisions.[38]

## Patients who temporarily lack capacity, consent in labour, and birth plans

A multitude of factors encountered in labour may temporarily compromise a previously competent woman's decision-making capacity. These include pain, lack of sleep, anxiety, opioid analgesia, and physiological disturbance caused by blood loss. It is therefore important to reassess her capacity for each new decision in labour. Any healthcare professional can make this assessment of capacity, and it is decision specific: a woman who has the capacity to consent to a vaginal examination does not necessarily have the capacity to decide whether to consent to anaesthesia for caesarean delivery.

Case law has recognized that 'confusion, shock, fatigue, pain or drugs' may temporarily incapacitate a woman in labour.[39] All practising obstetric anaesthetists will be familiar with the scenario of a deeply distressed labouring woman who appears to care little about any risks explained to her when discussing epidural analgesia. It is difficult, however, to be certain of the point at which a woman crosses the line between capacity and incapacity. The AAGBI recognizes the existence of factors that contribute to difficulties in establishing capacity in a labouring woman. However, its stated opinion is that 'the compromise will need to be severe to incapacitate her'.[40] The very same case law that offered recognition of the compromise to capacity that these factors may cause also gave the warning that healthcare professionals caring for such women should be careful in assessing whether 'such factors are operating to such a degree that the ability to decide is absent'.[39] No guidance is given by either of these sources, however, on how one can be sure that a labouring woman still has capacity.

Recall of risks discussed during the consent process has been used as a surrogate indicator of capacity. Failure of recall is taken to indicate lack of capacity, as the second of the four necessary components of capacity testing according to the Mental Capacity Act is not met. Swan and Borshoff demonstrated poor recall of conversations during labour concerning risks associated with epidural analgesia. They suggested that consent should therefore take place antenatally, where possible, as this led to improved recall.[41] The use of written information has been demonstrated to improve recall of risks associated with epidural analgesia following consent in labour.[42] However, it is far from clear that actual recall is a valid indicator of capacity. Although Affleck and colleagues demonstrated poor recall of risks discussed during labour, it was comparable with recall by patients receiving information about a variety of medical treatments such as chemotherapy, ophthalmic and cosmetic surgery.[43] It was also demonstrated that the pain scores of the parturients had no significant impact on their levels of recall.

Other research has focused on the opinions of women who have recently had neuraxial blockade in labour about the level of disclosure of risks that they deem to be appropriate during the consent process. On the whole, many of these women appear to want an in-depth explanation about potential complications.[44,45] This might suggest that the women involved felt able to handle the information delivered to them, and to use it to make a reasoned decision. Jackson and colleagues asked 38 women to assess whether they had met the Mental Capacity Act's four components of capacity at the time of their decision during labour to have an epidural.[46] Over 80% of the women felt that they could 'completely agree' that they were able to communicate a decision regarding epidural analgesia but less than 30% completely agreed that they could retain information. The implication of this is that by lacking one or more of the four components constituting capacity, fewer than 30% of these women deemed themselves to have capacity (according to the Act) at the time of their decision, although a high proportion of women were still satisfied with the consent process. Once again, recall appears to be an important sticking point in deciding whether labouring women have capacity. The Mental Capacity Act does not stipulate the duration of recall necessary to demonstrate capacity, just that 'The fact that a person is able to retain the information relevant to a decision for a short period only does not prevent him from being regarded as able to make the decision'.[37] Failure to recall details of the consent process after the event should not, therefore, necessarily lead to the assumption that the woman lacked capacity at the time of decision-making. The Act requires clinicians to take into account the wishes and preferences of an incapacitous patient and to involve her in decision-making processes to the best of her ability. Therefore anaesthetists should still attempt to explain risks and benefits as far as possible to all women in labour, even those considered to have borderline capacity.

There is a lack of conclusive research to define satisfactorily a 'cut-off' at which women can be deemed as having lost capacity as a result of factors associated with labour. Perhaps the fact that a request for epidural analgesia when experiencing severe labour pains seems so reasonable that the question of whether the mother has strict legal capacity is not always addressed. Likewise, if obstetricians recommend an urgent caesarean delivery for the sake of the baby's well-being, the woman's capacity to give consent is less likely to be called into question if she acquiesces to

the recommendation. Whilst the law reminds clinicians that an individual should not be deemed to lack capacity purely because her decision seems unreasonable,[48] it might seem that the opposite is true: we are ready to accept a woman as capacitous if she agrees with our recommendations. However, it should also be remembered that capacity is a decision-specific assessment. In the circumstances of a much-wanted baby's life being (potentially) at risk, a woman may retain the information regarding the risks and benefits of anaesthesia and surgical delivery for as long as it takes her to agree to this course of action. This process might require just a few seconds—the fact that she does not retain the information any longer than this should not necessarily lead to the conclusion that she lacks competence. Difficulty arises, however, when a birth plan (a form of Advance Decision) exists that has been made at a time when a woman supposedly has full capacity. Can a woman in the throes of labour request or accede to an intervention that she has previously expressly refused?

The NHS Choices website describes birth plans as 'a record of what you would like to happen during your labour and after the birth', and advises women that they should consider their wishes concerning pain relief, place and mode of delivery, and care of the baby after birth before writing one.[48] However, it reminds mothers of the 'need to be flexible and prepared to do things differently from your birth plan if complications arise with you or your baby'.

The AAGBI stresses the importance of providing information regarding anaesthesia and analgesia antenatally.[40] It may be considered that women are more able to make truly capacitous decisions about their future care at a time when their recall has been shown to be better and they are not compromised by pain, fear, fatigue, and drugs. Birth plans might therefore be viewed to represent the truly autonomous decisions of a woman about her labour. One aspect of informed consent is, however, lacking in the antenatal period. Until a woman is in labour, she has no personal experience of the pain associated with it.[49] Further, until there is evidence of fetal compromise, she has no true ability to evaluate the pros and cons of expediting delivery, for example, through the use of forceps. She therefore lacks the necessary information with which to make a valid decision.

In the event of loss of capacity in labour, a birth plan should be regarded as representing a form of Advance Decision.[40] However, birth plans vary greatly: although some are very detailed and specific about a woman's wishes, others contain merely a few statements regarding what her ideal labour would entail, and would not meet the criteria for a binding Advance Decision. It is quite possible that the woman did not intend her birth plan to be used as an Advance Decision—indeed, if she had read the guidance from the NHS Choices website she may not have been aware of the legal implications of writing such a plan. Where a woman has lost capacity, birth plans that have not been written in a manner to satisfy the requirements of an Advance Decision should be regarded as evidence of the woman's values and wishes, to be taken into account as far as possible when making decisions based on a best interests assessment.[37]

If following a birth plan entails a significant risk to the life of the mother, the plan must have been signed and witnessed and must state clearly that she would prefer death to whatever treatment has been refused. If there is risk to the baby's life then the plan must be specific enough to have included this eventuality. If it is considered that any of the circumstances of the situation could not have been reasonably anticipated by the woman at the time of writing the birth plan, this may also invalidate it for use as an Advance Decision. Obviously, no Advance Decision comes into force until its author loses capacity and so a woman who consents to treatments in labour that she had previously excluded in her birth plan is fully at liberty to change her mind in this manner so long as she has the capacity to do so.

The obstetric anaesthetist may occasionally face a birth plan in which a woman attempts to dictate her future care even if she changes her mind once in labour (the so-called Ulysses Directive).[50] A woman may state, for example, that she does not want to have epidural analgesia even if, once in labour, she begs for this method of pain relief. If written clearly, signed, and witnessed, such a directive would have the same legal footing as any other Advance Decision. However, for it to take effect, the woman must lose capacity. If she still retains capacity, then she is able to change her mind. In such circumstances, it is imperative to ensure a very thorough discussion of risks and benefits of epidural analgesia with the woman, involving her midwife and birth partner if permitted. In this way, the anaesthetist can clarify that the woman remains capacitous and that she appreciates the consequences of the decision she is currently making. This conversation should, of course, be fully documented and the AAGBI suggests that the woman should countersign the entry in the notes.[40] A woman who has been unable to meet the expectations she has made of herself in a birth plan may be upset and frustrated postnatally, and resentful of the healthcare professionals who aided her 'labouring self' to defy the wishes of her 'antenatal self'. A debrief with the woman after analgesia has been established and again after birth may help the woman reconcile the events that have occured.[50] Ideally, a woman should not even start labour without a discussion regarding the implications and limitations of a birth plan for directing future care.

## Voluntariness and consent

After provision of information and capacity, the third component of valid consent is freedom from coercion. Sources of coercion that may apply to a labouring woman are her birth partner, the father of her baby, other family members, healthcare professionals, and other paid providers of maternity care such as doulas. It is important to remember the inequality in 'power' that exists between a woman in labour and the healthcare team that attend her. The healthcare team are in a familiar environment, have extensive knowledge, may be under pressure of time, may arrive in groups to see her, may remain standing, may use unfamiliar terminology, and will know the patient's name and medical details. In contrast, the labouring woman is in an unfamiliar environment, may be minimally clothed, may have little knowledge of the events that are unfolding, may be in pain or fear and may not comprehend the roles or know the names of the staff. The resolution of this disparity is more of an ethical than a legal debate and so beyond the scope of this chapter.[51] Suffice to say here that all staff should be aware of these factors and their influence on a woman's decision-making.

A woman may have spoken extensively to others concerning her wishes for labour, utilizing such discussions in the same manner as some women use birth plans.[50] In the event of her changing her mind, these individuals may attempt to exert influence on the

woman in order to keep her to her prearranged plans.[50] However, a woman who retains capacity in labour is free to make her own decisions and healthcare professionals must make sure that such decisions are voluntary. In order to ensure voluntariness, the obstetric anaesthetist may need to speak alone with a labouring woman. The anaesthetist has a duty to voice any concerns that the opinion of others is interfering with the patient's right to decide her own medical management. Ultimately, consultation with the hospital legal team may be required in order to help manage a particularly persistent and intrusive third person.

Case law has demonstrated that the judiciary is prepared to find consent (or refusal of consent) invalid if it is believed that there has been excessive influence on a patient from other sources. *Re T* concerned a young woman, 34 weeks pregnant, involved in a road traffic accident.[47] She developed pneumonia and was admitted to hospital. Her condition necessitated the administration of oxygen and the use of pethidine for pain control. That night, T went into labour and a decision was made that delivery by caesarean delivery was necessary, so she was transferred to an obstetric unit. T was not a Jehovah's Witness but her mother was. During a visit from her mother, T informed a nurse that she would not accept blood products. She later stated the same to a doctor. A midwife produced a refusal form, which T signed without further discussion or clarification. After caesarean delivery of a stillborn baby, T's condition deteriorated due to a lung abscess and she was admitted to intensive care. Blood transfusion was deemed necessary but withheld because of T's documented refusal. T's father and boyfriend made a successful court application to authorize blood transfusion, arguing that T had been coerced by her mother.

There were many factors that compromised T's ability to make a valid refusal of treatment. Lord Donaldson praised her boyfriend and father for their application but stated that the hospital authorities should have taken the initiative the previous day. T was critically ill, she had a condition requiring oxygen, she had pain necessitating the use of pethidine, and she was in early labour following a car accident. In this condition, she might have been unduly receptive to her mother's religious beliefs. After her verbal refusal of consent, T signed a form refusing transfusion without further discussion of the consequences of such an action. T's refusal was therefore considered by the court to be invalid.

## Enforced caesarean delivery

The topic of decision-making in labour would not be complete without a discussion of enforced caesarean delivery. Although the case of T, discussed above, revolved around overriding a woman's refusal of consent as it was deemed to be invalid, Lord Donaldson made some important statements concerning the right to refuse treatment when he made his judgment. He stated that a competent adult had the right to choose to accept or to refuse treatment, regardless of whether her reasons were 'rational, irrational, unknown or even non-existent'.[47] *Re T* set the benchmark of an adult's right to refuse treatment, even if this will lead to certain death.[24] However, Lord Donaldson made an important caveat to this right: that where a woman's decision to refuse treatment might 'lead to the death of a viable fetus.'[47]

The decision in *Re S* followed the precedent set by Lord Donaldson.[52] S was in obstructed labour with a baby in a transverse lie and an elbow presentation. She refused caesarean delivery due to her religious beliefs. A very brief court hearing (at which S was not represented) did not analyse whether S had capacity, but followed directly the precedent set in *Re T* and authorized a caesarean delivery against the woman's wishes. A number of similar cases followed.[53,54]

*Re MB* broke the established trend.[39] The case concerned a needle-phobic woman who was advised to have a caesarean delivery after going into labour at term with a footling breech baby. She consented to the operation and wanted her baby to be born alive but refused to have an anaesthetic that involved her feeling a needle. The Court determined that although MB would usually have capacity to make decisions by herself, her fear of needles had temporarily incapacitated her. In the judgment of the Court of Appeal, it was made clear that the interests of the fetus should play no part in a decision to force a woman to undergo a caesarean delivery against her will. In this manner, a new precedent was set that directly contradicted that made by Lord Donaldson in *Re T*. A decision based on the best interests of an incompetent woman should consider the woman's desire to have a healthy, live baby, but should not consider this from the point of view of the baby. No competent woman should be forced to have a caesarean delivery against her will.

It may be difficult, however, for medical staff to watch a woman make decisions that compromise not only her own life but also that of a viable fetus. The doctors caring for S (a different S from that referred to previously) seem to have been desperate to prove that she was incompetent in order to deliver her baby by caesarean delivery against her will. S was diagnosed with pre-eclampsia at 36 weeks' gestation.[55] She refused admission for induction despite acknowledging that her decisions might result in the death of herself and her baby. She preferred to allow nature to take its course and stated that she did not want the baby anyway. S was compulsorily admitted to a psychiatric hospital under an assessment order from which she was transferred to the delivery suite of a neighbouring hospital against her will. A court order authorizing urgent caesarean delivery was granted on the premise that S was incompetent to refuse.

This decision to permit a caesarean delivery against the wishes of S was overturned at appeal, after delivery of the baby. The Court of Appeal reiterated that no competent woman should be forced to have a caesarean delivery against her will. The fact that S had been detained under the Mental Health Act did not equate to her being incompetent to make her own decisions. Furthermore, it was determined that her doctors would not have detained S if she had not been suffering from pre-eclampsia—it was a medical rather than a psychiatric problem that caused the doctors so much concern. S was not represented in the initial hearing and so did not have the opportunity to demonstrate her capacity to the Court. If she had been, she may have convinced them in a statement that she wrote for the doctors to explain her reasoning for refusing consent for caesarean delivery. In this statement, she clearly demonstrated that she understood the risks involved in refusing a caesarean delivery, had retained the information, weighed it up, and had reached a decision that she was capable of communicating back to her doctors.[55]

The Court reiterated that a fetus has no separate legal personality from its mother and thus its health and well-being cannot take precedence over the mother's rights, including the right to refuse treatment, however 'morally repugnant' that decision may be.[55]

The Court issued guidelines about how to handle future cases.[55] These guidelines state that no court will sanction a forced caesarean delivery on a competent woman. Where a competent woman refuses consent, written notes detailing discussions with the patient should be made and a signed refusal of treatment by the patient requested. Furthermore, the requirement was made that, in future, the woman who was the focus of the case should be legally represented in order that her opinions and evidence of her capacity be made known to the court. Only cases where there is uncertainty about a woman's capacity should be referred to the courts.

The case concerning O demonstrates the current position of case law on the subject of enforced caesarean delivery. O suffered from panic attacks that prevented her from being able to submit to a caesarean delivery. Her doctors believed that the panic attacks were sufficiently disabling as to incapacitate O temporarily. A court application was made to seek authority for an operative delivery against O's wishes. The judge who heard the case ensured that O had the opportunity to have legal representation and spoke directly to O. In this conversation, it was ascertained that O wanted to have the operation and did not wish to cause harm to herself or her baby. O had the insight to recognize that her panic attacks were preventing her from exercising her autonomous decision. The court therefore authorized the hospital to perform a caesarean delivery for O on the basis that she was temporarily incapacitated by panic attacks.[56]

The message is therefore clear: even if there is a risk of harm or death to a full-term fetus, medical staff are not permitted to override the refusal of consent of a capacitous woman. If, however, there are concerns about the woman's capacity then an application should be made to the courts for adjudication. The woman must be given the opportunity of representation in order that her views are heard. In the event that any delay is likely to result in serious morbidity or death, senior doctors in conjunction with a senior midwife should document the reasons why they believe that the woman lacks the capacity to refuse. The involvement of the hospital legal team should take place in parallel.

## Legal rights of a fetus

Once born, healthcare staff are obliged to provide their very best care to the baby and yet the above-mentioned cases demonstrate that whilst it remains *in utero*, their ability to provide it with care depends on the permission of the mother. It can be difficult to comprehend how the 'location' of the baby has such a profound impact on its legal status.

### The moral worth of a fetus

There is no universal ethical agreement on the point at which a fetus should be attributed the same moral status as a baby or an adult human and so be offered the same protection and rights. Being genetically human may be seen as the crucial factor, and this would imply that full moral status is achieved at the time of conception.[57] Another view is that no moral rights can be attributed to the cell mass that results from conception until after set time periods, before which it cannot be certain that conception will result in the development of a unique human individual,[58] or even until after birth. Further arguments revolve around the absence or presence of sentience, the definition of 'personhood', and the concept of 'potentiality'.[59]

This brief paragraph gives just a hint of the debate that has vexed ethicists, legal experts, religious and healthcare groups, and lay people for years. Even if unanimous conclusions could be reached concerning the point at which moral protection should be afforded to human life, there remains one more important issue: the rights of the woman in whom the new life is developing. If human life is given moral (and subsequently legal) rights antenatally, there will be occasions when these rights conflict with the woman's rights to bodily autonomy. It is on the background of these enormous ethical conundrums that inconsistencies in the approach of the law to the status of the fetus have developed.

### Abortion

Some form of protection of fetal life has existed in statutory law for many years. The Offences Against the Person Act 1861 made it a criminal offence for a woman to induce abortion in herself or for any other person to assist her in this process.[60] No statutory exceptions were made to this rule, although case law established that a doctor who performed an abortion in order to save the life of the mother would not be convicted of a criminal offence.[61] This exception was put on a statutory footing with the Infant Life (Preservation) Act 1929. To cause the death of a fetus that was capable of life independent from its mother (certainly from 28 weeks' gestation onwards, earlier if the prosecution could offer evidence to support their case) could result in a conviction for child destruction.

The Abortion Act of 1967 sought to clarify the law regarding when termination could be legal. According to the original statute, abortion is permissible if two doctors are in agreement that the circumstances satisfy one of two situations: that continuation of the pregnancy would result in injury to the woman's physical or mental health or that of her existing children greater than if termination occurred; or that there was a substantial risk of the baby being born with a serious mental or physical handicap. The provisions of the Infant Life Preservation Act remained and hence the 28-week limit for terminations.

The Abortion Act has since been amended by section 37 of the Human Fertilisation and Embryology Act 1990, with a reduction in the time limit on terminations on the grounds of injury to the mother's physical or mental health or that of her existing children to 24 weeks (in line with advances in survival of preterm infants). A termination is permissible at any gestation in order to prevent death of the mother, as previously, and now also at any point if there is a 'substantial risk' that the pregnancy will result in a child with mental or physical abnormalities causing it to be 'seriously handicapped'.[62] It has been noted that this Act has created an inequality in rights accorded to fetuses: a baby capable of life independent from its mother may now lawfully be killed, but only if it is disabled.[63] The extent of disability necessary for a termination to take place on these grounds has been extensively debated as the wording of the statute, like that of any other, is open to interpretation. A case was brought against West Mercia Police for their failure to investigate doctors who had permitted a termination at 28 weeks because the fetus had bilateral cleft lip and palate.[64] The Crown Prosecution Service, after hearing the evidence, decided that the doctors had acted appropriately, thus setting a precedent in case law for what may constitute being 'seriously handicapped'.

### Antenatal harm

The Congenital Disabilities (Civil Liability) Act 1976 is a route of redress for any child born disabled as a result of events (including medical treatment) that occurred pre-conception, during pregnancy or at the time of birth. For a claim to be successful, it must be demonstrated that the person who caused the damage failed in their duty of care to the child's parent, even if they did not cause actual or visible harm to the parent. The Act is complicated and requires proof that the disability has come about as a direct consequence of a specific occurrence for which an identifiable individual or individuals are responsible. It may be difficult for a claimant to achieve this level of proof.

Similarly, a criminal case can be brought against an individual who causes antenatal harm to a fetus that results in the subsequent death of the baby or child. A man who stabbed his pregnant girlfriend causing damage to their fetus and its premature birth was convicted of manslaughter when the baby eventually died as a consequence.[65] The Law Lords confirmed that a charge of murder might also be brought in similar circumstances if the level of intent required to prove a case of murder was present. However, they affirmed that if the baby was stillborn as a result of such actions, there would be no case of murder or manslaughter to answer: the baby must be born alive in order to achieve the legal personality necessary to become the victim of either murder or manslaughter.

### The duties of a mother

Under the terms of The Congenital Disabilities Act, a child damaged by antenatal events can bring a case in negligence against the individual who caused the damage. The one exception to this is the mother (unless the harm is caused by the mother's negligent driving).[66] Whilst a mother may have a moral responsibility to protect her unborn baby, an attempt to coerce her through the weight of the law (as has occurred in some states in the United States) can be counterproductive.[67] Harm may occur to a fetus before a woman knows she is pregnant. Criminalizing women for their behaviour in pregnancy is likely to require caregivers to report episodes of potential harm or face being complicit with a crime. This may result in a breakdown in the relationship of trust between a woman and the doctors and midwives caring for her. Women may therefore be less likely to seek healthcare in pregnancy in order to avoid such scrutiny, or may seek termination rather than continuance of pregnancy for fear that harm they have caused might be discovered.

The case of *Re F* demonstrated that the English courts were unwilling to use the force of the law to safeguard babies *in utero*.[68] A local authority attempted to make an unborn baby a ward of court as its mother, who suffered from mental health problems, was refusing all antenatal care. The application was refused on the basis that a fetus does not have legal personality in English law, that it would result in great practical problems, and that such an action puts the interests of the mother in direct conflict with those of the fetus.

## Confidentiality

Medical confidentiality is governed extensively by legal, professional, and employer requirements. It consists of a negative obligation, not to disclose information, but also a positive obligation, to ensure information is kept secure and not accessed improperly (Table 29.2).[69] Maternal confidentiality requires unique considerations, as information is likely to have consequences for the fetus and father.

### A duty to maintain confidentiality

The duty to maintain medical confidentiality derives from common law, which has typically focused on the public interest. For example, following a threat of disclosure of the identity of two general practitioners who had contracted HIV, the court decided that there was great public interest in maintaining medical confidentiality of people with HIV and AIDS in order that they should seek healthcare without fear of identification.[70] This interest, it was decided, outweighed the public interest in the freedom of the press to publish information that had been obtained improperly from hospital records. The decision turned on the balance of factors impacting on the public interest more than any privacy rights of the two doctors involved.

The Human Rights Act 1998 came into force in the United Kingdom in 2000. Article 8 offers legal protection to private information in the interests of the individual concerned, although it recognizes that disclosure is sometimes justified in the public interest.

When a breach of confidentiality has occurred, remedies in law would lie in negligence, equity and contract. The GMC[71] and the British Medical Association[72] have issued guidance to doctors reinforcing the duty of confidentiality and the courts are likely to place great emphasis on these when considering cases relating to breaches in confidence, as there is limited case law in this area. Negligence would require proof of harm and this tends to

**Table 29.2** Challenges to maintaining confidentiality

| Challenge | Example |
|---|---|
| Clinical details discussed in public settings | Curtains around bedspaces, conversations in corridors |
| Medical information shared with non-medical personnel (although it should be noted that these individuals have a common law duty to maintain confidentiality)[82] | Administrative staff, audit, clinical governance, adverse event analysis, chaplains, work experience students |
| Clinical information visible to members of public | Patient boards with detailed patient information, electronic check-in systems, openly accessible research |
| Portability of information | Laptops, smartphones, electronic medical records, memory sticks |
| Increasing subspecialization | Increased number of professionals requiring access to an individual patient's information, cross-site working with possibility for loss of patient records |
| Social media | Discussion of patients online |
| Clinical information requested by non-medical agencies | Employers, insurers, pharmaceutical companies |
| Educational activities | Conferences, educational meetings, journals, professional body publications |

be of a financial or physical nature rather than embarrassment. Breach of contract could be applicable with private patients but no contract exists between an NHS patient and doctor. However, the NHS doctor could be found in breach of his employment contract and professional obligations, and face disciplinary proceedings from both their employer and the GMC. Claims in equity are most likely to be sought. Equitable obligations of confidence require that the information disclosed was confidential in nature and was shared in a relationship of confidence. Legal claims for alleged breach of medical confidentiality are unusual due to the difficulty in satisfying legal requirements in negligence.

## A duty to disclose

The ethical duty to maintain confidentiality is not absolute and, in certain circumstances, the adverse consequences of maintaining confidentiality may override the individual patient's right to confidentiality. There are a number of situations where statutory law requires disclosure of patient information to certain authorities (Table 29.3) and situations where judgement must be used by the clinician.

The law permits disclosure where the public interest in disclosure outweighs the public interest for patients to trust their doctors.[73] Legally, information may only be disclosed if the clinician perceives there to be a real threat posed by maintaining confidentiality. Only the minimal information necessary should be disclosed and only to those with a legitimate interest.

HIV is not a notifiable disease but, in the context of maternal HIV infection, disclosure may be justifiable. Wherever possible the patient should be encouraged to share this information. However, if the patient refuses, the potential risk to the partner must be balanced against the harms to the mother. The GMC advises that, where disclosure of patient information is to take place, the patient should be informed in advance of this if it is considered possible and safe. Referral to such guidelines is essential as the courts are likely to be guided by these in the event of litigation. It is also important to seek advice from the trust legal team, Caldicott Guardian, and professional defence organizations. Ultimately, however, it is the clinician's responsibility to ensure that there are valid ethical reasons for the disclosure.

Case law has also considered occasions where a doctor might have had a duty to disclose confidential information but did not do so. For a case in negligence to be successful, the victim of harm must be someone who could reasonably have been identified as being at risk. In this manner, a duty of care (or duty to warn) is established. In *Palmer*, a health authority successfully defended itself against a claim of negligence for not acting to prevent a patient with a psychiatric disorder from committing murder, on the grounds that it did not owe a duty of care to the subsequent victim who could not have been identified in advance.[74] However, a NHS trust has accepted liability and a duty of care towards the family of a psychiatric patient who, upon release, killed his mother and himself.[75]

## Access to medical records

The Data Protection Act 1998 governs the processing of medical records of living persons. It applies to both manual and electronic records and the key principles relate to ensuring fair and lawful storage, handling and use.[76] Patients can apply to the courts if the terms of the Act are not met but would need to prove that harm had occurred in order to succeed in a case in negligence. Patients can apply to have access to their own medical records provided disclosure does not reveal information about a third party and will not cause serious harm to the patient or a third party.

The Access to Medical Reports Act 1988 gives individuals the right to obtain medical reports prepared for third parties (such as insurance companies or employers) before their release and the right to prevent release.

In the context of maternal confidentiality, it is common for partners to request medical information and refusal of disclosure may upset the patient and partner. GMC guidance is to obtain patient consent and discuss what information the patient would like to be shared, particularly if she is likely to lose capacity.[71]

## Research, audit, teaching and publication

Secondary uses of patient information may be essential to providing effective, safe and efficient clinical care. There is a balance between the obligation to protect an individual's right to privacy and the implications of this in areas including audit, research and public health, which may be in the public interest. The National Health Service Act 2006 section 251(1) permits disclosure of medical information without patient consent for these secondary uses, but requests are conditional on fulfilling certain criteria and are overseen by the National Information Governance Board for Health and Social Care. It must be shown that disclosure is necessary, consent is not practical or possible and the data are to be used in the interests of the public and patients.

The GMC states that when using information for secondary purposes, information should be anonymized wherever possible or express permission from the patient sought.[71] Before using patient information without prior consent, one should consider the nature of the information, the purpose and extent of disclosure, the adequacy of safeguards limiting disclosure, the advice of a Caldicott Guardian who is not involved with the secondary use, and the potential harms to the individual patient.

## Confidentiality and patients lacking capacity

The duty of confidentiality relating to minors is complex. Those aged 16 or over are presumed to have capacity and should be entitled to the same duty of confidentiality as capacitous adults. For those aged 15 years or under, professional discretion is required if the child refuses consent for sharing of information with those who have parental responsibility. This situation is unusual but considerations should include the competence of the child (her

understanding of the implications of disclosure or non-disclosure), the promotion of the child's welfare, and the harms and benefits of disclosure. The balancing of these factors should be undertaken in much the same manner as when deciding whether a child is sufficiently mature to give consent for her own medical treatment. Ultimately, if the clinician believes that the child's best interests are served by sharing information, this is permissible even if against the child's wishes. Doctors are obliged to communicate concerns regarding child abuse to the relevant authorities even if the child concerned has asked for the information to be kept confidential.[77]

In the case of incapacity, the key legal principle is to act in the best interests of the patient. It is generally justifiable to disclose information if it is necessary for the care of the patient. The GMC recognizes the potential 'need to share personal information with a patient's relatives, friends or carers to enable you to assess the patient's best interests … that does not mean they have a general right of access to the patient's records or to have irrelevant information about, for example, the patient's past healthcare'.[71]

The legal[78] and professional duty of confidentiality persists after death although this is not absolute. It is generally in the public interest that confidentiality of current patients is maintained following death. The GMC guidance relating to disclosure following death requires consideration of the wishes of the patient, the harms and benefits to the patient's family, whether disclosure will reveal information about the patient's family or a third party, and the purpose of the disclosure.[71]

In summary, the duty of confidentiality is not absolute. The predominant legal basis is that of public interest and the fair use of information. Sharing of information is recognized as necessary for clinical care. In situations where disclosure is necessary, the amount of information and the number of recipients should be kept to a minimum. Professional guidelines should be consulted as legal judgements are likely to refer to these in assessing the validity of a practitioner's reasons for disclosure.

## Teaching

The postgraduate training of a doctor is a complex mixture of academic learning, independent delivery of care, and apprenticeship-style training. In line with the increased awareness and respect of patient autonomy by the medical profession, non-consensual examination and unnecessary procedures purely for the purposes of training are not acceptable. There is very little case law concerning medical training, and standards are derived mostly from professional guidelines. Patients should be viewed as part of a three-way partnership of learning, along with the trainer and trainee. It may be argued that the patient has a moral duty to contribute to the education of junior doctors as they have themselves benefitted from the care of fully trained doctors who have learnt their skills through the involvement of previous patients.

### Consent and medical training

As with all other aspects of patient care, the importance of consent cannot be over-emphasized. The GMC stipulates that patients must be informed about the roles of the people involved in their care, the involvement of students, and their right to refuse to take part in teaching.[20] Department of Health guidance states that where a trainee or student undertakes a procedure (in which they are competent) for the purposes of patient care, it is not legally necessary to tell the patient that they are a trainee, although it is good practice.[79] However, if the trainee or student is planning on undertaking an assessment or examination that is purely for the purposes of their own education then it is important that this distinction is made clear to the patient.

Whilst knowledge can be learnt and some degree of development of manual skills can take place through simulation, ultimately, every doctor must perform every procedure in which they are to become competent on a patient for the first time. There is difficulty in deciding precisely how much information should be given to a patient regarding trainee involvement in a procedure. The AAGBI recognizes that most procedures have a number of components, that there are numerous learning points in the course of a single anaesthetic, and that it would be impractical to seek consent for every one of these learning points that involves a trainee anaesthetist.[40] It is also noted that every practitioner continues to learn with every procedure undertaken. The AAGBI offers the advice, however, that the trainer must assess the risks and benefits to the patient for each aspect of care that is to be delivered by a trainee. In minimizing the risks, the trainer must ensure that the trainee has adequate knowledge, has had the opportunity to make use of any appropriate simulation or skills based training, that there is close supervision and that there is clear purpose to teaching this particular trainee this particular skill (e.g. avoiding exposure of patients to the learning curve of a trainee attempting to develop a skill for which they have no longer-term need). In the case of certain procedures with definable risks, it will be necessary to gain specific, informed consent.[80]

### Supervision of trainees

Adequate supervision of trainees is an important component of minimizing the risks to patients of being involved in the training of junior staff. It is difficult to define a precise cut-off between the areas of care delivered by the trainee that are service delivery and those that constitute training, since the two overlap significantly. Medical training involves permitting trainees to develop their independent practice with ever more distant supervision. It is important to remember that when care is being delivered by a trainee, there should be a nominated consultant supervising that trainee at all times.[81] Trainees should ensure that they do not act beyond the limits of their capabilities and consultants should ensure that they are readily available and contactable for advice or assistance. Difficulty arises where communication has broken down and a consultant is unaware of cases being performed by a trainee.

### Trainees and the standard of care

When trainees are delivering patient care independently, it is important that the standard of care is that of a competent doctor working in the same post; inexperience will not be a sufficient defence against a claim in negligence. It is expected that trainee doctors should recognize the limits of their abilities and experience and call for assistance appropriately.[82]

## Conclusion

The key aspects of case and statutory law that relate to obstetric anaesthesia, and their impact on practice, have been presented in this chapter. The role of professional guidelines is of increasing importance in setting a benchmark for standards of care,

especially where precedent is absent. Medical law is greatly influenced by ethical values and reasoning in the development of guidelines, as the driving force for new statutory law and in judgements made in case law. The presence of the fetus adds a unique ethical and legal consideration in law relating to obstetrics and obstetric anaesthesia.

PART 8

# Obstetric complications

# CHAPTER 30

# High dependency and intensive care

Philip Barclay and Helen Scholefield

## Maternal critical care and recommendations from the triennial reports

The triennial Confidential Enquiries into Maternal Deaths in the United Kingdom have played a major role in the reduction of maternal mortality since the 1950s.[1] The importance of developing maternal critical care has long been recognized in reducing the significant number of deaths still associated with a substandard level of care. The 1988–90 triennial report[2] stated that every consultant obstetric unit should incorporate a properly staffed high dependency unit (HDU). The 1997–99 triennial report[3] emphasized the requirement that invasive monitoring should be available and used appropriately. The 2000–2002 report[4] focused on the need for earlier recognition of the sick parturient and to apply a higher level of care promptly before transfer to the intensive care unit (ICU). These requirements for maternal critical care formed a part of the Joint Royal Colleges Safer Childbirth document.[5]

## Critical care: replacing existing divisions between the HDU and ICU

The *Comprehensive Critical Care* document published in 2000[6] reviewed adult critical care services and recommended a new approach based upon severity of illness, as it was recognized that critically ill patients should receive an equivalent level of care outside of an ICU or HDU. The existing division between high dependency and intensive care beds would then be replaced by a classification focusing on the level of care required by the individual patient, with staff numbers, skill, and expertise deployed appropriately. Four levels of care were described in *Comprehensive Critical Care* from level 0 normal ward care through to level 3 intensive care.

The original descriptions of levels of critical care excluded patient care in the delivery suite. The guidelines have since been revised and updated by the Intensive Care Society's *Level of Critical Care for Adult Patients*[7] to describe levels of critical care in terms of the type and number of organ systems requiring support (Box 30.1).

The Critical Care Information Advisory Group now agrees that these definitions can be applied to obstetrics to describe critical care given on a delivery suite.

Wheatly described specific examples of levels of care most likely to be applicable to patients on a delivery suite, which were used in the Maternal Critical Care Working Group report *Providing Equity of Critical and Maternity Care for the Critically Ill Pregnant or Recently Pregnant Woman* (Table 30.1).[8,9] For example, if a woman in labour has pre-eclampsia requiring oral labetalol with an oxytocin infusion and an epidural, that would be classified as Level 1 care. If her blood pressure control requires an intravenous infusion of labetalol with arterial monitoring, that meets the definition of basic cardiovascular support, which is Level 2 care. If she then has an eclamptic convulsion and requires a magnesium infusion to treat the eclampsia, she then requires neurological support in addition to basic cardiovascular support. Her two-organ system support now defines her as receiving Level 3 care.

The definitions of levels of care provide a standard for critical care data collection throughout the United Kingdom using the critical care minimum dataset (CCMDS), which now includes a specific code for obstetrics area [CRITICAL CARE LOCATION 07].[10] This is useful to capture activity where Level 2 and Level 3 care is delivered outside of a critical care environment. It can also be used

**Box 30.1** Levels of critical care

**Level 0**

Care needs met on normal ward.

**Level 1**

At risk of their condition deteriorating or recently stepped down from higher level.

Care needs can be met on acute ward with additional support from critical care team (outreach).

**Level 2**

Detailed observation or intervention required, including single-organ support or postoperative care and step-down from level 3.

**Level 3**

Advanced respiratory support alone.

*Or*

Basic respiratory support plus at least two-organ system failure. Includes all complex patients requiring support for multiorgan failure.

Courtesy of The Intensive Care Society. *Levels of Critical Care for Adult Patients*. London: Intensive Care Society, 2009.

**Table 30.1** Maternity examples of levels of care

| Level of care | Maternity example |
|---|---|
| Level 0: normal ward care | Care of low-risk mother |
| Level 1: additional monitoring or intervention, or step down from higher level of care | Risk of haemorrhage: oxytocin infusion<br>Blood pressure control: mild pre-eclampsia on oral antihypertensives/fluid restriction etc.<br>Coexisting medical conditions: woman with medical condition such as congenital heart disease, diabetic on insulin infusion |
| Level 2: single-organ support | *Basic respiratory support (BRS):*<br>50% or more oxygen via facemask to maintain oxygen saturation<br>Continuous positive airway pressure (CPAP), bi-level positive airway pressure (BIPAP)<br>*Basic cardiovascular support (BCVS):*<br>Intravenous antihypertensives, to control blood pressure in pre-eclampsia<br>Arterial line used for pressure monitoring or sampling<br>CVP line used for fluid management and CVP monitoring to guide therapy<br>*Advanced cardiovascular support (ACVS):*<br>Simultaneous use of at least two intravenous, antiarrhythmic/anti- hypertensive/vasoactive drugs, one of which must be a vasoactive drug<br>Need to measure and treat cardiac output<br>*Neurological support:*<br>Magnesium infusion to control seizures (not prophylaxis)<br>Intracranial pressure monitoring<br>Hepatic support<br>Management of acute fulminant hepatic failure, e.g. from HELLP syndrome or acute fatty liver, such that transplantation is being considered |
| Level 3: advanced respiratory support alone, or support of two or more organ systems above | *Advanced respiratory support:*<br>Invasive mechanical ventilation<br>*Support of two or more organ systems:*<br>Renal support and BRS<br>BRS/BCVS[a] and an additional organ supported |

[a]BRS and BCVS occurring simultaneously during the episode count as a single organ support.

for funding, providing that the local critical care network accepts that care given is of an appropriate standard in terms of facilities, staff training, and competency.

## How many parturients require Level 3 critical care?

Escalation and transfer to Level 3 care is a well-defined and documented event but only a very small proportion of obstetric patients go to an ICU.[11] In our own hospital, between July 2004 and November 2008, 18 of 35,276 parturients were transferred for Level 3 care: 0.51/1000 deliveries. Larger-scale audits at a regional or national scale are therefore required to produce descriptive and comparative statistics that will help us understand Level 3 intensive care requirements in this population.

Hazelgrove et al.[12] examined obstetric admissions to 14 ICUs in Southern England over a 3-year period between 1994 and 1996. There were 210 women admitted, representing 1.8% of all ICU admissions, although this varied from 0.18% to 3.18% in individual ICUs. The ICU admission rate was 1.7/1000 deliveries. The overall mortality rate for those admitted to ICU was 3.3%, with seven maternal deaths.

The main reasons for admission to the ICU were complications of hypertensive disease of pregnancy, including HELLP (haemolysis, elevated liver enzyme levels, and low platelet count) syndrome (39.5%) and major haemorrhage (33.3%). The median duration of stay on the ICU was 1 day. Seven patients were transferred from general ICUs to specialist ICUs for neurological, renal, liver, and respiratory support. Forty-five per cent of patients required intermittent positive pressure ventilation, 20% needed cardiovascular support with inotropes, 13% had pulmonary artery catheters for haemodynamic monitoring, and 3% required renal support with continuous veno-venous haemofiltration.

In 35% of patients, no ICU interventions were required and their length of stay was less than 2 days. This was more likely in those admitted with pre-eclampsia (48%) and emphasized the need to develop high dependency facilities on the delivery suite as only 50% of the patients met the criteria for Level 3 care. This would have reduced their ICU admission rate down to 0.85/1000 deliveries.

Mirghani et al.[13] examined all obstetric patients admitted to the ICU at Al-Ain hospital, Al-Ain, United Arab Emirates over a 6-year period from 1997 to 2002. Of 23,383 deliveries, 60 were admitted to the ICU, a rate of 2.6/1000 deliveries. This represented 2.4% of all ICU admissions over this period. The main reason for admission was haemorrhage (28.4%) and pre-eclampsia (25%) whilst 31.8% were admitted due to severe pre-existing medical problems including cardiovascular disease, diabetes, asthma, and chronic renal failure. There were two deaths (3.3% of all obstetric ICU admissions); one due to cerebral malaria associated with acute respiratory distress syndrome and another with suspected aspiration after a general anaesthetic for placental abruption. There were no HDU facilities available on the delivery suite of that hospital. On retrospective review of illness severity, only 47% met the criteria for Level 3 ICU care, a similar finding to that of Hazelgrove et al.[12]

The largest reported series of obstetric admissions to ICU is from the Intensive Care National Audit and Research Centre (ICNARC) Case Mix Programme, which audited all admissions in England, Wales, and Northern Ireland between 1995 and 2003.[14] Of 219,468 admissions to 159 critical care units, 1452 (0.7%) had a direct obstetric cause. An additional group of 450 (0.2%) pregnant women had a coincidental reason for their ICU admission. The main direct obstetric reasons for admission are outlined in Table 30.2—33% were due to haemorrhage and 38% due to hypertensive disorders of pregnancy.

The reasons for indirect admission were far more varied, with a total of 115 different primary reasons. The commonest reasons are shown in Table 30.3.

**Table 30.2** Incidence of obstetric conditions as a direct cause of admission to ICU

| Obstetric cause of direct admission | Admissions (%) | Mortality (%) |
|---|---|---|
| Peripartum or postpartum haemorrhage | 29.1 | 0.6 |
| Pre-eclampsia | 18.2 | 2 |
| HELLP syndrome | 12.6 | 2.6 |
| Eclampsia | 7.4 | 3.5 |
| Ectopic pregnancy | 5.5 | 1 |
| Intrauterine death | 5 | 6.3 |
| Antepartum haemorrhage | 3.7 | 7.3 |
| Infected retained products of conception | 1.4 | 3.8 |
| Amniotic fluid embolus | 1.2 | 9.1 |
| Septic abortion | 0.9 | 11.1 |
| Amnionitis | 0.4 | 16.7 |
| Molar pregnancy | 0.2 | 25 |

**Table 30.3** Most common primary reasons for admission to ICU for indirect or coincidental obstetric admissions

| Commonest causes of coincidental admission | Admissions (%) |
|---|---|
| Pneumonia (bacterial and 'no organism isolated') | 5.1 |
| Status epilepticus or uncontrolled seizures | 4.2 |
| Asthma attack in new or known asthmatic | 3.6 |
| Septic shock | 3.6 |
| Non-cardiogenic pulmonary oedema (ARDS) | 2.4 |
| Anaphylaxis | 2.2 |
| Pulmonary embolus (thrombus) | 2.2 |
| Septicaemia | 2 |
| Acute kidney injury, other cause | 1.6 |
| Hypovolaemic shock | 1.6 |
| Pelvic infection or abscess | 1.6 |

The median length of stay on the ICU was 1.1 days for direct and 1.5 for coincidental admissions. The overall mortality rate for direct obstetric admissions was 2.2% compared with 6% for coincidental obstetric admissions and 19.6% for all non-obstetric female admissions in the 16–50 years age group. The lower mortality seen in the obstetric group was attributed to the lower admission threshold to ICU, change in maternal physiology, pregnancy identifying a group of patients with better health status, and the self-limiting nature of most obstetric pathology, given timely supportive care.

The ICNARC dataset specification was updated in 2006 to incorporate a number of obstetric-related fields. A further study was then carried out of all ICU admissions from 1 January to 31 December 2007 who were currently or recently pregnant.[15] Of the 38,461 admissions to the 107 ICUs who participated, 95 women were currently and 418 were recently pregnant. This was extrapolated to all 240 ICUs and compared with national pregnancy statistics, making an admission rate of 2.6/1000 deliveries. This compares with a maternal death rate in the 2006 to 2008 triennium of 0.11/1000.[16]

Of those who were currently pregnant, only 13.7% had an obstetric reason for admission, of which ectopic pregnancy, amnionitis, and pre-eclampsia were the most frequent. The commonest non-obstetric indication for admission was respiratory failure (35%), with 20% due to pneumonia and 7% due to asthma.

By contrast, 72% of those who were 'recently pregnant' had an obstetric indication for ICU admission. Peri- and postpartum haemorrhage was the commonest reason (34%) followed by hypertensive disorders of pregnancy (9%).

Zwart et al.[17] found a similar rate of ICU admission at 2.4/1000 deliveries in the Netherlands, with a maternal mortality rate of 3.5%.

A systematic review by Pollock et al.[18] examined 40 studies published between 1990 and 2008 that covered a total of 7887 pregnant and postpartum admissions to ICUs around the world; 60% of the studies were from developed countries. The median admission rate was 2.7/1000 deliveries (interquartile range (IQR) 1.9 to 5.4). The majority of admissions were for obstetric reasons (1.9/1000). The commonest obstetric reasons for admission were hypertensive disorders of pregnancy (0.9/1000), obstetric haemorrhage (0.7/1000), and sepsis (0.2/1000). Only 25 out of 40 studies reported whether the patients were currently pregnant on admission to ICU, with a median value of 16%.

There were no differences between developed and developing countries in their overall rates of ICU admission (3.0 vs 2.7) or the reasons for admission. There was a significant difference in maternal death rates on ICU (3.4% (IQR 0–18.4) vs 14.0% (IQR 0–14.0)) respectively and severity of illness scores on admission.

## How many women require high dependency care?

The maternal death rate (0.11/1000) and ICU admission rate (2.6/1000) are well defined with unequivocal end points but there is a further subset of women who develop severe illness during their pregnancy and require high dependency care.

Mantel et al.[19] looked at the progression from maternal health through to critical illness. He defined a maternal 'near miss' as a very ill parturient who would have died if her condition had not been diagnosed and she received appropriate treatment which prevented her progression to organ failure and then death at any

point during pregnancy or in the first 6 weeks after delivery/termination (Table 30.4).

They applied this to a prospective audit of 13,429 deliveries in the Pretoria health region, South Africa, during 1 year. There were 147 near misses (1.1%) and 30 deaths. They found that hypovolaemia was the commonest organ dysfunction in patients with near miss (37%), whereas respiratory (53%) and renal (30%) failure were commonest in those who died. Mantel's criteria for near miss have the advantage of being both objective and readily applicable in a district general hospital.

**Table 30.4** Mantel's criteria for maternal 'near miss'

| | Markers |
|---|---|
| **Organ system-based** | |
| 1. Cardiac dysfunction | i. Pulmonary oedema: a clinical diagnosis necessitating intravenous furosemide or intubation |
| | ii. Cardiac arrest |
| 2. Vascular dysfunction | i. Hypovolaemia requiring ≥ 5 units whole blood or packed cells for resuscitation |
| 3. Immunological dysfunction | i. Intensive care admission for sepsis |
| | ii. Emergency hysterectomy for sepsis |
| 4. Respiratory dysfunction | i. Intubation and ventilation for > 60 min for any reason other than for a general anaesthetic |
| | ii. Oxygen saturation on pulse oximetry < 90% lasting > 60 min |
| | iii. $PaO_2/FiO_2 \leq 3$ |
| 5. Renal dysfunction | i. Oliguria, defined as < 400 mL/24 h, which does not respond to either careful adequate intravascular rehydration or diuresis with furosemide |
| | ii. Acute deterioration of urea to > 15 mmol/L or of creatinine to > 400 mmol/L |
| 6. Liver dysfunction | i. Jaundice in the presence of pre-eclampsia |
| 7. Metabolic dysfunction | i. Diabetic ketoacidosis |
| | ii. Thyroid crisis |
| 8. Coagulation dysfunction | i. Acute thrombocytopenia requiring a platelet transfusion. |

In 2003, a continuous, prospective Scottish Confidential Audit on Severe Maternal Morbidity (SCASMM) was started, to capture data from all obstetric units using the Mantel criteria to provide a consistent definition of near-miss events. In 2010, 385 women were reported to the audit, making a near-miss incidence of 6.5/1000 births (95% confidence interval (CI) 5.9–7.2),[20] similar to the rate of 6.4/1000 births in the 2008 report.[21] Comparing these figures with maternal death rates in Scotland over the 2008–10 triennium, the mortality/morbidity ratio was 1:85. There was a significant variation in the rates of reported maternal morbidity amongst the 18 consultant-led maternity units, from 0 to 10.6/1000. This variation is thought to be due in part to different unit characteristics, with smaller units transferring high-risk women to larger units for delivery. Much of the variation, however, is due to the individual unit's diligence in case identification.[21]

The commonest cause of severe morbidity in pregnancy in Scotland is major obstetric haemorrhage (MOH), accounting for 85% of cases, at rate of 5.5/1000 births; 80% were post-partum, and 16% of women with MOH required admission to an ICU (Table 30.5).

Mantel's definition of maternal near miss was also thought to be the most stable and epidemiologically sound criterion in a recently published systematic review by Tuncalp et al.[22] A meta-analysis of the 11 studies that used Mantel criteria showed an incidence of 4.2/1000 deliveries (95% CI 4.0–4.4).

Zeeman et al.[23] audited 483 admissions to the obstetric intermediate care unit over a 2-year period at Parkland Hospital, Dallas, Texas. The admission rate was 1.7%, 15% of whom then required transfer to an ICU. Eighty per cent of the admissions

**Table 30.5** Causes of severe maternal morbidity in Scotland 2010

| Category of severe maternal morbidity | Number of events | Rate per 1000 births (95% CI) |
|---|---|---|
| Major obstetric haemorrhage | 328 | 5.55 (4.94–6.16) |
| Eclampsia | 12 | 0.20 (0.10–0.35) |
| Renal or liver dysfunction | 10 | 0.17 (0.08–0.31) |
| Cardiac arrest | 4 | 0.07 (0.02–0.17) |
| Pulmonary oedema | 3 | 0.05 (0.01–0.15) |
| Acute respiratory dysfunction | 3 | 0.05 (0.01–0.15) |
| Anaesthetic problem | 3 | 0.05 (0.01–0.15) |
| Cerebrovascular event | 1 | 0.02 (0.0–0.09) |
| Anaphylactic shock | 1 | 0.02 (0.0–0.09) |
| Septicaemic shock | 1 | 0.02 (0.0–0.09) |
| Coma | 0 | 0.00 (0.0–0.06) |
| Status epilepticus | 0 | 0.00 (0.0–0.06) |
| Massive pulmonary embolism | 0 | 0.00 (0.0–0.06) |
| Intensive care or coronary care admission | 76 | 1.29 (1.01–1.60) |

were post-partum. Two-thirds were admitted due to obstetric disorders, the commonest reason being hypertensive disorders of pregnancy (43%) and haemorrhage (18%).

Ryan et al. audited admissions to the two-bedded HDU at the Rotunda Hospital, Dublin,[24] from its inception in June 1996 to May 1998 and compared them with the rate of transfer to ICU in the 2 years before and 2 years after the unit opened. They found that 18% of the 123 admissions were antenatal. The HDU admission rate was 1.0% of all deliveries and 86% of HDU admissions were due to haemodynamic instability. There was a non-significant fall in the number of patients requiring ICU transfer after the HDU was established, from 12 (0.8/1000) in 2004–06 down to five (0.4/1000) in 2006–08 (Fisher's exact test P = 0.25).

Saravanakumar et al. analysed data for 3551 pregnant or recently pregnant women admitted to their obstetric HDU in Aberdeen between 1984 and 2007.[25] They found the admission rate had risen significantly from less than 1% in the 1980s to 5.01% at the end of the audit period, with an overall admission rate of 2.67%. The rise was thought to be due to a change in demographics, with an increasing number of women from ethnic minorities, maternal age, and Caesarean delivery rate. Obstetric-related conditions accounted for 75% of admissions and 11.3% of patients were antenatal. The commonest indication for admission was pre-eclampsia in the earlier years but this was overtaken by haemorrhage, accounting for 37.5% of admissions in 2006–07. Thirty-nine patients were transferred for ICU care in the last 4 year of the audit, a rate of 1.4/1000 deliveries.

High dependency care is required both for patients who have already met the criteria of sustaining a near miss and also for those who may do so in the future, so that they can receive appropriate monitoring and prompt treatment. There are many advantages for the parturient in keeping high dependency care within the delivery suite,[26] in terms of continuity of input from expert obstetrician and obstetric anaesthetic teams, holistic care from midwives, the ability to continuously monitor antenatal patients, and avoiding the hazards of emergency transport of the critically ill obstetric patient.[27]

What facilities for obstetric high dependency care (OHDC) are available on delivery suites in the United Kingdom? In 1994, Cordingley and Rubin surveyed lead obstetric anaesthetists in 262 UK obstetric units and received responses from 232 units.[28] They found that only 41% of units had dedicated OHDC beds, although 92% of units were able to provide temporary facilities when required; 81% of units had access to ICU on the same hospital site. The rate of transfer to ICU care in isolated units was lower than in non-isolated units (median rate of 0.92/1000 deliveries vs 1.33, P < 0.01).

Hussain et al. carried out a similar survey of OHDC facilities in 2006 and received 170 responses from 228 UK obstetric units.[29] They found that 96% of units were able to provide temporary HDU facilities, only 40% had at least one dedicated bed: almost unchanged over the past 12 years. The admission rate to HDU beds was 4.2%, considerably above the recommended figure of 1% quoted in *Safer Childbirth*[5] and similar to the 5% figure found by Saravanakumar.

## Intensive care unit physiological scoring systems

Many different scores have been developed to evaluate the severity of critical illness. The Acute Physiology and Chronic Health Evaluation (APACHE) score[30] was developed from the hypothesis that the severity of critical illness can be measured by quantifying the degree of physiological disturbance using multiple variables. Due to difficulties with previous predictive scoring systems, APACHE was not designed to assist in making individual treatment decisions but instead to classify groups of patients by their severity of illness. This allowed stratification by illness severity so that the outcome from intensive care could be evaluated[31] and the success of different treatment programmes compared.[32]

The original APACHE system was complex, producing a weighted score derived from 34 possible physiological measurements. A revised version, APACHE II, was introduced in 1985[33] to produce a simpler system that was more accurate. The number of variables used in APACHE II was reduced from 34 to 12 by discarding those that were infrequently measured and by evaluating each variable's impact on patient outcome using a multivariate analysis.

The APACHE II score is calculated from the degree of physiological disturbance, with a maximum of 4 points given to each of temperature, blood pressure, respiratory rate, heart rate, oxygenation, blood pH, sodium, potassium, creatinine, haematocrit, and white blood cell count. A neurological score is derived from the 15-point Glasgow Coma Scale (GCS) score, to a maximum of 12 points. This gives a total of 60 for severity of illness. A maximum of 6 points are added for age and 5 for comorbidity, making a total of 71. For female admissions to adult ICUs reported as currently or recently pregnant, a score of 0–17 is associated with a mortality rate of 1%, rising to 85% with APACHE II scores of greater than 42.[15]

The APACHE II system was found to have a good overall ability to stratify patients due to the strong association between acute physiological derangement and risk of death during acute illness. However, there remain significant variations in death rate by disease, due to nature of the underlying disease process. It is therefore essential to combine the APACHE II score with a description of the disease so that conditions with a high mortality such as septic shock can be differentiated from those with a better prognosis such as acute asthma. The risk of mortality for an individual can be calculated using an exponential equation, which combines the APACHE II with a weighting for the diagnostic category.

The value of APACHE II in obstetric patients was questioned by Koch et al.[34] who looked at the mortality predicted by APACHE II for 22 pregnant patients admitted to the medical ICU between 1984 and 1987. Eight maternal deaths occurred (36%), with three due to pre-eclampsia, two due to amniotic fluid embolism, and two assigned to immunodeficiency. The APACHE II scores were low, with no patient having a score greater than 20 and the predicted mortality from APACHE II was therefore only 11.5% for the whole group and 13.75% for the non-survivors. The underlying disease conditions in this series such as amniotic fluid embolism and HELLP syndrome are associated with a high mortality and this may explain the underestimation. The Koch et al. paper, however, does not give details of the diagnostic category weighting used to predict mortality.

Other authors since have found that APACHE II overestimates maternal mortality. Lewinsohn et al.[35] looked at predicted mortalities in 58 obstetric patients admitted to an ICU, together with a similar group of 120 non-pregnant young women, over an 8-year period. Their pattern of admission to ITU was quite different to

that reported by Koch et al., with the majority of patients being admitted due to sepsis and haemorrhagic shock. From the APACHE II scores, the predicted mortality rate in the obstetric patients was 16.6%, more than double the actual obstetric mortality rate of 4/58 (7%). By contrast, the predicted mortality rate in the non-obstetrical group was 10.1%, which was very close to the actual mortality rate of 12/120 (10%). Both obstetric and non-obstetric groups had similar mean APACHE II scores, indicating similar degrees of physiological derangement. The actual mortality for a given APACHE II score has been shown to vary considerably by ICU, with improved outcomes where there was good coordination between the intensive care staff.[36] The authors speculated that the obstetrician-intensivist performance, with good communication and open collaboration, led to better results.

The Simplified Acute Physiology Score (SAPS II) has also been used to predict mortality on admission to intensive care,[36] refined from the original SAPS using a multiple logistical regression model. It includes variables that are not used in APACHE II such as serum bilirubin and urine output. In addition, urea is substituted for creatinine and bicarbonate in place of arterial blood pH. SAPS II can be similarly used to calculate predicted mortality for obstetric patients admitted to the ICU. Scarpinato[37] used SAPS II to predict mortality for 29 obstetric patients admitted to the ICU. The SAPS II score predicted a higher mortality risk of 3% compared with the actual mortality of 0%, which was similar to Lewinsohn et al.'s findings with APACHE II.

The Mortality Probability Model (MPM II)[38] uses fewer physiological variables than APACHE II or SAPS II to estimate mortality at the time of ICU admission but includes additional information such as urine output, vasoactive drug therapy and raised prothrombin time together with computed tomography to estimate intracranial mass effect for patients with head injury.

El-Solh and Grant compared the predictive ability of APACHE II with SAPS II and the MPM II.[39] They applied the scoring systems to 93 obstetric patients admitted to the ICU between 1989 and 1995 and compared them with a control group of 96 non-obstetric female patients in the 17-41 year age group. Most admissions in the obstetric group were due to respiratory complications or emergency obstetric procedures. The observed mortality rates of each group were 10.8% and 10.4% respectively. There was no significant difference between the observed mortality and the mortality rates predicted by each scoring system. All three systems were found to be effective.

Bhagwanjee et al.[40] examined APACHE II scores in 105 women with eclampsia who were admitted to ICU in Durban, South Africa. The main indications for ICU admission were poor oxygenation, low GCS score, extreme restlessness, and laryngeal oedema. The overall mortality was 10.5% (11 patients). The APACHE II score was significantly higher in non-survivors than survivors but this was due to the contribution from the GCS score. The GCS score alone showed the same level of difference between the groups as the APACHE II, whilst the APACHE II–GCS showed no difference between the non-survivors and survivors. The number of organ systems failing was also significantly higher in non-survivors, most frequently respiratory failure. This reflects the multiorgan failure that accompanies severe eclampsia together with other complications such as HELLP syndrome.

Hazelgrove et al. measured the performance of APACHE II, APACHE III, and SAPS II scores in their study of 210 obstetric ICU admissions in Southern England.[12] Mortality ratios were assessed for each scoring system. Discrimination between survivors and non-survivors was assessed using the area under the receiver operating characteristic curve (AUC).[41] All three ICU scoring systems could accurately distinguish between survivors and non-survivors with APACHE II being the closest fit for the pregnancy population.

Harrison et al.'s study of 1902 obstetric ICU admissions using the ICNARC database[14] similarly evaluated the performance of APACHE II scores to discriminate between survivors and non-survivors using AUC values. The mortality predicted by APACHE II scores was calibrated using the mortality ratio, Hosmer–Lemeshow C statistic, and Cox regression calibration. The mean APACHE II score was 10.9, which was similar to the Acute Physiological Score as age points are only assigned above age 45 and the very severe chronic health conditions of APACHE II are rare in this population. Discrimination of the APACHE II score was good, with higher values for obstetric admissions (AUC 0.839; 95% CI 0.820–0.857) than for the control group of non-obstetric female admissions aged 16–50 years (AUC 0.812; 95% CI 0.807–0.818). The mortality predictions by APACHE II were similar to those found by Hazelgrove et al., with a mortality ratio of 0.245 for obstetric admissions compared to 0.907 for controls. The calibration plots (Figure 30.1) show how the APACHE II scores were able to predict mortality accurately in the control group but vastly overestimated mortality in the obstetric group.

Of the individual components of the APACHE II score, the GCS was the best predictor of mortality, a similar finding to Bhagwanjee's study of eclamptic patients.[40]

Rojas-Suarez et al.[42] reviewed 725 obstetric patients admitted to the ICU between 2006 and 2011. They found that APACHE II, SAPS II, and SAPS III overestimated maternal mortality whereas MPM II and MPM III were more accurate, with observed/predicted ratios of 0.89 and 1.25 respectively. They recommended that APACHE II should not be used to predict mortality in this population.

APACHE II is still popular in ICUs in the United Kingdom due to its simplicity but it has since been superseded by more accurate scoring systems: APACHE III [43] in 1991 and APACHE IV[44] in 2006. The authors of APACHE IV state that APACHE II is a useful summary measure of severity of illness but that it should no longer be used to predict mortality. APACHE IV instead uses a set of 142 variables in its mortality equation together with a more complex set of equations that require a computer to evaluate. The chart and scoring systems for APACHE II are freely available whereas APACHE III and IV are proprietary tools that have to be obtained from the developers, although the Cerner Corporation has recently made hospital mortality and length of stay algorithms available to registered users (https://apachefoundations.cernerworks.com/apachefoundations/login/auth).

APACHE IV provides ICU and hospital predictions for mortality and length of stay whilst MPM III and SAPS III only provide hospital mortality predictions. In the general adult intensive care setting, the latest versions of these ICU scoring systems have been shown to be more accurate than their predecessors.[45,46] Although newer scoring systems have better performance, the difference may not affect efficacy and choice of system depends on ease of use and local preferences.[47]

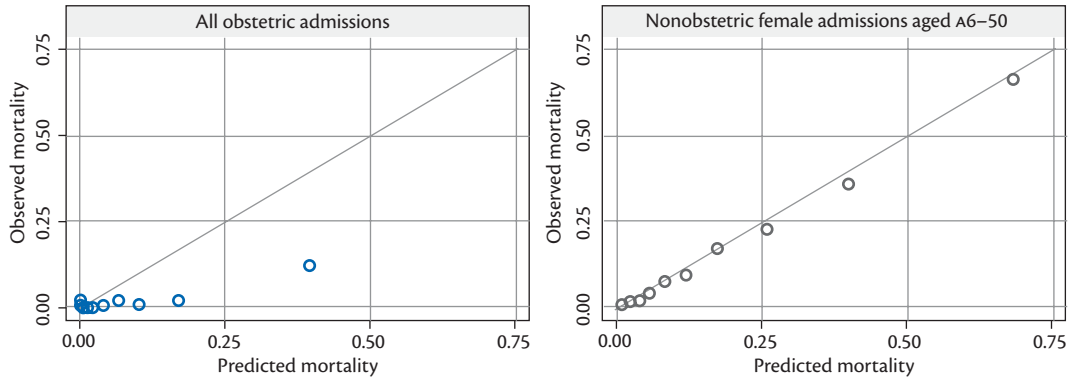

**Figure 30.1** Calibration plots for APACHE II mortality probability in obstetric and non-obstetric admissions. Observed mortality is plotted against deciles of predicted mortality. Diagonal line indicates perfect calibration.

APACHE, Acute Physiology and Chronic Health Evaluation.

Physiological scoring systems may perform poorly in obstetric critical illness due to the physiological changes in pregnancy or because of the unique scoring profile of obstetric conditions such as pre-eclampsia. These issues were considered by Gopalan and Muckart, who recommended using organ failure scoring systems.[48] They avoid many of these problems as the development of multiorgan failure is a common antecedent to death in all critically ill patients: the presence of three organ systems failures for 3 or more days, regardless of any other factors is associated with 100% mortality.[49,50] Several scores have been developed to quantify this, including Sequential Organ Failure Assessment (SOFA),[51] Multiple Organ Dysfunction (MOD),[49] and Logistic Organ Dysfunction (LOD).[50] However, none of these scoring systems have yet been validated in critically ill obstetric patients.

## Early warning scores

### General wards

Physiological deterioration precedes critical illness and it has became clear that many patients on general wards who have had an in-hospital cardiac arrest have documented evidence of clinical deterioration before the arrest, which was not acted on appropriately by the ward nurse or junior doctor.[52] Similarly, unplanned admissions to general adult ICUs are often associated with abnormalities in patients' vital signs that have been recorded without appropriate action taken.[53] Goldhill et al. applied the APACHE II scoring system to vital signs recorded in the 24 hours prior to ICU admission.[54] They found that 80% of patients had at least one value for heart rate, respiratory rate outside of the normal range, scoring one or more APACHE II points.

A number of early warning scoring systems have been developed that are based on physiological measurements used by APACHE II, using variables that are routinely measured on the acute general ward. These include Medical Emergency Team (MET) calling criteria,[55] Patient At Risk score (PAR),[56] and Modified Early Warning Score (MEWS).[57] All of the scoring systems assign a score dependent upon the degree of deviation from normality but differ in the number of parameters measured. The MET system is a list of calling criteria whereas both PAR and MEWS assign a weighted value according to the degree of deviation from normality and generate a total score.

Goldhill et al. showed that the number of physiological abnormalities and the PAR score both predicted hospital mortality.[56] All physiological variables contributed to the need for intervention, apart from temperature.

Hillman and colleagues introduced METs[55,58] to provide urgent attention for those with patients who met the MET calling criteria. Buist et al. showed that this reduced the incidence of deaths due to cardiac arrests.[59]

Hillman then conducted a large-scale prospective study to see whether the MET system could reduce the composite incidence of cardiac arrest, unplanned ICU admission, and unexpected death.[55] In a prospective study, 23 Australian hospitals were randomized to either continue as before or to introduce the MET system. The MET system did not improve the composite or individual secondary outcomes but did lead to an increase in emergency call outs.

Subbe et al. similarly found that the introduction of a MEWS failed to improve primary or secondary outcomes when introduced in a medical admissions unit in North Wales.[60]

However, Priestley et al. found that the introduction of Critical Care Outreach teams, together with a MEWS, in an acute general hospital did decrease in-hospital mortality compared with control wards (two-level odds ratio 0.52; 95% CI 0.32–0.85).[61]

Doubts about the clinical utility of early warning systems led to concern that the choice of both parameters and cut-offs was largely based on clinical intuition rather than the use of rigorous derivation and validation methodologies.[62]

The National Institute for Health Research Service Delivery and Organisation from ICNARC commissioned Gao and co-workers to review 36 studies on early warning scores (EWSs).[63] The search strategies were then updated to include a further 11 studies published after 2004 and this was used as the basis of evidence for the National Institute of Clinical Excellence (now the National Institute of Health and Care Excellence) (NICE) review on recognition of acutely illness in hospital.[64] NICE recommended that

aggregate weighted scoring systems should be used in UK hospitals. Although NICE recommended which physiological parameters should be monitored, it did not propose a standardized early warning system.

The wide variety of physiological parameters used in different early warning systems, together with the weightings given to individual parameters led to the problem that clinical staff in different hospitals or different clinical settings were unfamiliar with local systems. The Acute Medicine Task force stated that 'there is no justification for the continued use of multiple different EWSs to assess illness severity'.[65] They recommended the development of a national Early Warning Score to provide a standardize record of illness severity and urgency of need, from first assessment and throughout the patient journey. The report recognized that a key weakness in current practice was the lack of a standardized EWS embedded in the culture of the NHS, which prevent EWS being used as part of routine training and education for all staff.

The new National Early Warning Score (NEWS) developed by the Royal College of Physicians[66] used the same physiological parameters recommended in the NICE report,[64] with physiological weightings based on a published systematic review (Figure 30.2 and Figure 30.3). This compared performances from 33 warning systems when applied to a database of 9987 vital signs derived from an acute medical assessment unit, collected using the VitalPAC electronic data gathering system.[67] Only 12 of the systems reviewed showed reasonable discrimination, using an AUC method, and none achieved an AUC greater than 0.8.

The NEWS was found to achieve an AUC of 0.722 for cardiac arrest, 0.857 for unanticipated ICU admission, 0.894 for death, and 0.873 for any of the outcomes, all within 24 hours.[68] The NEWS is designed to be used for all acutely ill patients admitted to hospital apart from children or women who are currently or recently pregnant.

## Maternity early warning scores

The well-recognized problem of recognizing critical illness had led to a number of obstetric units introducing EWSs, some of whose parameters were modified for obstetrics, using local clinical judgement. This practice was highlighted and put as a top ten recommendation by the *Saving Mothers Lives* report of the Confidential Enquiry, published in 2007,[11] with a number of maternal death vignettes cited where MEWS may have helped staff realize the severity of illness. The report stated that a national Modified Early Obstetric Warning Score (MEOWS) should be developed and piloted from December 2008. This has not yet happened. The subsequent Confidential Enquiry report, published in 2011, repeated the top ten recommendation that a national MEOWS should be used, although there is no further update regarding the progress of this project.

There are several challenges in validating a national MEOWS. The PAR scoring system described by Goldhill et al. was used for acutely ill general patients requiring critical care outreach with an overall mortality of 14.6%.[56] This made it possible to distinguish which physiological variables of the PAR score were able to accurately predict mortality. Similarly, Subbe et al. were able to validate their modified EWS score in an acute medical admissions unit, with a mortality of 7.9%.[69] With an mortality rate of 0.011%[16] and an ICU admission rate of 0.26%,[15] it is not feasible to use these unequivocal endpoints for validation.

Carle et al. extracted a dataset of 2240 critically ill obstetric patients in the ICNARC case mix programme captured over a 13-year period and measured the ability of nine different MEWS scores, to distinguish between survivors and non-survivors.[70] All MEWS systems performed well, with AUCs of 0.967–0.985. However, the two 'obstetric' MEWS did not offer any additional benefit, with AUC values of 0.967 and 0.985. The obstetric dataset only contains data after admission to critical care. To evaluate a MEWS properly, the authors stated that parameters should be

**National Early Warning Score (NEWS)**

| PHYSIOLOGICAL PARAMETERS | 3 | 2 | 1 | 0 | 1 | 2 | 3 |

examined before admission but this was unlikely to be feasible in future studies.

A maternal early warning system that is based on physiological changes in disease also has to contend with physiological adaptations that occur in each trimester of normal pregnancy, labour and the post-partum period. There remains the question as to whether a modified early warning system should be further modified according to maternal gestation.

Singh et al. examined the use of MEOWS in 676 consecutive obstetric admissions:[71] 30% of the patients triggered the MEOWS and 13% had morbidity including haemorrhage, hypertension, and suspected sepsis. The MEOWS score had a positive predictive value of 39% and negative predictive value of 98%. There were no ICU admissions, cardiorespiratory arrests, or deaths during the study, making it impossible to measure the value of MEOWS in detecting severe morbidity or mortality. The authors also acknowledge that the triggers in the MEOWS are very close to the levels that define morbidity (e.g. high systolic blood that defines hypertensive disorder) so that this becomes a self-fulfilling prophecy.

In January 2012, an All Wales Consensus paper was written with the aim of agreeing the normal/abnormal physiological parameters for an obstetric EWS and to explore alignment with the National Early Warning System.[72] They noted that the MEOWS chart described in both Confidential Enquiry reports[11,16] relied on colour-coded triggers whereas NICE guidance CG50[64] recommends an aggregated numerical scoring system. Whilst colour-coded charts are of use in triggering an intervention, an objective scoring system allows a graded response and monitoring of progression of treatment.

Many different adaptations of MEOWS were in use throughout Wales. A survey of UK obstetric anaesthetists revealed the consensus of opinion that a national EWS should be used.[73] A draft Obstetric National Early Warning scheme was produced, with scoring system and escalation policy which mirrored that used for the general NEWS. However, on further enquiry, there was feedback from the service that there was no need for a new MEOWS as even if a new tool was devised, the need for further validation would delay its introduction.[74] It was agreed that maternity units should continue to use their existing MEOWS charts and would agree local escalation guidance based on the Royal College report.[9]

The Maternal Critical Care Working Group[9] similarly recommended that a national chart should be produced as a longer-term goal.

In Liverpool Women's Hospital, a MEWS has been in regular use for a decade. The six parameters of NEWS, adjusted for physiological changes in pregnancy, are monitored, together with urine output, if the patient is catheterized or has not passed urine for 7 hours.

## Recognition of the critically ill patient

The Maternal Critical Care Working Group[9] recommended that maternity services should implement the NICE guidance on care of the critically ill in hospital.[64] All admissions to hospital should have physiological observations recorded at the time of their admission or an initial assessment together with a clear monitoring plan that specifies which physiological observations should be recorded and how often. These should be recorded using an EWS or Physiological Track and Trigger system. This plan will depend upon whether the pregnancy is low- or high-risk, the reason for admission, co-morbidities and the agreed treatment plan. Table 30.6 shows the frequency of routine MEWS observations, and Table 30.7 shows the thresholds that are used to calculate weighted scores, at the Liverpool Women's Hospital.

**Table 30.6** Frequency of routine MEWS observations performed at the Liverpool Women's Hospital

| Condition | Frequency of observations |
|---|---|
| Lower segment caesarean delivery | ½-hourly for 4 hours<br>Hourly for 6 hours<br>4-hourly for 48 hours (use clinical judgement 24 hours during sleep)<br>Daily until discharge |
| Other procedures under anaesthesia | ½-hourly for 4 hours<br>Hourly for 6 hours (or until discharge)<br>4-hourly for 24 hours |
| Postpartum haemorrhage | ½-hourly for 4 hours (remain on CDS if possible)<br>4-hourly for 24 hours |
| Prophylactic Syntocinon® | 4-hourly for 24 hours |
| Diastolic of 90 or over | Minimum 4-hourly until discharge or start of labour |
| Identified antenatal in patients (diabetes, ruptured membranes, known or suspected infection) | 4-hourly (unless indicated otherwise) until discharge |
| Postnatal women with suspected or confirmed infection | 4-hourly for a minimum of 24 hours<br>Once daily until discharged |
| Medical management of miscarriage | Hourly from start of treatment until discharge |
| Blood transfusion | Prior to start of transfusion 15 minutes into transfusion Post transfusion<br>*(must be done for each unit of blood transfused)* |

**Table 30.7** Thresholds and scores in the MEWS used at the Liverpool Women's Hospital

| Score | 3 | 2 | 1 | 0 | 1 | 2 | 3 |
|---|---|---|---|---|---|---|---|
| Pulse (bpm) | <40 | 40–59 | 60–74 | 75–105 | 106–110 | 111–130 | >130 |
| Systolic BP (mmHg) | <80 | 80–90 | 95–140 | 141–150 | 151–199 | >200 | |
| Respiratory rate (breaths/min) | <6 | 6–8 | 9–14 | 15–20 | 21–25 | 26–29 | >30 |
| Temperature (°C) | <35 | | 35–36 | 36.1–38 | 38.1–38.5 | | >38.5 |
| UOC | <10 mL | <100 mL in 4 h | <50 mL in 2 h | | | | |
| UO no catheter | Not PU in 10 h | Not PU in 8 h and no bladder | | | | | |
| CNS | Unresponsive | Voice | Alert | | Confused | Agitated | |
| $SpO_2$ | <88% | 88–89 | 90–94 | >95% | | | |

A graded response strategy for patients should be agreed locally and harmonized with that used in the National Early Warning Score so that staff who also care for patients on general wards are familiar with the system. It should consist of three levels of scores:

Low risk: Total score 3–4.

Medium risk: Total score 5–6 *or* single parameter 3.

High risk: Total score ≥ 7.

CNS, central nervous system; PU, passed urine UO, urine output UOC,urine output in catheterized patient.

## Critical care competencies

The Department of Health document *Competencies for Recognising and Responding to Acutely Ill Patients in Hospital*[75] was produced in 2009, to support the implementation of the NICE guidance about care of acutely ill patients in hospital.[64] Critical care competencies define knowledge, skills, and attitudes required for safe and effective treatment, together with a chain of response from non-clinical staff all the way through to a critical care level tertiary responder (Figure 30.4). One staff group could play several different roles in the chain, for example, the recognizer may also be the primary responder.

- *Non-clinical staff*: they may also be the 'alerter' and include the patient herself or her visitor.
- *Recorder*: takes designated physiological measurements and records observations and information. This could be a maternity support worker, healthcare assistant, or midwife.
- *Recognizer*: monitors the patient's condition, interprets designated information that has been recorded, and adjusts the frequency of observations and level of monitoring. This would typically be a midwife, recovery nurse, or other nurse in the unit or a foundation doctor.
- *Primary responder*: goes beyond just interpreting the designated information to formulate a clinical management plan, for example, starting oxygen therapy, selection of intravenous fluids, and administering a bolus of intravenous fluids. This would be a core trainee or junior specialist trainee.
- *Secondary responder*: is likely to be called when the patient fails to respond to the primary intervention and continues to 'trigger' or 're-trigger' a response. This person will assess the clinical effect of the primary intervention, diagnose the problem, refine the management plan, and initiate a secondary response and have the knowledge when to refer to critical care. This is the role of the obstetric or anaesthetic senior specialist trainee (ST 3–7).
- *Tertiary responder*: role undertaken by staff with critical care competencies including advanced airway management, resuscitation, clinical examination, and interpretation of the critically ill patient. In a maternity unit, this role is provided by consultants in anaesthesia and obstetrics.

The competencies are mainly about clinical and technical level of care and delivery of effective patient management but are not exclusive and assume that generic competencies are in place. This assumption cannot always be taken for granted as many midwives are now 'direct entry' and gain little experience of nursing acutely ill patients during their training.

The key competency for all levels of staff is knowing when to refer to a clinician with greater knowledge and experience. The chain of response provides a tiered response but is not a fixed hierarchy—a recorder who recognizes a very sick woman should be able to access critical care expertise immediately, most straightforwardly through a 'crash call'.

The chain of response requires that staff recognize and respond to signs of deterioration in the patient. The EWS plays a part in this by providing a jointly agreed scale to measure the patient's degree of risk of further deterioration. It also allows escalation to an appropriate tier of competency. At the Liverpool Women's Hospital, patients who score an aggregate MEWS of 4 are referred to a primary responder, those with an aggregate score of 5–6 or a single parameter of 3 are referred to a secondary responder, whilst those with a score of 7 or more are referred directly to a tertiary responder. Review by the responder should be undertaken within 30 minutes, with escalation to a higher level if this does not occur (Figure 30.5).

Once escalation has occurred, a minimum of hourly MEWS observations are required to confirm that the patient has responded to the initial intervention. If the patient's score has not improved, further escalation is then required (Figure 30.5).

Implementing critical care competencies requires a system-wide approach with effective leadership and change management from board to ward. The approach required will depend upon the individual hospital's setting but may include the following elements:

- Identifying clinical and managerial leads and implementation team
- Monitoring outcomes with board-level reporting and intervention
- Critical incident analysis and peer supervision with regular multidisciplinary meetings to review severe maternal morbidity cases
- Education and training of competencies included in inducted and ongoing training plus formal performance review and development
- Appropriate resources in place
- Adapt local policies to clarify levels of authority and responsibility

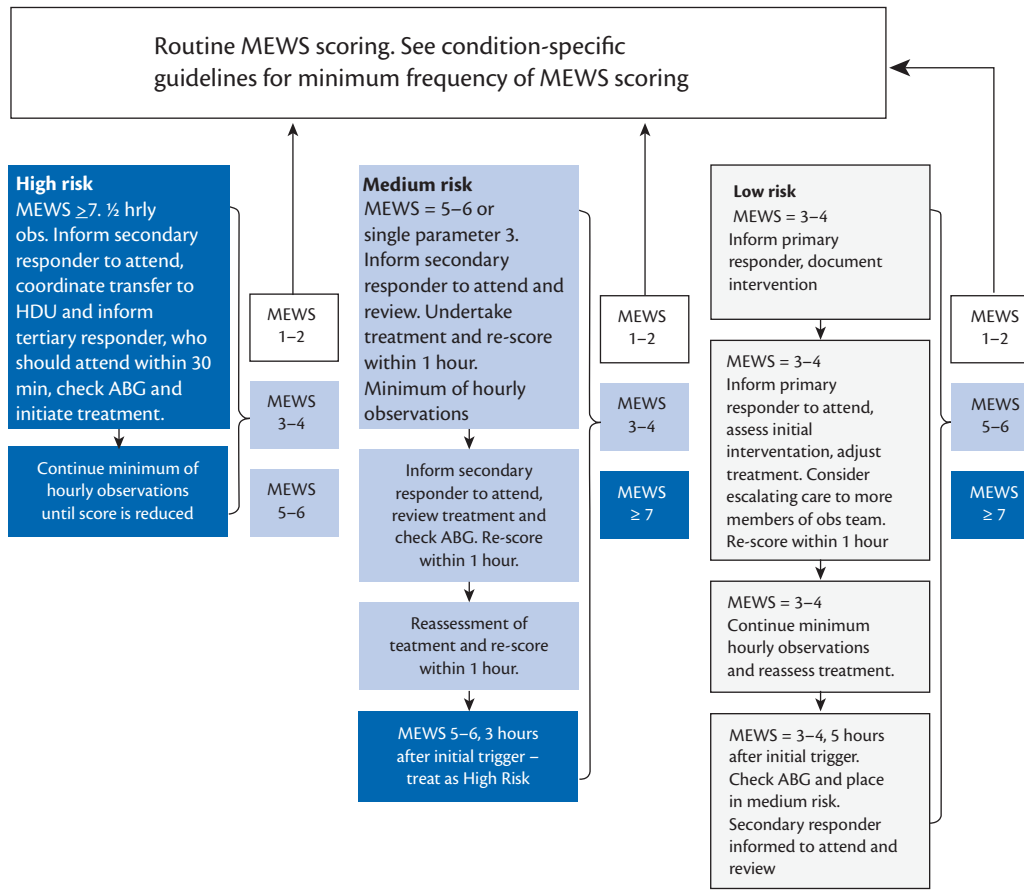

**Figure 30.5** Liverpool Women's Hospital MEWS escalation algorithm.
Liverpool Women's Hospital MEWS escalation algorithm. Reproduced with permission.

- Develop team working, assertiveness, and inter-professional working relationships. All team members must have confidence in the competency of their colleagues and are ready both to challenge and to be challenged.

## Workforce development

Lead professionals for maternity services have a responsibility to ensure that staff are adequately trained. There are a number of national, certified courses which will support workforce development in this area such as ALERT. Maternal critical care courses for trainee obstetricians and midwives have been developed by providers such as Leeds University (http://www.healthcare.leeds.ac.uk/study/PG/midwifery/PGC-CICBW-09/details.htm)

*SCOTTIE* (Scottish Core Teaching and Training in Emergencies) has been developed to provide a standardized training course in managing emergencies for all healthcare professionals who participate in the care of pregnant women. The course has been designed to cover the fundamental aspects of maternal emergencies and is suitable for all maternity-care professionals working in all care environments in Scotland (http://www.scottishmaternity.org/Courses/Introduction%20to%20The%20Courses/obstetric_emergencies.html).

*REACTS* (Recognition, Evaluation, Assessment, Critical Treatment and Stabilisation) has been developed to provide a standardized training course in recognizing and managing the critically ill obstetric patient for the many healthcare professionals who participate in the care of pregnant women. The course has been designed to cover the fundamental aspects of caring for critically ill women and is suitable for most maternity-care professionals working in Scotland. The Scottish Maternity REACTS course is one of the skills-based courses developed and rolled out by the Scottish Multi-professional Maternity Development Programme in support of maternity-care professionals across Scotland (http://www.scottishmaternity.org/Courses/Introduction%20to%20The%20Courses/scottish-maternity-reacts-course.htm).

The Critical Care competencies required at tertiary responder level are defined by the *Co*mpetency *Ba*sed *Tr*aining programme in *I*ntensive *C*are Medicine for *E*urope (CoBaTrICE) syllabus,[76] which includes a specific section on life-threatening maternal peripartum complications.

Critical care competencies are incorporated in the core training curriculum for anaesthetic trainees as well as being included in the revalidation programme. 'Assessment of the Critically Ill Parturient' is included in the Continued Professional Development for Anaesthetists matrix (2B06)[77] from the Royal College of Anaesthetists. Level 2 is based upon both the knowledge and skills that are relevant to an individual doctor's 'whole' practice.[78]

There are several simulation training courses also available (see Chapter 53 for more details).

## Transfers to and from critical care

Transfer to Level 3 care should be in accordance with Intensive Care Society guidelines:[79]

- All hospitals to have a lead consultant for critical care transfers.
- All must have systems to resuscitate, stabilize, and transport critically ill, with a plan for all critical care areas.
- Training: all staff must have appropriate training in transfer medicine.
- Equipment: all must have access to a transfer trolley, with all monitoring and equipment mounted in a suitable way to be compliant with the Comité Européen de Normalisation (CEN) 1789:2007 European Union standard for ambulances. Ideally all equipment within a region should be standardized to enable seamless transfers.
- Prior to transfer, a risk assessment must be made by a consultant or other suitably experienced member of staff, to determine the competences of staff required for the transfer.
- Patients should be resuscitated and stabilized before transfer, with pre-transfer checklists.
- Minimum standards of monitoring must be used, continuously visible to accompanying staff, with a written record of observations.
- Safety: patients secured, equipment secured, staff seated and using seat belts. If unanticipated intervention is required, the ambulance should be stopped in a safe place before administering treatment.
- Standardized documentation should be used.[79]

In addition, a clear plan is required to meet the maternal, fetal, or postnatal needs of the patient.

An intensive care transfer form must be completed for all transfers, documenting the:

- reason for transfer
- history of stabilization prior to transfer
- date and time of transfer
- identification of staff involved in the decision to transfer to HDU/ITU.

## The acutely ill parturient in a general critical care area

The main principle in managing an acutely ill pregnant woman is that optimal management of the condition causing critical illness is paramount. Fetal considerations are secondary, including the need for maternal imaging and medication.

Maternal collapse in pregnancy needs to be managed in accordance with physiological changes, outlined in the Royal College of Obstetricians and Gynaecologists (RCOG) green top guideline.[80]

The following need to be considered:

- *Aortocaval compression*: after 20 weeks gestation, can reduce cardiac output by 30–40% when supine and significantly reduces efficacy of chest compressions during resuscitation.
- *Changes in lung function*: increased risk of hypoxia and make ventilation more difficult.
- *Difficult intubation risk*: this is more likely in pregnancy and critical illness due to the presence of large breasts reducing access to the laryngoscope and laryngeal oedema.
- *Increased risk of aspiration*: early intubation is required in critical illness, with the use of cricoid pressure, non-particulate antacids, and $H_2$ antagonists.

- *Blood pressure*: limits are different in pregnancy. A blood pressure (BP) of 90/60 mmHg is normal in healthy women whilst in pregnancy-induced hypertension, aim to keep BP <150/100 mmHg.
- *Blood loss*: high cardiac output and uterine blood flow means that large volumes can be lost quickly.
- *Hypercoagulopathy*: all parturients will require venous thromboembolism prophylaxis if prolonged immobilization and critical illness.
- *Nutrition*: need an extra 300 kcal/day plus micronutrients.

### Specific points for antenatal care of a critically ill parturient

- Patients should be nursed in left lateral tilt position in third trimester.
- There is an increased risk of urinary tract infection, which requires regular mid-stream urine specimens sent to bacteriology.
- Women with pregnancy-induced hypertension tolerate fluid overload poorly—fluid management should be in accordance with NICE guidelines.[81]
- Access to a delivery set will be required for vaginal or caesarean delivery in case of urgent delivery.
- In terms of care for the fetus, antenatal steroids will be required for fetal lung maturation. A fetal monitoring surveillance plan is required with regular fetal growth ultrasound and daily fetal heart rate monitoring if no maternal perception of fetal movements after 28 weeks of gestation.

### Specific points for postpartum care

- Breastfeeding should be encouraged, with consideration given to the safety of medications in breast milk.
- A diuresis is normal, as the transition occurs from maternal to non-pregnant physiology.
- Thromboprophylaxis will be required for all women, once coagulopathy has been corrected.
- Routine post-delivery checks will be required such as anti-D for rhesus-negative parturients and perineal care.

### Maternity and general critical care interface

A daily review is required by the multidisciplinary team, who must include a named obstetrician and a named senior midwife. Contact telephone numbers for the team should appear on the patient's chart, together with a management plan for obstetric/midwifery care. Ongoing obstetric issues need to be discussed with the critical care team (e.g. pre-eclampsia) so that they are not overshadowed by current medical emergency.

## Resources available to look after the critically ill mother

Appropriate equipment must be available within Level 2 care rooms (Box 30.2) and all electrical equipment must be kept plugged in at all times to ensure that batteries are fully charged.

**Box 30.2** Equipment required in Level 2 rooms

- Wall suction and the relevant accessories
- Airway adjuncts
- Piped oxygen and oxygen masks, with high-concentration oxygen masks available
- Equipment to secure intravenous and administer fluids
- Intravenous pumps and syringe drivers
- Monitoring equipment for pulse oximetry, ECG, non-invasive blood pressure, and transducer facility for invasive monitoring
- Equipment for insertion and management of invasive monitoring
- Intravenous fluid warmer
- Forced air warming device
- Blood gas analyser, with facility to measure serum lactate
- Emergency massive haemorrhage trolley
- Emergency eclampsia box
- Transfer equipment: monitor and ventilator
- Computer terminal for access to blood results, patient administration systems, and intranet for access to local guidelines
- Resuscitation trolley with defibrillator and airway management equipment.

## Maternal critical care admission criteria

### Admission criteria for Level 2 care on the delivery suite

#### 1. Escalation in care for women within the delivery suite

- Patients who require stabilization of hypertension.
- Patients who require seizure control.
- Patients with pre-existing co-morbidity, which affects daily living.
- Patients with massive blood loss (2000 mL or smaller loss associated with cardiovascular instability).
- Patients who require greater than 4 units of blood transfused.
- Patients requiring more than 40% oxygen via a fixed concentrated mask.
- Patients who show signs of severe sepsis.
- Patients who trigger a MEWS score of 7 or higher.
- Management of invasive lines.
- Patients who develop coagulopathy.

#### 2. Step-down after Level 3 care or specialist care

This will require joint medical and midwifery judgement regarding the level of critical care required, taking into account all factors pertaining to the actual case including the patient's wishes and availability of other beds.

### 3. Transfer criteria for Level 2 respiratory support

If Level 2 respiratory support is thought necessary, expert advice should be sought from the on-call consultant anaesthetist. Women should be transferred for Level 2 care if any of the following are present:

- Tachypnoea with a respiratory rate greater than 20 breaths/min
- $SpO_2$ consistently less than 93 % on air
- $PO_2$ of 8.0 kPa on air
- $PCO_2$ of 5.0 kPa
- Pulmonary oedema confirmed by chest X-ray
- MEWS 7 or above.

### Escalation to Level 3 care

Expert advice should be sought from the consultant intensivist at the receiving ICU, prior to stabilization and transfer, where further deterioration has occurred. Women requiring the following support must be transferred to Level 3:

- Mechanical ventilation
- Advanced renal support
- Multisystem organ failure
- Plasmapheresis
- Coronary care.

Safe transfer is the responsibility of the consultant anaesthetist on call.

### Discharge criteria

Discharge from maternity HDU is generally appropriate when the condition that has led to the admission has been adequately treated or stabilized or when the patient no longer requires the level of monitoring and nursing provided on the maternity HDU and can be managed on the ward. This should be considered when the patient has been stabilized and no longer require close monitoring. In addition, discharge of a patient from the HDU (Level 1 or 2, to 0, or vice versa) should be considered in order to accommodate another patient. This decision must be by the consultants involved.

### Critical care outreach

Critical Care Outreach developed in the United Kingdom in response to the finding that suboptimal care was often evident at the time of critical admission,[6] with increasing evidence linking this to missed opportunities for earlier intervention and poor outcome.[82]

The Critical Care Outreach service is defined by the Intensive Care Society as a multidisciplinary approach to the identification of patients at risk of developing critical illness, and those patients recovering from a period of critical illness, to enable early intervention or transfer (if appropriate) to an area suitable to care for that patient's individual needs.[83]

Outreach should be a collaboration and partnership between the critical care department and other departments to ensure a continuum of care for patients regardless of location, and should enhance the skills and understanding of all staff in the delivery of critical care. It is not a remedy for inadequate provision of a critical care bed, inadequate ward facilities for lower dependency patients, decreasing ward nursing numbers, or inexperienced trainees with lack of supervision. The outreach team should be prepared to take over or at least direct the care of critically ill patients whose admission to a critical care facility is delayed.

The majority of general hospitals in the United Kingdom have intensive care nurse-led outreach systems, supported by critical care doctors.[84] In the Liverpool Women's Hospital, the critical care outreach team is led by midwives from the HDU, supported by on-call anaesthetists and obstetricians.

## Care of the critically ill parturient in different settings

The National Service Framework for Children, Young People and Maternity Services requires that consultant-led obstetric units have adequate facilities for comprehensive emergency obstetric care, including transfer to intensive care. Pathways must therefore be designed at local level to ensure that a critically ill parturient has equitable access to critical care, with arrangements taking into account local configuration, size, and complexity of maternity and critical care services.[9] These pathways should facilitate mother and baby staying together unless precluded by clinical reason.

Different models of care may include:

- designated area within the delivery suite for Level 2 care, with medical input from anaesthetists and obstetricians, staffed by suitably trained critical care midwives, supported by escalation policies to Level 3 care
- importing critical care skills onto the delivery suite using critical care outreach or other arrangement with local critical care services
- transferring women to a general Level 2 unit, with local arrangements to provide obstetric and midwifery input, whilst maintaining direct contact between mother and baby.

## Monitoring in the high dependency unit

All critically ill patients in the HDU require pulse oximetry, electrocardiogram (ECG), and blood pressure monitoring. There should be a low threshold for using arterial lines in HDU, particularly where the patient is unstable or requires repeated arterial blood samples.

Central venous pressure monitoring can be used as a guide to right ventricular filling pressures. However, titrating fluid challenges against central venous pressure should be performed cautiously, due to poor correlation between right- and left-sided filling pressures, particularly in patients with pre-eclampsia.[85]

### Cardiac output monitoring

Measurement of blood pressure alone gives the clinician little information about its constituent components of cardiac output and systemic vascular resistance, which is essential information in both the diagnosis and management of critical illness.

Cardiac monitoring is not routinely used at present in obstetric practice. A recent survey of tertiary referral centres found that only 22% of obstetric anaesthetists had experience of cardiac

output monitors although half those surveyed believed that they should be available in all obstetric units in the next 10 years.[86]

## Pulmonary artery catheters

The pulmonary artery catheter (PAC) was first described by Swan, Ganz, and associates in 1970[87] and rapidly evolved from a research device into a clinical tool. It was widely used in adult general ICUs to measure intracardiac pressures and cardiac output and became very popular with over 2 million catheters sold worldwide in 1996.[88]

However, unequivocal proof that information from PACs improved outcome was scarce. A review of the use of PACs in obstetric critical illness questioned the lack of proven benefit from the haemodynamic information when set against the potential risk of complications such as pneumothorax, ventricular arrhythmias, air embolism, pulmonary infarction, pulmonary artery rupture, sepsis, local vascular thrombosis, intracardiac knotting, and valve damage.[89]

There are also concerns about the use of PACs in general ICUs. An observational study of 5735 critically ill adults using case-matching analysis showed that PAC use was associated with increased 30-day mortality, increased stay in ICU, and increased utilization of resources, with no apparent benefit from using the PAC.[90] The accompanying editorial in *JAMA*,[91] suggested a complete moratorium on their use until the matter was resolved but it was clear that many physicians intending to continue using PACs. A Consensus Conference held in December 1996[92] examined the risks and benefits of using PACs in different critical care scenarios. For its use in maternal critical care, no evidence was found that routine use of PACs reduced complications and mortality associated with pre-eclampsia but it was agreed that it may be of use when dealing with severe pre-eclampsia. There was also uncertainty as to whether PACs improved outcomes in patients with septic shock but it was agreed that they may be useful in patients who have not responded to initial fluid resuscitation and vasopressors. The conference did find that the PAC provided information that altered diagnosis and treatment in patients admitted with respiratory failure. The conference concluded that there should not be a moratorium on the use of PACs.

PACs remained in regular use for obstetric patients admitted to ICUs, although there was a wide variation in their use.[12] A retrospective review of PAC use in severe pre-eclampsia at the obstetric ICU at the Groote Schuur Hospital, Cape Town, South Africa, was performed between 1995 and 1997.[93] Of the 598 women admitted to the unit, 115 required pulmonary artery catheterization; 53% had renal failure, 30% pulmonary oedema, and 17% had eclampsia. Review of the ICU charts showed that the initial readings from the PAC allowed a determination of maternal fluid status that was judged to be helpful in guiding management in 93% of cases. Four per cent of patients developed complications: three cases of venous thrombosis and one case of cellulitis. There were no cases of pulmonary haemorrhage or infarction.

The initial high incidence of complications from PACs improved with better medical and nursing care, for example, pneumothorax has fallen from 6% to less than 0.1%; pulmonary infarction from 7.2% to 0–1.3% and pulmonary artery rupture from 0.1– 0.2% to less than 0.1%.[94]

By 2001, Hazelgrove et al. found that there was a wide variation amongst different ICUs in the use of PACs for haemodynamic monitoring of critically ill parturients.[12]

In 2003, a large-scale randomized, blinded study by Sandham et al. of 1994 patients showed that there was no benefit to therapy directed by PACs over standard care.[95] There was a higher incidence of pulmonary embolus in the PAC group: eight patients versus none in the standard care group.

A Cochrane review published in 2013 found that the use of PACs did not alter the mortality or length of stay in ICU or hospital and recommended that newer, less invasive haemodynamic tools needed to be validated against PACs prior to clinical use in critically ill patients.[96]

## Transthoracic and transoesophageal echocardiography

Echocardiography is readily accepted by pregnant women as ultrasonography is used routinely in pregnancy in childbirth to monitor mother and fetus and has been shown to have an excellent safety profile. Cardiac output may be measured at a number of anatomical locations: the left ventricular outflow tract, ascending aorta, pulmonary artery, right ventricular outflow tract, and mitral valve. Transthoracic echocardiography (TTE) uses an ultrasound probe placed on the chest well whereas transoesophageal echocardiography (TOE) requires an ultrasound transducer to be placed within the oesophagus. Both methods allow an assessment of filling status, myocardial contraction, valvular function, and detection of pericardial effusion as well as being used for measurement of haemodynamic variables.

TTE is truly non-invasive and suitable for all obstetric patients. During pregnancy, anterior and left displacement of the heart together with an elevated diaphragm and partial lateral tilt facilitate apical and lateral views with TTE.

TOE provides clearer images and better views of the atria and septa but requires the patient to receive sedation or general anaesthesia, which makes it less suitable for routine use in the parturient. There are many case reports in the literature of its use in critically ill women with cardiac disease or emergencies.[97–104]

Haemodynamic measurements made using echocardiography have been shown to compare well to those with the gold standard of pulmonary artery thermodilution. Belfort et al.[105] showed a high correlation between ultrasound-derived measurements and PAC measurements for stroke volume, cardiac output, cardiac index, left ventricular filling pressure, pulmonary artery systolic pressure, and right atrial pressure in 11 critically ill obstetric patients. Right atrial pressure is calculated by measuring the maximum and minimum size of the inferior vena cava in inspiration and expiration. The Doppler-derived stroke volume and two-dimensional estimates of end-diastolic volume were used to calculate ejection fraction.

A subsequent study showed that results obtained from M-mode echocardiography and two-dimensional Doppler yielded similar results and proved reliable in critically ill pregnant women.[106]

Belfort et al. then conducted a subsequent study to see if these values could be used in clinical patient management of critically ill women with an indication for invasive monitoring.[107] These included oliguria unresponsive to boluses of crystalloid, severe, pregnancy-induced hypertension despite hydralazine, and patients with other cardiac conditions that put them at a high risk of developing pulmonary oedema. Fourteen patients were studied and all but two were managed without the need to proceed to pulmonary artery catheterization. Of these, one had a hypertensive cardiomyopathy whilst the other had severe asthma

requiring intubation and ventilation. Of the six oliguric patients, all had pre-eclampsia and had previously received fluid challenges with crystalloid. Echocardiography excluded volume overload in all patients and none developed pulmonary oedema or required invasive monitoring. The authors concluded that a knowledge of the ejection fraction, intracardiac pressures, and cardiac output allowed a more informed decision to be made regarding whether a preferential vasodilator (e.g. calcium channel blocker or arterial vasodilator) should be used or an agent with a predominantly negative inotropic effect such a beta blocker. One patient with pre-eclampsia and oliguria had developed a coagulopathy due to placental abruption and intrauterine fetal death in which circumstances central line insertion would have been hazardous.

More recently, TTE has been used intraoperatively to guide fluid management and ensure an adequate pre-load in a patient with severe hypertrophic cardiomyopathy.[108] The authors intended to repeat the TTE on the intensive care 4 hours after surgery but this was not possible for logistic reasons, due to the lack of specialist skills to perform TTE. The consequence was that an insidious postpartum bleed was not acted on overnight, which subsequently required interventional radiology.

Recent advances in image quality, device portability, and ease of use now enable TTE to be used for obstetric applications in locations such as the delivery suite, operating theatre, and HDU.[109] The frequent absence of a 24-hour immediate TTE service has provided an incentive for clinicians to be trained in bedside TTE. This has the additional advantage that the clinician can use TTE to answer clinical questions and then perform repeated measurements to follow the response to intervention.

Echocardiography has been used in recent research to examine haemodynamic changes accompanying severe pre-eclampsia. Dennis et al. compared TTE studies of non-pregnant, healthy pregnant and women with pre-eclampsia.[110] Patients with pre-eclampsia had a predominantly raised cardiac output, due to a raised stroke volume, with only a mild increase seen in systemic vascular resistance compared with healthy parturients and reduced diastolic function. These findings support the hyperdynamic model of pre-eclampsia.

## Arterial pulse waveform analysis

Arterial pulse waveform analysis methods of measuring stroke volume are attractive for the obstetric anaesthetist as they provide beat-by-beat assessment and can be used both for critical care and research in the delivery suite and operating theatre.[111] They are particularly suitable for use in the awake parturient as they only require an arterial line. This has the advantage that many critically ill patients already have an arterial line *in situ* and enables monitoring of changes in cardiac output and stroke volume on continuous basis.

Limits of agreement of up to 30% between new cardiac output monitors and gold standard devices such as PACs are regarded as acceptable.[112] Current commercially available devices that meet these criteria consist of the calibrated LiDCOplus® (LiDCO, Cambridge, United Kingdom) and PiCCOplus® (Pulsion Medical Systems, Munich, Germany) and the uncalibrated Flotrac-Vigileo® monitor (Edwards Lifesciences, Irvine, CA, United States).

The LiDCOplus® monitor uses arterial pulse power analysis to measure and monitor stroke volume from the arterial pulse pressure waveform from a standard peripheral arterial line.[113] The system can be calibrated using a lithium dilution method. LiDCOplus® has been used to study cardiac output changes during caesarean delivery.[114–116] It has also been shown to predict fluid responsiveness in mechanically ventilated patients,[117] although this is of limited value on the obstetric HDU where most patients breathe spontaneously. LiDCOplus® haemodynamic readings in patients with pre-eclampsia agreed closely with those obtained from pulmonary artery catheterization.[118]

The PiCCOplus® system uses an algorithm that analyses the systolic component of the arterial waveform.[119] Calibration is performed using transpulmonary thermodilution, which requires cannulation of both a proximal artery and a central vein. This has limited its use to intensive care settings and to date there are no studies published using PiCCOplus® in obstetric anaesthesia or maternal critical care research.

The Flotrac-Vigileo® monitor analyses waveform characteristics from a specialized transducer using a multivariate polynomial equation that does not require calibration. It has been used to monitor cardiac output changes during caesarean delivery.[120] Despite software revision, there is a poor agreement with gold standard measures of cardiac output.[121]

Doppler velocimetry may also be used to measure cardiac output. When an ultrasound beam is reflected from moving red blood cells, a change in frequency is seen that is proportional to their velocity. Aortic cross-sectional area can be estimated from nomograms or measured directly and multiplied by total flow to calculate stroke volume. Oesophageal Doppler monitoring (ODM) uses a transducer introduced under sedation or general anaesthesia.[122] ODM is recommended by NICE guidelines for fluid optimization during major surgery to reduce the need for central venous lines, hospital stay, and postoperative complications.[123] It has shown to be of benefit in many different types of surgery[124] but these do not include any obstetric procedures. It has been used to assess critically ill patients with pre-eclampsia, where it was found to underestimate cardiac output by up to 40%, although it did follow trends accurately over time.[125]

Red blood cell velocity in the aortic outflow tract can alternatively be measured using an ultrasound probe placed in the suprasternal notch (USCOM®, USCOM Pty Ltd, Coffs Harbor, NSW, Australia). This is completely non-invasive and has a steep learning curve.[126] USCOM® has been used to measure cardiac output in pregnancy[127] and to assess fluid status during caesarean delivery.[128]

Bioimpedance techniques were first described in the 1970s. Vascular blood flow within the thorax causes a change in electrical resistance, which is detected by skin electrodes. It is non-invasive and low cost but validation studies in critically ill and septic patients have shown poor results.[122]

Bioreactance measures changes in phase shift of an oscillating current passed across the thorax to produce an improved signal:noise ratio. The technique is gaining acceptance with a number of obstetric anaesthetic research studies now published.[129–131]

Aortic blood flow can also be estimated from finger arterial pressure (Portapres®, Finapres Medical Systems, Amsterdam, the Netherlands). This compares reasonably to sphygmomanometry in pregnant patients[132] but was shown to consistently underestimate stroke volume.[133] It was also found to have discrepancies when measuring changes in peripheral vascular resistance[134] or hypovolaemia,[135] making it unsuitable for regular use in obstetric clinical practice.

**Table 30.8** Devices that can be used to monitor the cardiovascular system in obstetric HDU/ITU

| Technology | Device | Advantages | Limitations |
|---|---|---|---|
| Pulse pressure waveform analysis | LiDCO™plus | Continuous haemodynamic data from patients with arterial lines | Calibration with Lithium dilution |
| | PiCCO® | | Proximal artery cannulation required for calibration |
| | Vigileo Monitor® with FloTrac® sensor | | Poor agreement and slower response than LiDCO or PiCCO |
| Oesophageal Doppler monitoring | CARDIOQ-ODMTM monitor | Proven value in high-risk general surgery | Requires sedation or general anaesthesia |
| Continuous wave Doppler ultrasound | USCOM 1A® | Steep learning curve. Non-invasive | Repeated measurements required |
| Bioimpedance | Oriel 4000® | Low cost, simplicity | Poor validation in critically ill patients |
| Bioreactance | NICOM® monitor | Low cost, simplicity | |

Table 30.8 summarizes the devices that can be used in an obstetric patient, their mode of action, advantages, and disadvantages.

## Other patient monitors used in maternal critical care

### Monitoring haemoglobin

The Hemocue® (HemoCue Ltd, Sheffield, UK) gives rapid and accurate measurement of haemoglobin concentration in parturients from either venous blood or capillary blood samples.[136] This is of value in the differential diagnosis of shock but requires a clinical decision regarding the timing of measurements (see Chapter 35).

Ideally, it would be possible to continuously monitor haemoglobin in critically ill patients using a non-invasive device so that clinicians could be alerted to a fall in haemoglobin concentration before the clinical signs of shock became apparent. The Rainbow SET® Radical 7 Pulse Co-Oximeter (Masimo Corp., Irvine, CA, United States) uses a seven-wavelength spectrophotometer in place of the conventional two-wavelength pulse oximeter to give a continuous non-invasive estimation of haemoglobin concentration (SpHb). The finger probe is wrapped in an optical shield to prevent interference from outside light. Preliminary studies appeared promising, with a mean difference between haemoglobin concentrations from SpHb and arterial blood of 1 g/dL.[137] Unfortunately, subsequent publications have shown that the device is far less accurate. One study of five women undergoing caesarean hysterectomy showed a median difference of 2 g/dL in 16 out of 17 SpHb readings.[138] Another study in patients undergoing spinal surgery showed that 22% of readings disagreed with laboratory values by more than 2 g/dL.[139] Accuracy of SpHb readings were affected by finger perfusion, with increased variability in the presence of major haemorrhage. There is great potential for SpHb monitoring but the inaccuracies demonstrated in some patients mean that invasive measurement of Hb cannot be abandoned.[140]

## Care bundles

Care bundles have been shown to result in a demonstrable reduction in morbidity in the acute hospital setting. Robb et al.[141] examined the impact of eight care bundles on hospital mortality within an acute hospital in North West London. Thirteen diagnoses were targeted by the care bundles, which had accounted for 1142 deaths in 2006–07. This included sepsis and heart failure bundles (available from http://www.bmj.com/content/suppl/2010/03/31/bmj.c1234.DC1). By 2007–08, the crude death rate had fallen by 174 for the targeted diagnoses. These mortality reductions were maintained over the subsequent years between 2009 and 2011.

In 2008, the 1000 Lives Plus campaign was introduced in Wales with the aim of reducing 1000 deaths in acute trusts and 50,000 adverse events. The programme succeeded, reducing mortality by an estimated 1199 lives from April 2008 to April 2010.[142]

The lessons learnt by the 1000 Lives Plus campaign have now been applied to maternity services in the Transforming Maternity Services report.[143] This focused on the need to reduce avoidable harm in two key areas in maternity: acute deterioration and venous thromboembolism. To ensure early detection of critical illness, a mini-collaborative was set up to ensure that MEWS systems were used consistently in all maternity units. One focus of the collaborative was the implementation of care bundles that enable a rapid response in a way that is owned by the clinical team responsible for patient care, without adding a significant burden of work. The Surviving Sepsis Campaign Sepsis Care bundles contain interventions that have strong evidence of improving mortality in sepsis.[144] The 1000 Lives Plus campaign enabled acute and critical care teams to implement the care bundles, with particular emphasis on the sepsis six. This is important in the management of genital tract sepsis, highlighted by a special Centre for Maternal and Child Enquiries (CMACE) emergent theme briefing[145] which showed the need for clear recognition and prompt management, clear leadership, careful documentation, prompt antibiotics, careful fluid balance, and a collaborative approach.

Improved communication is also essential in the care of the acute deteriorating parturient. Clinical teamwork often involves hurried interactions between different human beings with varying styles of communication. The SBAR (Box 30.3) system improves this, originating in the nuclear submarine service.

**Box 30.3** SBAR system

S—Situation: What is happening at the present time?
B—Background: What are the circumstances leading up to this situation?
A—Assessment: What do I think the problem is?
R—Recommendation: What should we do to correct the problem?

Adapted from the SBAR Toolkit, available from the Institute for Healthcare Improvement at: http://www.ihi.org/knowledge/Pages/Tools/SBARToolkit.aspx. The SBAR Toolkit was originally developed by Michael Leonard, Doug Bonacum, and Suzanne Graham at Kaiser Permanente of Colorado.

The mini-collaborative aims to ensure that care bundles are introduced based on guidance from CMACE, NICE, and RCOG. They recommended that four care bundles are introduced:

1. Admissions bundle: within 2 hours of admission (earlier if 'unwell'), all women admitted should have a full set of observations and a plan for frequency of observations, which has been communicated to all clinical staff. This should include a DVT risk assessment and a recorded body mass index. This is in accordance with NICE CG50.[64]
2. Recognition bundle: all women should have a plan for risk assessment using MEWS, screening for sepsis if found to be at risk, and DVT risk assessment, together with communication with the clinical team.
3. Response bundle: all women should have a plan for escalation of care if their condition deteriorates, including change of frequency of observations and input from junior and senior medical staff. The cardiac arrest team needs to ensure that they have full details of how to access the maternity department. Appropriate prophylaxis should be given to all women according to their risk assessment. An acute care or critical care outreach team service should be utilized appropriately.
4. Sepsis six: within 1 hour of diagnosis, all women with suspected sepsis should receive:
   a. oxygen to achieve an oxygen saturation of greater than 94%
   b. fluid resuscitation
   c. blood cultures should be taken before antibiotic administration
   d. broad-spectrum antibiotic
   e. serum lactate and haemoglobin should be checked, ensuring haemoglobin concentration is greater than 8 g/dL
   f. urine output should be monitored hourly, using catheterization or self-void.

Care bundles represent a grouping of best practices for a disease process that individually improve care but when applied together may result in a significantly greater improvement. The 1000 Lives Plus campaign implemented care bundles for interventions such as central lines and ventilators and achieved a compliance of more than 95%. There has been an association with this very high compliance and improvements in patient outcome such as a marked reduction in the rate of central line and ventilator-related infections.

The care bundles are not intended as a comprehensive list of all actions to be taken nor are they a care pathway. The main aim is to reduce the opportunity for omission of any of the essential elements of the process. By using care bundles to implement systems for the detection and early treatment of the acutely deteriorating patient, it is possible for clinical teams to demonstrate improvements in one area without having to change everything at once.

# Management of the critically ill obstetric patient

## Respiratory failure

### Acute respiratory distress syndrome

Acute respiratory distress syndrome (ARDS) is a process of non-hydrostatic pulmonary oedema and hypoxaemia which is diagnosed according to the North American-European Consensus Conference criteria (Table 30.9).[146]

The commonest causes of ARDS in pregnancy are haemorrhage and infection. Direct damage may occur to alveolar lung cells or indirect damage may occur due to systemic disease, leading to an acute inflammatory lung injury. The inflammatory response occurs in exudative, proliferative, and fibrotic phases, which result in progressive hypoxaemia and respiratory failure. This may then be complicated by nosocomial pneumonia, pulmonary hypertension, and ventilator-induced lung injury.

Despite recent advances in lung protective mechanical ventilation, the mortality from ARDS remains unacceptably high at around 50–60%.[147] The most frequent cause of death in ARDS is sepsis syndrome with multiorgan failure rather than irreversible respiratory failure.

The management of ARDS involved respiratory support together with identification and treatment of the precipitating

**Table 30.9** North American-European Consensus Conference ARDS and acute lung injury criteria

| | **ARDS** |
|---|---|
| Timing | Acute onset |
| Oxygenation | $PaO_2/FiO_2 \leq 200$ mmHg (26.7 kPa), regardless of PEEP |
| Chest X-ray | Bilateral infiltrates |
| Paw | ≤ 18 mmHg, if measured or no clinical evidence of left atrial hypertension, to exclude cardiogenic pulmonary oedema |
| | **Acute lung injury—same criteria as ARDS except** |
| Oxygenation | $PaO_2/FiO_2 \leq 300$ mmHg (40 kPa), regardless of PEEP |
| $PaO_2$ | Partial pressure of oxygen in arterial blood |
| $FiO_2$ | Fraction of inspired oxygen |
| $PaO_2/FiO_2$ ratio | Normal range is 300–500 mmHg (40–66.7 kPa) |
| Paw | Pulmonary capillary wedge pressure, used to measure left atrial pressure |

Paw, airway pressure; PEEP, positive end expiratory pressure.

Data from Bernard GR, Artigas A, Brigham KL, *et al.* Report of the American-European consensus conference on ARDS: Definitions, mechanisms, relevant outcomes and clinical trial coordination. *Intensive Care Medicine*, volume 20, issue 3, pp. 34–56. Copyright © 1994 Springer.

cause. For mild acute lung injury, oxygen therapy, physiotherapy, and diuretics to reduce extravascular lung water may suffice. More severe lung injury/ARDS will require mechanical ventilation with a protective lung strategy.

With widespread usage of pulse oximetry, arterial hypoxaemia can be readily detected and confirmed by measurement of arterial blood gas tension.

### Shock

Shock is defined as acute circulatory collapse with inadequate delivery of oxygen at a tissue level. The commonest causes of shock in pregnancy are massive haemorrhage and sepsis.

The causes of shock in pregnancy can be divided into low and high cardiac output states (Table 30.10). Shock causes physiological disturbances, detectable on routine monitoring (Table 30.11). Patients with a high cardiac output shock are 'warm and dilated' with a bounding pulse and are flushed.

Patients with low cardiac output are peripherally vasoconstricted and shutdown with a low volume pulse. In hypovolaemia, a low central venous pressure will differentiate from the high pressures seen in obstructive or cardiogenic shock. However, central venous pressure is not a reliable measurement of volaemic status in previously healthy obstetric patients due to their ability to compensate for volume loss by maintaining both blood pressure and central venous pressure.

Early detection and prompt management is required as mortality increases after the first hour. Generic supportive treatment includes oxygen therapy to improve oxygen delivery, and appropriate intravenous fluids and inotropic or vasopressor drugs to maintain circulation.

It is essential to diagnose the underlying cause promptly to ensure that the correct treatment is given. Patients with cardiogenic shock require very careful intravenous fluid administration and inotropic support of blood pressure whereas patients with hypovolaemic shock due to concealed haemorrhage require aggressive fluid therapy and identification of the source of blood loss.

## Sepsis and systemic inflammatory response syndrome

### 2001 Sepsis definitions

Sepsis was defined at the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) 'Consensus Conference in 1991. In 1992, the ACCP and SCCM introduced the concept of Sepsis and Systemic inflammatory Response Syndrome (SIRS), which is defined as the presence of at least two of the following quartet:

**Table 30.10** Causes of shock in pregnancy

| | |
|---|---|
| **Low cardiac output: 'cold and clammy'** | |
| Hypovolaemic | Loss of circulating blood volume with major haemorrhage or diabetic ketoacidosis |
| Obstructive | Embolus (pulmonary or amniotic fluid) or cardiac tamponade |
| Cardiogenic | Low cardiac output, e.g. after myocardial infarction |
| **High cardiac output: 'warm and dilated'** | |
| Early sepsis | Decreased venous return due to low systemic vascular resistance |
| Anaphylactic | Allergic induced vasodilation |
| Neurogenic | Loss of sympathetic outflow due to lesion above T6, causing vasodilation and bradycardia |

**Table 30.11** Signs of 'shock'

| | |
|---|---|
| Hypotension | Systolic < 100 mmHg |
| Tachycardia | Pulse > 100 bpm (except neurogenic) |
| Tachypnoea | Respiratory rate > 30 breaths/min |
| Oliguria | Urine output < 30 mL/h (0.5 mL/kg/h) |
| Level of consciousness | Confused, agitated, or drowsy |

**Table 30.12** Diagnostic criteria for sepsis, where infection is documented or suspected

| | |
|---|---|
| **General** | |
| Temperature | Fever (>38.3°C) or hypothermia (<36°C) |
| Heart rate | >90/min |
| Respiratory | Tachypnoea |
| Level of consciousness | Altered mental status |
| Circulation | Significant oedema or positive fluid balance (>20 mL/kg over 24 h) |
| Glucose control | Hyperglycaemia (>7.7 mmol/L), in absence of diabetes. |
| **Inflammatory** | |
| White cell count | >12,000 cells/μL or < 4000 cells/μL *or* normal with >10% immature forms |
| C-reactive protein | >2 SD above normal value |
| Plasma procalcitonin | >2 SD above normal value |
| **Haemodynamic: sepsis induced hypotension** | |
| Blood pressure | Systolic < 90 mmHg *or* mean arterial pressure < 70 *or* fall of > 40 mmHg |
| **Organ dysfunction** | |
| Oxygenation | $PaO_2/FiO_2$ < 300 |
| Renal | Urine output < 0.5 mL/kg/h for > 2 h despite fluid resuscitation |
| | Creatinine rise of > 44.2 μmol/L |
| Clotting | International normalized ratio > 1.5 or activated partial thromboplastin time > 60 s |
| | Platelet count < 100,000 cells/μL |
| Hepatic | Bilirubin > 70 μmol/L |
| Gastrointestinal | Ileus |
| **Tissue perfusion** | |
| Acidosis | Lactate > 1 mmol/L |
| Clinical | Decreased capillary refill or mottling |

SD, standard deviations.

1. Body temperature, greater than 38°C or less than 36°C
2. Heart rate greater than 90 bpm
3. Hyperventilation evidenced by a respiratory rate of greater than 20 breaths/min or a $PaCO_2$ of less than 32 mmHg
4. White blood cell count of greater than 12,000 cells/μL or less than 4000 cells/μL.

The 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference addressed these definitions so that they could be readily applied by clinicians.[148]

(With kind permission from Springer Science + Business Media: *Critical Care Medicine*, 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference, 2003 31(4): 1250–6. Levy M, Md F, Fink M, et al.)

### Sepsis

Sepsis is the clinical syndrome defined by both the presence of infection (probable/documented) together with a systemic inflammatory response. An infection is the invasion of a normal sterile tissue fluid or body cavity by pathogenic or potentially pathogenic microorganisms. This is not a perfect definition: the colitis caused by *Clostridium difficile* is due to overgrowth in the non-sterile colon, with inflammatory effects occurring due to the cytopathic effects of the exotoxin produced by the bacteria. Thus, sepsis may occur without microbiological confirmation.

A systemic inflammatory response may be produced by a variety of infectious and non-infectious conditions (e.g. burns and acute pancreatitis). Table 30.12 shows a list of possible signs that prompt an experienced clinician to conclude that an infected patient 'looks septic'. None of these are specific to sepsis and could occur as an inflammatory response to major surgery or trauma. In many cases of early sepsis, the patients do not exhibit the classic signs or symptoms (Table 30.12) but experienced clinicians often intuitively make the correct diagnosis without any hard evidence. Once there is a clinical suspicion, the source of sepsis is then sought.

**Table 30.13** Parameters of severe sepsis

| | |
|---|---|
| **Haemodynamic: sepsis-induced hypotension** | |
| Blood pressure | Systolic < 90 mmHg or fall of > 40 mmHg |
| **Tissue perfusion** | |
| Acidosis | Lactate above upper limit of laboratory normal range |
| **Organ dysfunction** | |
| Oxygenation | $PaO_2/FiO_2$ < 250 in absence of pneumonia or < 200 with pneumonia |
| Renal | Creatinine > 176.8 μmol/L |
| Clotting | International normalized ratio > 1.5 |
| | Platelet count < 100,000 cells/μL |
| Hepatic | Bilirubin > 34.2 μmol/L |

### Severe sepsis

Severe sepsis is sepsis plus sepsis-induced organ dysfunction or tissue hypoperfusion. Organ dysfunction can be defined using the definitions in the SOFA[51] score. Dellinger et al.[144] include a table (Table 30.13) which is adapted from Levy et al.'s paper.[148]

Septic shock has developed when hypotension persists despite adequate fluid resuscitation. Severe sepsis is the leading cause of multiorgan failure, acute kidney injury, and ARDS and has a mortality of 40–60%. It is the commonest cause of death in general ICUs and the commonest cause of direct maternal death in the latest triennial Confidential Enquiry report.[4]

Goals in management of sepsis are to restore cardiac output and oxygen supply to vital tissues. This requires fluid administration, oxygen, and respiratory support, together with vasopressors to maintain blood pressure. Identification of the cause is essential to ensure that the correct antibiotics are given.

More detail of obstetric sepsis can be found in Chapter 34.

## Conclusion

Outcomes from critical illness are improved if diagnosis and effective treatment is provided at the earliest opportunity. Physiological changes in pregnancy may mask the signs of impending critical illness and it is therefore essential to have robust mechanisms in place so that escalation of care occurs in a timely fashion. Obstetric anaesthetists have a prominent part to play in the multidisciplinary team that provides higher levels of care on the delivery suite.

# CHAPTER 31

# Maternal mortality and morbidity

Suni Halder and Steve Yentis

## Introduction

Anaesthetists are acutely involved in the prevention of maternal mortality and morbidity. First, they have an important role in promoting and improving safety in a wide variety of clinical areas, and particularly in the delivery suite, where high-risk cases are all too common. Second, anaesthetists have skills and knowledge that are very relevant to resuscitation of critically ill obstetric patients, whether in the delivery suite, critical care units, or elsewhere. And third, anaesthesia itself is an important potential cause of maternal death; until relatively recently, anaesthesia consistently featured as a major direct cause of mortality in the United Kingdom's Confidential Enquiries into Maternal Deaths (CEMD; see later in this chapter), and the potential for anaesthesia to cause significant maternal morbidity, if not mortality, must never be forgotten.

As for anaesthesia outside obstetrics, where improving standards have led to large reductions in perioperative mortality such that much emphasis is now placed on morbidity, so it is with obstetrics. Thus, in developed countries at least, the numbers of maternal deaths have fallen to the point where some have argued that continuing to focus on death is now less productive than concentrating on morbidity.[1–7] However, maternal mortality continues to be an important outcome measure in developed countries, as well as worldwide, for a number of reasons: first, it ought to be a relatively easy outcome to record on an individual patient basis—there usually being little disagreement about when death has occurred—although counting *all* deaths within a region or country may not always be straightforward. Second, there are agreed national and international definitions for maternal death statistics that allow comparisons between countries and regions.[8–11] Third, such figures are generally accepted as being valid markers of the quality of the underlying healthcare infrastructure including education, resources, staffing levels and skill, sanitation, and family planning.[11–15] Fourth, regular or continuous analysis of trends in maternal mortality statistics allows changes to be detected that might otherwise go unnoticed.[13,17–19]

Maternal morbidity is much harder to define than mortality, although attempts have been made to monitor morbidity in the same way as for mortality, with some systems successfully providing useful feedback as part of an overall regional or national risk management strategy (discussed in more detail below). In practical terms, healthcare workers (including obstetric anaesthetists) are much more likely to encounter morbidity on the delivery suite than mortality.

## Maternal mortality

### Definitions

As in so many other areas of healthcare, the use of standardized definitions is crucial when comparing maternal mortality figures between regions or countries.

#### International definitions

The following definitions are those used by the World Health Organization (WHO) and classified by the Tenth Revision of the International Classification of Diseases, Injuries and Causes of Death (ICD-10):[8]

- *Maternal death*: death of a women while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and site of pregnancy, from any cause related to or aggravated by the pregnancy or its management but not from accidental or incidental causes.[8]
- *Pregnancy-related death*: death of a woman while pregnant or within 42 days of termination of pregnancy, irrespective of the cause of death.[8]
- *Maternal mortality ratio (MMR)*: direct and indirect maternal deaths, but not late maternal deaths, per 100,000 live births.[8]

#### UK definitions

Because of the importance of the CEMD over the last 50 years, it is important to be aware of the definitions used in this audit even though they differ somewhat from those used internationally:[10,11]

- *Direct maternal death*: death resulting from obstetric complications of the pregnant state (pregnancy, labour, and puerperium), from interventions, omissions, incorrect treatment, or from a chain of events resulting from any of the above.[10,11]
- *Indirect maternal death*: death resulting from previous existing disease, or disease that developed during pregnancy and which was not the result of direct obstetric causes, but which was aggravated by the physiological effects of pregnancy.[10,11]
- *Late maternal death*: death occurring between 42 days and 1 year after abortion, miscarriage, or delivery that is the result of direct or indirect maternal causes.[10,11]
- *Coincidental death*: death from unrelated causes which happen to occur in pregnancy or the puerperium.[10] (NB the ICD-10 refers to these deaths as 'fortuitous', as did previous reports from the CEMD; however, the latter changed the term to 'coincidental' because of widespread confusion between 'fortuitous'

(which means 'by chance') and 'fortunate' (which means 'lucky')).

- *Maternal mortality rate*: direct and indirect maternal deaths, but not late maternal deaths, per 100,000 maternities (pregnancies resulting in a live birth or stillbirth at greater than 20 weeks' gestational age).[10,11]

It should be noted that the international maternal mortality *ratio* and the CEMD's maternal mortality *rate* differ in two important respects: first, the former uses data only from death certificates for its numerator, whilst CEMD's numerator includes all deaths related to pregnancy, even those not noted on death certificates, by cross-checking death certificate data against other national registries and the Office for National Statistics (ONS); this has occurred since the mid 1990s. Second, the international MMR has as its denominator all *live births*, whereas the CEMDs' denominator is *maternities*, which includes live births and stillbirths. This has led to confusion (not helped by the similarity in the statistics' names) between the two figures, most recently the suggestion that maternal mortality in the United Kingdom was considerably higher than it actually was.

The CEMD's classification and definition system itself may give rise to some anomalies. For example, all cardiac deaths are included in figures on indirect deaths even though peripartum cardiomyopathy could be considered a 'complication of the pregnant state'. Similarly, an anaesthetic death arising from failed intubation at caesarean delivery would be a direct maternal death, whereas death from failed intubation in a pregnant woman undergoing appendicectomy would, strictly speaking, classify as an indirect death since the reason for the intervention was not related to pregnancy but the intubation was adversely affected by her pregnant state.

## Methods of estimation of maternal mortality

If comprehensive records of deaths and causes of deaths exist then accurate maternal mortality statistics could, theoretically, be obtained easily. However, there are very few countries in the world where this occurs. The United Kingdom is thought to have one of the most comprehensive and accurate systems to estimate maternal mortality through the CEMD, especially via its cross-linking process to ascertain all deaths. In developed countries, the process is aided by having relatively accurate death certification services. Countries' civil registration systems whereby routine birth and death data are recorded historically provide the largest data pool used to calculate international maternal mortality rates. Only one-third of countries are known to have complete civil registration data.[13] However, even in developed countries there may be inaccuracies; for example, a recent record-linkage study from Italy suggested considerable under-reporting of maternal deaths, with only a third of actual deaths accounted for in official (death certificate) figures.[20] This problem has been shown to exist in other countries, including the United States.[21] In the developing world, death certification systems are much less robust to start with, so that other methods (e.g. surveys,[22] censuses,[23] and verbal autopsies[24]) have to be used to estimate the number of maternal deaths. WHO is trying to improve the system for identifying maternal deaths by adding a checkbox on death certificates for recording a woman's pregnancy status, and by the publication of a new guide to reduce errors in coding for maternal death.[9,25] It should be noted that a failure in reporting or obtaining the correct number of deaths would always result in an underestimation rather than overestimation. Furthermore, if a country cannot provide basic maternal healthcare needs for its population, it may well be unlikely to be able to provide accurate mortality statistics. This can be due to a number of factors, including not recording maternal deaths because of the unknown pregnancy status of women of childbearing age; further, in some developing countries medical certification of cause of death does not exist.[13] Attempts to improve matters include the RAMOS (reproductive age mortality survey) method, which triangulates multiple sources of information and can be applied in local languages to improve reporting accuracy.[26] Using regression models, new global and regional estimates of maternal mortality can be developed at regular intervals.[13]

## The global picture: developing countries

WHO produces statistics on the annual estimates of MMR from 194 countries (Figure 31.1). The most recent world estimate of the overall MMR is around 210/100,000 live births. By the defined WHO regions of the world, the MMR is highest in sub-Saharan Africa (500/100,000), followed by South Asia (220/100,000), Oceania, excluding Japan, Australia and New Zealand (200/100,000), and the Caribbean (190/100,000). The MMR is relatively low in developed countries (16/100,000). These figures hide wide variations even within countries, as major discrepancies can exist between remote and urban areas as well as between affluent and poorer members of the population.

The majority of maternal deaths—over 99%—still occur in the developing world. In sub-Saharan Africa, there is an exceptionally high mortality rate, thought to be related to poor infrastructure and medical provision combined with a high fertility rate and poor compliance with contraception.[13–15] In the developing world as a whole, a 15-year-old woman has a 1/150 chance of mortality, whereas in the developed world the chance of mortality is 1/3800.[15] In Sub-Saharan Africa, when a women is of reproductive age she has a 1/10 chance of death as a result of pregnancy or delivery

There has been an encouraging downward trend in deaths overall: from 1990 to 2010 there has been a decline in maternal mortality of 47%, a fall of 3% per year. In 1990 there were an estimated 540,000 maternal deaths worldwide; this number has been reduced to 287,000 by 2010. This reduction has occurred despite the improvements in reporting within developing countries.[13] A worrying statistic, however, is that around one-third of these deaths occurred in just two countries: 19% of total global maternal deaths occurred in India and 14% occurred in Nigeria.[13] This is a very high death toll, with around one death every 2 minutes. However, it should be noted that over the period from 1990 to 2010, the MMR has incrementally decreased in India from 600 in 1990 to 200 in 2010, giving an average annual 5.9% decrease in MMR; in Nigeria the MMR has reduced from 1100 in 1990 to 630 in 2010, giving an average annual 2.6% decrease in MMR.[13] In India it is thought that the large number of maternal deaths is due to the vast overall population as opposed to an extremely high MMR.

To address worldwide health issues including maternal mortality, the United Nations (UN) set up some Millennium Development Goals (MDGs) in September 2000. These were goals that UN member states agreed to try to achieve by 2015.[27–29] The

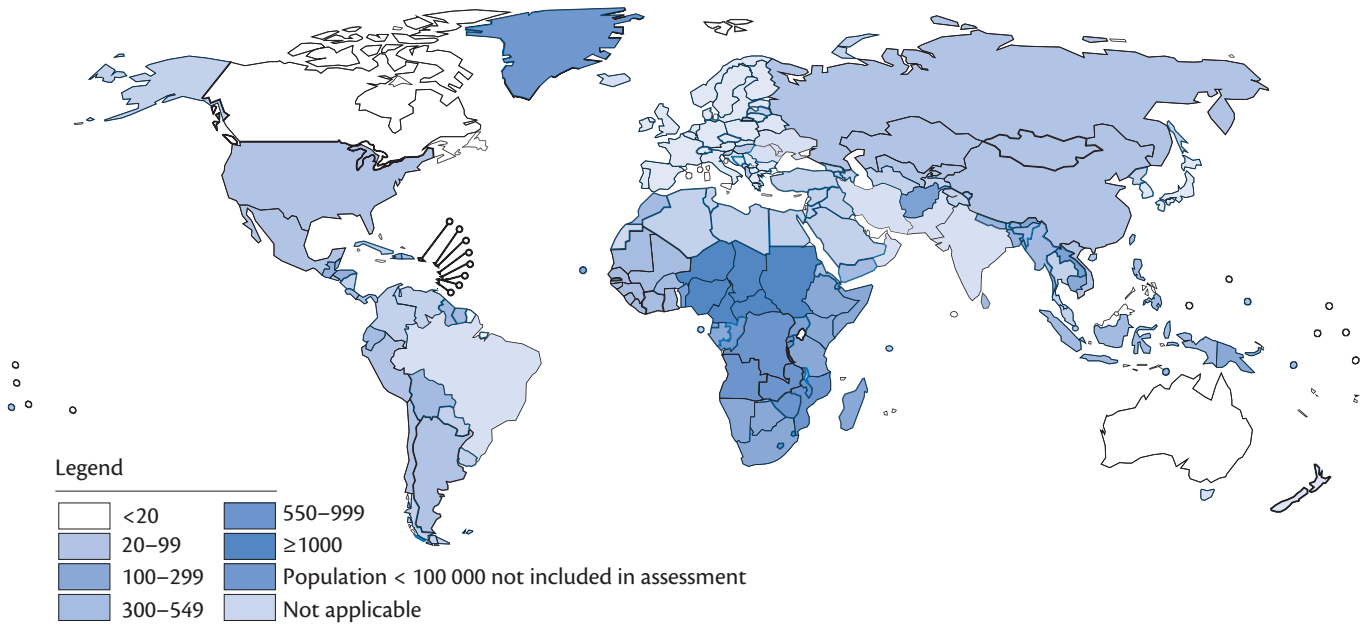

**Figure 31.1** (See colour figure section). Maternal mortality ratio (per 100,000 live births) worldwide, 2010.

bold overview was to 'improve maternal health', with two targets being to 'reduce by three-quarters, between 1990 and 2015, the maternal mortality ratio' and achieve, by 2015, 'universal access to reproductive health'. Despite the significant decline in death rate discussed above, maternal mortality by 2010 has only achieved half the required target reduction of MMR between 1990 and 2015. Globally, overall, a figure of 3.1% reduction per year was obtained; this is, however, far from the 5.5% per year required to obtain the MDG.[13,29,30] Encouraging data reveal that ten countries have already reached the target: Estonia (95% reduction), Maldives (93%), Belarus (88%), Romania (84%), Bhutan (82%), Equatorial Guinea (81%), Islamic Republic of Iran (81%), Lithuania (78%), Nepal (78%), and Vietnam (76%).[13] The reasons for the improvement made in some countries include improvement in healthcare systems, increased female education, and easier physical access to health facilities.[13]

In the developing world, there is a strong correlation between maternal and newborn mortality, with 3 million newborn and 2.5 million stillborn deaths each year.[31,32] Worldwide, the proportion of women attending antenatal care has increased secondary to the MDGs, with 81% of women seen once during the antenatal period in 2009, compared with 64% in 1990.[13] This proportion in 2009, however, reduces to 55% of women when the recommended minimum of four antenatal appointments is taken into account. The proportion of deliveries attended by skilled personnel, a key determinant to reduce maternal and perinatal mortality, is currently above 90% in only three of the six WHO regions. Overall, worldwide in 1990, 55% of women were attended by skilled personnel, this number increasing to 65% by 2009.[12,13] Alarmingly, in some regions, such as sub-Saharan Africa, the attendance rate is less than 50%.[13] As one might expect, the highest mortality rate is among women from poorer and more rural areas.

The major complications that cause maternal mortality in the developing world include severe bleeding, infections, high blood pressure, obstructed labour,[33,34] and unsafe abortion.[27,35-40] Worldwide, unsafe abortion, defined by WHO as 'a procedure for terminating an unintended pregnancy either by individuals without the necessary skills or in an environment that does not conform to minimum medical standards, or both', [35] accounts for a large proportion, around 13% of maternal deaths worldwide. The prevalence of unsafe abortion is highest in South America, with 30 or more unsafe abortions per 100 live births. Other deaths in the developing world can be attributed to malaria and human immunodeficiency viral (HIV) infection. In some Southern African countries such as Botswana, Lesotho, Namibia, South Africa, and Swaziland, the MMR increased from 1990 to 2000, mainly due to a HIV epidemic. This increase in MMR was reduced in the 2000s by the availability of antiretrovirals in these countries, with all five countries preventing mother-to-child transmission to 80% of pregnant women living with HIV.[13] It should be noted that without adequate laboratory facilities, deaths resulting from sepsis would be underestimated.[41] As haemorrhage is a major cause of death in the developing world, pre-existing severe anaemia secondary to poor diet, haemoglobinopathy, or parasitic infection with malaria can all increase the risk of mortality.[42] Many of the causes of maternal death in the developing world are preventable.[18,43] For all the MDGs to be reached, factors in the developing world such as poverty, lack of information and transport, inadequate services, and cultural practices all need to be addressed.[13,16,44–50] This is highlighted in a study of a religious group in the United States whose members, even though they were in a good state of health, refused modern obstetric and medical care because of their beliefs, leading to a maternal mortality rate similar to that in the developing world.[51] When obstetric anaesthetic services are provided in the developing world they tend to be less well funded, with fewer staff and equipment resources.[52–54] This leads to a greater incidence of maternal death due to inexperience and a lack of education, especially relating to the anaesthetic management of

high-risk patients who may have severe untreated co-morbidities and present with hypovolaemic or septic shock.[55,56] Caesarean delivery is a common surgical procedure in the developing world, especially in Africa.[57,58] However, airway problems secondary to general anaesthesia are also a common cause of mortality, as is the lack of availability of blood products.[59–62]

### South Africa Confidential Enquiry

The South African Confidential Enquiry analysing maternal deaths has been in operation since 1997, with the first report published in 1999, reviewing deaths during 1998 only. Since then, subsequent reports have looked at triennia. The latest triennial report, 'Saving Mothers 2008–2010', was published in 2012.[63] Data on institutional MMR, perinatal mortality rate, stillbirth rate, and early neonatal death rate per district are given in the report. Information about maternal deaths is confidentially reported to the National Committee for Confidential Enquiries into Maternal Deaths (NCCEMD) Secretariat and entered on the Maternal Morbidity and Mortality Audit System (MaMMAS) database, where data are collated and reports are produced. The general annual trend of maternal mortality since the Enquiry started is upwards, with 676 maternal deaths reported in 1998, 1173 maternal deaths reported in 2004, and 1643 maternal deaths reported in 2010. This increase is thought to be due to the greater proportion of cases reported and also the number of women dying.[63] In the latest triennial report, the MMR has increased overall to 176/100,000 live births, compared with 152/100,000 live births in 2005–2007. The major causes of maternal death in the latest (2008–2010) report include non-pregnancy related infections (40.5%, mainly due to HIV infection complicated with tuberculosis (TB) and/or pneumocystis pneumonia), obstetric haemorrhage (14.1%), complications of hypertension in pregnancy (14.0%), pregnancy-related sepsis (9.1%, including puerperal sepsis and septic miscarriage), and medical and surgical disorders (8.8%). These five account for 86.5% of all maternal deaths.[63] HIV infection is the most common contributing factor to maternal death in South Africa. Almost 80% of women who died in pregnancy, childbirth, or the puerperium were tested for HIV infection throughout South Africa. Of these women, 70% were infected with HIV. The majority of pregnant women with the acquired immunodeficiency syndrome (AIDS) (67%) had respiratory complications, namely TB (26.9%), pneumocystis pneumonia (13.3%), and other non-specified pneumonia (26.7%). The majority of emergency events occurred in the antenatal period (52%), whereas the majority of the women (61%) died postnatally.[63] Anaemia was a common factor, with 42.9% of women who died having a haemoglobin concentration lower than 10 g/dL.[63] Obstetric haemorrhage was the most common avoidable cause of maternal death. Postpartum haemorrhage during or after caesarean delivery accounted for 26.2% of deaths due to obstetric haemorrhage. The largest number of deaths due to haemorrhage were associated with caesarean delivery occurring at district hospitals but the numbers at regional and tertiary hospitals were also reported and caused concern. Resuscitation was poorly carried out in 22.3% of cases.[63] The 2008–2010 report made specific recommendations for the management of non-pregnancy-related infections, complications of hypertension in pregnancy, and obstetric haemorrhage. These included widespread screening for and treatment of HIV infection; recognition and protocols for immediate treatment of severe hypertension, imminent eclampsia, eclampsia, and the haemolysis, elevated liver enzymes, low platelets (HELLP) syndrome (including availability of magnesium sulphate, antihypertensives, and monitoring); and prevention of anaemia and safe management of labour.[63]

## The global picture: developed countries

### The United Kingdom: Confidential Enquiries into maternal deaths

The most recent Confidential Enquiry, Saving Lives Improving Mothers' Care (MBRRACE-UK) report,[11] covering the years 2009-2012, describes a significant reduction in maternal mortality rate from 11 per 100,000 maternities in 2006-2008 to 10 per 100,000 maternities. (See Table 31.1).

Following the trend of the previous report, indirect deaths i.e. of women with pre- existing disease are twice as frequent (6.87 per 100,00 maternities) as those who die directly as a result of their pregnancy (3.25 per 100,000 maternities) possibly owing to better

**Table 31.1** Rolling three year average Direct and Indirect maternal mortality rates per 100,000 maternities; UK 2003–12

| 3-year period | Total UK maternities | Direct deaths | | | Indirect deaths | | | Total Direct and Indirect deaths | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | n | Rate | 95% CI | n | Rate | 95% CI | n | Rate | 95% CI |

management of 'direct' obstetric conditions and/or an increase in co-morbidities and risk factors over this period, in particular obesity[66] and increasing maternal age. (Figures 31.2 and 31.3).

### CEMD: direct deaths

*Sepsis*

An increase in the number of deaths related to sepsis was noted during the collection and reporting process of the 2006–2008 CEMD report,[10] and this led CMACE to the unusual step of releasing an interim statement.[67] The final report for 2006–2008 revealed sepsis to be the leading direct cause of maternal death, with 26 deaths during this period (maternal mortality rate 1.13/100,000 maternities), compared with 18 deaths (maternal mortality rate 0.85/100,000 maternities) in the previous triennium. This increase reflects a generally increasing trend over the last 20 years and follows a dramatic fall in the rate in the 1950s that is thought to be related to the introduction of antibiotics, better general healthcare, and sanitation, the Abortion Act of 1968, and increased awareness due to the CEMD process itself.

In the 2006-2008 CEMD report, genital tract sepsis due to group A streptococcal disease was the predominant cause; however, other pathogens were also isolated.[68] Nine women died following caesarean delivery, highlighting the need for timely administration of antibiotics.[69] A lack of recognition of severe sepsis and absent or late involvement of senior medical staff and multidisciplinary critical care were highlighted. The CEMD report also emphasized the sometimes very atypical or non-specific histories and symptoms with which women with sepsis may present, the risk of rapid decompensation when their physiological reserves are exhausted, and the need for prompt treatment according to internationally accepted sepsis guidelines including early broad spectrum antibiotics, careful fluid resuscitation, and circulatory support if required.

Although not specific to sepsis, the 2006–2008 CEMD report[10] highlighted the usefulness of early warning scores, raised in the 2003–2005 report,[65] in monitoring mothers' physiological variables over time and aiding the detection of gradual deterioration, with triggers for seeking medical input (and at an appropriate level of seniority). Such modified early obstetric warning scores (MEOWS)[70] are an extension of the concept of early warning scores (EWS) used in general hospital wards and a national EWS has recently been developed by the Royal College of Physicians.[71] A specific national MEOWS is less well developed although the process of developing such a system based on proper evaluation/evidence is underway .

In the recent MBRRACE-UK report,[11] sepsis was no longer the leading cause of maternal mortality but was still responsible for a

quarter of the deaths. One in 11 maternal deaths was due to influenza and increasing the immunisation rates for seasonal flu is seen as a priority for health services.

*Thromboembolism*

Thromboembolism is once again the commonest cause of direct maternal death with 56 women dying from this condition in the recent MBRRACE-UK report.[11] The reduction in the number of deaths from thromboembolism previously seen is evidence of the success of both the CEMD and the use of national guidelines on thromboprophylaxis. In the 2006-2008 CEMD report, the number of deaths from this cause was the lowest reported in 20 years, with the most dramatic reduction between 2003–2005 (41 deaths; 1.94/100,000 maternities) and 2006–2008 (18 deaths; 0.79/100,000 maternities). The publication of national guidelines on thromboprophylaxis for caesarean delivery in 1995,[72] and for pregnancy/labour/vaginal delivery in 2004,[73] was followed in each case by a reduction in the number of deaths in the following triennium (Figure 31.5).

In the 2006–2008 report, 16 deaths were from pulmonary embolism and two were from cerebral venous thrombosis. The reduced mortality was mainly seen in the antenatal period and in women delivering vaginally. The main risk factor still appears to be obesity, with 14 of the 18 women having a body mass index (BMI) exceeding 25 kg/m$^2$. Guidance on thromboprophylactic dosing in obesity was published by CMACE and the Royal College of Obstetricians and Gynaecologists in 2009.[74] At the time of publication, the effect of this guidance is still yet to be seen. Substandard care, present in over half of the deaths, included inadequate risk assessment and thromboprophylaxis as well as failure to investigate and treat women when they presented with often classic symptoms of deep vein thrombosis and/or pulmonary embolism.

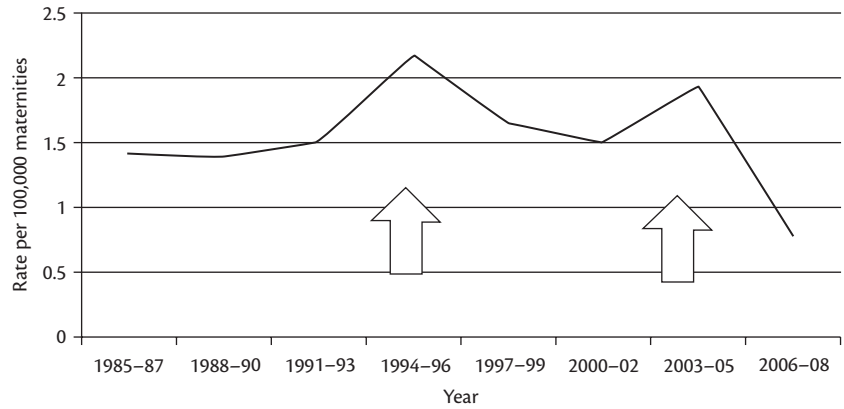

**Figure 31.5** Maternal mortality rates per 100,000 maternities in the United Kingdom due to thrombosis and thromboembolism: 1985–2008. Publication of national guidelines on thromboprophylaxis for obstetrics and gynaecology in 1995 and thromboprophylaxis during pregnancy, labour and after vaginal delivery in 2004 are shown by the vertical arrows.

*Pre-eclampsia and eclampsia*

In 2003, deaths from acute fatty liver of pregnancy (AFLP) have been included in those from pre-eclamptic toxaemia (PET)/eclampsia, on the basis that they may be part of the same spectrum of disease. The total number of deaths from these combined conditions has remained approximately constant between 1997–1999 (20) and 2006–2008 (22), with four and three deaths, respectively, from AFLP.

Over the previous 30-year period there has been an overall reduction in the death rate from pre-eclampsia and eclampsia (Figure 31.6). The likely reason for the decreasing trend is thought to be earlier recognition and treatment of hypertensive disorders in pregnancy. In the 2006–2008 report,[10] nine deaths occurred secondary to intracranial haemorrhage and four from anoxia following cardiac arrest after an eclamptic seizure. The report emphasizes the importance of severe headache and epigastric pain as warning signs, and of systolic pressure, not just diastolic pressure, as a target for more intensive treatment. Substandard care was noted in 20 out of the 22 deaths; in 14 cases, this was classified as major. The predominance of intracranial bleed and absence of pulmonary complications as the cause of death reflects a continuation of the trend whereby pulmonary oedema and acute lung injury (considered now to be related to excessive administration of intravenous fluids in order to prevent renal injury) was the most common cause of death in women with PET/eclampsia 20–30 years ago but is uncommon now. NICE released guidelines for management of hypertension in pregnancy in 2010,[75] and figures from the most recent MBRRACE report[11] indicate that the mortality rate from hypertensive disease in pregnancy in 2009–2012 is the lowest since the Confidential Enquiries began in 1952. This is a major achievement and is thought to reflect adherence to protocols and guidelines on recognition and timely treatment of the condition.

*Amniotic Fluid Embolism*

Numbers of deaths due to amniotic fluid embolism (AFE) have remained small but consistent over the last 30 years (Figure 31.7); in the 2006–2008 CEMD report there were 13 deaths due to AFE, compared with 17 in the previous triennium.[10,65] The MBRRACE report[11] from 2009–2012 identified 11 women from the United Kingdom and Ireland who died from AFE. Evidence from elsewhere[76] suggests that AFE should no longer be considered an

invariably fatal condition. There was substandard care in many cases, mostly related to the general management of critically ill obstetric patients (communication/referral/transfer) and failure to deliver by perimortem caesarean delivery quickly enough, although it is uncertain whether these women would have survived even had care not been substandard.

*Haemorrhage*

The death rate from haemorrhage fell dramatically between the 1950s and the 1970s, possibly owing to better recognition of high-risk mothers and their elective admission to hospital for delivery, better resuscitation before transfer to hospital if bleeding occurred at home or in smaller units, better management of coagulopathy, and earlier hysterectomy. In the last 30 years the mortality from haemorrhage has stayed relatively constant, reflecting early recognition and active treatment (Figure 31.7). In the 2006–2008 CEMD report, there were nine maternal deaths from haemorrhage (0.39/100,000 maternities), reduced from 14 in the previous report.[10,65] Worryingly, six of these women were assessed as receiving substandard care, in particular a lack of postoperative observations/monitoring and/or a failure to act on them, with the assessors judging that different management could have altered the outcome in six cases. The importance of diagnosing and treating antenatal anaemia was highlighted,[42] as was the requirement for effective multidisciplinary team-working with senior clinical involvement in cases of massive obstetric haemorrhage. Reassuringly, it was noted that the management of expected major haemorrhage in patients with placenta accreta had improved from the previous triennium.[65] Recommendations were made that patients with known major risks of haemorrhage should be delivered in maternity units with access to critical care, cell salvage, and interventional radiology.

In the MBRRACE-UK report[11] there were 17 deaths in the United Kingdom and Ireland accounting for 10% of maternal deaths in 2009-2012 and responsible also for significant maternal morbidity. There is a continuing trend toward increasing incidence of postpartum haemorrrhage.

*Anaesthesia*

In the 1970s to 1980s, anaesthesia was the third most common direct cause of maternal death. The dramatic decline in the number of deaths related to anaesthesia is rightly seen as a major achievement of the specialty, and of the CEMD itself (Figure 31.8). The factors that have contributed to the fall in anaesthetic deaths are thought to be the emergence of obstetric anaesthesia as a consultant-led subspeciality, the provision of dedicated anaesthetic cover for delivery suite especially out of hours, the increased use of neuraxial anaesthesia over general anaesthesia for caesarean delivery and other procedures, and better standards of monitoring, anaesthetic assistance, equipment, and general anaesthetic safety. It should be noted, however, that the impressive results shown in Figure 31.8 do not demonstrate the even more impressive improvement in safety associated with caesarean delivery. Since the caesarean delivery rate has increased so markedly over the years, the actual mortality rate due to anaesthesia has fallen from 36/100,000 caesarean deliveries in 1964–1966, to 6/100,000 in 1982–1984, and just 1/100,000 in 2000–2002.[77]

Factors that have been associated with substandard care over the years have included inadequate assistance for the anaesthetist, a lack of dedicated anaesthetic cover, inadequate antacid prophylaxis, a lack of referral to senior staff and to critical care services, inadequate antenatal referral of high-risk cases to anaesthetists, and inadequate airway management including failure to recognize oesophageal intubation and persistence with attempts

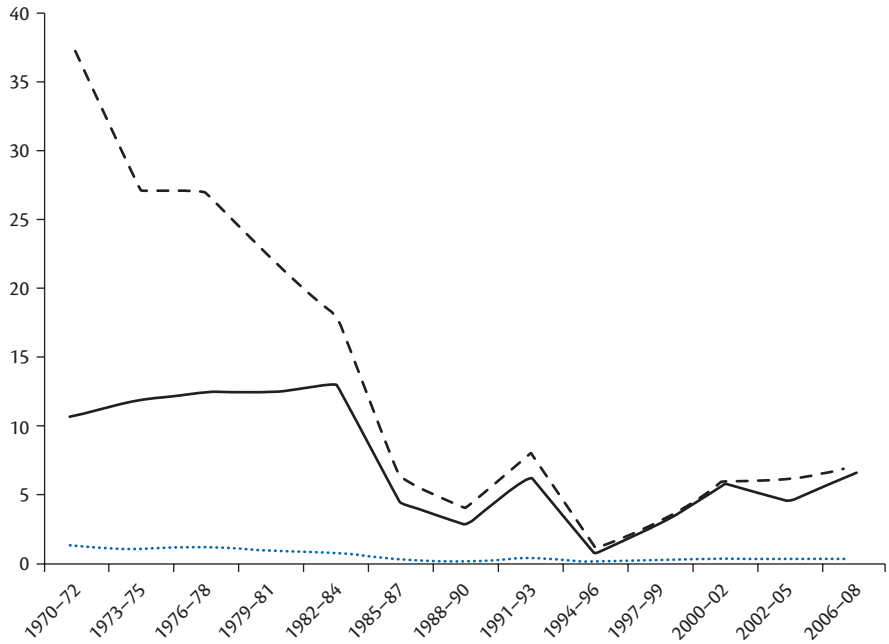

**Figure 31.8** Maternal mortality due to anaesthesia in the CEMD over the last 40 years. Dashed line = number of deaths; solid line = proportion of direct deaths; dotted line = rate per 100,000 maternities.

at tracheal intubation instead of using alternative methods of oxygenation. Many of these have been addressed over the years through training and provision of adequate resources, though the same lessons continue to be highlighted, even in recent reports, with anaesthesia continuing to contribute to maternal deaths even if not their direct cause. Other factors include the provision of anaesthetic care out of hours largely with relatively junior staff, and the increase in maternal age, obesity, and other morbidity.

Because the actual number of deaths directly due to anaesthesia has fallen to such low levels, it is difficult to extrapolate too much from discussion of individual cases, although as stated above, the same points tend to be raised each triennium. In the 2006–2008 CEMD report,[10] there were seven deaths directly due to anaesthesia, making it the seventh leading cause of direct maternal death. Six deaths were thought to involve substandard care, although the outcome was judged as being affected by this in only three. Two of the deaths were airway related; in one of these a working epidural was not topped up for caesarean delivery. Four deaths occurred postoperatively, one from opioid toxicity thought to be associated with patient-controlled analgesia, one possibly associated with incompatible blood transfusion, one associated with substance abuse, and one from aspiration of gastric contents. One death was attributed to acute haemorrhagic leucoencephalitis, a rare condition, that followed spinal anaesthesia. Eighteen further deaths had some anaesthetic contribution, with 12 deaths noted as involving anaesthetists and intensivists too late. Key learning points included improvements in communication, human factors and non-technical skill awareness, maintenance of airway and life support skills, and adequate topping-up of effective epidurals, if clinically appropriate, to avoid general anaesthesia and the need for tracheal intubation for emergency caesarean delivery.

In the 2009–2012 MBRRACE-UK report[11], there were 4 deaths directly attributable to anaesthesia. Two deaths occurred after accidental dural puncture (ADP) resulting in a subdural haematoma in one patient and a cerebral vein thrombosis in the other and highlight the need for hospital follow up and primary care notification after ADP. Two patients also died following periods of hypoventilation during or following general anaesthesia, highlighting the need for vigilance and high standards of perioperative and post operative care.

## CEMD: indirect deaths

### *Cardiac disease*

The spectrum of cardiac disease in the CEMD reports has changed over the years, reflecting changing patterns of disease generally. In the 1960s to the 1980s, the majority of deaths (70–85%) were from acquired disease, usually rheumatic heart disease, with congenital conditions a minority. By the mid to late 1980s, the deaths were approximately equally split between acquired and congenital, but this changed back over subsequent reports such that acquired disease again accounts for the majority of deaths (60–80% in the most recent two triennia). Rheumatic heart disease features only rarely in recent reports (there were no deaths from this cause in 2006–2008), most acquired disease consisting of myocardial infarction and cardiomyopathy. Over the last 30 years the number of deaths secondary to cardiac disease has increased (Figure 31.9). This is thought to reflect the increasing age at which women are becoming pregnant, with concomitant risk factors such as obesity and smoking, and advancements in surgical treatment of congenital cardiac disease in early life.

In the 2006–2008 CEMD report, cardiac disease was the leading overall cause of maternal mortality, with 53 deaths (a mortality rate of 2.31 per 100,000 maternities).[10] The main causes were sudden adult death syndrome (SADS), myocardial infarction, thoracic aortic dissection, and cardiomyopathy. Death from SADS is assumed to be due to idiopathic arrhythmias leading to sudden cardiac death. Half of the deaths were in obese patients with a BMI greater than 30 kg/m$^2$. Substandard care was noted in 51% of cases, including inappropriate diagnosis/investigation of symptoms such as chest pain, especially where other risk factors such as obesity, hypertension, and smoking were known.

The 2009–2012 MBRRACE-UK report[11] has also found that cardiac disease remains the single largest cause of indirect maternal deaths.

### *Psychiatric disease*

Deaths from suicide have only been analysed and discussed separately in the CEMD reports since the 1993–1997 report, and the discussion of deaths from psychiatric causes has widened to include deaths associated with substance abuse, including alcohol. It became clear from cross-linking with the ONS that many deaths from suicide were missed from previous reports, leading

to a sudden increase in the number of cases in 2000–2002, due to better case ascertainment. A particular feature that arose from more detailed analysis of maternal death from suicide is the high incidence of violent death (e.g. jumping from buildings) compared with non-pregnant women, in whom medication overdose is the main cause of self-inflicted death. The analysis and discussion of psychiatric disease, including the influence of substance abuse and other indicators of vulnerability, including domestic violence, demonstrates the importance of the CEMD in commenting on and influencing the social aspects of healthcare in pregnancy.

In the 2006–2008 CEMD report, there were 67 deaths associated with psychiatric causes, including suicide, drug overdose, medical conditions associated with the psychiatric condition, and accidents.[10] Areas of substandard care relate to service provision in general rather than to specific areas in which anaesthetists might be involved.

*Other Indirect Causes*

This description includes a varying number of deaths from causes too uncommon to warrant their own chapter in the CEMD reports. In the 2006-2008 report,[10] there were 88 such deaths, 36 involving the central nervous system, and 18 involving the respiratory or metabolic/endocrine/immune systems. Over the years, subarachnoid haemorrhage and epilepsy have been consistently highlighted. Care was judged to have been substandard in 51 cases, in 28 of them serious enough to have influenced the outcome.

### *Other relevant lessons from the CEMD*

**Critical care**

Over 50% of women reported in each CEMD report have been admitted to a critical care unit. Review of Intensive Care National Audit and Research Centre (ICNARC) data has revealed that 11.4% of women between 16 and 50 years old admitted to critical care units are obstetric patients, of whom 80% were reported as 'recently pregnant' rather than 'currently pregnant'.[10] The most common pregnancy-related diagnosis, accounting for 34% of admissions, was haemorrhage, with sepsis being another major cause. Lessons highlighted from CEMD reports include the importance of providing critical care support early to severely unwell women—including before formal admission to the intensive care unit (ICU)—and early protocol-driven multidisciplinary management of severe sepsis and severe obstetric haemorrhage, including guidelines for the rate and composition of fluid administration.[10] The role of simulation in improving the management of life-threatening obstetric emergencies was also highlighted.

**Obesity**

This is an increasing problem in developed countries. In 2007, 24% of women in the United Kingdom were classified as obese, compared with 16% noted in 1993. Forty per cent of women who died in the 2006–2008 report were obese.[10] Obesity was associated with an increased risk of cardiac disease (61%) and thromboembolism (78%). The risks of gestational diabetes, pre-eclampsia, and ICU admission are all increased in obese patients.[66]

**Age**

There is a recognized associated between increasing maternal age and the risk of pregnancy-associated death. In the triennium of 1985–1987, there were 35 deaths in the age range 35–39 years and 13 in the over 40s; in the 2006–2009 CEMD report these numbers have increased to 71 and 24, respectively.[10]

**Emergency care**

Deaths in women who presented several times to emergency departments led to the highlighting of emergency medicine as an area of focus in recent CEMD reports.[10,65] In the 2006–2008 CEMD report, 27 women died in emergency departments, the majority having cardiac arrests before arrival to hospital.[10] The need for perimortem caesarean delivery in these cases was again highlighted, as was the need for pregnancy tests for all women of childbearing age and review of frequent attenders by senior clinicians. A lack of input from appropriately trained senior doctors in high-risk emergency cases was also highlighted. Key learning points were the development of clear guidelines to aid junior staff to escalate calling for senior help early and appropriately.

## Other national schemes (in developed countries) for reporting maternal mortality

Many other developed countries have attempted to establish their own systems for analysing maternal deaths, including the United States,[17,78–87] France,[88,89] Australia,[90,91] and Canada.[17,92]

### *United States of America*

In the United States, maternal death counts from 1900 were collated by the National Center for Health Statistics (NCHS); MMR data was produced by the NCHS from 1915.[78] In 1915, the US MMR was reported as 600 deaths per 100,000 live births, this number reduced to 10 by 1980.[78] The accuracy of this data was limited as the system at that stage relied on death certification data, not on surveillance. Also, the death certification process was the responsibility of individual states, with considerable variation. In 1987, the Centers for Disease Control and Prevention (CDC) partnered with the State Health Department and the American College of Obstetrics and Gynecology to form the Pregnancy Mortality Surveillance System (PMSS).[85] The PMSS recommended active voluntary surveillance systems for maternal deaths with death certificates and matching live birth or fetal death certificates for all pregnancy-associated deaths. Each state thus collates its own data through maternal mortality review committees and forwards this summated information to the CDC, where epidemiologists review the data to identify all pregnancy-related deaths. In the United States, two systems collect information on women who die from maternal complications. The National Vital Statistics System (NVSS) reports on maternal mortality and publishes this maternal mortality data for the United States, to be used for comparisons with other countries. The PMSS conducts voluntary epidemiologic surveillance of pregnancy-related deaths collated by the CDC, including clinical information. Even with the resources available, a number of maternal deaths are still not reported, leading to underestimation.[21] To improve the detection of pregnancy-related deaths, state death certificates now include a specific question or tick box about the pregnancy status at the time of death.[93] In the period between the 1980s and 1990s, the MMR ranged between 6.6 and 8.4 per 100,000 live births. For the period between 2006 and 2007, the MMR was 15.1 deaths per 100,000 live births. The increase in MMR over this period has been attributed to improvement of identification of cases and the use of ICD-10 classifications[8] for coding of US death certificates, increasing the criteria whereby death could be linked with pregnancy.[86,94] Maternal obesity, increasing age, and co-morbidities have also increased the MMR. Causes of maternal mortality in the United States during the period from 2006 to 2007 are listed

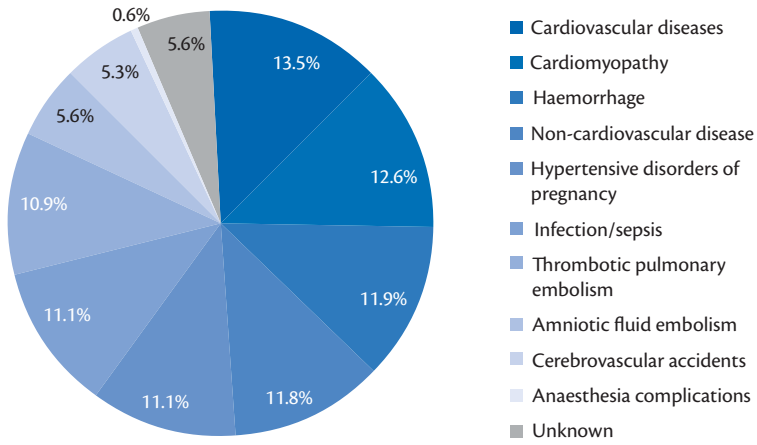

**Figure 31.10** (See colour figure section). Causes of pregnancy-related deaths in the United States: 2006 to 2007.
Data from Berg CJ. From identification and review to action--maternal mortality review in the United States. *Semin Perinatol* 2012; 36:7–13, Copyright © 2012 Elsevier.

in Figure 31.10. These figures show that in the United States, cardiac disease features as the leading cause of death. Sepsis is also an important cause of death; however, there is a greater proportion of deaths from haemorrhage compared with UK data.[10,84] As with UK data, it can be seen that in recent years the numbers of indirect deaths in the United States are on the increase: there has been a rise from 6.1% in 1995 to 25.5% in 2005.[79–83,95-100] In the United States, there still exist significant racial disparities, with 15.1 deaths per 100,000 live births for white women, 34.8 deaths per 100,000 live births for black women, and 15.7 deaths per 100,000 live births for women of other races.[84] The strongest factors in the United States that appear to cause maternal deaths in varying racial groups are medical co-morbidities, deficient medical care, and poor social circumstances.

### *Australia*

A triennial confidential enquiry into maternal deaths has occurred in Australia since 1964.[91] The Australian enquiry involves several levels of reporting and review. Initially, maternal deaths are notified to the local State and Territory Maternal Mortality Committees (STMMC) by doctors, midwives, hospitals, public health departments, and through the coroner and postmortem investigations. Maternal deaths are further ascertained from death certificates from perinatal and hospital morbidity collections and the Australian Bureau of Statistics. Every separate STMMC is responsible for conducting confidential death enquiries to determine primary and contributory causes of each maternal death. Regional variation in roles and responsibilities of each the STMMC occurs. Some STMMCs perform root cause analysis of maternal deaths while others do not. A national report on maternal deaths is prepared on a triennial basis on behalf of the Australian Institute of Health and Welfare (AIHW) by the National Perinatal Statistics Unit (NPSU), with expert input from the National Advisory Committee on Maternal Mortality (NACMM). The NACMM comprises of members from STCMM, professional medical colleges, patients, indigenous Aboriginal representation, National Health and Medical Research Council (NHMRC), Australian Commission on Safety and Quality in Healthcare (ACSQH), and other stakeholders.[101] A subcommittee reviews all anonymous maternal death data, ensuring consistency. It provides information so a clinical commentary can be produced from the data collected, allowing identification of substandard care and flagging areas that require protocol and guideline development. Case review has shown around 50% of the maternal deaths in Australia are potentially preventable. The MMR has been relatively static in Australia for over 30 years with no sustained improvement. The period 1973–1999 revealed 646 maternal deaths, including 397 (61.5%) direct deaths and 249 (38.5%) indirect deaths.[102] The MMR was 9.8 deaths per 100,000 maternities during this period, having declined from 12.7 in 1973–1975 to 6.2 in 1991–1993. The leading causes of all maternal deaths during 1973–1999 were cardiovascular disease (15.3%), haemorrhage (11.8%), pulmonary thromboembolism (11.3%), hypertensive disorders of pregnancy (9.9%), AFE (7.4%), and infection (6.7%).[102] The main direct causes of death remained unchanged during the period 1973–1999, with pulmonary embolism accounting for nearly 20% deaths. Indirect deaths were dominated by cardiovascular disease, which accounted for an average of 40% of maternal deaths per triennium.[102] In the 2003–2005 triennial report, published in 2008, the MMR was 8.4/100,000 maternities, with a total of 65 deaths (29 direct (44.6%) and 36 indirect (55.4%) deaths). The main direct causes of maternal death were AFE (27.6%), hypertensive disorders of pregnancy (17.2%), and thrombosis and thromboembolism (17.2%). Significant indirect causes were cardiac conditions (27.8%), psychiatric causes (16.7%), and infection (11.1%). The MMR for Aboriginal and Torres Strait Islander women at 21.5/100,000 maternities was more than two and a half times that of other non-indigenous women at 7.9/100,000 maternities.[91] Recommendation from the 2008 report revealed that the current data collection process did not provide enough quality and sufficient information on clinical pathways and management to inform recommendations on practice and policy.

### *Canada*

The Public Health Agency of Canada produces a Canadian Perinatal Health Report that has 29 healthcare indicators, including maternal mortality. The Public Health Agency of Canada works with the Canadian Perinatal Surveillance System (CPSS) to collate maternal mortality data. The 2008 report is the fifth report that the CPSS has produced.[103] The CPSS collaborates with Statistics Canada, the Canadian Institute for Health Information,

healthcare organizations, provincial and territorial governments, patient groups, and university delegates. Within the CPSS the Maternal Health Study Group assesses the maternal mortality. MMRs for the CPSS are calculated using National Vital Statistics (NVS) data from death certificate information. The NVS data are collated locally within provinces to ensure accuracy and can be used to verify inpatient maternal mortality data. According to CPSS data, the MMR in Canada has increased significantly over 30 years from 3.4/100,000 in 1984–1986 and 1990–1992 to 5.5/100,000 live births in 2002–2004.[103] The CPSS recognized in its 2008 report that as the data were obtained from death certificates, the MMR was an underestimation; in the future it is intended to include data from coroner/medical examiners, medical death review teams, and inpatient statistics.[103] One non-governmental group has looked at trends in maternal mortality in Canada using a combination of NVS and inpatient data and found a very different trend from the CPSS data,[104] with maternal mortality rates in the period 1981–2007 increasing significantly from 4.5/100,000 in 1981–1983 to 4.7/100,000 in 1996–1998, and 7.2/100,000 live births in 2005–2007.[104] The most common causes of maternal death were cardiac disease, postpartum haemorrhage, and hypertensive disorders of pregnancy.[104] Maternal mortality rates from inpatient data were higher but did not increase over time.[104] The non-governmental group revealed that provincial maternal mortality rates from NVS data showed varying degrees of under-ascertainment (12–70%) compared with inpatient data.[104] Recently, the Public Health Agency of Canada has started to publish data on maternal mortality based solely on inpatient data placed in biennial cohorts.[105] This has revealed that during the 10 years from 1996 to 2010, MMR fell from 11.9/100,000 deliveries in 2000–2002 to 6.8/100,000 deliveries in 2004–2006, rising to 7.8/100,000 deliveries in 2008–2010. The most common causes of death from 2002 to 2010 were cardiac disease (25.7%), postpartum haemorrhage (13.0%), hypertensive disorders of pregnancy (13%), and venous thromboembolism or AFE (11.5%).[105] The striking message when reading through the Canadian national reports on maternal mortality is that although they give information on statistics, they do not give information on strategies for prevention of the maternal deaths or information on the major lessons learnt.

#### *France*

In France, the national confidential enquiry into maternal deaths (ENCMM) and its committee (CNEMM) collect all data on maternal deaths in the country. Two assessors (one obstetrician and one anaesthetist) gather information on patients after being informed of the maternal deaths by the epidemiological centre on medical causes of deaths (CépiDC); they gather information by the means of a detailed and specific questionnaire. The anonymous files are then reviewed by a committee at the CNEMM. Maternal mortality rates and ratios are then calculated, looking at specific causes of death and identifying substandard care.[89,106] The MMR from France has been relatively stable over the previous 15 years: in 1999 it was 7.4/100,000, from 2001 to 2006 it was 8.0/100,000, and from 2003 to 2004 it was 7.0/100,000.[107] From 1996 to 2006, 729 maternal deaths were included in the confidential enquiry process, of which 553 were reviewed by the CNEMM. Direct causes formed the majority of maternal deaths (73%): haemorrhage (22%), AFE (12%), venous thromboembolism (10%), and complications of pregnancy-associated hypertension (10%). Fifty per cent of maternal deaths were assessed by the CNEMM as being preventable, mainly from haemorrhage and sepsis.[106]

## Maternal morbidity

Healthcare staff are much more likely to encounter pregnant women suffering morbidity than maternal deaths, and as numbers of deaths have declined there has been increased emphasis on examining cases of morbidity in order to learn lessons and improve the care of obstetric patients. Although morbidity is more common, however, it is much more difficult to obtain accurate data about the spectrum of conditions encountered and their incidence, although attempts to do so are ongoing.[108]

### Methods of estimation of maternal morbidity

In developing countries, attention is rightly focused on preventing maternal mortality as the major priority, though the importance of severe morbidity should not be forgotten. Severe maternal morbidity occurs in around 1% of maternities in the United States compared with 3.01–9.05% in some developing settings.[3] However, collecting data on morbidity in such environments is usually considered too difficult or not as urgent compared with mortality. In developed countries, the identification of severe maternal morbidity has emerged as a complement to the investigation of maternal deaths, the assumption being that conditions causing morbidity may ultimately lead to maternal deaths.[5,10,108]

The main difficulties with collecting and analysing maternal morbidity data are first, establishing a system for reliable reporting and second, setting definitions that are meaningful and reproducible—and ideally, widely accepted, so that systems in different regions/countries can compare their findings, as for mortality data. As far as reporting systems are concerned, their strength is also their weakness: the potentially large numbers involved (that can give rise to more robust data with narrower confidence intervals than those describing small numbers) can make it difficult to capture all the cases, especially where the healthcare/communication infrastructure is itself less reliable. Difficulties in standardizing definitions for morbidity have led to a more fragmented approach to morbidity studies than for mortality.

#### Definitions

Initially, reports on maternal morbidity focused on admission to the ICU as a proxy measure of morbidity.[109–113] However, admission rates to ICU vary widely between units and especially in different countries, depending on case mix, admission criteria, and availability of ICU resources. This led to attempts to define maternal morbidity in terms of specific organ dysfunction.

In 1998, Mantel et al. referred to severe acute maternal morbidity as the concept of maternal 'near-miss', defining this as 'a women with severe organ dysfunction or organ failure'.[113] There were specified defined criteria for each organ dysfunction. A maternal 'near-miss' was noted as an event where a pregnant woman comes close to death, but does not die. In 2004, Brace et al. referred to severe maternal morbidity using 14 categories that were a combination of organ dysfunction, diagnosis and management strategies. An example would be renal dysfunction secondary to massive obstetric haemorrhage leading to ICU admission.[114,115] In 2005, Wen et al. proposed their definition for severe maternal morbidity, consisting of one or more of: venous thromboembolism; eclampsia; pulmonary, cardiac, or central nervous system

complications of anaesthesia; cerebrovascular disorders in the puerperium (including intracranial venous sinus thrombosis); uterine rupture; adult respiratory distress syndrome; pulmonary oedema; myocardial infarction; acute kidney injury after labour and delivery; cardiac arrest/failure or cerebral anoxia after obstetric surgery; severe postpartum haemorrhage requiring hysterectomy or transfusion; and the need for assisted ventilation. With definitions becoming increasingly complicated, Zhang et al. tried to simplify the definition for severe maternal morbidity in 2005 by relating it to the commonest causes of maternal morbidity based on defined criteria for pre-eclampsia, severe obstetric haemorrhage and sepsis.

In 2005, WHO established five factors with respect to maternal death during pregnancy, childbirth and the first week postpartum. The five factors were admission to the ICU, blood transfusion, hysterectomy, eclampsia, or cardiac and renal complications. It was assumed that combinations of these factors indicated severe maternal morbidity and could be considered maternal near-misses.[116] In 2011, WHO defined a maternal near-miss case as 'a woman who nearly died but survived a complication that occurred during pregnancy, childbirth or within 42 days of termination of pregnancy'.[116–120] To allow the identification of near-misses and maternal deaths, WHO has produced a set of signs of organ dysfunction, describing inclusion criteria for dysfunction of the cardiovascular, respiratory, renal, coagulation, hepatic, neurological, and uterine systems (Table 31.2).[119,121,122]

## Morbidity studies

In general, there are three broad approaches to studying maternal morbidity: individual 'one-off' studies in single units or areas/regions, usually involving admissions to critical care units; continuous surveillance of morbidity across regions/countries; or specific reporting of individual rare events/conditions.

### *Single studies*

There have been many studies based in a single unit or small groups of units within single cities; of more interest in global terms are those attempting to broaden the scope of study by including units across wider regions. Some of these are described below.

#### Netherlands Assessment of Severe Maternal Morbidity

In 2008, Zwart et al. reviewed cases of severe maternal morbidity collected over a 2-year period in 98 maternity units, covering a population of around 371,000.[123] Severe maternal morbidity had an incidence of 7.1/1000 deliveries, ICU admission 2.4/1000 deliveries, eclampsia 6.2/1000 deliveries, uterine rupture 6.1/1000, and major obstetric haemorrhage 4.5/1000. Immigrant women had the highest risk, with a 1.3-fold increased risk compared with western women. Substandard care was noted in 62% of cases.[123]

#### European Audit of Severe Maternal Morbidity

In 2005, Zhang et al. conducted a study looking at morbidity data from nine European countries.[124] Severe maternal morbidity was defined using criteria based on three common causes of morbidity of pregnancy: severe haemorrhage, pre-eclampsia (including eclampsia and HELLP), and sepsis. Data were gathered prospectively for the majority of cases; however, French data were retrospective. Overall differences between countries were mainly attributed to differences in haemorrhage data, which ranged from 8.8/1000 deliveries in Finland to 0.7/1000 deliveries in Austria. This was thought to reflect differences in the age of the women giving birth and in the care that was provided. It was noted that around 25% of women with severe maternal morbidity were admitted to ICU, with a great variation in regions (e.g. 25% admission rates in some regions (Belgium, France, Italy, and the United Kingdom), and 50% in others (e.g. Austria)). The conclusions were that using standardized definitions and a population-based approach, severe maternal morbidity was more common than previously thought and ICU admission was not a good surrogate marker.[124]

**Table 31.2** Inclusion criteria of organ dysfunction from WHO 'near-miss' assessment of severe maternal morbidity

| Organ dysfunction | Criteria |
|---|---|
| Cardiovascular | Shock |
| | Cardiac arrest |
| | Severe hypoperfusion (lactate > 5 mmol/L or > 45 mg/dL) |
| | Severe acidosis (pH < 7.1) |
| | Use of continuous vasoactive drugs |
| Respiratory | Acute cyanosis |
| | Gasping |
| | Severe tachypnoea (respiratory rate > 40 breaths/min) |
| | Severe bradypnoea (respiratory rate < 6 breaths/min) |
| | Severe hypoxaemia ($O_2$ saturation < 90% for ≥ 60min or $PAO_2/FIO_2$ < 200) |
| | Intubation and ventilation not related to anaesthesia |
| Renal | Oliguria non responsive to fluids or diuretics |
| | Severe acute azotaemia (creatinine > 300 µmol/ml or > 3.5 mg/dL) |
| | Dialysis for acute kidney injury |
| Coagulation/ haematological | Failure to form clots |
| | Severe acute thrombocytopenia (<50 × $10^6$/L) |
| | Massive transfusion of blood or red cells (≥5 units) |
| Hepatic | Jaundice in the presence of pre-eclampsia |
| | Severe acute hyperbilirubinaemia (bilirubin > 100 µmol/L or > 6.0 mg/dL) |
| Neurological | Prolonged unconsciousness or coma (lasting > 12 h) |
| | Stroke |
| | Uncontrollable fit/status epilepticus |
| | Global paralysis |
| Uterine | Hysterectomy due to uterine infection or haemorrhage |

Data from Cecatti JG, Souza JP, Oliveira Neto AF, *et al.*, Pre-validation of the WHO organ dysfunction based criteria for identification of maternal near miss. *Reprod Health* 2011; 8:22–29, Copyright © 2011 Springer Science+Business Media.

#### English Audit of ICU admissions

Hazelgrove et al. conducted a multicentre study involving 14 ICUs in Southern England.[125] Retrospective analysis was performed over a 2-year period from 1994 to 1996. Data revealed that 1.84% of admissions to ICUs during the period were from pregnant or postpartum patients. The majority of admissions were due to complications of postpartum haemorrhage (33.3%) and hypertensive disorders of pregnancy (39.5%); the overall mortality rate in these patients was 3.3%, and 35.7% of patients had an ICU stay

shorter than 2 days. The study concluded that obstetric admissions required minimal interventions and had low associated mortality rates.[125]

### *Ongoing surveillance studies*

#### ICNARC Case Mix Programme

The Intensive Care National Audit and Research Centre (ICNARC) was established in 1994 and established a system that identifies key indicators in the management of adults who require critical care management.[126] It involves voluntary data collection from currently 82% of ICUs in England, Wales, and Northern Ireland. In 2006, the Royal College of Anaesthetists, Royal College of Obstetricians and Gynaecologists, and Obstetric Anaesthetists' Association jointly commissioned ICNARC to include new fields into its electronic data collection form to include 'currently pregnant' and 'recently pregnant'. The first report was produced in 2009 and reviewed data from 2007 on level 3 obstetric critical care admissions.[127] The incidence of such patients admitted to critical care areas was 260 per 100,000 maternities, higher than the deaths for that period noted from the CEMD (13.95/100,000).[10] During 2007, obstetric patients represented of 11.4% of ICU admissions in females aged 16–50 years. Of these, 18.5% were classified as 'currently pregnant' and 81.5% as 'recently pregnant'. The majority (86%) of 'currently pregnant' women were admitted with non-obstetric related problems, the most common of these (20%) being pneumonia. In the 'recently pregnant' group, most patients (61%) were admitted secondary to obstetric reasons, most commonly (34%) postpartum haemorrhage. The 'recently pregnant' and 'currently pregnant' patients had a much lower critical care unit mortality compared with age-matched controls (2% vs 11%, respectively) and overall in-hospital admission (8 days vs 11 days, respectively).

#### Scottish Confidential Audit of Severe Maternal Morbidity

In Scotland, an audit of specified severe maternal morbidities has been running in all consultant (attending) led maternity units since 2003, covering a population of around 60,000 births per annum. Data collection is entirely voluntary, but it is hoped that most of the data available is collected. A designated coordinator within each unit identifies cases and sends completed datasets to the Reproductive Health Programme of NHS Quality Improvement Scotland. The data are then analysed and an annual report is produced. Collated morbidity data are based on work originally conducted in South Africa,[113] which looked at 14 variables associated with morbidity including major haemorrhage, eclampsia, renal/liver dysfunction, cardiac arrest, pulmonary oedema, respiratory dysfunction, coma, cerebrovascular disease, status epilepticus, anaphylaxis, septic shock, anaesthetic problems, pulmonary embolism, and ICU/coronary care unit admission (additional information on interventional radiology has also been collected from January 2010). Two particular areas of interest are major obstetric haemorrhage and eclampsia. Detailed information for each case of major haemorrhage and eclampsia are gathered and discussed by risk management teams locally. Following analysis, reports are sent to the Reproductive Health Programme. There is a lag time of around 2 years from collection of data to production of reports.[128] The consistent use of the same auditing tools and case definitions have allowed the identification of changes in numbers and rates of certain morbidities, compliance with national guidelines and changes in clinical management. The Scottish Confidential Audit of Severe Maternal Morbidity (SCASMM) has also disseminated information through anecdotal vignettes and produced data on clinical use of resources within Scotland. From January 2009, SCASMM has also collected sociodemographic data. This has revealed that deprivation, obesity, smoking, and substance misuse are all factors linked with increased maternal morbidity.

Figure 31.11 shows SCASMM data for 2006–2008.[128–130] Comparisons between Figure 31.11 and Figure 31.2 shows how morbidity and mortality data vary for presumably similar populations receiving similar levels of care—albeit with the SCASMM population forming part of the population covered by the CEMD data. Such comparisons demonstrate how studies of morbidity can complement those of mortality, and the difference between conditions that are common but rarely fatal, and those that are rare but with a high mortality rate.

Exploration of two particular conditions, haemorrhage and eclampsia, illustrates how the data from SCASMM can be used.

*SCASMM Haemorrhage Data*

The collection of morbidity data for the audit allows review of all cases of massive haemorrhage, ideally at the local level to

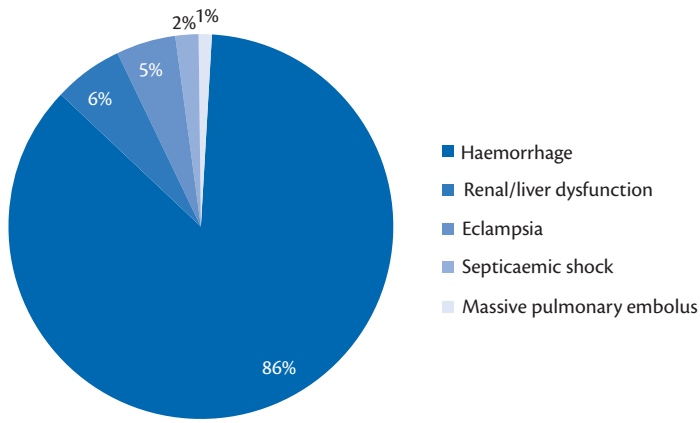

**Figure 31.11** (See colour figure section). Causes of maternal morbidity (as a percentage of total) from Scottish Confidential Audit of Severe Maternal Morbidity: 2006–2008.

Data from various sources (see references).[129–31]

assess whether local guidelines are being followed. Data can be obtained on exact medical therapy given and surgical interventions received, including interventional radiological procedures. During the period 2006–2008, risk factors for massive obstetric haemorrhage included previous caesarean delivery (16%) and delivery by emergency caesarean delivery (46%), with 21% of those emergency caesarean deliveries taking place at full dilatation. There was an increase in conservative surgical techniques (intrauterine balloon tamponade and uterine brace sutures). The standard of care was assessed as being high in 64% of cases, but direct obstetric consultant involvement only occurred in 78%, thought to reflect the number of massive obstetric haemorrhage cases occurring out of hours.[128–130]

*SCASMM eclampsia data*

The reported incidence of eclampsia has stayed relatively constant during 2006–2008: in 2008 the rate of admission to ICU for eclampsia was 1.5/1000 live births. It was noted that few of the cases presented with classical prodromal signs and symptoms. Appropriate care was assessed as being present in only 41% of cases, with a consultant obstetrician present in fewer than half. Recommendations for protocol-driven pathways and senior early involvement were made.[128–130]

**South Africa Audit of Severe Maternal Morbidity**

In the Pretorian region of South Africa, four hospitals combine to form the Pretoria Academic Complex. They have performed audits looking at severe acute maternal morbidity since 1997,[113,131] with morbidity and maternal deaths identified at daily audit meetings using specific organ dysfunction criteria to define 'near-misses'. Since 2006, data have been recorded electronically using the MaMMAS software developed by the local research team.[132] The audits over the years highlighted that severe complications of obstetric haemorrhage, hypertension in pregnancy, non-pregnancy related sepsis, and pregnancy-related sepsis are increasing. The increase in prevalence of HIV-infected pregnant women is known to be the cause of increased non-pregnancy sepsis.[133] However, the increase in severe complications due to obstetric haemorrhage and hypertension was a cause for concern, leading to the implementation of new guidelines for managing obstetric haemorrhage and hypertension in all maternity facilities within the Pretoria Academic Complex.

**Brazilian Audit of Severe Maternal Morbidity**

In 2009, Brazil set up a multicentre, cross-sectional study in 27 obstetric units in different geographical regions.[121,134,135] The population of the cross-sectional component consists of women surviving either potentially life-threatening conditions (severe maternal complications) or life-threatening conditions (the maternal near-miss criteria) and maternal deaths. The definitions used are in accordance with the new WHO definition and criteria. A study to validate the WHO definition of a 'near-miss' was conducted and revealed that maternal near-miss criteria were associated with maternal deaths (positive likelihood ratio 106.8 (95% confidence interval (CI) 99.56–114.6)). In the same study a maternal severity index (MSI) model was also developed and found to be able to describe the relationship between life-threatening conditions and mortality (area under the ROC curve: 0.95 (95% CI 0.91–0.99)).[120]

**Canadian Perinatal Surveillance System**

The CPSS has collected yearly morbidity data since 1995.[103] Morbidity data are extracted from the Canadian Institute for Health Information and the Discharge Abstract Database from inpatient hospital admissions. A panel from the Maternal Health Study Group selects specific conditions deemed indicative of severe maternal morbidity including eclampsia, pulmonary oedema, and severe obstetric haemorrhage requiring blood transfusion.[92] Of note, the audit has revealed that the majority of maternal morbidity in Canada occurs in previously healthy women and that having a pre-existing co-morbidity did not increase the likelihood of developing severe maternal morbidity.[136]

### *Surveillance of rare events*

**UKOSS**

The UK Obstetric Surveillance System (UKOSS) was established in 2005 to study rare disorders of pregnancy, based on a successful paediatric surveillance system that has been running in the United Kingdom for over 25 years. Reporters (anaesthetists, midwives, and obstetricians) in all consultant-led maternity units within the United Kingdom are contacted monthly to indicate on a card the number of women who have any of the morbidity conditions under study. If there are no cases the units are requested to confirm this as a 'nil report', hence UKOSS provides an active negative surveillance system. This allows exact numbers to be obtained and produces the denominator population to allow calculation of disease incidences.[137] As with the CEMD, clinicians are sent data collection forms for further details when a case is identified. Details on control patients are also requested.

The UKOSS programme has led to the publication of several reports including on peripartum hysterectomy,[138] eclampsia,[139,140] acute fatty liver,[141] antenatal pulmonary embolism,[141] tuberculosis,[143] gastroschisis, extreme obesity,[66,144] therapies for peripartum haemorrhage,[145] multiple repeat caesarean delivery,[146] pregnancy in renal transplant recipients,[147] myocardial infarction,[148] uterine rupture,[149] risk factors for progression from severe maternal morbidity to death,[150] and H1N1 influenza in pregnancy.[151–154] Ongoing topics at the time of writing include adrenal tumours in pregnancy, AFE,[76,155] anaphylaxis in pregnancy, cardiac arrest in pregnancy, massive transfusion in major obstetric haemorrhage, pituitary tumours, stage 5 chronic kidney disease, advanced maternal age and pregnancy outcomes in women with artificial heart valves.[156]

**Amniotic Fluid Embolism Registry**

The original AFE registry was established in the United States by Clarke[157] and a similar registry based in the United Kingdom was set up in 1996 by Tuffnell.[158] This project was incorporated into the UKOSS study of AFE. The incidence of AFE thought to be around 2/100,000 deliveries.[76]

**Obstetric Anaesthetists' Association UK Registry**

This project ran from 1996 to 2003 collecting data voluntarily reported on women who had severe co-morbidities requiring anaesthetic input. Cardiorespiratory disease was the initial topic studied, with a smaller report on neurological disease following.[71,94,106] The project was subsequently superseded by UKOSS.

## Common themes in maternal mortality and morbidity studies

Some common themes arise out of the mortality and morbidity studies and surveillance systems outlined above, that have relevance to every health system. Some have particular relevance to obstetric anaesthetists:

### Resources

A lack of adequate numbers of trained staff and essential equipment and drugs is a common theme in developing countries,[10,11,14] and attempts to improve this is a constant priority of all programmes to improve maternal health worldwide.[10,11,14,16,49] Such attempts are considerably hampered where there is poor underlying infrastructure, both locally (e.g. communication networks, availability of blood products, and intensive care facilities) and nationally. The diversion of resources away from public health issues in favour of other programmes (e.g. arms development) may also be a problem in some countries. Concerns about resources and their allocation are also increasingly common in developed countries in the current economic climate, albeit at a different level. Recent events in Mid-Staffordshire in the United Kingdom have highlighted the hazards of putting financially-based targets above basic patient care, and although not focusing on maternity care, obstetric anaesthetists will recognize the concerns raised in the aftermath of the final report.[159,160]

### Training/education

A lack of knowledge and skill in healthcare staff is one of the leading potentially avoidable causes for poor management leading to morbidity and ultimately to mortality.[10,11] Remedies include the institution and maintenance of proper training programmes, especially in developing countries, with education of the women themselves as well as all staff who may come into contact with pregnant women, and those responsible for managing services. A lack of resources for effective training and education is a particular problem, and increasingly one that is not confined to developing countries.

Simulation is increasingly accepted as an important tool in medical/paramedical training and its use in obstetrics has been highlighted (and indeed, recommended) in recent CEMD reports. Training programmes based on simulation are often expensive in terms of equipment and staff, though it is likely that their uptake will continue to increase in developed countries.

### Antenatal screening/referral

Many of the reports on morbidity and mortality throughout the world define at-risk groups during (or before) pregnancy, and stress the importance of identifying these groups in advance. For example, in response to the high number of maternal deaths in immigrants in the 2003–2005 CEMD report who were late or non-attenders for antenatal care and subsequently presented late to delivery suites with serious co-morbidities, the report recommended that all immigrants should be screened with a full medical history and examination at booking or as soon as possible after.[65] Similarly, routine antenatal screening for psychiatric problems was improved throughout the United Kingdom following the 2000–2002 CEMD report,[77] and the importance of detecting antenatal anaemia has been noted by several reports.[27,42,161–165] Indeed, the provision of good antenatal care is one of the aims highlighted in programmes to improve maternal mortality in developing countries, as noted above.[11]

A particular area of antenatal care of relevance to anaesthetists is the appropriate referral of women for anaesthetic assessment, either early in pregnancy in known high-risk cases, later in pregnancy when complications occur, or pre-delivery in women who become acutely unwell. This problem is not limited to anaesthesia: the CEMD reports repeatedly comment on late or absent involvement of specialists, especially of adequate seniority, in the care of high-risk parturients.[10,11] In some cases, failure to obtain early referral occurs at community level (e.g. the general practitioner), or even with the woman herself; in the 2006–2008 CEMD report, 41 of the women who died had no antenatal care, of whom the majority were late bookers or poor attenders for care and six had concealed pregnancies.[10]

The same concerns apply to pre-conception counselling and support for women with known significant co-morbidities.

### Recognition of severe illness

When pregnant women, especially those who are healthy beforehand, deteriorate, it may be difficult to detect this, since their compensatory mechanisms often maintain basic observations such as blood pressure and pulse rate until a very rapid decline. This is consistently highlighted in the various mortality and morbidity reports, and has led to the interest in early warning scores in maternity care, as recommended by recent CEMD reports.[10,11,68,70,166,167]

### Human factors

The place of human factors in acute medicine, both as an important factor in adverse outcomes and as a focus for training,[168,169] is now well established, and the environment of maternity care is one where such factors are particularly pertinent, with several disciplines working together and the mother (and partner/family) supposedly at the centre of her care.[170] A common and consistent theme in mortality and morbidity reports is of poor team working, with inadequate communication between staff of different disciplines, and between staff and patients, absent or late involvement of senior help, insufficient use of protocols and guidelines to guide care (especially for rare disorders or emergencies), and a general absence of a risk management culture. In the United Kingdom, increased emphasis on such factors over the last decade, the use of simulator training (especially multidisciplinary)[10,11] and the use of financial incentives such as provided by the Clinical Negligence Scheme for Trusts (whereby premiums paid by hospital trusts are reduced if there are appropriate aspects of good risk management in place) has raised awareness of these issues.[171] In developing countries some of these initiatives may be seen as luxuries; however, even simple ones such as the WHO surgical safety checklist may improve outcomes.[172,173]

## Conclusion

The death of a parturient is a catastrophe for the family she leaves behind and a hugely stressful event for the local healthcare team. This impact should not be lost when viewing regional, national,

or global figures, when such an event may be merely one of many. Investigating and monitoring maternal mortality and morbidity beyond analysis of individual cases locally requires great effort and both financial and political commitment, but few, if anyone, involved in maternity care would doubt its importance. The fact that maternity care is often seen as a surrogate for the provision of healthcare in general reinforces the need to continue to support all initiatives that aim to improve the health of pregnant women. Anaesthetists have been central to achieving enormous improvements in maternal outcomes as charted by the CEMD reports, and continue to have a central role in maintaining this improvement despite increasing challenges locally/regionally, as well as assisting other disciplines and those in other healthcare systems around the world.

# CHAPTER 32

# Problems in early pregnancy

W. Colin Duncan

## Normal pregnancy

### The establishment of pregnancy: basic physiology

After menstruation, the follicular phase of the ovarian cycle is associated with growth and selection of a dominant follicle and increasing oestradiol secretion. High oestradiol, signifying a mature follicle, induces a luteinizing hormone (LH) surge that causes ovulation. After ovulation the cells of the dominant follicle form the corpus luteum (CL) that produces large amount of progesterone. Progesterone prepares the endometrial lining to support a pregnancy and promotes uterine quiescence. The CL has a limited lifespan and will lose its functional and structural integrity in a process known as luteolysis after 14 days.[1] It is this loss of progesterone support that induces menstruation.

*A woman ovulates 2 weeks before her menstrual period. If her cycle is 28 days in duration she will ovulate on day 14, and if she has a regular 35-day cycle she will ovulate on day 21.*

Shortly after ovulation the oocyte enters the Fallopian tube where fertilization occurs. The embryo will continue to the uterine cavity where implantation occurs approximately 7 days after ovulation.[2] The implanting blastocyst secretes rapidly increasing amounts of human chorionic gonadotropin (hCG). It can be detected in the urine in sensitive pregnancy tests 1 or 2 days before the expected date of menstruation. Exponentially increasing hCG acts on the CL to rescue it from luteolysis to maintain progesterone secretion, prevent menstruation, and support the early conceptus. The CL supports the pregnancy for approximately 8 weeks when the early placental tissue becomes the main source of progesterone support.[3]

*In the first few weeks of pregnancy, serum concentrations of hCG will normally double every 48 hours.*

It is relatively common for positive pregnancy tests to occur around the time of the expected period but for menstruation to occur as expected or 1 or 2 days later. This transiently positive hCG is a result of pregnancy failure during the early stages of implantation and it is known as a biochemical pregnancy. This is one of the pitfalls of carrying out pregnancy testing prior to the anticipated date of menstruation. More commonly women delay taking a pregnancy test after a missed period. This is because women have premenstrual symptoms in the early stages of pregnancy and may believe that menstruation is about to occur.

### Key points in normal development

*The gestational age is calculated from the last menstrual period (LMP) rather than the time of conception.*

When a patient is 6 weeks pregnant, they have conceived 4 weeks previously. This is important as it sometimes causes the patient some confusion as it assumes a 28-day cycle. If a woman has a 35-day cycle 7 weeks after her LMP she may only be 6 weeks pregnant based on the size of the fetus.

A transvaginal ultrasound scan (TVS) can detect an early gestational sac, the first sign of pregnancy, around 5 weeks' gestation. A few days later, a round yolk sac can be seen within the gestational sac and the embryonic fetus, which is associated with the yolk sac, can be identified after 5.5 weeks' gestation (Figure 32.1). The heartbeat may be visible as early as 6 weeks' gestation. As there is a time when the pregnancy test is positive but no definitive gestational sac can be seen in the uterus, a 'discriminatory zone' has been defined.[4] This is the concentration of serum hCG that should be associated with scan evidence of an intrauterine pregnancy.

*A normal pregnancy with serum hCG concentrations of greater than 1500 IU/L should be able to be confirmed as intrauterine on ultrasound scan.*

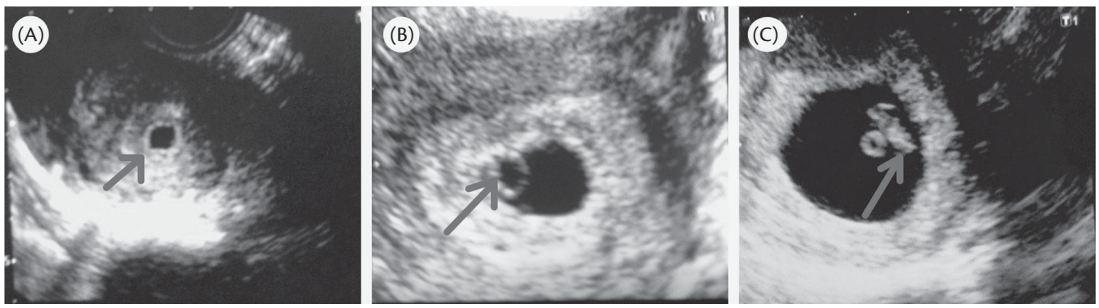

**Figure 32.1** Intrauterine scan findings in a normal pregnancy. (A) Early pregnancy sac at 5 weeks' gestation (arrow). (B) Before 6 weeks' gestation the yolk sac is visible (arrow). (C) Pregnancy at 7 weeks' gestation with yolk sac and fetal pole (arrow).

### Assisted reproduction and pregnancy

Infertility affects one in seven couples in the United Kingdom[5] and the number of pregnancies that result from assisted conception is increasing. In the United Kingdom, approximately 1.5% of births are a result of *in vitro* fertilization (IVF) while in Denmark it is three times higher.[6] As the length of ovarian stimulation and timing of embryo transfer varies, the gestation should be calculated as 2 weeks more than the date of oocyte collection, which corresponds to ovulation in a natural cycle. It is more complicated after frozen embryo replacement or egg donation. Generally the timing of 'ovulation', for gestational calculation, will be between 2 and 5 days before transfer.

During assisted conception, the ability of the CL to produce normal levels of progesterone may be impaired. That means that women will usually take progesterone supplementation in the form of vaginal pessaries twice daily.[7] The highly vascular CL secretes angiogenic and vascular permeability molecules such as vascular endothelial growth factor.[1] After IVF there are multiple CL and the markedly increased capillary permeability can cause loss of fluid from the vascular space. Ovarian hyperstimulation syndrome occurs in 2–4% of IVF cycles with ascites, pleural effusions, and hypercoagulability and, as hCG stimulates CL, it worsens in early pregnancy. Management involves heparin thromboprophylaxis, intravenous volume expansion, and consideration of paracentesis.[8]

## Assessment of early pregnancy

### The diagnostic tools

Early pregnancy problems can present in disparate ways to multiple health professionals when a woman is unaware of her pregnancy. There should be a high suspicion of the possibility of pregnancy in all women of reproductive age and a low threshold for urinary pregnancy testing. Increased awareness of ectopic pregnancy (EP) in women and healthcare providers is associated with earlier and more accurate diagnosis and timely management.[4,9]

*The greatest assessment tool is the awareness of the possibility of pregnancy and knowledge of early pregnancy problems.*

Similarly, an awareness that acute medical, gynaecological, or surgical conditions not related to pregnancy, such as urinary tract infection, ovarian torsion, or appendicitis, may also occur in pregnancy is also essential. It is fundamentally important to assess the woman clinically and not to rely entirely on the results of investigations to manage the patient. For example, ruptured ectopic pregnancies can occur when there is a negative pregnancy test,[10] or very low levels of hCG, and in acute situations delaying management to facilitate ultrasound scanning may adversely affect outcomes.

*The possibility of an ongoing intrauterine pregnancy should not preclude clinically necessary investigations, such as a chest X-ray or diagnostic laparoscopy.*

A pelvic ultrasound scan is the mainstay in the assessment of early pregnancy problems (Figure 32.1). It allows systematic assessment of uterine abnormalities, intrauterine contents, ovarian cysts, adnexal masses, and free fluid in the pelvis.[11] While transvaginal ultrasonography is the gold standard for early pregnancy assessment, transabdominal scanning may also be appropriate and is particularly useful where there is pelvic pathology such as fibroids and large ovarian cysts.[9] The other key investigative tool is the measurement of serum hCG concentrations. Quantification of hCG is required in the assessment of pregnancies of unknown location, ectopic pregnancies, or suspected gestational trophoblastic disease.

*Serum hCG assessment is not useful in the diagnosis of viability when it is known that the pregnancy is intrauterine in location.*

## Problems in early pregnancy

### Early pregnancy assessment units

The mainstay of the investigation and management of problems in early pregnancy is a dedicated outpatient early pregnancy assessment unit (EPAU). This provides a comprehensive service that improves and streamlines care and reduces the need for admission to hospital. The dedicated staff ensure sensitive discussion and empowers women to make informed decisions about their care and treatment. Many EPAUs offer a 7-day service with direct patient access through a self-referral appointment system.

Women generally attend the EPAU with vaginal bleeding and/or lower abdominal pain that may be central or unilateral in nature. They may present with altered pregnancy symptoms, such as loss of breast tenderness or excessive vomiting. In addition, some women are routinely seen because of a past history of recurrent miscarriage or EP. After clinical assessment, the most appropriate investigation is often a pelvic ultrasound scan.

### Ongoing pregnancy

Ultrasonography may reveal an ongoing pregnancy with an intrauterine gestational sac with a yolk sac and fetal pole with fetal heart motion (Figure 32.1). Further scans are not indicated unless the bleeding worsens or persists for more than 14 days.[9] One in three women will experience per vaginal (PV) bleeding in early pregnancy. As around 60% of women with light bleeding will have an ongoing pregnancy[12] women are often initially reassured by the EPAU staff and advised to observe the bleeding for 24 hours.

The CL is maintained in early pregnancy and this may result in an enlarged or cystic ovary on the side of ovulation that may cause unilateral pain, particularly at the time of the luteo-placental shift when it begins to regress. In addition, as the CL causes increased vascular permeability, there is often a small accumulation of fluid in the pelvis that can be detected by ultrasonography. As luteal cysts are transient, and are required to maintain pregnancy, their management is usually conservative in the clinically stable patient.

*It is not uncommon for women to experience bleeding or unilateral abdominal pain in a normal ongoing pregnancy.*

Adjacent to an ongoing pregnancy there may be a haematoma or a second sac that represents a non-viable twin gestation. The patient would be expected to experience further PV bleeding as the abnormality resolves. There is no good management strategy that can be used in a threatened miscarriage to reduce the risk of subsequent miscarriage. While both rest and progesterone supplementation can reduce the amount of bleeding there is no good quality evidence from adequately powered trials that they change the outcome of the pregnancy.[13,14] However, there is widespread use of progesterone supplementation internationally and in the United Kingdom there is an increasing expectation among patients for progesterone supplementation to be prescribed and its use is becoming more common.[9]

*There is an unmet need for the safety and efficacy of this progesterone supplementation to prevent miscarriage to be robustly assessed.*

Although the pregnancy is ongoing, there may be concerns about the scan findings. There may be a mismatch of the gestational sac and fetal size, a slow or irregular fetal heart rate, an irregular gestational sac, or the presence of cystic areas or 'bumps' associated with the developing placenta.[15,16] These may increase the chance of future miscarriage and management usually involves a repeat ultrasound scan.

*A further ultrasound scan, where required, should routinely be arranged at least 1 week from the previous scan.*

## Miscarriage

Miscarriage is common, occurring in 10–20% of clinical pregnancies, with the risk increasing as a woman ages. Before the age of 30, one in ten pregnancies will end in miscarriage while at the age of 35, the change of miscarriage is 20%. This has increased to approximately 40% at the age of 40 and in women over the age of 45, 80% of pregnancies miscarry.[17]

Women usually present with PV bleeding that is often associated with cramping lower abdominal pain, which is usually central but may be unilateral and radiate to the back. Miscarriage can be diagnosed on clinical assessment when confirmed products of conception have been passed or the cervical os is open on vaginal examination (VE). It is striking, however, how much a woman can bleed and continue to have a viable pregnancy. Tissue trapped in the cervix during miscarriage can cause cervical shock and resuscitation involves VE and removal of tissue from the cervix. Cervical shock is due to dilatation of the cervix and an autonomic response resulting in bradycardia and hypotension, common with dilatation of many organs with smooth muscle (e.g. anus and oesophagus). Apart from the surgical treatment, resuscitation may require oxygen, fluids, glycopyrrolate, and vasopressors. General anaesthesia is performed as neuraxial anaesthesia is contraindicated in the face of sympathetic block.

A single ultrasound scan can diagnose miscarriage if there is irregular pregnancy tissue within the cavity consistent with retained products of conception. The diagnosis of miscarriage on one scan where there is an intrauterine gestation sac depends on rigorous criteria with clear national guidelines.[9,18] This is because of the variability of scan measurements between observers[19] and the absolute necessity to ensure that a viable pregnancy is not misdiagnosed[20] (Box 32.1).

Once a miscarriage is diagnosed there are three main management options with regards to pregnancy tissue that remains within the uterine cavity. The first is expectant management and in around 40% of cases a complete miscarriage will occur within 7 days.[18] Miscarriage can take much longer when the pregnancy sac is intact and it may be useful to review the patient after 14 days if the miscarriage has not occurred. After miscarriage it is not necessary to repeat the ultrasound scan to confirm completion if the pain and bleeding resolve normally. Women, however, may be advised to take a urinary pregnancy test after 3 weeks and return if it is positive.

*There is no evidence that expectant management is associated with an increased risk of infection or adverse effects on future fertility.*

The second strategy is medical management using single-dose vaginal or sublingual administration of the prostaglandin E analogue misoprostol.[18] This is increasingly used in an outpatient setting to allow the miscarriage to complete at home with review or repeat the following day if PV bleeding has not started. There may be a role for repeated misoprostol and/or pre-treatment with the progesterone antagonist mifepristone and this is popular in some units.[21] The side effects include pain, vomiting, and diarrhoea and women are routinely provided with pain relief and antiemetics. The success rate for completion of miscarriage varies from study to study but it is generally over 80% although bleeding may persist for up to 21 days.[18] Like expectant management there is no need for routine scan follow-up although a post miscarriage pregnancy test is recommended.[9]

The third option is surgical management of miscarriage and this is preferred if women favour that option, or if there is persistent excessive bleeding or haemodynamic instability. It can be done by manual vacuum aspiration under local anaesthetic in an outpatient clinic setting but more commonly it is done as a day case in theatre under general anaesthesia.[22] Vaginal or sublingual misoprostol is frequently used to ripen the cervix to facilitate cervical dilatation for suction curette insertion and reduce the risk of trauma and haemorrhage.[18] Women may continue to bleed for up to 2 weeks after surgical management of miscarriage. In the absence of reflux, women usually have a short general anaesthetic for this with propofol and a laryngeal mask plus a short-acting opiate and antiemetic. If there is reflux, a rapid sequence induction with endotracheal tube is required.

There is an increased incidence of infection after surgical management and there should be a low threshold for antibiotic use if there is increasing pain, bleeding, and discharge after the procedure. There is not enough evidence to suggest routine antibiotic prophylaxis is beneficial but the clinical indications for antibiotics should be reviewed in each case and routine screening for *Chlamydia trachomatis* should be considered.[18]

*In the presence of sepsis, delaying the procedure for 12 hours to allow intravenous antibiotic initiation is recommended if the patient is stable.*

In addition to infection, the risks associated with surgical evacuation of the uterus include significant haemorrhage during or

**Box 32.1** The diagnosis of miscarriage

**Transvaginal scan shows fetal pole with no identifiable heartbeat**

- If the crown–rump measurement is ≥7 mm, and a second observer has confirmed this measurement, a miscarriage can be diagnosed.
- If the measurement is <7 mm, a second scan is required a minimum of 7 days after the first to make the diagnosis.

**Transvaginal scan VS shows gestational sac with no fetal pole**

- If the mean gestational sac diameter is <25 mm, a second scan is required a minimum of 7 days later.
- If the mean diameter is ≥25 mm, a miscarriage can be diagnosed after a second opinion on the scan.
- A third scan may be required if there is significant change before a definitive diagnosis can be made.

immediately after the procedure. Although in the first trimester of pregnancy the oxytocin responsiveness of the uterus is poor there is a role for bolus oxytocin as well as bimanual compression in the management of haemorrhage.[23] Another immediate risk is uterine perforation, with an incidence of 1/1000, which is usually recognized immediately and often requires laparoscopic assessment because of the risk of intraperitoneal bleeding. The risk of Asherman's syndrome, associated with intrauterine adhesions and subsequent amenorrhoea and infertility,[24] is difficult to quantify although it occurs more frequently than perforation.

*Miscarriage can be a very distressing experience and the psychological impact, sense of bereavement, and feelings of depression and anxiety should not be underestimated.*

In the United Kingdom, the Association of Early Pregnancy Units and the Miscarriage Association have championed a change in the key terminology of miscarriage. It is now recommended that 'miscarriage' is used rather than 'spontaneous abortion' and that 'surgical management of miscarriage' is preferred to 'evacuation of retained products of conception'.

*Women should be reassured that after a miscarriage they are not at increased risk of miscarriage in subsequent pregnancies.*

## Recurrent miscarriage

While most miscarriage is sporadic and associated with genetic or structural defects, some couples, however, do experience recurrent miscarriage. Recurrent miscarriage is defined as the loss of three or more consecutive pregnancies and it affects 1% of couples.[17] As this is greater than would be expected by chance there must be factors increasing the likelihood of miscarriage in some of these couples. After three consecutive losses the chance of subsequent miscarriage is increased to approximately 40%.

Advancing age is a risk factor for recurrent miscarriage, as both maternal and paternal age increase the chance of miscarriage, as does obesity. There is an association with antiphospholipid syndrome and investigation of recurrent miscarriage should involve testing for inherited and acquired thrombophilias[25] as aspirin and low-dose heparin can reduce the miscarriage rate by 50% in these cases. Parental or fetal karyotyping can identify balanced translocations that may suggest preimplantation genetic diagnosis or gamete donation. The uterine structure is assessed as congenital uterine abnormalities, including uterine septum and cervical weakness, may be amenable to surgery.

*Although treatment with progesterone, corticosteroids, or metformin has been advocated, and randomized studied are underway, there is insufficient evidence to recommend their use at present.*

Most couples, however, have unexplained recurrent miscarriage and although empirical treatment has not been shown to be effective, their prognosis for a good outcome in future pregnancy is excellent.[17] The value of psychological support and serial ultrasound scans during pregnancy in recurrent miscarriage has been demonstrated in several non-randomized studies although the mechanism is unclear.[26]

## Ectopic pregnancy

One of the primary roles of EPAUs is the timely diagnosis and management of EP. Approximately 1 in every 80 pregnancies and 4% of cases seen in the EPAU is an EP, occurring when the blastocyst implants outside the normal uterine cavity, generally in the Fallopian tube. In the United Kingdom, EP is the leading cause of maternal mortality in the first trimester because of its association with tubal rupture and massive intraperitoneal haemorrhage (Figure 32.2). The chance of dying of an EP is 1 in 3000[4] and 9% of deaths directly related to pregnancy are a result of EP.[27]

There is a long list of factors that are associated with an increased risk of EP.[4] These may cause adhesions around or affect the structure and/or function of the Fallopian tube (Box 32.2). These should be considered along with symptoms in the appraisal of the risk of EP and the need for urgent clinical assessment.[28]

*There is a fourfold risk of EP in heavy smokers and in those conceiving during IVF treatment.*

*More than half of women diagnosed with an EP do not have identifiable risk factors or evidence of pre-existing tubal damage.*

Some women present acutely in early pregnancy with shock, pallor, abdominal pain associated with rebound, cervical excitation on VE, and referred pain to the shoulders, and the clinical diagnosis facilitates timely surgery. The diagnosis is clear when a woman presents. Such an acute presentation is unusual and one-third of patients with an EP have no clinical signs and up to 10% have no symptoms. The classical symptoms of EP are unilateral abdominal pain associated with PV bleeding presenting between 5 and

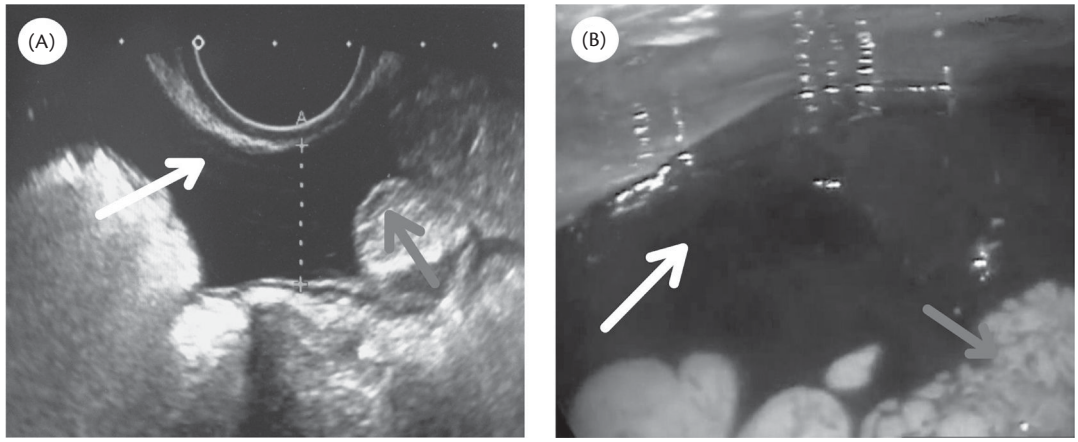

**Figure 32.2** Haemoperitoneum in ruptured ectopic pregnancy. (A) Transvaginal scan and (B) laparoscopy of ruptured actopic pregnancy showing intraperitoneal blood (white arrows) surrounding the bowel/omentum (black arrows).

**Box 32.2** Risk factors for ectopic pregnancy

**Prior Fallopian tube damage with scarring**

- Past pelvic inflammatory disease
- Past chlamydia/gonorrhoea
- Previous appendicitis or abdominal surgery
- Previous pelvic surgery
- Documented tubal disease or tubal surgery
- Endometriosis
- Sterilization and reversal of sterilization.

**Functional alterations in the Fallopian tube**

- Smoking
- Age over 35
- Hormonal contraceptive failure.

**Additional risk factors**

- Infertility
- Infertility treatment including IVF
- Previous ectopic pregnancy
- Conception with intrauterine contraceptive device in place.

8 weeks of gestation although gastrointestinal upset and central cramping pain are common.

*Most women with symptoms of an EP will not have an EP.*

A TVS showing an empty uterus with an adnexal mass has a sensitivity of 90% and specificity of 95% in the diagnosis of EP.[29] Typically the adnexal mass is separate from, medial, and superior to the ovary (Figure 32.3), usually on the same side as the CL, and may contain a small gestational sac surrounded by a hyperechoic ring. Free fluid, particularly when it surrounds the ovary, is suggestive of intraperitoneal bleeding.[30] One of the pitfalls is the presence of an intrauterine pseudo-sac in some EPs that mimics a gestational sac although it is transient, midline rather than eccentric, and is not surrounded by a hyperechoic decidual reaction.

However, in up to 50% of women with an EP the diagnosis is not made on first attendance and they are labelled as having a pregnancy of unknown location (PUL). The 2006–08 Centre for Maternal and Child Enquiries (CMACE) report into maternal deaths highlighted that PUL is not a diagnosis and every PUL is a potential EP.[27]

*The mainstay of investigation of a PUL is measurement of serum hCG concentrations that is repeated 48 hours later.*

If the hCG rises by more than 63% it is likely that there is a developing intrauterine pregnancy although an EP has not been excluded and emergency contact details are provided should her symptoms deteriorate.[9] An ultrasound should be arranged in 7 to 14 days' time, or earlier if symptoms worsen or continue and a predicted doubling of hCG every 2 days would predict a level of 1500 IU/L or higher. A decline in hCG by more than 20% suggests a spontaneous miscarriage although as an EP has not been excluded, further serial monitoring of hCG concentrations are often required.[4] If the fall is greater than 50%, then all that may be required is a urinary pregnancy test 2 weeks later.[9]

In a tubal EP, serial hCG patterns are variable although usually they rise at a slower rate than a viable intrauterine pregnancy or fall slower than a complete miscarriage. Often more than two hCG samples are required to assist in making the diagnosis and one pattern suggestive of an EP is a rise after an initial fall in hCG concentrations. When the pattern of serial hCG assessment is consistent with an EP, a repeat ultrasound scan may now identify an adnexal mass although when absent an EP should be assumed and a management strategy clearly documented.

There is sometimes a role for a diagnostic laparoscopy in the assessment of a PUL. It is particularly valuable when on first attendance there has been minimal bleeding, the ultrasound scan is inconclusive, and serum hCG is well within the discriminatory zone. An endometrial biopsy with urgent histology looking for the presence chorionic villi may also have a diagnostic role in a chronic PUL with static hCG.

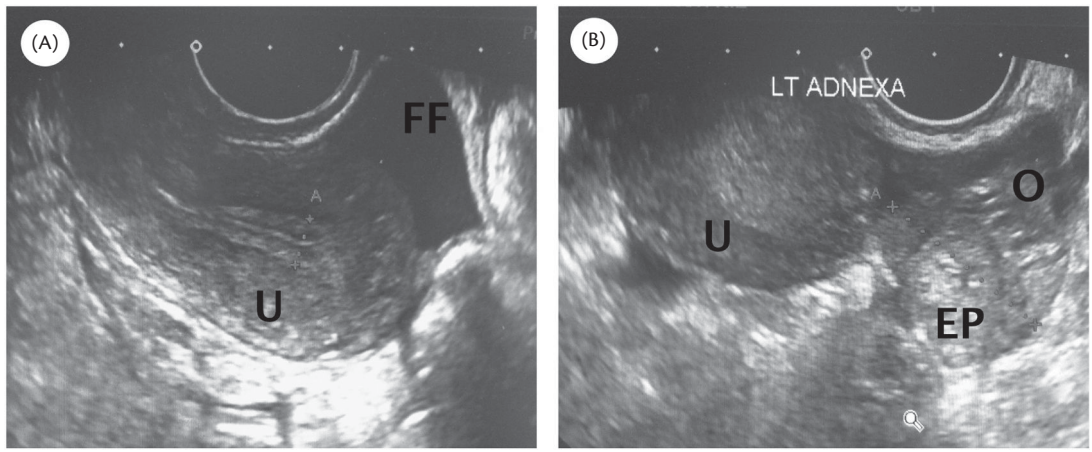

**Figure 32.3** Ultrasonography of a tubal ectopic pregnancy. (A) Uterus (U) with a normal endometrial echo (measurement A) with free fluid (FF). (B) In the left adnexa next to the uterus (U) and medial to the ovary (O) is the adnexal mass (measurement A) representing the ectopic pregnancy (EP).

Once diagnosed, an EP can be managed surgically, medically, or expectantly depending on past history, clinical presentation, results of investigations, and patient preference.[31]

Surgical management is required if there is significant pain, clinical or sonographic evidence of tubal rupture, or a large EP. This includes the presence of moderate free fluid particularly if it is around the ovary,[30] an adnexal mass of 35 mm or larger, the presence of a fetal pole with evidence of cardiac activity, or hCG concentrations generally higher than 3000 IU/L and certainly greater than 5000 IU/L.[9,32]

The standard surgical treatment is laparoscopic in nature, although in the presence of haemodynamic instability the treatment should be the one that prevents further blood loss most quickly, and this might be laparotomy.[32] The operation of choice is a salpingectomy rather than a salpingotomy which has a similar future intrauterine pregnancy rate but an increased risk of subsequent EP.[31] However, if the contralateral tube is absent or visibly damaged, a salpingostomy is recommended[32] after which hCG concentrations are measured as up to one in five women will have residual trophoblast that requires further management.[9]

*Medical treatment involves intramuscular methotrexate that is generally administered as a single dose of 50 mg/m$^2$ body surface area.*

Methotrexate is particularly suited to women with minimal symptoms and hCG concentrations less than 1500 IU/L (Box 32.3).[4,32] Although it is commonly used up to hCG concentrations of 3000 IU/L, and can be used up to 5000 IU/L, it becomes less cost-effective and more likely to fail with increasing hCG concentrations. Methotrexate use is increasing and the proportion of EPs treated medically is now approaching that of those treated surgically. Women should abstain from alcohol and strong sunlight for 7 days, and avoid pregnancy in the 3 months after methotrexate treatment.

**Box 32.3** Criteria to assess suitability for medical management of ectopic pregnancy

**Clinical features**

- Clinically stable with minimal pain.

**Scan features**

- Adnexal mass < 35 mm diameter
- No more than minimal free fluid
- No fetal cardiac activity within the EP.

**Serum hCG concentrations**

- Ideally hCG < 3000 IU/L
- No significant anaemia
- Normal renal and liver function.

**Patient features**

- Prefers medical option
- Able to attend prolonged follow-up
- No active peptic ulcer disease
- No concurrent potentially nephrotoxic or hepatotoxic medication.

Side effects of methotrexate include some lower abdominal discomfort and bloating and transient elevation of liver function tests. After methotrexate, serum hCG is routinely measured 4 and 7 days later and once or twice weekly thereafter until negative. Although a fall by day 4 is a useful predictor of future success[33] the main initial assessment of success is a fall in hCG concentrations from day 4 to day 7 of greater than 15%.[32] If this fall has not occurred, further management, generally a repeat injection of methotrexate, is indicated. Around 15% of patients will require a repeat dose and 10% will require surgery, although this is generally for failure of the hCG to adequately fall rather than acute tubal rupture.[9,32,34]

As some EPs will resolve spontaneously without risk to the patient there is a role for expectant management with serial hCG assessment in some cases. This is most effective if the initial hCG level is low (< 1000 IU/L) and is consistently falling,[9,32] particularly if this is associated with a low serum progesterone concentration.[4] The follow-up regimen mirrors that of medical management and it is successful in up to 80% of suitable patients with the others requiring medical or surgical intervention.

*After an EP, the risk of a future EP is increased to around 18% and an early location scan in any future pregnancy is indicated.*

That risk will fall to approximately 5% if the next pregnancy is intrauterine and triple if the next pregnancy is also an EP.[4] With regards to fertility, if the tube is removed or blocked as a result of the EP there will be a reduction in fertility. Fertility on the month where the egg is released on the damaged side will be reduced so it will take longer to become pregnant although most women will achieve a pregnancy before referral to an infertility clinic is indicated.

A very important, and difficult to diagnose, EP is a heterotopic pregnancy that is the coexistence of an EP with an intrauterine pregnancy. It occurs in 1/40,000 spontaneous pregnancies although the incidence is increased after IVF.[35] As serial hCG assessment is not useful, the diagnosis is generally scan based and the key elements are clinical suspicion and not delaying surgical management because of the coexisting intrauterine pregnancy. As medical management is not possible, and expectant management cannot be monitored, treatment is surgical.

Although 98% of ectopic pregnancies are in the Fallopian tube, the 2% in other sites cause management difficulties.[36] Implantation can occur in the cervix, caesarean delivery scar, ovary, peritoneal cavity, and interstitial portion of the Fallopian tube. In these cases, the EP can progress further and become increasingly vascularized before rupture with an increased risk of catastrophic intraperitoneal bleeding. The standard investigative pathways can diagnose these unusual ectopic pregnancies but surgical management is more complex and the risk of hysterectomy is increased.[36] As they are rare, intervention is individualized and although this may involve surgery, direct injection of drugs into the EP to interrupt its growth, or embolization, systemic methotrexate, with one or more repeated doses as an inpatient, is the most common initial strategy in the stable patient. The increased risk of future EP is difficult to quantify but an early location scan is indicated in subsequent pregnancy.

*Recommendation on future mode of delivery will depend on the site of the EP, nature of surgery, and the risk of uterine rupture during labour.*

Anaesthesia for EPs can be challenging as there may be significant blood loss into the peritoneum. Large-bore intravenous access should be secured and blood available. A rapid sequence induction is indicated. The surgeon should be scrubbed ready to start the procedure before the patient is anaesthetized as suxamethonium will cause paralysis of the rectus muscles and resultant loss of tamponade with subsequent bleeding. Profound hypotension may ensue, so rapid surgical access to the source of bleeding, and ligation of the appropriate vessels is indicated. Cell salvage is an underused technique in this area and should be considered.

## Hyperemesis gravidarum

Seventy per cent of women experience nausea and vomiting in pregnancy and hyperemesis affects up to 2% of pregnant women. This is an extreme form of persistent vomiting associated with dehydration, ketonuria, and a loss of 5% of pre-pregnancy weight.[37] It is important that other causes of nausea and vomiting, such as urinary tract infection, diabetic ketoacidosis, hyperparathyroidism, cholecystitis, or small bowel obstruction, are considered. Severe cases can have electrolyte imbalance, vitamin deficiency, thyroid and liver dysfunction, and coagulation defects. Management is often supportive (Box 32.4) and symptoms usually peak around 9 weeks' gestation and subside in the second trimester.[38] Although there are links with reduced birthweight, women should be reassured about fetal development.[38]

**Box 32.4** Management of hyperemesis gravidarum

**Lifestyle**

- Ginger
- Small frequent light meals.

**Fluid and electrolyte replacement**

- Avoid dextrose-containing fluids
- Potassium replacement usually required.

**Antiemetic therapy**

- Regular prescription
- Intramuscular or intravenous initially with oral or rectal maintenance
- Combination drugs may be required:
  - First line: one or two of prochlorperazine, cyclizine, or metoclopramide
  - Second line: addition of ondansetron
  - Third line: glucocorticoids.

**Nutrition**

- Nil by mouth progressing to frequent small intake
- Clear fluids initially
- Dietetic involvement
- Total parental or enteral nutrition in extreme cases.

**Additional treatment**

- Vitamin supplementation (thiamine)
- Thromboprophylaxis.

## Molar pregnancy

Gestational trophoblastic disease (GTD) is a group of disorders consisting of complete and partial molar pregnancies and malignant conditions such as invasive mole and choriocarcinoma. Overall, the incidence of GTD in the United Kingdom is approximately 1/750 live births.[39] The incidence of GTD increases with age progressively over the age of 40 and women from Asia have double the risk of GTD than non-Asian women.

*There is an effective supraregional registration programme for GTD in the United Kingdom and monitoring and treatment is managed nationally.*

Complete moles are diploid but both sets of chromosomes are paternal in origin resulting either from duplication of the male pronuclei (75%) or dispermic fertilization (25%) with loss of the female pronuclei.[39] Paternally imprinted genes regulate placental development and there is no evidence of fetal tissue. Partial moles are generally triploid with two sets of paternal chromosomes as a result of dispermic fertilization and there is usually evidence of fetal tissue.

Although GTD can present with hyperemesis, hyperthyroidism, early pre-eclampsia, large uterine size, or metastasis, most molar pregnancies present in the first trimester of pregnancy with irregular vaginal bleeding.[40] Although ultrasound examination can suggest the diagnosis at presentation (Figure 32.4), definitive diagnosis is made by histological examination of the products of conception when suspicion has been raised.[39]

*The recommendation that tissue from all failed pregnancies is examined for molar change is difficult to achieve in practice, but products from repeat evacuations should undergo histological assessment.*

Suction curettage is the method of choice for the evacuation of molar pregnancy except in partial moles with a fetus over 14 weeks in size where medical evacuation of the uterus may be required. Surgical expertise is important because of the increased risk of excessive bleeding and the need to completely empty the uterus. As well as histological analysis, tissue may need to be sent, with paired parental blood samples if possible, for cytogenetic analysis. Although there is a theoretical risk of trophoblast embolization after prolonged prostaglandin use, preparation of the cervix immediately prior to evacuation is safe although the use of an oxytocic prior to evacuation is not recommended.[39]

Follow-up of GTD is by serial monitoring of hCG for 6 months from the evacuation of the uterus or from normalization of hCG, when this has taken more than 56 days. Follow-up is arranged through supraregional centres. Women should be advised not to conceive until their follow-up is complete although hormonal contraception before hCG has normalized may slow resolution. The need for chemotherapy following a complete mole is 15% and following a partial mole is 0.5% and there is an excellent cure rate even with metastatic disease. The risk of further GTD is 1 in 80 and hCG monitoring is required after any subsequent pregnancy.[39,40]

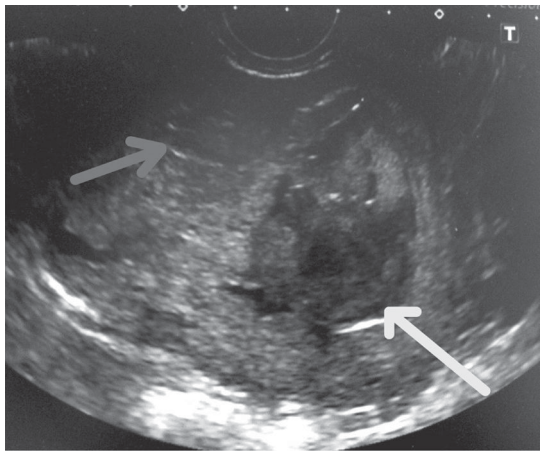

**Figure 32.4** Ultrasound features suggestive of a molar pregnancy. Inside the uterus (white arrow) there is irregular cystic pregnancy tissue (black arrow) with no clear pregnancy sac, yolk sac or fetal pole suggestive of a complete mole.

## Important issues in early pregnancy care

### Quality care provision

The CMACE enquires into maternal death highlight the need for clear documentation, communication and management planning, and the success of EPAUs. The biggest challenge in reducing morbidity and mortality associated with early pregnancy problems is increasing the access of disadvantaged women and minority ethnic groups to timely care.[27]

### Anti-D administration

As rhesus isoimmunization can occur after early pregnancy problems, there are some circumstances where women who are rhesus negative require anti-D prophylaxis.[41] All women who have a surgical procedure to manage an EP or miscarriage should be offered anti-D at a dose of 50 mcg (250 IU) as soon as possible but within 72 hours. In the first trimester of pregnancy, a Kleihauer test is not needed to quantify fetomaternal haemorrhage and anti-D is not required for threatened, incomplete, or complete miscarriage. Anti-D may not be required after the medical management of miscarriage or EP but guidelines differ[9,41] and prophylaxis is often given.

### Sensitive disposal of pregnancy tissue

It is important that there are clear pathways for the appropriate disposal of tissue from pregnancy losses whether or not fetal tissue can be identified.[42] In recognition of the sensitivity around early pregnancy loss it is no longer considered acceptable for pregnancy tissue to be disposed of by clinical waste incineration. In the United Kingdom, the minimum standard is collective disposal in a crematorium or collective burial where such disposal is not available. Women may decline this disposal and are free to make alternative arrangements if they wish.

### Guidelines

There are excellent national guidelines available in the United Kingdom for the assessment and management of early pregnancy problems (Box 32.5).

## Conclusion

The management of early pregnancy problems involves an awareness of normal pregnancy and early pregnancy problems, and their investigation and treatment which may be surgical or medical. The multidisciplinary team involved in the care of women with these problems includes primary care, radiographers, midwives, nurses, gynaecologists, and reproductive medicine specialists. The anaesthetist is also a key member of the team as they often have to provide anaesthesia for evacuation of the products of conception or ectopic pregnancies in women who may be hypovolaemic and an understanding of the physiology and pathology surrounding their care is therefore essential.

# CHAPTER 33

# Prematurity, multiple gestation, and abnormal presentation

Oonagh Keag and E. Sarah Cooper

## Preterm labour and delivery

Preterm labour is defined as the onset of regular contractions accompanied by cervical change prior to 37 completed weeks of gestation. Preterm delivery is defined by the World Health Organization as delivery between 20 and 37 weeks of gestation.

In high-income countries, the incidence of preterm birth is estimated at 6–10% of all births[1] and has remained unchanged over the last four decades despite intensive antenatal care programmes aimed at high-risk groups, the widespread use of pharmacological agents to inhibit preterm birth (tocolytics), and a series of other preventive and therapeutic interventions.

Prematurity remains a leading cause of neonatal morbidity and mortality in developed countries, accounting for 60–80% of deaths of infants without congenital anomalies.[2] Survival rates continue to improve with advances in neonatal intensive care but are very much dependent on gestational age and birth weight with smaller and earlier gestation infants carrying a higher risk of long-term morbidity or mortality. Mortality increases from about 2% for infants born at 32 weeks of gestation to more than 90% for those born at 23 weeks of gestation.[3]

Short-term morbidities associated with preterm delivery include respiratory distress syndrome, intraventricular haemorrhage, periventricular leucomalacia (brain injury involving necrosis of white matter around fluid-filled areas), necrotizing enterocolitis, bronchopulmonary dysplasia, sepsis, and patent ductus arteriosus. Long-term morbidities include cerebral palsy, mental retardation, and retinopathy of prematurity. Cerebral palsy is defined as a non-progressive motor disorder and complicates approximately two per 1000 of all live births. Causes may be attributed to antenatal, intrapartum (10% of cases), or postnatal events, though in many cases there is no identifiable cause. The relative risk for a preterm infant developing cerebral palsy is nearly 40 times that for term infants. Approximately 8–10% of surviving newborns weighing less than 1000 g at birth will develop cerebral palsy. These infants also have substantially higher rates of mental retardation and visual disabilities, as well as neurobehavioral dysfunction and poor school performance.[2,4]

Preterm birth may have huge psychosocial and emotional effects on the family, as well as being costly for health services.

### Aetiology

About two-thirds of preterm births result from spontaneous preterm labour or preterm premature rupture of the membranes (PPROM), with the remainder iatrogenic due to medical interventions for maternal or fetal indications such as pre-eclampsia or severe intrauterine growth restriction.[2] One in five preterm births is associated with multiple pregnancy, and these have been greatly increased by assisted reproduction techniques.[5]

The pathophysiology of preterm labour is poorly understood, but infection is thought to play a major role, present in 40% of preterm deliveries. Infection is often subclinical and can occur spontaneously within the amniotic sac or can originate in another system such as the urinary or genital tract and cause intrauterine infection or spontaneous PPROM and subsequent chorioamnionitis. Organisms that have been associated with histological chorioamnionitis include *Ureaplasma urealyticum, Mycoplasma hominis, Gardnerella vaginalis*, peptostreptococci, and *Bacteroides* species.[6] Positive amniotic fluid cultures increase the risks of neonatal sepsis, respiratory distress syndrome, chronic lung disease, periventricular leucomalacia, intraventricular haemorrhage, and cerebral palsy.[7–9]

The presence of subclinical infection is associated with increased production of various cytokines in the amniotic fluid particularly tumour necrosis factor alpha, interleukin (IL)-lβ, -6, and -8, with subsequent activation and production of prostaglandins $F2_{\alpha}$ and $E_2$ resulting in uterine contractions. It is thought that the microorganisms gain access to the amniotic fluid and fetus by ascending from the vagina through the cervix and into the choriodecidual space during pregnancy.[10]

Bacterial vaginosis is a common condition where due to pH imbalance there is overgrowth of certain vaginal commensal bacteria causing a malodorous off-white vaginal discharge. This condition is associated with preterm labour and if discovered during pregnancy should be treated with a course of metronidazole.

*Chlamydia trachomatis* infection has also been associated with preterm delivery, and in Scotland, women under the age of 25 are routinely screened for this at the antenatal booking appointment using first-void urine or a self-taken low vaginal swab. Women and their partners are treated as necessary, usually with azithromycin. Contact tracing is arranged and repeat testing ('test of cure') performed.

Urinary tract infections (UTIs) during pregnancy increase the risk of pyelonephritis, and are associated with preterm labour. It has been suggested that as many as 40% of preterm births may be attributable to untreated UTIs.[11] For this reason, any pregnant woman with symptoms or urinalysis suggestive of a UTI must be treated promptly with appropriate antibiotics.

Aside from infection and multiple pregnancy, there are other predisposing factors for preterm labour. These can be divided into

**Table 33.1** Causes of preterm labour

| Maternal factors | Fetal factors | Obstetric factors |
|---|---|---|
| Past history of preterm labour | Genetic abnormalities | Recurrent antepartum haemorrhage |
| Uterine abnormalities | Fetal death | Cervical incompetence |
| Trauma | Multiple pregnancy | Abnormal placentation |
| Abdominal surgery | | Preterm premature rupture of membranes |
| Acute or chronic systemic disease | | Polyhydramnios |
| Age < 17 or > 35 years | | |
| Low socioeconomic status | | |
| Low prepregnancy BMI | | |
| Smoking or substance misuse | | |
| Working hours > 35/week | | |
| High-stress jobs | | |

various categories, as seen in Table 33.1. Maternal factors include a past history of preterm labour, uterine abnormalities such as bicornuate uterus, trauma, abdominal surgery during the pregnancy, or acute or chronic systemic disease. Other risk factors in this category include extremes of age (<17 or >35 years), low socioeconomic status, low prepregnancy body mass index (BMI), tobacco use, and substance misuse. Observational studies of working conditions, for example, long working hours (>35 hours/week) and high-stress jobs, have had conflicting results but despite many confounding factors, these conditions are thought to be associated with an increased risk of preterm labour.[2] Fetal factors predisposing the woman to preterm labour include intrauterine growth restriction, genetic abnormalities, and fetal death. Obstetric factors include persistent bleeding throughout the pregnancy, incompetent cervix (this could be secondary to previous large loop excision of the transformation zone treatment for abnormal smears), abnormal placentation, PPROM, and polyhydramnios.[12–14]

It is important to note that PPROM does not always lead to premature labour, but occasionally labour is induced or expedited if there are concerns for maternal or fetal well-being. Close monitoring of these patients in the form of maternal temperature, white cell count, C-reactive protein, and high vaginal swabs is essential to make an informed decision of when to intervene. These patients are also prescribed prophylactic antibiotics.[15] Guidelines produced by the Royal College of Obstetricians and Gynaecologists (RCOG) recommend that erythromycin should be given for 10 days following the diagnosis of PPROM.[16] A meta-analysis of 22 trials has shown the use of antibiotics following PPROM is associated with a statistically significant reduction in chorioamnionitis, in the numbers of babies born within 48 hours, and a reduction in neonatal infection.[17] In the presence of Group B *Streptococcus* infection, penicillin should be administered 4-hourly.

## Cervical cerclage

For those patients with a history of three or more previous midtrimester losses or preterm births, the RCOG recommends 'history-indicated' cervical cerclage. This is a transvaginal cervical suture inserted electively at 12–14 weeks as a prophylactic measure. For patients with a history of one or more midtrimester losses or preterm deliveries, transvaginal scans can be arranged to assess the cervical length between 14 and 24 weeks' gestation. If there is evidence of shortening of the cervix, that is, if the cervix is 25 mm or less, 'ultrasound-indicated' cervical cerclage may be offered to prevent preterm labour. In women with a previous failed transvaginal cerclage, insertion of a transabdominal cerclage via laparotomy or laparoscopy may be considered and this may be performed preconceptually or in early pregnancy. 'Rescue cerclage' may be indicated as a salvage measure in the case of premature cervical dilatation with exposed fetal membranes in the vagina. The decision to insert a rescue cerclage will depend on the presentation and the gestation of the pregnancy, as it poses the risk of severe preterm delivery and neonatal mortality and morbidity. Rescue cerclage may delay delivery by a further 5 weeks on average compared with expectant management alone, but the risk of cerclage failure increases with cervical dilatation. Cervical cerclage is not recommended in multiple pregnancy.[18] Other contraindications to cervical cerclage include active preterm labour, evidence of chorioamnionitis, continuing vaginal bleeding, and PPROM.

### Anaesthesia for cervical cerclage

Both general and spinal anaesthesia are appropriate for cervical cerclage. Many women are understandably anxious due to their poor obstetric history and therefore opt for general anaesthesia (GA). As these operations are carried out in the first trimester, a laryngeal mask can be used unless there is a contraindication. Most anaesthetists would use a total intravenous technique although there is no reason why an inhalational technique is not acceptable or safe as none of the agents are teratogenic. Other women prefer to be awake and the procedure can be done with a low-dose spinal technique (2.0 mL 0.5% heavy bupivacaine). Postoperative pain is not severe and intrathecal opiates are not indicated.

If a mini-laparotomy is performed for an abdominal approach to cervical cerclage, a GA is indicated with muscle paralysis to facilitate the surgery which is often challenging for the obstetrician. At the end of the procedure, some units use a non-steroidal anti-inflammatory drug (NSAID), indomethacin 100 mg, two doses at 12-hourly intervals, to prevent premature labour. NSAIDs are cyclooxygenase (COX) inhibitors and prevent prostaglandins synthesis, thus preventing uterine contractions. The woman is confined to bed for a further period and therefore anticoagulation should also be prescribed.

## Diagnosis of preterm labour

For any woman admitted with suspected preterm labour, the accuracy of the expected date of delivery should be re-checked especially at extremes of gestational age below 24 weeks. Clinically, the diagnosis of preterm labour is made when there are regular painful, palpable contractions, lasting longer than 30 seconds, accompanied by evidence of a change in the position, consistency, length, and/or dilatation of the cervix. This is determined by sterile speculum examination initially if there is suspected rupture of membranes, followed by digital vaginal examination if there is a strong suspicion that the woman may be in labour.[19]

When preterm labour is established, a diagnostic workup should include the assessment of any risk factors that could be modified together with a complete medical history, a thorough physical

examination, ultrasound assessment of fetal growth, morphology, well-being and presentation, together with infectious screening (high vaginal swab, midstream sample of urine) and blood screening (white cell count, C-reactive protein). Fetal heart rate monitoring should be commenced and any acute causes of preterm labour excluded such as placental abruption or sepsis.

In uncertain cases when membranes are intact, fetal fibronectin (FFN) testing may be performed. FFN is a glycoprotein found in high concentrations in the placenta and amniotic fluid. FFN is detectable in the cervicovaginal secretion in about 4% of pregnant women after 20 gestational weeks, possibly reflecting transudation of amniotic fluid or disruption of the choriodecidual interface.[20] FFN is most sensitive when measured before 34 weeks' gestation with a sensitivity of predicting preterm birth ranging from 21 to 94% (median 80%).[21] If FFN is absent (negative test result), the risk of preterm delivery within 1 or 2 weeks is less than 1%, and the patient can be reassured.[22]

## Management

Once the diagnosis of preterm labour is established, the woman must be admitted to an obstetric unit with facilities for resuscitating and managing a preterm infant. In some cases, depending on the gestational age and if time allows, an *in utero* transfer is required. If delivery is thought to occur within the next few days, corticosteroids should be administered to the mother. A Cochrane review of 21 studies (3885 women and 4269 infants) showed that treatment of women at risk of preterm birth with a single course of antenatal corticosteroids reduced the risk of neonatal death by 31% (95% confidence interval (CI) 19–42%), respiratory distress syndrome by 44% (95% CI 31–57%), and intraventricular haemorrhage by 46% (95% CI 31–67%). Antenatal corticosteroid use is also associated with a reduction in necrotizing enterocolitis, respiratory support, intensive care admissions, and systemic infections in the first 48 hours of life compared with no treatment or treatment with placebo.[23] The recommended dose is two doses of betamethasone 12 mg, 24 hours apart or four doses of dexamethasone 6 mg, 12 hours apart by intramuscular injection. Antenatal corticosteroids have been shown to have effect if administered between 24 and 34 + 6 weeks gestation. The decision to administer corticosteroids between 23 and 23 + 6 weeks should be made at a senior obstetric level in conjunction with the parents and the neonatologists after a full discussion of survival rates and a sonographic measurement of estimated fetal weight. The evidence shows that a single course of antenatal corticosteroids does not appear to be associated with any significant short-term maternal or fetal adverse effects.[24]

As mentioned above, if the membranes have ruptured, antibiotics are recommended. Randomized controlled trials and a meta-analysis have concluded that antibiotics prolong pregnancy and reduce maternal and neonatal morbidity.[15, 25] There is insufficient evidence that antibiotics are useful when the membranes are intact.[26]

The gestation at which delivery should be considered following PPROM remains a contentious issue. A balance must be struck between the neonatal morbidity risk (mainly respiratory) of immediate delivery and the increasing risk of chorioamnionitis with expectant management. Randomized controlled trials are in progress but the current RCOG guideline recommends consideration of delivery at 34 weeks' gestation.[16]

### Tocolysis

Tocolysis is a method of suppressing uterine contractions to prolong pregnancy. This is particularly important in women at very early gestations or in women who require transfer to a tertiary obstetric unit with appropriate neonatal facilities. However, it may not always be appropriate to prolong pregnancy, for example, in the presence of intrauterine infection or placental abruption where prolonging pregnancy could be hazardous to the mother or her baby. A systematic review has shown that tocolytic drugs are associated with prolonging pregnancy for up to 7 days but with no significant effect on preterm birth and no clear effect on perinatal or neonatal mortality or morbidity.[27] RCOG guidelines state that they should be considered to allow time to complete a course of corticosteroids or an *in utero* transfer.[28] There is insufficient evidence to support the use of tocolytic drugs in multiple pregnancy or in cases of PPROM.

A range of tocolytic agents have been used to inhibit preterm labour and postpone preterm birth (and are the topics of Cochrane systematic reviews) including nitric oxide donors glyceryl trinitrate,[29] calcium channel blockers (commonly nifedipine),[30] betamimetics,[31] magnesium sulphate,[32] COX inhibitors,[33] and oxytocin receptor antagonists (atosiban).

The popularity of the betamimetics, ritodrine and terbutaline, for tocolysis has declined in recent years and ritodrine has been withdrawn from UK and US markets. In the United Kingdom, terbutaline is only indicated for external cephalic version (ECV) or when the uterus is hypertonic usually as a result of Syntocinon® (oxytocin) overstimulation. In addition to its beta-2 effects on smooth muscle causing bronchial and uterine relaxation, it also causes vasodilatation and hypotension. Beta-1 effects include tachycardia and arrhythmias which limit its usefulness. Life-threatening pulmonary oedema has also been reported.

According to the RCOG guidelines, atosiban and nifedipine have comparable effectiveness in delaying preterm birth for up to 7 days. These both have fewer side effects and nifedipine has the advantage of oral administration and low cost. The use of multiple tocolytic drugs is associated with a higher risk of adverse effects and so should be avoided.[34] A recent systematic review and meta-analysis looked at data from 95 randomized controlled trials and found that prostaglandin inhibitors and calcium channel blockers had the highest probability of delaying delivery and improving neonatal and maternal outcomes.[35] Table 33.2 displays the different tocolytics available, their mode of action, contraindications, and salient maternal and neonatal side effects.

### Magnesium sulphate

For women in suspected preterm labour under 30 weeks' gestation, a 2011 RCOG Scientific Impact Paper[36] has recommended the use of magnesium sulphate as neuroprotection for reduction of the incidence of cerebral palsy and motor deficits. A loading dose of 4 g is recommended, followed by an infusion of 1 g per hour for 24 hours or until delivery, whichever occurs soonest. Side effects include facial flushing, chest pain, palpitations, nausea, transient hypotension, sedation, and blurred vision.[37,38] These may be exaggerated if the woman is also taking calcium channel antagonists. Absolute contraindications to the use of magnesium sulphate include myasthenia gravis and heart block. Relative contraindications include underlying renal disease and recent myocardial infarction. Pulmonary oedema has been reported in

**Table 33.2** Properties and side effects of tocolytics

| Tocolytic | Mode of action | Contraindications | Maternal side effects | Fetal or neonatal side effects |
|---|---|---|---|---|
| Terbutaline | Beta-agonist | Cardiac arrhythmias | Tachycardia, tremor, cardiac arrhythmias, pulmonary oedema, myocardial ischaemia | Fetal tachycardia, hyperinsulinaemia, hypoglycaemia |
| Nifedipine | Calcium channel blocker | Cardiac disease, hypotension. Caution if concomitantly with magnesium sulphate | Flushing, headache, dizziness, nausea, hypotension | |
| Atosiban | Oxytocin antagonist | | Nausea, headache, dizziness, tachycardia | |
| Magnesium sulphate | Myosin light chain inhibitor | Myasthenia gravis | Flushing, lethargy, headache, muscle weakness, diplopia, pulmonary oedema, cardiac arrest | Lethargy, hypotonia, respiratory depression |
| Indomethacin | NSAID | Late pregnancy, hepatic or renal impairment | Nausea, reflux | Constriction of ductus arteriosus, pulmonary hypertension, impaired renal function, intraventricular haemorrhage |

approximately 1% of women treated with magnesium sulphate. Because of the potential risk of fluid overload, periodic assessment of fluid intake and output is essential.[39] Magnesium can fortuitously cause uterine relaxation, useful if there is also premature labour.

### Delivery

The method of delivery of the preterm infant depends on the aetiology of the preterm labour, the gestation, and presentation and the decision should be made in conjunction with the parents and the neonatology team. Often in iatrogenic cases, for example, if delivery is indicated for severe intrauterine growth restriction, induction of labour is not possible either due to malpresentation or the presence of features of fetal distress on cardiotocographic (CTG) monitoring. In such cases, a caesarean delivery would be the most appropriate method of safe delivery of the preterm infant.

In established spontaneous preterm labour where the presentation of the fetus is cephalic, and there are no concerns about fetal heart rate monitoring, the woman is encouraged to deliver vaginally. It must be noted though, that preterm infants, and especially very early preterm infants, are more vulnerable to trauma during delivery than fetuses at term. They are far more likely to suffer soft tissue damage, neurological injury, and traumatic intracranial haemorrhage than term infants.[39] For this reason, the fetal heart rate should be monitored closely and special care should be taken not to traumatize these infants, for example, by avoiding the use of ventouse and fetal scalp electrodes where at all possible, especially under 34 weeks' gestation. Forceps are also generally avoided but in the past were used to protect the fetal skull from sudden decompression when exiting the genital tract. In the incidence of suspected fetal distress, fetal blood sampling is not used as the preterm fetus has more fragile skull bones, and is less able to cope with acidosis and so immediate delivery is indicated.

### Analgesia and anaesthesia for preterm delivery

As with a woman labouring at term, women in established preterm labour may also request an epidural. During preterm labour, an epidural is advantageous in providing a relaxed pelvic floor and perineum to facilitate a smooth controlled delivery of the more vulnerable preterm vertex, and in inhibiting inappropriate maternal expulsive efforts prior to complete cervical dilatation. In addition, it is thought that epidural analgesia decreases maternal concentrations of catecholamines and in some patients it may improve uteroplacental perfusion.[40]

If a caesarean is indicated, and as long as there were no contraindications, neuraxial anaesthesia is the technique of choice. The drugs used in GA cross the placenta and may further depress the already compromised preterm infant.[41] Pre-eclampsia is one of the commonest causes of premature delivery and GA in these patients can be even more hazardous due to the hypertensive response to laryngoscopy which can result in myocardial ischaemia or cerebral haemorrhage, and potential difficult intubation due to laryngeal oedema. Further, if magnesium has been used as a prophylaxis against eclampsia prior to GA, as it is a calcium antagonist, it prevents release of acetyl choline at the neuromuscular junction and has the potential for prolonged neuromuscular blockade. If muscle relaxants are used, a smaller dose is required and neuromuscular monitoring performed particularly when reversal is attempted. Prolonged neuromuscular block may be exacerbated by combining magnesium with nifedipine.[42]

A spinal or combined spinal–epidural (CSE) can be used for most operative deliveries where the fetus is premature. A larger dose of local anaesthetic is necessary to achieve the desired block height. This is due to the smaller fetus causing less uterine compression of the vena cava and engorgement of the epidural blood vessels. The subarachnoid and epidural spaces have thus larger volumes than with the term fetus and require more volume of local anaesthetic to spread to the appropriate height. Magnesium can cause vasodilatation and if neuraxial anaesthesia is employed, hypotension may occur and should be prevented with suitable vasopressors.

## Key points

- Preterm labour is a common cause of neonatal morbidity and mortality.

- Transfer to a neonatal unit with appropriate facilities is key.
- Tocolysis may be useful to enable transfer or administration of corticosteroids.
- Chorioamnionitis is a significant complication and antibiotic prophylaxis is essential.
- Neuraxial anaesthesia is generally preferred where possible.
- Local anaesthetic requirements are increased.

## Multiple gestation

The incidence of multiple pregnancy is rising, mainly as a result of increasing assisted reproduction techniques including *in vitro* fertilization. Currently, the rate of twins is about 1/67 births, triplets 1/5000, and quadruplets 1:360,000.[43] This chapter will focus mainly on twin pregnancy. Triplets and higher-order multiples are generally delivered by elective caesarean delivery.

Twin pregnancies are described according to the number of ova originally fertilized (zygosity) and the number of placentae (chorionicity). Two-thirds of twin pregnancies are dizygotic, where two separate ova are fertilized by two separate sperm resulting in two separate gestational sacs with two placentas—they are dichorionic and diamniotic. These twins may be of different sex. Monozygotic twins result from the division of a single embryo; therefore, these twins are genetically identical. The chorionicity will depend on the stage at which the embryo separates and this is demonstrated in Figure 33.1.[44] Monozygotic twins can be diamniotic dichorionic, diamniotic monochorionic, monoamniotic monochorionic (1% of pregnancies), or, if the separation occurs later after 12 days, conjoined twins. The rate of dichorionic twins is 1/80, and the rate of monochorionic twins is 4/1000.

### Diagnosis

The diagnosis of multiple pregnancy and determination of chorionicity is best determined by ultrasound scan in the first trimester. Those scans with a 'lambda' or 'twin-peak' sign at the membrane insertion are dichorionic. Those with a dividing membrane thicker than 2 mm are often dichorionic or indeed if there are different sex fetuses, they are dichorionic.[45]

### Management of twin pregnancy

Twin pregnancies are high-risk pregnancies requiring consultant-led antenatal care which should include regular growth scans. The RCOG has produced Study Group guidelines outlining the careplan each woman with twin pregnancy should follow.[46] The first scan at 10–13 weeks should determine viability, chorionicity, and nuchal translucency to assess risk of aneuploidy. Women with a dichorionic twin pregnancy will then have a structural anomaly scan at 20–22 weeks' gestation. Following this, serial fetal growth scans will be performed from 24 weeks

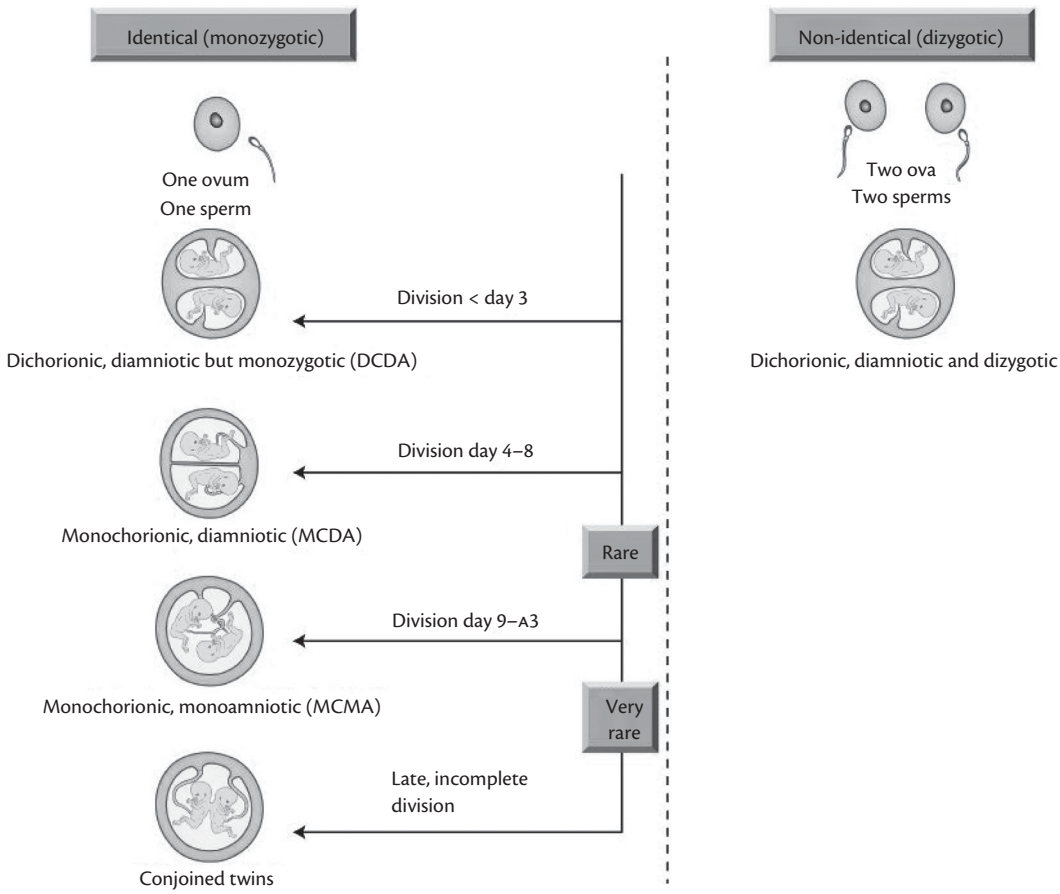

**Figure 33.1** Mechanisms of twinning.

at 4-weekly intervals. Blood pressure monitoring and urinalysis should be performed at 20, 24, and 28 weeks' gestation and fortnightly thereafter. Elective delivery is recommended at 37–38 completed weeks' gestation.

For monochorionic twin pregnancies, monitoring is more frequent due to an increased risk of complications. Following the initial scan at 10–13 weeks' gestation, ultrasound surveillance begins at 16 weeks' gestation and 2-weekly thereafter, to highlight any growth discordance or twin-to-twin transfusion syndrome (TTTS; see 'Complications of Monochorionic Twin Pregnancy'). The structural anomaly scan at 20–22 weeks will also include a fetal echocardiogram. As with dichorionic twins, blood pressure monitoring and urinalysis should be performed at 20, 24, and 28 weeks of gestation and fortnightly thereafter. Elective delivery is recommended at 36–37 completed weeks of gestation in uncomplicated monochorionic twin pregnancies.

## Complications

There is a higher risk of obstetric complications associated with multiple pregnancy and these can be classed as fetal or maternal, as demonstrated by Table 33.3.

### Complications of monochorionic twin pregnancy

A completely separate but serious complication of monochorionic twin pregnancy is TTTS. This affects about 10–15% of monochorionic twins and left untreated has an 80% mortality rate.[47] It is caused by placental vascular anastomoses which result in transfusion of blood from the 'donor' twin to the 'recipient' twin. As a result, the donor twin becomes hypovolaemic, anaemic, and develops growth restriction and oligohydramnios. The recipient twin becomes hypervolaemic and polycythaemic with a large bladder and polyhydramnios. There may be evidence of fetal hydrops in this twin (ascites, pleural and pericardial effusions). The mother may present with a sudden increase in swelling of her abdomen or breathlessness, and urgent ultrasound is advised. Treatment options for TTTS include laser ablation of the placental anastomoses, selective feticide, serial amnioreductions, or septostomy which allows equilibration between the two amniotic sacs. In the incidence of death of a co-twin in a monochorionic pregnancy, an acute TTTS can occur, causing a high risk of death or neurological damage in the surviving twin of up to 50%.

A further complication specific to monochorionic twin pregnancy is twin reversed arterial perfusion sequence (TRAP). This occurs when one twin is acardiac but continues to be partially perfused through vascular connections from the surviving twin. This is a rare complication but one which has a high mortality for the donor twin, usually secondary to cardiac failure and prematurity. Cord ligation has been beneficial in some cases.[45]

Monochorionic monoamniotic twins carry all the risk of complications as already mentioned but with an additional risk of cord entanglement. This may hinder fetal movement and development and complicate labour. For this reason, it is recommended that all monochorionic monoamniotic twins are delivered by elective caesarean delivery at 32 weeks' gestation after corticosteroid administration.[45] Conjoined twins also pose mechanical difficulties for labour and so are delivered by elective caesarean delivery at a time to suit the entire multidisciplinary team including obstetricians, anaesthetists, and paediatric surgeons.

**Table 33.3** Risks associated with multiple pregnancy

| Maternal risks | Fetal risks |
|---|---|
| Hyperemesis gravidarum | Increased risk of miscarriage |
| Anaemia | Congenital abnormalities |
| Pre-eclampsia | Intrauterine growth restriction |
| Gestational diabetes | Preterm labour—40% of twins deliver before 37 weeks |
| Polyhydramnios | Increased perinatal mortality |
| Placenta praevia | Increased intrauterine death |
| Antepartum and postpartum haemorrhage | Increased risk of disability |
| | Increased risk of cerebral palsy |

## Delivery of twins

It is recommended by the RCOG that dichorionic twins are delivered at 37–38 weeks' gestation. If the presenting twin is cephalic and there are no other complications, a trial of vaginal delivery is encouraged but in some cases the mother may request elective caesarean delivery. Forty per cent of twin pregnancies have both twins in cephalic presentation at term.[43]

When a woman with twin pregnancy presents in labour or for induction of labour, an ultrasound scan should be performed to determine the lie and presentation of the twins. Intravenous access should be obtained with a large-bore cannula and a group and save sample should be taken due to the risk of postpartum haemorrhage. A Syntocinon® infusion should be prepared in advance in anticipation of uterine atony after delivery.

Fetal distress is more common when labouring with a twin pregnancy, and fetal distress in twin two is a concern, particularly after delivery of twin one.[48] For this reason, continuous monitoring is essential throughout labour. Usually the presenting twin is monitored via fetal scalp electrode and twin two is monitored abdominally. Once twin one has delivered vaginally, twin two must be 'stabilized'; this is where the midwife or obstetrician palpates the abdomen keeping the twin stable in a longitudinal lie. Vaginal examination and ultrasound will determine the presentation and station of the second twin. If fetal monitoring of the second twin remains reassuring, labour can be allowed to continue and as the twin descends into the pelvis, amniotomy can be performed. It is usual for contractions to become more infrequent after delivery of twin one and so an infusion of Syntocinon® should always be available. Providing there is no fetal distress of the second twin, there is no specified time to wait before commencing the infusion.

The management of fetal distress in twin two will depend on the presentation and station. If the presenting part is above the ischial spines or if there is transverse lie, a caesarean delivery is indicated. Caesarean delivery for twin two occurs in 10% of twin deliveries.[46] For this reason, some units choose to have mothers deliver in the operating theatre, or have a low threshold for transferring to theatre when the CTG is non-reassuring. Another option would be internal podalic version and total breech extraction. If twin two is cephalic and at the ischial spines or lower, instrumental delivery is indicated for fetal distress.

In uncomplicated monochorionic twin pregnancies, the RCOG recommends that women aim for vaginal delivery unless there is a clinical indication for caesarean delivery such as the presenting twin lying breech. Delivery should be planned for 36–37 weeks'

gestation.[45] Continuous surveillance of both twins during labour is essential as there is a small risk of acute transfusion during labour. Some units deliver all monochorionic twins by planned caesarean delivery.

### Analgesia and anaesthesia for twin delivery

For women opting for vaginal delivery of twins, epidural anaesthesia is strongly recommended. Twin labour and delivery can be unpredictable. Epidural anaesthesia will keep the mother comfortable during a possibly long labour and two deliveries which may require Syntocinon® augmentation, while being flexible in affording anaesthesia in cases requiring instrumental or caesarean delivery. Anaesthetists should be aware that analgesic requirements may change rapidly according to fetal monitoring and presentation, particularly once twin one is delivered. It is strongly recommended that the anaesthetist stays within the vicinity of the patient delivering twins.

Whether elective or emergency, caesarean delivery may be performed under spinal, epidural, or general anaesthesia. However, because of the increased uterine contents, both fetuses and amniotic fluid, there is a reduced dose requirement of local anaesthesia. This is because the very gravid uterus compresses the vena cava, engorging the epidural vessels and creating effectively a space-occupying lesion in the epidural space. This squeezes the local anaesthetic cephalad and if the standard doses of local anaesthetic are used, the block can rise too high and cause significant hypotension. although a recent study has challenged this.[49]

As with vaginal delivery, there is an increased risk of uterine atony and postpartum haemorrhage therefore all twin deliveries should be followed by administration of a prophylactic Syntocinon infusion. If bleeding continues, further oxytocics may be requested by the obstetrician and in some cases, Bakri or Rusch balloon insertion may be required to tamponade the bleeding. In extreme cases emergency hysterectomy may be necessary. See Chapter 35 for more details.

### Key points

- Chorionicity should be determined early and antenatal care tailored accordingly.
- Twin pregnancies are high risk with many potential complications, especially when monochorionic.
- Mode of delivery will depend on the lie of the presenting twin.
- Epidural anaesthesia during labour is advised.
- Local anaesthetic requirements are reduced.
- Postpartum haemorrhage is a serious and common complication and the necessary preparations should be made in anticipation.

## Abnormal presentation

The presentation of a fetus is the portion of that fetus which overlies the pelvic inlet. This can be determined via abdominal palpation of the pregnant uterus, vaginal examination, or ultrasound. The presentation may be cephalic, breech, or shoulder. Cephalic presentations can be further divided into vertex, brow, and face presentation.

The lie of the fetus refers to the direction of the fetal spine in relation to the mother's spine and can be longitudinal (in the majority of cases), transverse, or oblique. The lie of the fetus can also be classed as unstable, where it is constantly changing. The recommended method of delivery for transverse, oblique, and unstable lie is caesarean delivery. Abnormal lie and some breech presentations are associated with the risk of cord prolapse therefore all women are warned of this possibility and to present to hospital if membranes have ruptured. This obstetric emergency requires prompt delivery by caesarean delivery, usually under GA.

### Abnormal cephalic presentations

The position of the fetus is determined by vaginal examination and describes the cranial sutures of the fetus in relation to the mother's pelvis, for example, the occiput or posterior fontanelle will be anterior, posterior, or transverse. Occipito-posterior (OP) positions are associated with a longer and more painful labour and delay in the second stage. Epidural anaesthesia is strongly recommended for OP labours as not only will it provide good analgesia but also anaesthesia for interventive deliveries which is common in OP presentations. Spontaneous vaginal delivery of this position occurs in one-third of primiparous and 55% of parous women,[50] but in prolonged second stage in OP or occipito-transverse positions, it may be necessary to transfer the woman to theatre for a trial of rotational instrumental delivery. If this is not successful or if the vertex is above the ischial spines, a caesarean delivery will be performed. Therefore, any neuraxial anaesthesia given for a trial of forceps in theatre should have a sufficient block to enable a caesarean delivery.

#### Face

Face presentation occurs in about 1/500 live births and 70–80% of these can be delivered vaginally.[51] The success of this depends on the position of the chin. Mento-anterior positions (90% of face presentations) tend to be successful whereas mento-posterior positioned babies require delivery by caesarean delivery.

#### Brow

This is where the head occupies a position midway between full flexion and full extension. Brow presentation occurs in between 1/1000 and 1/3500 deliveries and when persistent, requires caesarean delivery. Spontaneous flexion or extension of the neck may occur during labour, allowing vaginal delivery.[43,51]

### Breech presentation

The incidence of breech presentation decreases from about 20% at 28 weeks of gestation to 3–4% at term, as most babies turn spontaneously to the cephalic presentation.[52] Persistent breech presentation is associated with abnormalities of the baby, the amniotic fluid volume, the placental localization, or the uterus (Box 33.1). One per cent of breech deliveries occur in multiple pregnancy, and these rates are rising with the increase in assisted reproduction techniques. There is higher perinatal mortality and morbidity with breech than cephalic presentation, due principally to prematurity, congenital malformations, and birth asphyxia or trauma.[53,54] Caesarean delivery for breech presentation has been suggested as a way of reducing the associated perinatal problems.[54,55]

Breech presentation can be further classified (usually by ultrasound scan) into frank or extended breech, where the legs are

**Box 33.1** Fetal abnormalities associated with breech presentation

- Hydrocephalus
- Anencephaly
- Neural tube defects
- Neck masses
- Aneuploidy

flexed at the hips and extended at the knees with the buttocks presenting. This is the most common breech presentation (70% of cases); 15% of cases are flexed breeches with the legs flexed at the knees so buttocks and feet are both presenting, and 15% of cases are footling breeches where one leg is flexed and one extended.

## External cephalic version

Women are given the option of ECV which aims to convert a breech to cephalic presentation. Success rates have been reported as between 30% and 80%. Spontaneous reversion to breech presentation after successful ECV occurs in less than 5%.[56,57] The highest success rates are seen with multiparous, non-white women with a relaxed uterus, where the breech is not engaged and the head is easily palpable.[58] Absolute contraindications include antepartum haemorrhage, ruptured membranes, and multiple pregnancy. Relative contraindications include intrauterine growth restriction, reduced liquor volume, and previous caesarean delivery.

The RCOG recommends tocolysis with beta-sympathomimetics at the time of ECV as it has been shown to increase the success rate. Terbutaline or salbutamol may be given subcutaneously or intravenously. The procedure should be offered from 36 weeks' gestation in nulliparous women and from 37 weeks in multiparous women. Women should be counselled that ECV has a very low complication rate, though they should also be aware of the possible complications. These include fetal bradycardia or non-reassuring CTG features which may be transient but in around 1/300 cases persist and require emergency caesarean delivery. The incidence of placental abruption during ECV is 1/1000. For these reasons, ECV should take place in a unit where monitoring is available and arrangements can be made for immediate delivery if necessary. Therefore all women having ECV should be fasted and have been given ranitidine. Women should also be advised that ECV may be painful and that the procedure can be suspended at any point. There is a higher rate of successful ECV with spinal anaesthesia but this has not been adopted by the obstetric community.[59]

## Mode of delivery for breech presentation

Women who have breech presentation diagnosed, or those who have had an unsuccessful ECV, should be given information on the options of vaginal breech delivery versus planned caesarean delivery. They should be informed that planned caesarean delivery carries a reduced perinatal mortality and early neonatal morbidity for babies with a breech presentation at term compared with planned vaginal birth.

A systematic review of randomized trials including the Term Breech Trial, compared a policy of intended caesarean delivery with a policy of intended vaginal birth, and involved 2396 participants.[60] Caesarean delivery occurred in 1060/1169 (91%) of those women allocated to planned caesarean delivery and 550/1227 (45%) of those allocated to a vaginal delivery protocol. Perinatal or neonatal death (excluding fatal anomalies) or short-term neonatal morbidity was reduced with a policy of planned caesarean delivery (relative risk (RR) 0.33; 95% CI 0.19–0.56) and perinatal or neonatal death alone (excluding fatal anomalies) was reduced with a policy of planned caesarean delivery (RR 0.29; 95% CI 0.10–0.86). Although these conclusions are still somewhat disputed,[61] caesarean delivery is recommended for breech presentation. However, there is still a place for vaginal breech delivery, for example, in the case of twin two, in advanced labour where caesarean delivery would be technically difficult, or on maternal request. See Box 33.2 for factors regarded as unfavourable for vaginal breech delivery.

### *Caesarean delivery for breech presentation*

According to the RCOG, women should be informed that planned caesarean delivery for breech presentation carries a small additional risk of serious immediate complications compared with planned vaginal birth, in terms of abdominal pain, but no there is no evidence of any additional risk to their long-term health. Spinal anaesthesia is the usual technique for caesarean delivery in breech presentation. Occasionally, abdominal delivery of the fetus may be difficult if skin and uterine incisions are insufficient, or if there are fetal abnormalities such as hydrocephalus. In certain circumstances, the obstetrician may request provision of a uterine relaxant, such as glyceryl trinitrate or terbutaline. In some cases, women who have opted for a planned caesarean delivery go into spontaneous labour. Each of these cases is managed individually and many will proceed to vaginal breech delivery if labour is too advanced.

### *Vaginal delivery for breech presentation*

Vaginal breech delivery may occur in three different ways. The first is spontaneous breech delivery where there is no manipulation or traction other than support of the infant's body. In assisted breech delivery, the infant is delivered spontaneously as far as the umbilicus and the chest and after-coming head are

**Box 33.2** Factors regarded as unfavourable for vaginal breech birth

Factors include the following:

- Other contraindications to vaginal birth (e.g. placenta praevia, compromised fetal condition)
- Clinically inadequate pelvis
- Footling or kneeling breech presentation
- Large baby (usually defined as >3800 g)
- Growth-restricted baby (usually defined as <2000 g)
- Hyperextended fetal neck in labour (diagnosed with ultrasound or X-ray where ultrasound is not available)
- Lack of presence of a clinician trained in vaginal breech delivery
- Previous caesarean section.

delivered with the assistance of the obstetrician. Total breech extraction is only really ever used for delivery of a second twin, where the obstetrician applies traction on the feet and ankles to deliver the entire body of the infant. The RCOG states that spontaneous delivery of the trunk and limbs is preferable. If there is delay in delivery of the arms, they may be delivered by sweeping them across the baby's face and downwards or by the Lovset manoeuvre (rotation of the baby to facilitate delivery of the arms). For delivery of the after-coming head, suprapubic pressure by an assistant may be used to assist flexion of the head, and the Mauriceau–Smellie–Veit manoeuvre should be considered. This involves two fingers of the right hand placed over the maxilla and two fingers of the left hand at the back of the head to flex it[52,62] (Figure 33.2). Forceps are occasionally used to facilitate delivery of the after-coming head.

If there is delay in the second stage of labour, caesarean delivery should be considered, as this would be a sign of relative fetopelvic disproportion. In cases of fetal head entrapment, Dührssen incisions to the cervix may be necessary, at the 4 and 7 o'clock positions; however, this is associated with genitourinary trauma and haemorrhage. Alternatives would be administering a smooth muscle relaxant such as glyceryl trinitrate, or performing an emergency caesarean delivery.

### Anaesthesia for vaginal breech delivery

There is no evidence that epidural analgesia is essential,[52] but certainly women would be given this option during labour for vaginal breech delivery. As well as adequate pain relief, its advantages would also be the inhibition of early pushing (as pushing past a cervix which is not fully dilated has implications for fetal head entrapment), a relaxed pelvic floor and perineum for delivery, and the option of extending the block in cases requiring emergency caesarean delivery.

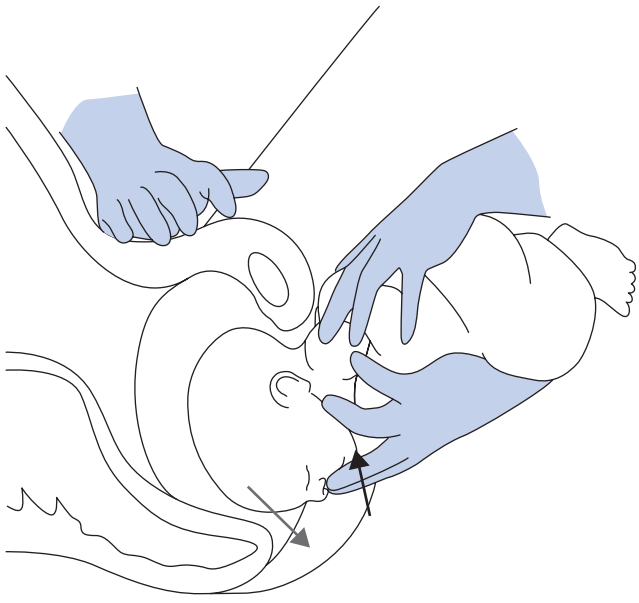

**Figure 33.2** Delivery of the head by jaw flexion and shoulder traction.

## Other abnormal presentations

### Transverse lie

Transverse lie or shoulder presentation is principally managed by performing caesarean delivery. This is most difficult if the baby is 'back-down' in which case a classical uterine incision may be made. Vaginal delivery may be possible following successful ECV or following internal podalic version and breech extraction of a second twin.

### Compound presentation

Compound presentation is where an extremity (usually an upper extremity) is prolapsed alongside the main presenting fetal part and occurs in 1/400 to 1/1200 deliveries. Complications include umbilical cord prolapse in 10–20% for which immediate caesarean delivery is required, and neurological or musculoskeletal damage to the involved extremity.[51] However, labour and delivery can occur safely and manipulation of the prolapsed extremity should be avoided.

## Key points

- Abnormal presentation can take many forms: abnormal cephalic presentations, breech, transverse, oblique, and compound.
- Women should be offered information on the risks and benefits on modes of delivery for breech presentation.

# Conclusion

In conclusion, patients with preterm labour, multiple gestation, and pregnancies with malpresentation are all high-risk obstetric cases requiring a multidisciplinary approach using local and national guidelines. This chapter has endeavoured to highlight the important issues in each of these high-risk situations to enable safe and effective clinical care.

# CHAPTER 34

# Sepsis in obstetrics

Nuala Lucas, Colleen D. Acosta, and Marian Knight

## Introduction

Sepsis in obstetrics is an important cause of maternal mortality and morbidity worldwide, accounting for 15% of all maternal deaths.[1] In the United Kingdom, the maternal mortality rate from sepsis has almost tripled in the last 25 years[2] and in the penultimate Confidential Enquiry into Maternal Death in the United Kingdom, sepsis was the leading cause of direct maternal death. There has also been an increase in the incidence and severity of sepsis morbidity in other parts of the resourced world including other European countries and the United States.[3–5] The Scottish Confidential Audit of Severe Maternal Morbidity showed a rate of septicaemic shock of 0.13/1000 maternities in the 2003–2005 triennium.[6] In a retrospective analysis covering 10 years between 1998 and 2008 and using data from the Nationwide Inpatient Sample, Bauer et al. demonstrated that of 44,999,260 hospitalizations for delivery, sepsis complicated 1/3333 (95% confidence interval (CI) 1/3151–1/3540) deliveries with severe sepsis complicating 1/10,823 (95% CI 1/10,000–1/11,792) deliveries.[5]

Sepsis in the obstetric population poses significant challenges: the physiological changes of pregnancy may mask the clinical signs of sepsis and lead to a delay in diagnosis and treatment. When sepsis occurs in the antenatal period, maternal deterioration can quickly lead to fetal compromise. Early recognition and diagnosis with rapidly instituted therapy are key to ensuring a good outcome.

## History of obstetric sepsis

> There was never a time when this disease did not exist.
>
> Nathaniel Hulme, *A Treatise on the Puerperal Fever* (London, 1772)

Like all infectious diseases, the history of 'childbed fever' is a tragic one, rooted in the incomprehension of contagiousness. Historically, childbed fever referred to puerperal sepsis due to infection, primarily by Group A *Streptococcus* (GAS), contracted from aseptic, unsanitary birthing conditions. Until the recent era of antibiotics, puerperal sepsis was the leading cause of maternal mortality worldwide. In eighteenth-century England, sepsis accounted for approximately 50% of all maternal deaths.[7] During this time and up until the latter part of the nineteenth century, the concept of germs or how infection was spread was unknown or misunderstood. Hence, there was no form of antisepsis at this time. Births were attended to by midwives or accoucheurs (licensed physicians with some training in midwifery), and it was these medical professionals who unknowingly acted as vectors of transmission. As obstetrics became a more formal part of medical practice in mid-nineteenth-century Europe and America, physicians reluctantly began to accept the contagious nature of puerperal infection. Louis Pasteur and Robert Koch confirmed this several decades later with their development of germ theory. After the advent of penicillin in 1944, severe puerperal sepsis was finally relegated to the rare case study in most obstetricians' careers—until recently.

Although insufficient written accounts were made or have survived from before the seventeenth century to make an estimate of the burden of maternal sepsis, it is generally thought that the incidence was relatively rare. This is attributed to the fact that women gave birth at home and were usually attended to by another female family member.[7] In seventeenth-century Europe however, several determinants of maternal health changed, and so too did rates of childbed fever.

Seventeenth-century Europe saw the burgeoning of hospital establishments and with it the beginning of 'lying-in' hospitals. One of the first schools of midwifery and lying-in wards was established at the Hôtel Dieu Hospital in Paris in 1610.

Although viewed by impoverished women as preferable to giving birth in squalor outside of the hospital, accounts of conditions inside the hospital were appalling. As the only hospital in the city, it was severely overcrowded with often more than 2000 patients occupying its 1200 beds.[8] Most patients shared beds and it was not uncommon to find a live patient occupying a bed with another who had already died.[8] At this time, obstetricians or accoucheurs were still not recognized in the medical profession. Obstetric surgery was performed by barber-surgeons, and physicians were seen as superior to either barber-surgeons or midwives. When physicians on occasion had to visit the wards, it is said that they held sponges soaked in vinegar or perfume to their noses to block the vile stench of the sick and dying destitute.[8]

It was in these noxious wards, where mortality is estimated to have been one in four to five,[9] that conditions were rife for epidemics of childbed fever. After the establishment of the Hôtel Dieu lying-in ward in Paris, other lying-in wards and hospitals were founded throughout the eighteenth century in many European cities including Berlin, Vienna, Amsterdam, Stockholm, Copenhagen, Dublin, and London. The first documented epidemic of childbed fever occurred at the Hôtel Dieu in 1646. Subsequent epidemics followed in Paris and other European cities throughout the eighteenth and nineteenth centuries. In the 1770s, the highest annual mortality rate during an epidemic year in the London General Lying-in Hospital was 398/10,000 deliveries.[7] In the Vienna Maternity Hospital during the 1820s, the

highest annual mortality rate of an epidemic year was 745/10,000, and in the Paris Maternité during the 1830s the highest annual mortality rate of an epidemic year was 880/10,000.[7] These rates compare sharply with those of poor women attended to at home by charity midwives. For example, from 1831 to 1843, the rate of mortality due to puerperal sepsis among home births attended to by the Royal Maternity Charity in London was 10/10,000 births, while the mortality rate at the London General Lying-in Hospital was over 600/10,000 births.[7] During epidemic periods, case fatality rates in lying-in hospitals could soar to over 80%. In two of the most devastating epidemics, in the Hôtel Dieu in 1746 and another in Edinburgh, the case fatality rate was 100%—every woman in the wards died.[7]

These epidemics are today widely accepted as having been caused by GAS, mainly due to the fact that puerperal fever epidemics closely correlated with other less invasive GAS infections, particularly erysipelas. In lying-in hospitals midwives, barber-surgeons or accoucheurs would carry out frequent vaginal examinations and successively deliver women without any form of antisepsis in between. In addition, because women were crowded onto the wards and often shared beds, direct transmission of GAS from one woman, with either erysipelas or puerperal fever, to their bed-partner would have been likely.

As accounts of epidemics in lying-in hospitals and towns became more frequently known, what did people think caused this illness? Physicians and midwives agreed that puerperal sepsis was in some way contagious and seasonal, peaking in the winter. Germ theory, however, was not developed until the late nineteenth century. In 1843, Oliver Wendell Holmes published the results of a scholarly review of all published reports of puerperal fever epidemics in the *New England Quarterly Journal of Medicine*. He emphasized the thesis of his work, which was:

> The disease known as puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses.[10,11]

He went on to write:

> The time has come when the existence of a private pestilence in the sphere of a single physician should be looked upon not as a misfortune, but a crime; and in the knowledge of such occurrences, the duties of the practitioner in his profession, should give way to his paramount obligations to society.[10,11]

Almost at the same time, a similar story was unfolding independently in Vienna. In the 1850s, the Vienna Lying-in hospital was the largest in the world with approximately 7000 births per year.[7] Because of the large volume of patients, in 1833 the hospital was divided into two clinics which admitted patients on alternating days. In 1839, one clinic was allocated to serve as the teaching hospital for male medical students training to be obstetricians, and the other was allocated to female midwifery students. After the teaching allocation, the mortality rate of the physicians' clinic rose to three times that of the midwifery clinic (984/10,000 deliveries vs. 388/10,000 deliveries).[7] In 1846 a physician by the name of Ignaz Semmelweis was appointed as assistant to the physicians' teaching clinic. He soon realized that the mortality difference was a result of medical students and physicians going directly from postmortem dissections to examinations on the wards without washing their hands in between.

Despite dogged resistance to Holmes and Semmelweis, the climate of opinion eventually swayed in the latter half of the nineteenth century. This occurred for several reasons. Firstly, Holmes, Semmelweis and their predecessors had created enough controversy on the topic of contagion and antisepsis to begin to cast doubt in budding and open-minded obstetric practitioners. Secondly, the vehicle of transmission was eventually confirmed by the development of germ theory by Louis Pasteur in 1865 and Robert Koch in the 1870s and 1880s. Lastly, the introduction and acceptance of antisepsis in surgery and childbirth by Joseph Lister in the 1860s resulted in a remarkable decrease in puerperal morbidity and mortality that continued into the twentieth century.

At the turn of the century until the introduction of sulphonamides in 1936, rates of puerperal sepsis mortality were on average 175 per 100,000 births per year in England and Wales.[12] From 1936 to 1943, they had fallen to below 30/100,000, which is a testament to the impact of sulphonamides. By 1950, after the introduction of penicillin, the rate was four and by 1960 there was only one death per 100,000 births.[7] Between 1985 and 1987, the rate of death from puerperal sepsis in England was nearly zero (Figure 34.1).[7] This dramatic decrease in puerperal sepsis mortality was mirrored in the United States and the rest of Europe.

However, since the 1980s there has been an increase in the maternal death rate from sepsis (Figure 34.2). This was first highlighted by the UK Confidential Enquiry into Maternal Death covering the 2006–2008 triennium.[2] In this report, sepsis was noted to be the leading cause of direct maternal deaths, accounting for 29 deaths (26 'direct' deaths and a further three deaths classified as 'late direct'). This was in the context of a decline in maternal deaths from other causes, notably thromboembolic disease and haemorrhage (Figure 34.3).[2] Bauer et al. used data from the Nationwide Inpatient Sample in the United States to investigate the frequency and trends in maternal morbidity and mortality from sepsis. They found that sepsis-related death complicated 1/105,263 (95% CI 1/83,333–1/131,579) deliveries.[5]

## Definitions

There is currently no universally accepted definition of sepsis in obstetric practice. Various terms are used interchangeably but there are important distinctions. 'Infection' describes a microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by these organisms. Bacteraemia describes the presence of viable bacteria in the blood.

The term sepsis includes illness that ranges from minor signs and symptoms through to organ dysfunction and shock. The term puerperal sepsis is still used to describe sepsis occurring after delivery and the World Health Organization (WHO) has defined it as 'infection of the genital tract occurring at any time between rupture of membranes or labour, and the 42nd day postpartum', in which two or more of the following are present (Box 34.1).[13]

A widely used definition for sepsis in the non-pregnant patient came from the American College of Chest Physicians and the Society of Critical Care Medicine (Box 34.2).[14] This was modified in 2001 by the International Sepsis Definition Forum to include alterations in physiological variables, in order to more accurately convey the clinical experience. However, because of the physiological changes of pregnancy and particularly those around the time of delivery, this definition lacks validity in obstetric patients.

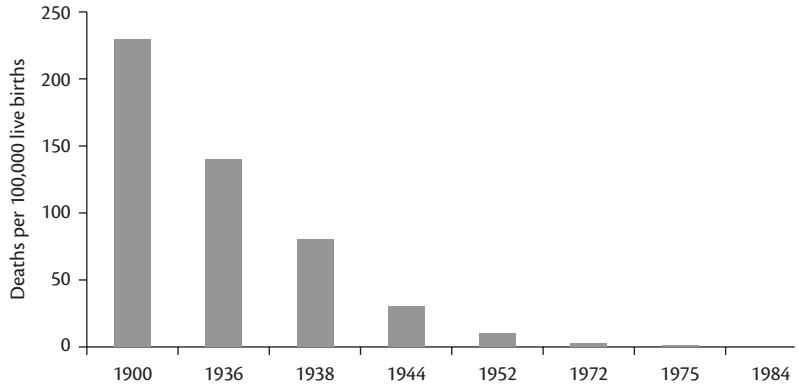

**Figure 34.1** Mortality rates from puerperal sepsis in England and Wales 1900–1984.
Data from: Loudon I. The Tragedy of Childbed Fever. 1st ed. Oxford University Press, USA; 2000; and UK Confidential Enquiries 1972, 1975 and 1984.

There are various other reasons that add to the difficulty of defining sepsis in obstetric practice. Sepsis may arise in an obstetric patient at any time: before delivery, during labour, or in the postnatal period. In addition, sepsis in obstetric patients can arise from many sources and is not limited to infections arising from the genital tract. This difficulty in reaching a definition is demonstrated by the organization of cases in the UK Confidential Enquiry reports. Deaths due to group A beta-haemolytic *Streptococcus pyogenes*, as well as other infections related to pregnancy or delivery, are classified as direct deaths, whereas deaths from infections unrelated to the genital tract such as pneumococcal meningitis and HIV disease are classified as indirect maternal deaths. A new pathological classification has been proposed for future confidential enquiries.[2]

The WHO Technical Working Group has introduced the term puerperal infections as a more general term than puerperal sepsis, to include not only infections related to genital tract sepsis, but also all extragenital infections and incidental infections (Box 34.3).[13]

## The immune system in pregnancy

Pregnancy has traditionally been viewed as an immunocompromised state arising as a result of the necessity not to immunologically reject the fetus, and therefore placing the mother at increased risk of infectious diseases. However, there is now a wealth of evidence to suggest that rather than being an immunosuppressed state, pregnancy presents a modified immune state whereby there may be contrasting responses to different infections, responses that are also determined by the stage of pregnancy.[15,16,17] From a logical and evolutionary perspective a successful pregnancy is key to the conservation of the species and it has been suggested by Wilson that pregnancy is a 'paradoxical immune state where foreign tissue is not only tolerated but nurtured'.[18]

A competent immune response is essential to protect the mother directly and the fetus indirectly. The immune response depends on either cell-mediated immunity (particularly T lymphocytes) or the humoral response (antibodies secreted by B lymphocytes and plasma cells). During pregnancy, progesterone and oestrogen reduce T-cell proliferation and there is consequently a reduction in cell-mediated immunity which might otherwise prove harmful to the fetus. The maternal immune system is therefore biased towards humoral immunity.[19] Coupled with this is the developing active immune system of the fetus, which will also modify the maternal response to infection.

Three distinct immunological phases have been described in pregnancy, roughly corresponding with the first, second, and third trimesters, and associated with dramatic changes in cytokine levels.[17] The combined effect of these interactions serves to explain why pregnancy women may exhibit a diverse response to infection, depending not only on the infecting organism but also on the stage of the pregnancy, for example, pregnant women living in malarial endemic areas are more susceptible to malarial infection in the first half of pregnancy and this susceptibility decreases as the pregnancy progresses.[20]

**Box 34.2** American College of Chest Physicians and Society of Critical Care Medicine definitions related to sepsis

**Systemic inflammatory response syndrome**

Systemic inflammatory response syndrome (SIRS) is a widespread inflammatory response to a variety of severe clinical insults. This syndrome is clinically recognized by the presence of two or more of the following:

- Temperature > 38°C or < 36°C
- Heart rate > 90 beats/min
- Respiratory rate > 20 breaths/min or $PaCO_2$ < 32 mmHg
- White blood cells > 12 × $10^9$/dL or < 4 × $10^9$/dL or > 10% immature (band) forms.

**Sepsis**

Sepsis is the systemic response to infection. Thus in sepsis, the clinical signs describing SIRS are present together with definitive evidence of infection.

**Severe sepsis**

Sepsis is considered severe when it is associated with organ dysfunction, hypoperfusion, or hypotension. The manifestations of hypoperfusion may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status.

**Septic shock**

Septic shock is sepsis with hypotension despite adequate fluid resuscitation. It includes perfusion abnormalities such as lactic acidosis, oliguria, or an acute alteration in mental status. Patients receiving inotropic or vasopressor agents may not necessarily be hypotensive at the time that perfusion abnormalities are present.

**Box 34.3** World Health Organization definition of puerperal infections

Infections of the genitourinary system related to labour, delivery and the puerperium:
Infections related to the uterus and its associated structures (endometritis)
Infections related to the urinary tract
Infections specifically related to the birth process but not of the genitourinary system:
e.g. breast abscess
Incidental infections:
e.g. malaria, respiratory tract infections

## Risk factors for sepsis in obstetrics

Sepsis can arise at any time during pregnancy and the puerperium, and may develop as a result of bacteraemia (although bacteraemia does not always lead to sepsis), or as a result of local infection. Risk factors for maternal sepsis may be divided into intrinsic patient factors and obstetric factors, and these are summarized in Box 34.4. In addition, women from poor socioeconomic backgrounds are at greater risk of sepsis although the mechanisms are unclear.[21] Although none of the women who died from sepsis in the 2006–2008 UK Confidential Enquiry report were obese, obesity remains a significant risk factor for obstetric sepsis; in the 2003–2005 report, the majority of the women who died from sepsis were obese.[22] More recently in a Scottish population-based case–control study, obese women had twice the odds of uncomplicated sepsis, that is, with no diagnosis of septic shock or additional organ dysfunction (adjusted odds ratio (aOR) 2.12; 95% CI 1.14–3.89) compared with women of normal weight.[23] The same study also identified other significant risk factors as age less than 25 years (aOR 5.15; 95% CI 2.43–10.90) and multiparity (aOR for uncomplicated sepsis and severe sepsis, 6.29, 12.04 respectively). It

has been suggested that a possible explanation for sepsis associated with the identified risk factors is low serum 25-hydroxyvitamin D (25(OH)D) concentrations.[24] Vitamin D has been found to reduce the risk of sepsis through induction of antimicrobial peptides known as cathelicidin and defensins.[25] Women who are obese have lower serum 25(OH)D concentrations because of their larger body mass. It is well established that chronic comorbid conditions such as congestive heart failure, chronic liver disease, and chronic renal disease are risk factors for sepsis in the general population and Bauer et al demonstrated these associations for parturients also.[5] In the same study, systemic lupus erythematosus was also identified as a risk factor, likely as a result of the immunological effects of the disease itself but also secondary to the use of steroids and immunosuppressive medications. Although women with these conditions are a relatively small proportion of obstetric patients, the study authors suggested that the magnitude of risk associated with these conditions prompted consideration of the diagnosis and treatment of sepsis in patients with these conditions.

In patients with sickle cell disease, functional asplenia results in increased susceptibility to bacterial infection; three women whose deaths were reported in the 2006–2008 Confidential Enquiry were noted to have either sickle cell disease or sickle trait. An analysis of maternal outcomes in almost 18,000 deliveries by women with sickle cell disease found that there was a significantly higher rate of sepsis in this group (odds ratio (OR) 6.8) compared to women without sickle cell disease.[26] This risk may be further compounded by the presence of anaemia.[27] Sickle cell trait has in the past been viewed as a benign carrier state but there is now some evidence that it can be viewed as an intermediate disease phenotype.[28] A study of maternal outcomes amongst haemoglobinopathy carriers found an increased risk of bacteriuria in women with sickle cell trait.[29]

## Causes of sepsis in obstetrics

The causes of sepsis in obstetrics may be divided into obstetric causes and other causes, and are summarized in Box 34.5. In early pregnancy, the commonest causes of sepsis are septic abortion and termination of pregnancy. Caesarean delivery endometritis used to be a major cause of postpartum infection with the incidence of sepsis following operative delivery once being as high as 36%.[30] Women undergoing caesarean delivery still have a 5–20-fold greater risk for infection and infectious morbidity compared with a vaginal birth.[31] A cohort study from Denmark of over 32,000 women compared the risk of postpartum infections within 30 days of delivery, following vaginal delivery, or emergency or elective caesarean delivery. The risk of postpartum infection for all women delivered by caesarean delivery was 7.6%, versus 1.6% for women who had a vaginal delivery (aOR 4.71).[32] Routine antibiotic prophylaxis at caesarean delivery was in place during the study period and therefore even with this precaution infection was five times more likely in women who delivered by caesarean delivery rather than vaginal delivery. The authors also found a nearly 50% higher risk of postpartum wound infection after emergency caesarean delivery compared to elective caesarean delivery (OR 1.49).

Smaill et al. reviewed 86 studies involving over 13,000 women.[31] They found prophylactic antibiotics in women undergoing caesarean delivery substantially reduced the incidence of febrile morbidity, wound infection, endometritis, and serious maternal

  - Breast infection—abscess/mastitis
  - Septic pelvic thrombophlebitis.

**Non-obstetric causes**

- Human immunodeficiency virus
- Pneumonia
- Tuberculosis
- Malaria.

infectious complications. The mandatory use of prophylactic antibiotics at caesarean delivery has been a recommendation for some time. However, the timing of prophylactic antibiotics has been the subject of some discussion.[33] Largely because of concerns about neonatal infection, the prevailing practice in the United Kingdom has been to use narrow-range antibiotics after cord clamping, compared to the practice of broad-spectrum preincision antibiotics which is standard in non-obstetric surgery. A recent meta-analysis suggests the latter approach may be more effective in reducing infections after caesarean delivery, without any detrimental effect on the neonate.[34] The American College of Obstetricians and Gynecologists recommends this strategy[35] and in the United Kingdom the National Institute for Health and Care Excellence (NICE) *Caesarean Section* guideline update has also made similar recommendations.[36] The appropriate and optimal antibiotic for prophylaxis likewise remains unclear.[37] A Cochrane review found there was no conclusive evidence of any outcome difference between cephalosporins and penicillins in regard to maternal sepsis, endometritis, fever, wound infection, urinary tract infection, and adverse effects.[38]

Septic abortion was once the leading cause of maternal death around the world and remains a significant cause of maternal mortality in the under-resourced world, largely as a result of illegal abortions. According to the WHO, an estimated 21.6 million unsafe abortions took place worldwide in 2008 with deaths from unsafe abortion accounting for 13% of all maternal deaths (as a result of sepsis and haemorrhage).[39] In the UK Confidential Enquiry into Maternal Death, eight women died as a result of infection associated with spontaneous miscarriage or therapeutic/artificial abortion. Initially infection involves the endometrium and any retained products of conception, thus removal of retained products of conception are essential in the early management. Rarely hysterectomy may be required.[40]

Chorioamnionitis may be defined as acute inflammation of the membranes and chorion of the placenta. It typically arises secondary to ascending bacterial infection in the presence of membrane rupture, although it can occur with intact membranes.[41] More rarely it occurs as result of haematogenous spread[42] or as an iatrogenic infection secondary to an invasive procedure. The incidence of chorioamnionitis varies according to different diagnostic criteria (clinical, microbiological, or histopathological). Risk factors for the development of chorioamnionitis include prolonged rupture of membranes,[43,44] multiple vaginal examinations,[43] the use of internal monitoring,[43] meconium-stained amniotic fluid,[45,46] and bacterial vaginosis.[47] Women who smoke are also at increased risk.[44] In addition to the risks of infection, chorioamnionitis is associated with significant other risks to both the mother and baby; for the mother there is an increased risk of caesarean delivery and postpartum haemorrhage, likely as a result of dysfuntional uterine activity.[48] Fetal/neonatal risks include fetal death, neonatal sepsis, intraventricular haemorrhage, and long-term disability including cerebral palsy.

It has been estimated that after vaginal delivery, mastitis and urinary tract infections are the commonest causes of infection.[49] Mastitis affects up to 20%[50] of postpartum women but is comparatively rare as a cause of postpartum sepsis. It is usually unilateral and associated with hardening of the affected breast, erythema, and severe pain. It has been estimated that one-third of women admitted with mastitis develop breast abscesses that require surgical drainage. The majority of these are caused by community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA).[51,52] One of the deaths in the 2006–2008 UK Confidential Enquiry into Maternal Death occurred as a result of sepsis arising from mastitis. There are isolated case reports of toxic shock syndrome occurring as a result of mastitis.

As a result of the physiological and anatomical changes of pregnancy within the urinary tract there is increased susceptibility to urinary tract infection and urosepsis. There is renal pelvic and ureteric dilatation secondary to mechanical obstruction by the gravid uterus. Progesterone-induced smooth muscle relaxation leads to decreased peristalsis of the ureters, increased bladder capacity, and urinary stasis. Asymptomatic bacteriuria has an incidence in pregnancy of between 2% and 10% but it has been estimated that if left untreated as many as 20–40% will go on to develop pyelonephritis.[53,54] A retrospective cohort study of over half a million pregnancies in the United States found an incidence of acute antepartum pyelonephritis of 0.5%.[55] Pyelonephritis in pregnancy is associated with increased maternal and fetal morbidity, including acute kidney injury, acute respiratory distress, stillbirth, and preterm birth.[56] The presence of a urinary catheter in association with operative delivery and/or neuraxial analgesia increases the risk.[57] A Cochrane review found that antibiotic treatment compared to placebo or no treatment was effective in clearing asymptomatic bacteriuria (risk ratio (RR) 0.25; 95% CI 0.14–0.48) and that the incidence of pyelonephritis was also reduced (RR 0.23; 95% CI 0.13–0.41). Antibiotic treatment was also associated with a reduction in the incidence of low birthweight babies (RR 0.66; 95% CI 0.49–0.89) but there was no difference in preterm delivery.[58]

Postpartum ovarian vein thrombophlebitis is a rare complication of sepsis in pregnancy. The incidence varies from 1/600 to 1/2000 deliveries.[59] It occurs as a result of the hypercoagulable state of pregnancy combined with blood flow stasis and is then further compounded by vessel wall damage by direct trauma which then predisposes to infection. The right ovarian vein is involved in the majority of cases.[60] The right-sided prevalence is due to two factors: the physiological dextrorotation of the uterus during pregnancy, which compresses the ovarian vein on the right; and to the direction of postpartum blood flow, which is antegrade in the right ovarian vein and retrograde in the left ovarian vein. The symptoms of ovarian vein thrombosis usually develop within 4 weeks of delivery, most frequently within the first 4 days. Symptoms may be vague and can include abrupt onset fever, rigors, and lower abdominal pain. The differential diagnosis includes endometritis, acute appendicitis, and pyelonephritis.[61] Abdominal examination may reveal a tender elongated mass and the diagnosis may be confirmed by ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). Treatment involves broad-spectrum antibiotics and anticoagulation and may rarely require surgical intervention.[62] One study estimated a mortality of 5% if untreated.

Pneumonia as a cause of sepsis in pregnancy is associated with significant morbidity and mortality.[63] It is one of the leading causes of sepsis arising in the antepartum period. The true incidence of antepartum pneumonia is difficult to ascertain but has been estimated at 0.78–2.7/1000 deliveries.[64,65] In the United Kingdom, pneumonia is the most common reason for admission to intensive care for pregnant women;[66] in the United States, respiratory failure as a result of pneumonia is the third leading

indication for intubation during pregnancy.[67] The risk of developing pneumonia appears to increase with advancing gestation with the lowest risk in the first trimester and the highest risk in the third trimester. There are various maternal risk factors associated with an increased incidence of developing pneumonia; these include co-morbidities such as cardiac disease and asthma, one study showed a fivefold increase for the risk of pneumonia in a pregnant woman with asthma. Maternal obesity is another significant risk factor.[68,69] In pregnant women who develop pneumonia, there is a higher rate of complications such as respiratory failure. Fetal outcome in pregnant women with pneumonia is significantly worsened: the fetus is vulnerable to intrauterine growth retardation and *in utero* death; preterm delivery may be required to improve maternal respiratory function.[68]

The clinical features of pneumonia can mimic the physiological changes of pregnancy and delay diagnosis and treatment leading to a poor outcome. The specific respiratory physiological changes of pregnancy predispose the parturient with pneumonia to rapid desaturation and a reduced ability to compensate for the development of a metabolic acidosis.

The differential diagnosis of pneumonia in pregnancy includes pulmonary embolus and pulmonary oedema. It is essential to remember that pregnancy does not exclude the use of chest radiography. The most common bacterial agent causing pneumonia in pregnancy is *Streptococcus* pneumoniae. The consequences of viral pneumonia in pregnancy have been particularly topical in recent years as a result of the H1N1 flu pandemic. Women in pregnancy and the puerperium are known to be at higher risk of complications of seasonal flu than the non-pregnant population. In previous flu pandemics, pregnant women had significantly higher mortality and morbidity rates and this effect was seen in the 2009 pandemic.[70,71] A UK-based case–control cohort study found that pregnant women admitted to hospital with H1N1 influenza had significantly higher rates of adverse pregnancy outcomes than uninfected pregnant women. These included three to four times higher rates of preterm birth, four to five times higher rates of stillbirth, and four to six times higher rates of neonatal death.[72]

Risk factors associated with admission to hospital with 2009/H1N1 in pregnancy include maternal obesity, asthma, multiparity, multiple pregnancy, black or other minority group ethnicity, and smoking. A delay in starting treatment with antiviral drugs, more than 2 days after the onset of symptoms, was associated with an increased risk of admission to intensive care.[70–72]

## Microbiology

The genitourinary tract is colonized with a wide variety of organisms; however, not all of these will cause infection and sepsis. Pregnant women who develop sepsis are very likely to be infected with more than one organism. Analysis of the microbiological causes of deaths from sepsis (direct and indirect) over the last 20 years of the UK Confidential Enquiries is shown in Table 34.1.

Historically, although they were not characterized serologically by Rebecca Lancefield until 1933, it seems likely that GAS was the predominant cause of obstetric sepsis in the first half of the twentieth century.[73,74] Outbreaks were frequently described, particularly when scarlet fever was also prevalent. In the latter part of the twentieth century, factors such as improved antiseptic techniques, the use of antibiotics, and an increase in natural immunity lead to a decline in the virulence of this organism. Gram-negative organisms such as *Escherichia coli* then became more common sources of infection. However, over the past 20 years Gram-positive organisms, and in particular GAS infections, have again become predominant. This is consistent with the pattern of GAS infections in the general population of the developed world, where there has been a dramatic rise in the number of such infections.[75,76] The Lancefield classification of *Streptococcus* species is based on their haemolytic properties. GAS are β-haemolytic species that cause complete rupture of red blood cells in culture media leading to a clear zone around the bacteria. They have a number of factors that affect their virulence, for example, M proteins which form complexes which adhere to vascular endothelium and cause endothelial leaks and hypercoagulability leading to disseminated intravascular coagulation. Other factors that further contribute to the virulence of GAS include the production of toxins such as streptokinase, streptolysins, and exotoxins.[77] The epidemiology of GAS is of relevance in obstetric sepsis. It has been estimated that in the resourced world between 5% and 30% of the community are asymptomatic carriers of GAS, usually on the skin or in the throat. It is present in the vaginal tract of only 0.03% of pregnant women; however, postpartum women have a 20-fold increased incidence of GAS infection compared with non-pregnant women.[78] In the 2006–2008 Confidential Enquiry, the majority of the deaths were noted to occur between December and April; GAS upper respiratory tract infections are most common during winter and early spring in contrast to skin infections caused by GAS which are seen more frequently during the summer, when the skin is exposed and abrasions and insect bites are more likely to occur. In many of the women who died in the Confidential Enquiry there was a history of a recent upper respiratory tract infection and/or of contact with young children.[2] It is thought that women auto-inoculate themselves, through contamination of the perineum, and the organism then ascends leading to systemic infection. GAS is highly communicable and this has implications for identifying the source of infection and also for contacts of a parturient with GAS infection, including healthcare workers.

A major source of concern is sepsis arising as a result of extended-spectrum beta-lactamase (ESBL)-producing organisms.[79] ESBLs are enzymes that can be produced by bacteria making them resistant to third-generation cephalosporins commonly used for treatment of serious infections. The first beta-lactamase was identified in an isolate of *Escherichia coli* in 1940[80] and since then an increasing number of organisms producing ESBL have been identified. Initially ESBLs were mostly found in *Klebsiella* species in hospital, particularly intensive care patients. However, a new group of ESBLs (called CTX-M enzymes) has emerged and these have been widely detected among *Escherichia coli* bacteria.[81]

The emergence of these bacteria has been attributed to the extensive use of broad-spectrum beta-lactamase in empiric therapy and rapid plasmid-mediated distribution of resistance genes between bacterial species. Although ESBL-producing organisms occur principally in *Enterobacter* species, particularly *Escherichia coli, Klebsiella pneumoniae*, and *Proteus mirabilis* (all recognized causes of obstetric sepsis), they can occur in other members of the non-enteric organisms, such as *Acinetobacter* species.[82]

In the developing world, there are more limited data on the specific microbiological causes of obstetric sepsis. Available evidence suggests a similar pattern of bacterial causes to that in the developed world.[83] However, in recent times the HIV/AIDS pandemic

Number of deaths in table may not equal actual number of deaths from reports as full microbiological data not always available.

has undoubtedly been the most important factor with regard to sepsis-related maternal morbidity and mortality in the developing world. A major WHO analysis assessing progress towards the Millennium Development Goal of reducing maternal mortality, found that in 2008 there were an estimated 342,900 maternal deaths worldwide from all causes, a 34% decline from 1980.[84] It is estimated that HIV disease accounted for 61,400 of these deaths. The impact of this disease was greatest in sub-Saharan Africa, where WHO estimates for 2008 suggest that without HIV/AIDS-related deaths, the maternal mortality ratio for sub-Saharan Africa would have been 580 maternal deaths per 100,000 live births instead of the actual figure of 640.[85]

Pregnant women with HIV/AIDS are more susceptible to sepsis and postsurgical complications. Many opportunistic infections associated with HIV/AIDS may complicate pregnancy and cause maternal mortality.[86] *Pneumocystis jirovecii* (previously *carinii*) pneumonia has a more aggressive course during pregnancy, with an increase in both morbidity and mortality.[87] The South African confidential enquiry into maternal deaths, 'Saving Mothers', found that bacterial pneumonias, bacterial sepsis, atypical pneumonia, cryptococcal meningitis, and tuberculosis (TB) are common co-morbid conditions associated with HIV/AIDS, and may be the primary causes of maternal death in that country.[88] Worldwide the most significant infection contributing to maternal mortality in HIV-infected women is TB. TB accounts for about 700,000 deaths annually in women of reproductive age,[89] and is by far the most common opportunistic infection associated with HIV in the developing world. A 5-year review of maternal mortality at a

tertiary referral centre in Johannesburg found that mortality in HIV-infected women was 6.2 times greater than in HIV-negative women and that 31% of HIV-related deaths were due to TB.[90]

Postnatal care is often poor in African countries, and puerperal sepsis is a major cause of maternal mortality.[91] It has been suggested that the impact of puerperal sepsis could be significantly reduced if, following delivery, women were to remain in hospital for at least 24 hours, and/or improved arrangements were put in place for postnatal follow-up. Clinical experience suggests that HIV-infected women may be clinically well at the time of early discharge, only to be re-admitted with florid sepsis 7–10 days after delivery.[88]

## Clinical presentation and diagnosis

Sepsis is a clinical diagnosis and microbiological investigations may be negative. The onset of sepsis may be insidious and non-specific, particularly given the physiological changes of pregnancy, labour, and the puerperium. There is significant overlap with the clinical features associated with the physiological changes of pregnancy (particularly around the time of delivery) and the pathophysiology of sepsis. Diagnosis can therefore be difficult, especially in the early stages. Conversely the disease process can be fulminant, overwhelming, and rapidly fatal.[92–94] The clinician must often rely on a high index of clinical suspicion rather than objective criteria. Women at risk of infection (e.g. the immunocompromised) should be identified early in pregnancy.

Initially infection may present with non-specific symptoms such as fever, malaise, and muscle ache. A careful history should aim to elicit features of localized symptoms and clarify the possible source of infection; the presenting features vary depending on the source of infection (Table 34.2). Maternal infection can rapidly affect the fetus: the uteroplacental circulation does not exhibit autoregulation, so that fetal perfusion and oxygenation is dependent on maternal oxygenation and cardiovascular stability.

**Table 34.2** Symptoms and signs of sepsis

| Symptoms | General | Specific |
|---|---|---|
| | Fever | Premature contractions |
| | Influenza-like symptoms | Abdominal pain |
| | Sore throat | Sickle cell crisis |
| | Diarrhoea | Atonic uterus precipitating postpartum haemorrhage |
| | Vomiting | Mastitis |
| | Shortness of breath | Vaginal discharge—profuse and/or malodorous |
| | Wound infection | |
| **Signs** | Pyrexia or hypothermia, < 36°C | |
| | Early pregnancy loss/abnormal fetal heart rate/death *in utero* | |
| | Tachycardia > 100 beats/min | |
| | Tachypnoea > 20 breaths/min | |
| | Elevated white cell count and neutrophilia or low white cell count/neutropenia | |
| | Rising C-reactive protein | |
| | Lactic acidosis | |
| | Signs of organ decompensation: hypoxaemia; hypotension; cool extremities; reduced capillary refill; oliguria | |

Thus the septic woman may present with an abnormal fetal heart rate pattern or intrauterine fetal death.

Women will invariably experience some degree of pain following caesarean delivery or significant vaginal tears. However, the presence of constant, severe abdominal or perineal pain, poorly responsive to analgesics and disproportionate to that which would be anticipated, is a cause for concern, particularly when it is associated with diarrhoea, and sepsis must then always be considered in the differential diagnosis.[2] When mastitis that does not respond to conservative management within 24 hours, and the woman is becoming systemically unwell, then the breasts must be considered as a possible source of sepsis.

The onset of sepsis is characterized by a hyperdynamic circulation, reduced systemic vascular resistance secondary to arterial vasodilatation, and increased respiratory rate in association with the development of anaerobic metabolism and lactic acidosis. Therefore when sepsis develops not only can diagnosis be made more difficult because of the physiological changes of pregnancy, but in addition the combined effect of pathological processes superimposed on a state of increased physiological demand may result in a particularly severe disease burden.

Pyrexia is common in sepsis but normothermia may also be present. Hypothermia is a particularly significant finding. Swinging pyrexia suggests a persistent source of infection or inadequate treatment.[2] Although an elevated white cell count is commonly associated with sepsis, pregnancy also leads to an increase in white cell count, particularly during labour. After delivery, the white cell count usually decreases to prepregnancy levels within a week: a white cell count that fails to decrease to normal levels or conversely decreases rapidly or becomes less than $4 \times 10^9$/L may indicate severe infection. One of the most sensitive and earliest clinical signs of sepsis is tachypnoea which arises as a result of pyrexia, lactic acidosis, or cytokine-mediated effects on the respiratory centre. The overlapping physiological changes of pregnancy and clinical features of sepsis will often pose diagnostic difficulty and the existence of a suitable biomarker in this context would be particularly useful. In the intensive care community, there has been significant interest in the use of biomarkers to help establish a diagnosis of sepsis. Much of this discussion has focussed on procalcitonin. Procalcitonin is a peptide precursor of the hormone calcitonin and is produced by the parafollicular cells of the thyroid and the neuroendocrine cells of the lung and the intestine. Procalcitonin levels rise specifically in the presence of bacterial but not viral or fungal sepsis.[95] Therefore laboratory measurement of procalcitonin levels can potentially assist with diagnosis. However, meta-analyses have produced conflicting results on whether procalcitonin is an effective and useful sepsis biomarker.[96,97] A recent comprehensive review states that clinical judgement should remain the cornerstone of clinical decision-making. A more encouraging role for procalcitonin is its measurement to guide duration of antibiotic therapy.[98] Paccolat and colleagues have published work establishing procalcitonin levels during pregnancy, delivery, and postpartum.[99]

## Management and the surviving sepsis campaign

Management of the septic pregnant patient follows the same principles as that of any septic patient: resuscitation, identification

and treatment of the source of sepsis, management of complications such as hypotension and tissue hypoxia, and the application of organ-protection strategies. The management of sepsis arising in the antenatal period is complicated by the presence of the fetus; in this situation, maternal resuscitation is key to ensuring fetal well-being[100] and attempting early delivery in women with cardiovascular compromise due to sepsis may increase maternal and fetal mortality.[101] However, when intrauterine infection is suspected as the source of sepsis, delivery should be expedited.[102]

Early recognition of the obstetric patient with sepsis is vital to ensuring optimal outcome. As noted previously, the physiological changes of pregnancy can make early detection difficult and at the same time exacerbate the course of sepsis in an obstetric patient. The use of early warning scores was a recommendation in the 2003–2005 UK Confidential Enquiry.[22] Clear evidence of outcome benefit is, however, lacking, with one major study on the use of early warning scores and medical response teams in the non-obstetric hospital population failing to demonstrate a reduction in mortality, though this has been attributed to a possible lack of sensitivity in the criteria used for triggering clinical calls.[103] The importance of developing maternity early warning scores with appropriately sensitive parameters for use in obstetric patients has been emphasized by a retrospective review[104] and work in this area is starting to emerge. A prospective review of almost 700 obstetric admissions evaluated a maternal early warning score (MEOWS) chart adapted from the Confidential Enquiry into Maternal and Child Health report.[105] The authors looked at completed MEOWS charts for triggers and hospital notes for evidence of morbidity. Two hundred patients (30%) triggered and 86 patients (13%) had morbidity according to preset criteria, including haemorrhage (43%), hypertensive disease of pregnancy (31%), and suspected infection (20%). The MEOWS was 89% sensitive (95% CI 81–95%), 79% specific (95% CI 76–82%), with a positive predictive value of 39% (95% CI 32–46%) and a negative predictive value of 98% (95% CI 96–99%). There were no admissions to the intensive care unit (ICU), cardiorespiratory arrests, or deaths during the study period. Although these results are encouraging, the authors recognize that adjustment of the trigger parameters may lead to an improvement in positive predictive value. Another group has used data from direct obstetric admissions from the Intensive Care National Audit and Research Centre's Case Mix Programmed Database to design and validate an aggregate weighted early warning scoring system specific to the obstetric population that could be used in the ward environment.[106] Over two thousand direct obstetric admissions from the Intensive Care National Audit and Research Centre's Case Mix Programmed Database were randomly allocated to model development and a similar number allocated to validation sets. The authors analysed physiological variables collected during the first 24 hours of critical care admission and used logistic regression analysis for mortality in the model development set to create a statistically based early warning score. The statistical score was then modified to create a clinically acceptable early warning score. Again, this work produced encouraging results though the study did have some limitations. Although the dataset analysed a large number of admissions these were from admission to the ICU. Therefore it has been postulated that after multiple medical interventions have already taken place, such data may not actually be reliable enough to base an obstetric early warning score on. It is clear that this is an important area and studies such as the Oxford 4P study Pregnancy Physiology Pattern Prediction will provide further valuable information in the future.[107]

Recommendations from the Royal College of Obstetricians and Gynaecologists are that sepsis should be managed in accordance with the Surviving Sepsis Campaign guidelines.[108] This campaign, a collaboration between the European Society of Intensive Care Medicine, the Society of Critical Care Medicine, and the International Sepsis Forum, was launched as a major international health initiative in 2002 and recently updated.[109] It aimed to improve outcome in sepsis and advocated a standardized 'bundle'-based approach for management of the (non-pregnant) critically ill septic patient. A clinical care bundle is a set of interventions, usually no more than five, that when grouped and implemented together lead to better outcomes with a greater impact than if performed individually. The elements in a bundle are ideally based on high-quality or level 1 evidence such as systematic reviews of multiple, well-designed randomized controlled trials. In clinical practice, the application of these elements may not always be done consistently, leading to variations in patient care, so a bundle aims to tie the care elements together into a cohesive unit that must be strictly adhered to for every patient, every time. Lastly, all the components of a clinical care bundle must be completed in a specified time period and place ('the golden hour'). Compliance is measured in an 'all or none' approach.[110]

The Surviving Sepsis Campaign guidelines described two clinical care bundles—the resuscitation bundle and the management bundle. The Royal College of Obstetricians and Gynaecologists advocates the use of these in obstetrics.

The following care bundle, shown in Box 34.6, should be applied immediately where possible or within 6 hours and has been shown to significantly improve survival rates.[111]

**Box 34.6** Surviving sepsis care bundle

**To be completed within 3 hours**

1. Measure lactate level.
2. Obtain blood cultures prior to administration of antibiotics.
3. Administer broad spectrum antibiotics.
4. Administer 30 mL/kg crystalloid for hypotension or lactate ≥ 4 mmol/L.

**To be completed within 6 hours**

5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥ 65 mmHg.
6. In the event of persistent hypotension after initial fluid resuscitation [MAP <65 mm Hg] or if initial lactate was greater than or equal to 4 mmol/L, reassess volume status and tissue perfusion and document findings.
7. Remeasure lactate if initial lactate was elevated.

Antibiotic therapy via the intravenous route and in high therapeutic doses should be started as early as possible, and preferably within 1 hour. There is overwhelming evidence that delay in starting antibiotics is associated with increased mortality[112] and this has consistently been cited as an area of substandard care in successive UK Confidential Enquiries. Causes of delay include errors in administration, prescription errors, patients awaiting senior review, and patients being transferred between departments, and strenuous efforts must be made to avoid such delays.[113] Broad-spectrum antibiotics should be used initially and two or more agents are likely to be needed.[114,115] Urgent microbiological advice should be sought as soon as possible but should also not delay starting antibiotics. The physiological changes of pregnancy, including the increased volume of distribution, which can also be increased in sepsis, can have an effect on the pharmacodynamic and pharmacokinetic profile of the drug. Some women may have impaired renal or hepatic function and serum drug levels may need to be monitored to ensure correct dosage. However, the appropriate loading dose when starting antibiotic therapy is independent of the patient's renal function and the initial loading dose is particularly important to ensure appropriate serum concentrations of drugs.[116]

Regular reassessment of antibiotic therapy should occur in relation to the patient's clinical condition. Treatment should be for a minimum of 7–10 days and it is essential that treatment is not discontinued too soon.[2,22] The 2006–2008 UK Confidential Enquiry[2] suggested a stratified approach to antibiotics in sepsis (Box 34.7); antibiotic regimens should be altered to adapt to the requirements of the local population and the particular clinical situation of the patient.

Early haemodynamic resuscitation is a key goal of therapy.[118,119] The objective is to restore adequate oxygen delivery to peripheral tissues. It is well recorded that in high-risk surgical patients with sepsis, early haemodynamic optimization before the development of organ failure reduces mortality by 23% in comparison with those optimized after the development of organ failure.[120,121] In hypotensive septic patients with a serum lactate greater than 4 mmol/L, volume resuscitation should be used initially, aiming to reach the following clinical endpoints: central venous pressure 8–12 mmHg, mean arterial pressure 65 mmHg, and a urine output of 0.5 mL/kg/h. If measurable, a central venous oxygen saturation of greater than 70% should be aimed for. There is no evidence to support one type of intravenous fluid over another[122] but it is important to note that starch solutions have been withdrawn in the light of recent evidence suggesting they are associated with increased mortality in the critically ill septic patient.[123] Vasopressor support may be considered even before optimal intravenous loading has been achieved.[124] Transfusion of red blood cells may be considered if tissue oxygen delivery still remains inadequate.[125]

Fluid management is difficult in sepsis and may be particularly so in the severely ill obstetric patient: fluid overload leading to pulmonary oedema has contributed to the deaths of some women in UK Confidential Enquiries reports.[2] There are various reasons why the obstetric patient may be vulnerable to fluid overload: the physiological changes of pregnancy are such that at term the parturient is already in a relatively volume overloaded state; co-morbidity such as pre-eclampsia may be present and uterotonic drugs that are known to predispose to fluid retention (e.g. oxytocin) or pulmonary oedema (e.g. prostaglandins) may have been used. Oesophageal Doppler monitoring to guide intravenous fluid therapy has been endorsed by NICE. [126] Although this report did not assess its use in obstetric patients, the oesophageal Doppler has successfully been used in the obstetric emergency situation.[127] A variety of other minimally and non-invasive techniques for maternal cardiac output monitoring are available[128] and it would seem likely and appropriate that these should become increasingly used in obstetric practice. Further details on these devices are available in Chapter 30.

Supplemental oxygen therapy is recommended even if there is no respiratory distress. Tracheal intubation and ventilation should be considered if the level of consciousness is reduced or if there is hypoxia or progressive respiratory distress.[129]

A simplified strategy for the bundle-based approach to sepsis (the 'sepsis six'), has recently been shown to be effective in a general hospital setting (Box 34.8.[130])

In addition to starting antibiotic therapy and the strategies described above, it is essential that any septic focus is identified and removed wherever feasible. Even with effective antibiotics the woman may continue to deteriorate unless the source of infection is identified. Relevant swabs and cultures should be taken

**Box 34.7** Suggested antibiotic therapy in obstetric sepsis

**Where the organism is unknown and the woman is not critically ill**

- Co-amoxiclav 1.2 g 8-hourly or cefuroxime 1.5 g 8-hourly or cefotaxime 1–2 g 8-hourly or 6-hourly *plus* metronidazole 500 mg 8-hourly
- In cases of allergy to penicillin and cephalosporins, use clarithromycin 500 mg 12-hourly or clindamycin 600 mg to 1.2 g 8-hourly or 6-hourly *plus* gentamicin to give Gram-negative cover, while waiting for microbiological advice

**In severe sepsis or septic shock**

- Piperacillin–tazobactam 4.5 g 8-hourly or ciprofloxacin 600 mg 12-hourly *plus* gentamicin 3–5 mg/kg daily in divided doses every 8 hours[a]
- A carbapenem such as meropenem 500 mg to 1 g 8-hourly ± gentamicin
- Metronidazole 500 mg 8-hourly may be considered to provide anaerobic cover
- NB If Group A streptococcal infection is suspected, clindamycin 600 mg to 1.2 g three or four times daily 8-hourly is more effective than penicillins

If there are risk factors for MRSA septicaemia, add teicoplanin 10 mg/kg 12-hourly for three doses, then 10 mg/kg 24-hourly or linezolid 600 mg 12-hourly.

[a]Gentamicin is more commonly given as a once-daily dose: studies have shown increased efficacy and reduced nephrotoxicity with this strategy.[117]

**Box 34.8** The sepsis six

**The sepsis six to be delivered within 1 hour**

1. Deliver high-flow oxygen
2. Take blood cultures
3. Administer empiric intravenous antibiotics
4. Measure serum lactate and send full blood count
5. Start intravenous fluid resuscitation
6. Commence accurate urine output measurement.

Daniels R, Nutbeam T, McNamara G, *et al*. The sepsis six and the severe sepsis resuscitation bundle: a prospective observational cohort study. *Emerg Med J* 2011; 28:507–12.

before antibiotic therapy is started but should not delay treatment. Where applicable, these should include placental and neonatal swabs, as well as breast milk culture in the presence of mastitis. In women with endometritis, particularly after surgical instrumentation (caesarean delivery or septic abortion) or in patients who fail to respond to antibiotic therapy, imaging with ultrasound or CT is indicated to detect abscess formation. The choice of imaging depends on the condition of the patient and the presence or absence of localizing features. Although ultrasound is more portable than other imaging modalities, the information yielded may not be as helpful and advice from radiologists will be useful. A surgical opinion should be sought as soon as possible with surgery where required.

Necrotizing fasciitis is rare but constitutes a surgical emergency. It has been described in association with caesarean delivery [131] and can present as a perineal infection after vaginal delivery.[132] It is characterized by widespread necrosis of the subcutaneous tissue and fascial layers and can progress to necrosis of muscle. It is most commonly associated with GAS infection, though a mixed bacterial flora including anaerobes is often present. In the early stages it may be difficult to distinguish between cellulitis and necrotizing fasciitis and any patient with a wound infection and signs of systemic sepsis needs careful evaluation to exclude necrotizing fasciitis. Distinguishing features include the presence of copious and malodorous discharge, dusky skin discolouration, and radiological or clinical evidence of gas in the soft tissues.[133] Markedly severe pain disproportionate to that which would be anticipated in the context of individual patients may be present initially but as the condition advances can become painless as a result of disruption in blood supply and innervation. Surgical exploration and extensive debridement is indicated and without early aggressive treatment the mortality is 100%.

## Timing of delivery in the septic parturient

Traditionally it was thought that fetal outcome is entirely dependent on maternal outcome and that delivery is not mandated by the presence of maternal sepsis. However, this approach is being re-evaluated particularly in the context of care of the critically ill parturient, although there is limited data in this area. The considerations of whether there is potential benefit to the mother and fetus need to be balanced against the risks of delivery to both (including issues around fetal viability) and the method of delivery (caesarean or possibly vaginal delivery). From a maternal perspective, there seems to be some evidence that maternal respiratory function and oxygen requirements in the critically ill ventilated parturient may be improved by delivery of the fetus.[134] In a study of obstetric sepsis, worsening maternal respiratory function was the primary indication for delivery.[135] From a fetal perspective, oxygenation is dependent on maternal oxygen delivery, uterine/placental blood flow, with a relative maternal hypocapnia facilitating fetal carbon dioxide extraction. All of these factors may be adversely affected in severe sepsis. Fetal assessment with cardiotocography is indicated and may show fetal tachycardia with an absence of variability occurring as a result of maternal pyrexia. The production of endotoxins can cause uterine contractions. An editorial suggested possible criteria, shown in Box 34.9, that might be considered to indicate a need for delivery.[136]

**Box 34.9** Suggested criteria indicating early delivery when sepsis present

1. Maternal rapid deterioration
2. Failure to maintain adequate blood oxygenation
3. Difficulty with mechanical ventilation due to the gravid uterus
4. Multiorgan failure
5. Fetal compromise
6. Other obstetric indications.

The same authors emphasized that such decisions must be made in discussion with the patient or her family emphasizing our current lack of firm evidence.

A further consideration in this area is the paucity of evidence on the fetal effects of drugs used in the management of maternal sepsis (antibiotics and inotropes). Decisions relating to the delivery of the baby are ultimately the responsibility of the obstetrician, though the obstetric anaesthetist may be able to advise on the timing of this decision in relation to maternal resuscitation. The key elements of maternal status, fetal status, and gestational age need to be carefully weighed to ensure optimal outcome.

## Role of the anaesthetist

Anaesthetists have broad experience in all the elements (resuscitation skills, organ support techniques, and a thorough knowledge of obstetric physiology) required to care for a critically ill parturient and thus the obstetric anaesthetist may have a pivotal role in the management of the septic parturient.[137]

In UK practice, acute management and stabilization of the septic obstetric patient in the maternity unit is most often conducted by the obstetric anaesthetic team. The initial multidisciplinary 'golden hour' of immediate treatment needs to be guided by using a specially adapted sepsis bundle written for the parturient.[108] If the patient does not respond rapidly and the decision is made to escalate her care to level 3 critical care, this transfer should be carried out by an appropriately skilled doctor. Transfer of the critically septic patient requires satisfactory stabilization, rigorous

en route monitoring, and close communication with the receiving unit. Lack of early and precise communication between specialties is an ongoing problem with clinicians involved with obstetric emergencies, and the anaesthetist is often best placed to communicate between the various teams involved.[2,22]

When the decision to deliver has been made, the anaesthetist then has to make a decision about whether to recommend surgery using neuraxial or general anaesthesia. It is generally agreed that neuraxial anaesthesia is relatively contraindicated in patients with severe sepsis. The biggest concerns are the hypothesized increased risk of epidural abscess or meningitis. Quantifying these risks is difficult—the white cell count increases in pregnancy and particularly during labour[138] and there is little correlation between white cell count and the presence of bacteraemia in pregnancy.[139]

Epidural abscess in association with neuraxial blockade can occur as a result of direct introduction of microorganisms on the needle, via local infection at the puncture site, contaminated fluids, or the epidural catheter acting as a foreign body and a nidus for infection in the presence of bacteraemia. Spontaneous cases unrelated to neuraxial anaesthesia are also described and while underlying medical conditions such as diabetes can increase risk, epidural abscesses have also occurred in postpartum women without risk factors and who did not receive neuraxial block.[140] The incidence in all patients admitted to hospital has been estimated at 0.2–1.2/10,000.[141] The Third National Audit Project of the Royal College of Anaesthetists found an incidence of 1/47,000 cases although the majority of reports were in perioperative patients;[142] there was only one report in an obstetric patient. Scott and Hibbard in a retrospective review found only one case in 505,000 women who received epidural anaesthesia for vaginal delivery or caesarean delivery.[143] An incidence of 3% has been quoted in patients who had epidural catheters inserted for chronic pain procedures.[144] Similarly there are several case reports in the literature of meningitis following spinal and epidural anaesthesia and also epidural blood patches,[145–147] but it is difficult to draw firm conclusions from isolated reports. Common features to these reports include difficult procedures, multiple attempts, and epidural catheters remaining *in situ* for extended periods.

In 2004, the American Society of Regional Anesthesia and Pain Medicine convened a Practice Advisory Panel on the Infectious Complications Associated with Regional Anesthesia and Pain Medicine who produced a series of practice guidelines.[148,149] They noted that all patients with local or systemic infection who require neuraxial anaesthesia should be considered at risk of central nervous system infection. The current evidence suggests that patients with evidence of systemic infection may safely receive spinal anaesthesia provided the patient has been commenced on antibiotics and has begun to show a response to treatment. Regarding epidural insertion, evidence is limited to very small studies in women with chorioamnionitis which suggest that it may be safe in similar circumstances. Only in the most unusual circumstances should central neural blockade be performed in patients with untreated systemic infection.

Two final points to consider in relation to neuraxial anaesthesia and sepsis are that a septic hypotensive patient may not tolerate the sympathetic blockade and that coagulopathy may have developed. Ultimately the decision to perform an epidural or spinal in these circumstances must be considered on a case by case basis, assessing the risk:benefit ratio for that individual.

General anaesthesia may often be indicated and once achieved this can facilitate initiating invasive vascular monitoring and inotropic support, if indicated. Decisions as to the reversal of general anaesthesia will depend on the stability of the patient. It may be safer to first transfer the sedated, intubated, ventilated patient to a more appropriate environment.

When radiological imaging (CT or MRI scanning) is required to help identify the source of sepsis, this should only occur in the stabilized patient. Early removal of the source of sepsis is recommended whenever possible and suitably cross-matched blood and blood products may be required before and during surgery.

A secondary role in this area for the anaesthetist is that of education and training in the recognition and management of obstetric sepsis. A systematic review on the effectiveness of multidisciplinary teamwork training in a simulation setting was found to be potentially effective in the prevention of errors and improved patient safety in acute obstetric emergencies.[150] Sepsis shares many features of other obstetric emergencies that simulation training is used for and would benefit from addition to an obstetric training programme.

A strategy including a mandatory rigorous annual training programme and computerized guidelines in an emergency department had a beneficial effect on the management of sepsis, as evidenced by earlier administration of antibiotics and more liberal use of intravenous fluids.[151] In the obstetric setting, anaesthetists are uniquely placed to lead on similar teaching initiatives.

## The future

Sepsis is a major cause of morbidity and mortality worldwide and much work has been directed at improving the outcome of this condition. The management of sepsis in obstetric practice is likely to benefit from this work. The UK maternal death enquiry (Mothers and Babies, Reducing Risk through Audit and Confidential Enquiries across the UK, MBRRACE-UK), are currently conducting a detailed themed review of maternal sepsis and this is likely to yield further valuable information. Recommendations from the 2006–2008 UK Confidential Enquiry emphasize the importance of early recognition of and response to the septic obstetric patient in a 'back to basics' manner.

# CHAPTER 35

# Obstetric haemorrhage

Jane E. Norman and Vicki Clark

## Definitions

Obstetric haemorrhage encompasses both antepartum (APH) and postpartum haemorrhage (PPH).

### Antepartum haemorrhage

The Royal College of Obstetricians and Gynaecologists (RCOG) defines APH as 'bleeding from or into the genital tract, occurring from 24 weeks of pregnancy and prior to the birth of the baby'.[1] This symptom-based definition will be used throughout this chapter.

### Postpartum haemorrhage

PPH is defined as loss of 500 mL or more of blood from the genital tract within 24 hours of the birth of a baby.[2] PPH can be minor (500–1000 mL) or major (more than 1000 mL). These definitions are endorsed in a World Health Organization (WHO) guideline on the management of PPH.[3] Secondary PPH is defined as abnormal or excessive bleeding from the birth canal between 24 hours and 12 weeks postnatally. The tenth revision of the International Classification of Diseases (ICD-10) code for PPH [072] is defined as 'haemorrhage after delivery of the fetus or infant' with no specific volume or time interval attached (Box 35.1).

In the Scottish Confidential Audit of Severe Maternal Morbidity (SCASMM), major obstetric haemorrhage has been defined as occurring in women with 'estimated blood loss of ≥2500 mL, or who are transfused 5 or more units of blood or receive treatment for coagulopathy (fresh frozen plasma, cryoprecipitate, platelets)'.[4]

## Statistics

Major obstetric haemorrhage was reported to occur in around 3.7/1000 births in Scotland during the period 2003–2005 (95% confidence interval (CI) 3.4–4.0).[5] Most recent data from Scotland suggests that the rate of major obstetric haemorrhage has increased to 5.5/1000 births in 2010.[4] This increase has been attributed to better ascertainment rather than increased incidence, although the fact that PPH itself is increasing raises cause for concern (see later in this section). Less than 10% of major obstetric haemorrhages occur antenatally (usually due to praevia or abruption) with the remainder occurring either intrapartum (10%) or postpartum (80%).[4] These data confirm major obstetric haemorrhage to be the commonest major obstetric complication. On the background of this increasing incidence of major obstetric haemorrhage, it is reassuring that the rate of direct maternal deaths due to haemorrhage (i.e. deaths resulting from obstetric haemorrhage complications of the pregnant state (pregnancy, labour and puerperium) is stable[6] (Table 35.1). In the last 'Saving Lives, Improving Mothers' Care (MBRRACE)' report for which data is available (2009–2012), the maternal death rate due to haemorrhage was 0.49/100,000 maternities (95% CI 0.29–0.78).[6]

Worldwide rates of PPH (of which major obstetric haemorrhage occurs in a subset) are around 30–70/1000 births, and have also been found to be increasing.[7–10] Increasing rates of atonic PPH appear to be a major cause.[7,9,10] There is a significant regional variation in PPH rates, perhaps reflecting either differences in methods to measure blood loss, or a truly lower prevalence in Asian compared with European women.[11]

Major obstetric haemorrhage is the commonest reason for intensive therapy unit (ITU) admission amongst pregnant women, accounting for nearly 50% of admissions. The outcome for the baby is also compromised, with perinatal mortality rates of 55.3/1000 in the last SCASSM report.[4,12]

## Risk factors for postpartum haemorrhage

Uterine atony is the commonest cause of major obstetric haemorrhage,[4] occurring in 52% of those affected. A further 18% have retained placenta/fetal membranes. Women undergoing emergency caesarean delivery are over-represented amongst those with major obstetric haemorrhage, with 44% of major obstetric haemorrhage associated with this scenario (compared to 15% of those without).

In a large population-based study of over 850,000 deliveries, the following were independent risk factors for PPH due to uterine atony that was sufficiently severe to require blood transfusion: age less than 20 or greater than 40 years, caesarean delivery, hypertensive diseases of pregnancy, polyhydramnios, chorioamnionitis,

**Box 35.1** Obstetric haemorrhage—definitions

The ICD-10 codes antepartum haemorrhage by both aetiology (e.g. premature separation of the placenta (abruption placentae) [045], and placenta praevia (a condition in which the placenta is implanted in the lower part of the uterus) [044]) and by symptoms (e.g. antepartum haemorrhage not elsewhere classified [046], which specifically excludes haemorrhage in early pregnancy, placenta praevia, and abruption placentae; and intrapartum haemorrhage [067]). These definitions are important for international comparisons, but include women with pathology (placenta praevia) who are not actively bleeding.

Data from various sources (see references).

**Table 35.1** Direct deaths by type of obstetric haemorrhage 1994–2012

| Time period | Placental Abruption | Placental praevia | Postpartum haemorrhage | | Total deaths from haemorrhage | Direct haemorrhage death rate per 100,000 maternities | |
|---|---|---|---|---|---|---|---|
| | | | Atony | Genital Tract Trauma | | rate | CI |
| 1994–06 | 4 | 3 | 5 | 5 | 17 | 0.77 | 0.45–1.24 |
| 1997–99 | 3 | 3 | 1 | 2 | 9 | 0.42 | 0.19–0.80 |
| 2000–02 | 3 | 4 | 10 | 1 | 18 | 0.9 | 0.53–1.42 |

†Figures for UK and Ireland. All other figures are UK only.

*One placenta praevia percreta.

**Includes one woman who had a portion of retained placenta which contributed to the bleeding, and one who also sustained vaginal tears.

***There were four ruptured uteri, two others were lower genital tract trauma, and one had trauma sustained in the form of angle extensions at caesarean section.

multiple pregnancy, retained placenta, and APH.[13] The adjusted odds of PPH were stronger after emergency compared with elective caesarean delivery, but the greatest odds of PPH were observed in association with retained placenta, leading to a 4.1 (3.1–5.5) adjusted odds of atonic PPH requiring transfusion. In another population-based study of 650,000 deliveries, extremes of age, caesarean delivery, hypertensive diseases of pregnancy, polyhydramnios, chorioamnionitis, and multiple pregnancy were also confirmed as risk factors for atonic PPH, with the presence of a large fetus, maternal diabetes, genital tract trauma, and instrumental delivery being additional risk factors.[9] The highest relative risk (RR) of haemorrhage was in women diagnosed with a morbidly adherent placenta who had a markedly higher risk of total PPH (unadjusted RR 13.14; 95% CI 11.43–15.11).[9] Other known risk factors for PPH include upright position in labour (RR 1.65; 95% CI 1.32–2.60, although there is evidence of publication bias),[14] obesity[15] and antidepressant use in pregnancy (RR 1.4–1.9-fold[16]). Elective and/or postdates induction of labour may be protective against PPH.[17] Having a mother or grandmother with PPH does not appear to confer increased risk.[18]

The association between caesarean delivery and PPH noted in both the above-mentioned large prospective studies and in Scottish data on major obstetric haemorrhage is important. Given that emergency caesarean delivery (particularly emergency caesarean at full dilatation) is a stronger risk factor than elective caesarean delivery, it is possible that the association derives from common risk factors for both (such as poor uterine contractility), rather than the process of caesarean delivery itself. The independent effect of caesarean delivery can be inferred from the few randomized trials of caesarean delivery compared with vaginal delivery, either for breech presentation[19] or in the scenario of previous caesarean delivery.[20] In the former scenario, there were no significant differences in rates of maternal PPH between the groups (with the trends favouring elective caesarean delivery).[19] A randomized trial of mode of delivery in women with a previous caesarean delivery favoured repeat elective caesarean delivery, with the risk of major haemorrhage (blood loss > 1500 mL and/or need for blood transfusion) actually being lower in the elective caesarean delivery group in women with a previous caesarean delivery (RR 0.37; 95% CI 0.17–0.80).[20]

## Antenatal and intrapartum optimization

### Prevention of anaemia

A major strand of antenatal optimization of major obstetric haemorrhage involves ensuring pregnant women maintain their haemoglobin concentrations during pregnancy. The National Institute of Health and Care Excellence (NICE) identifies maternal anaemia (haemoglobin of <8.5g/dL) as a possible risk factor for PPH, although it notes that the evidence is inconclusive. Regardless, women with a low haemoglobin are evidently more at risk of adverse consequences following any further blood loss. Screening for anaemia is part of good antenatal care, with NICE advising that 'Screening should take place early in pregnancy (at the booking appointment) and at 28 weeks when other blood screening tests are being performed. This allows enough time for treatment if anaemia is detected'.[21] This is a grade B recommendation. NICE further suggests that haemoglobin levels outside the normal UK range for pregnancy (that is, 11 g/100 mL at first contact and 10.5 g/100 mL at 28 weeks' gestation) should be investigated and iron supplementation considered if indicated (grade A recommendation).[21] Although routine iron supplementation reduces the risk of maternal anaemia, it is associated with adverse maternal effects without improving outcomes and is not therefore recommended. Despite these recommendations, which are not new, the recent Confidential Enquiries on Maternal Health again identified a low haemoglobin at the time of delivery as a factor in maternal haemorrhage due to atony attributed to depleted uterine myoglobin levels necessary for uterine contraction.[6] Parenteral iron preparations should be considered in women who are unable to take or are unresponsive to oral iron (see Chapter 48).

### Antenatal identification of placenta praevia/accreta

Pre-delivery identification has a major role to play in optimizing outcomes in women with placenta praevia or accreta. All women with a previous caesarean delivery should have ultrasound localization of placental site performed in the third trimester because of the increased risk of placenta praevia and accreta in this scenario.[3] The risk of both praevia and accreta is proportional to the number of previous caesarean deliveries—women with three or more caesarean deliveries *and* placenta praevia in the index pregnancy have over a 50% risk of each of placenta accreta and hysterectomy, and over an 80% risk of composite maternal morbidity. Although magnetic resonance imaging is increasingly used before delivery as an adjunct to ultrasound in women with suspected placenta accreta, MRI is not 100% accurate in the diagnosis of accreta and current expert advice is that ultrasound is sufficient unless there is uncertainty.[22]

## Intrapartum and immediate postpartum care

### Routine management of the third stage after vaginal delivery

The mainstay of 'routine' obstetric management to prevent major obstetric haemorrhage is 'active' management of the third stage of labour. This is a package of care consisting of prophylactic administration of a uterotonic agent, early cord clamping and controlled cord traction to deliver the placenta. Active management of third stage of labour is associated with a major reduction in the risk of blood loss over 1 L (RR 0.34; 95% CI 0.14–0.87),[23] although recent evidence suggests that controlled cord traction adds little to the efficacy of the other components of active management, and can be omitted with minimal effect on major haemorrhage rates.[24] NICE indicates that 'Active management of the third stage is recommended, which includes the use of oxytocin (10 international units [IU] by intramuscular injection), followed by deferred clamping and cutting of the cord and controlled cord traction'.[25] In view of the maternal side effects of active management (nausea, vomiting, and headache), and the strong wish by some women to have a 'physiological' third stage, NICE also suggests that 'Women at low risk of postpartum haemorrhage who request physiological management of the third stage should be supported in their choice.'

Importantly, the oxytocic agent endorsed by NICE is oxytocin, 10 IU.[25] Although there is evidence that routine oxytocin–ergometrine (Syntometrine) is superior to oxytocin alone for prevention of PPH (with the odds of blood loss > 500 mL in the oxytocin–ergometrine group being 0.82 times that of the oxytocin group),[26] the side effects of combination therapy are considered to be too great to warrant routine use. Sublingual misoprostol also reduces the risk of severe PPH (compared with no treatment), but is associated with both a greater risk of severe PPH *and* a greater risk of maternal shivering and pyrexia compared with conventional injectional uterotonics, so its use is best restricted to countries where other agents are not available.[27]

### Routine management of the third stage during caesarean delivery

In women undergoing caesarean delivery, 5 IU of oxytocin given slowly intravenously is recommended to prevent PPH—this dose appears as effective as a 10 IU dose but is associated with fewer side effects such as hypotension and tachycardia.[28,29] The oxytocin analogue carbetocin may reduce the requirement for further uterotonics, but does not appear to be superior to Syntocinon® in terms of prevention of PPH.[30]

### Delivery of women with placenta praevia/accrete

Where placenta praevia and/or placenta accreta is identified, delivery should be by caesarean. In asymptomatic women, delivery should be deferred until at least 38 weeks of gestation for women with placenta praevia and 36–37 weeks of gestation for women with suspected placenta accreta. Delivery in both these scenarios should be conducted in units that can cope with the risk of major obstetric haemorrhage—blood transfusion and intensive care facilities should both be available. In women with placenta praevia but not accreta, the RCOG suggests that the method of anaesthesia can be a decision for an individual anaesthetist.[3] Where there is anterior placenta praevia, a strategy of inserting the operator's hand through the lower segment incision and then superiorly between the uterus and the placenta to access the fetus is likely to be safer than cutting through the placenta.

Good practice advice is that women with suspected placenta accreta should be cross-matched before delivery and the use of cell salvage considered. If the placenta is morbidly adherent, consideration should be given to leaving it *in situ* rather than risking its traumatic avulsion.[3] There is no evidence for the efficacy of methotrexate in this scenario[22] but follow-up with human chorionic gonadotropin and ultrasound may be useful in confirming regression of placental tissue. Alternatively, where there is accreta, the use of a fundal uterine incision may avoid placental incision, although the latter is preferred by some authors.[31]

Interventional radiology (IR) balloon occlusion techniques are increasingly used to prevent haemorrhage in placenta accreta. Additionally, IR-administered embolization is increasingly used therapeutically in PPH. If an obstetric patient is at high risk of haemorrhage (e.g. has placenta accreta or fibroids), then prophylactic internal iliac balloons can be inserted prior to caesarean delivery (Figure 35.1). There is some controversy regarding the efficacy of this, with some studies demonstrating a reduction in blood loss or need for hysterectomy and others showing no difference.[32] This may be due to non-standardization of the techniques applied. Further, there is substantial collateral circulation to the uterus from the ovarian artery and vaginal plexuses so that even total occlusion of the internal iliac arteries may still result in bleeding.

There is also controversy about where surgery for the bleeding obstetric patient should take place—the obstetric theatre or the IR suite. Patients with suspected placenta accreta can be managed in the IR suite but this must match theatre standards of sterility and safety. If the patient is to be looked after in the obstetric suite, then an image intensifier and a radiologically compatible theatre table must be available.

Regardless of the therapeutic strategy employed, senior obstetric and anaesthetic staff should be readily available for the delivery of all women with placenta praevia, and directly involved in the delivery of all women with suspected placenta accreta.

## Resuscitation in obstetric haemorrhage

### Initial management

Management of obstetric haemorrhage requires more than one attendant, so help should be requested as soon as possible. Many

**Table 35.2** Signs of haemorrhagic shock

| | Compensated | Mild | Moderate | Severe |
|---|---|---|---|---|
| Blood loss (mL) | <1000 | 1000–1500 | 1500–2000 | >2000 |
| Pulse rate (beats/min) | <100 | 100–120 | 120–140 | >140 |
| Systolic blood pressure | >100 | <100 | <80 | Unrecordable |
| Peripheral extremities | Warm | Slightly cool | Very cool | Cold |
| Respiratory rate (breaths/min) | <20 | 20–25 | 25–30 | >30 |
| Urinary output (mL/h) | >30 | <30 | <20 | Anuric |
| Conscious level | Normal | Agitated | Confused | Lethargic, unresponsive |

hospitals have an emergency protocol in place whereby the switchboard will set off simultaneous pagers of all the relevant staff, that is, obstetricians, anaesthetists, midwives, operating department practitioners, and porters. The presence and experience of senior staff are essential in a major obstetric haemorrhage and in several CEMD reports[6,33,34] attendance of senior personnel too late in the care of such a patient and lack of continuity of care[6] have been criticized.

Assessment of the amount of blood loss can be difficult due to loss outside the hospital, on the bed linen, and floor. In some placental abruptions, blood loss may be entirely concealed. Observations of pulse rate, blood pressure, and peripheral circulation may guide assessment but often it is a 'guesstimate'. It is important to note that healthy parturients may maintain their blood pressure remarkably well until they have a lost a significant part of their (unreplaced) circulating blood volume by compensatory vasoconstriction, so pulse rate is a better indication of blood loss than blood pressure. Oliguria and poor capillary refill are other important signs, as is tachypnoea (Table 35.2). All these parameters normalize as the patient is appropriately resuscitated.

Obstetric haemorrhage should be treated, as all emergencies, along ABC lines. Most women are conscious unless hypovolaemia has compromised cerebral perfusion. Therefore the airway usually does not need to be secured. A Hudson mask and high-flow oxygen should be given to maximize oxygen saturation. If the patient is antenatal, the wedged position is vital as aortocaval compression which reduces venous return, will worsen an already hypotensive situation.

Two large-bore cannulae should be inserted and appropriate blood samples sent for a full blood count, coagulation screen, biochemistry profile, and, most importantly, a group and save sample for cross-match.

From a practical point of view, both venous cannulae should be sited preferably in the same arm. Siting cannulae in different arms results in one cannula being occluded whenever the non-invasive blood pressure cuff is inflated and also reduces access for obtaining blood samples later. However, a patient who has lost significant blood may have peripherally collapsed veins and if it is only possible to gain venous access in both arms, then this should be pursued.

Many rapid infuser devices are available (e.g. the Belmont™ infusers). These can infuse at 1000 mL/min and simultaneously warm the fluids. Hypothermia should be avoided as this worsens coagulopathy.

Recently the intraosseous (IO) needle has been introduced to gain venous access when peripheral veins cannot be found (Figure 35.2).[35] This is particularly useful in the patient who is 'shut-down' or in the obese. The needle is inserted into the humerus or near the tibial tuberosity and fluids pumped into the medullary canal. The infusion rate through the IO needle can be 68–205 mL/min (without and with pressure bag)[36] and once the patient is resuscitated, conventional venous access may become easier.

Most obstetric patients should be able to withstand a degree of hypovolaemia without permanent effects. However, in previously healthy labouring women during PPH, Karpati et al. found that low systolic (<88 mmHg) and diastolic (<50 mmHg) pressures

**Figure 35.2** EZ IO® (intraosseous needle).

and a tachycardia of more than 115 beats/min were independent predictors of myocardial ischaemia[37] and therefore every effort should be made to maintain normotension and avoid tachycardia.

The patient who is bleeding should be resuscitated first with crystalloid fluid, for example, Hartmann's solution or saline to a maximum of 2 L. But if the patient is hypotensive, colloid is an alternative. No more than 1.5 L of colloid should be given. There is a danger of inducing pulmonary oedema and dilutional coagulopathy if large volumes of fluid are given.

### Monitoring in obstetric haemorrhage

Essential monitoring includes electrocardiography, non-invasive blood pressure, and pulse oximetry. The patient should also be catheterized and placed on a Modified Early Warning Score (MEWS) chart (see Figure 35.3).

An arterial line is useful in a patient with major haemorrhage as it will give continuous blood pressure, is useful to guide inotropic support if needed, and also allows easy access for blood sampling. A central venous catheter (CVC) can also be useful to guide fluid therapy and to give inotropes. However, invasive lines are not without potential complications. Arterial spasm, thrombosis, and aneurysm formations are all well-known complications of arterial lines. CVC insertion may complicated by pneumothorax, carotid puncture, and air embolism. The risks versus the benefits should be considered before placing these lines.

## Treatment of specific causes of bleeding

### Management of antepartum haemorrhage

The major causes of APH include abruption and/or placenta praevia. Effective treatment of *both* of these causes of APH involves delivering the baby, and this should be undertaken in good time if the pregnancy is at term. When there is major haemorrhage, delivery by caesarean delivery is normally required in the maternal interest regardless of gestation. When bleeding is 'minor' (e.g. <500 mL), conservative treatment to enable fetal maturation or (in the case of abruption) induction of labour, may be appropriate. A detailed discussion of when it is reasonable to delay delivery in women with a preterm APH is discussed in Chapter 33. As described previously, caesarean delivery can be a challenging operation in women with massive obstetric haemorrhage, and senior assistance is advisable.

### Pharmacological management of postpartum haemorrhage

Effective 'treatment' of PPH requires identification of the cause and appropriately directed therapy. Uterine atony is the single biggest cause of PPH. In the '4Ts' nomenclature, a useful method of remembering the causes of PPH, uterine atony is described as problems with 'tone'. This may be aggravated by 'tissue'—retained products of conception. Other causes include 'trauma' of the genital tract and 'thrombin' problems—coagulation defects.

#### Conservative therapy/examination under anaesthesia

Where uterine atony appears the likely cause of PPH, and when haemorrhage is minor, it is reasonable to attempt conservative therapy with oxytocic agents without transferring the woman to theatre. Where bleeding is heavier, regardless of the suspected cause of bleeding, transfer to theatre and examination under anaesthetic (EUA), including exploration of the uterine cavity, is wise. Any retained products of conception can then be removed. If bleeding is thought to be due to genital trauma, packing may be a useful interim measure, or an alternative to formal suturing if a repairable source of bleeding cannot be identified. The decision of which women can reasonably be managed conservatively is difficult, especially for the inexperienced clinician—PPH is a condition which can deteriorate rapidly and a low threshold both for requesting senior help *and* for transfer to theatre for EUA is advisable.

#### Atonic postpartum haemorrhage

Retained placental fragments can contribute to PPH—exploration of the uterine cavity is useful to determine firstly whether there are any placental fragments and secondly to remove them. Thereafter, bimanual compression of the uterus may temporarily halt the bleeding and gain some time. The evidence base for pharmacological management (in contrast to prevention) of PPH is limited. The following is based on good practice advice from the RCOG, and represent widely used strategies for the management of this condition. In order, relevant treatment strategies are: Syntocinon® 5 IU by slow intravenous administration (may be repeated); ergometrine 0.5 mg either intramuscularly or intravenously (note this can cause vomiting and is contraindicated in women with hypertension because of the risk of further amplifying hypertension and associated cerebrovascular accidents); and Syntocinon® 10 IU/h intravenously (administered as 40 IU in a 500 mL bag of crystalloid, administered at 125 mL/h).[2] Thereafter, further measures include carboprost 0.25 mg administered intramuscularly, to a total of eight doses at 15-minute intervals (there are some reports of improved outcomes with intramyometrial injection, although this is not normally recommended, and women with asthma should not be given carboprost regardless of route of administration as

## How to calculate a Maternal Early Warning Score (MEWS) in NHS Lothian

The clinical observations used to calculate a MEWS score are:

- Respiratory rate
- Oxygen saturation
- Temperature
- Systolic and diastolic blood pressure
- Heart rate
- Sedation/Neurological score (AVPU)
- Urine output

The MEWS chart is colour coded to identify when a clinical observation is outside the normal range. A MEWS of 0-3 is allocated to each parameter using the MEWS key as shown.

**MEWS KEY**

| 0 | 1 | 2 | 3 |
|---|---|---|---|

All the observations have to be recorded and the total score added up. **A MEWS score of 3 or more** is an alert that a patient is acutely ill or deteriorating and an appropriate response using the escalation procedure is required... MEWS should NOT replace sound clinical judgement. Immediate action and appropriate escalation should take place if there are any concerns regarding a patient's clinical condition. Staff are accountable for seeking further help if not reassured by the response and action taken.

**Staff should use SBAR in all communications**

**Definition**

## Pain Assessment & Management Guidelines

**How to score pain:**

**Acute pain:** Score current pain on movement e.g. deep breathing

| Pain Score: | | Action: |
|---|---|---|
| **0** | **NONE** | Continue to assess pain with every set of observations (**must be** at least daily) |
| **1-3** | **MILD** | Continue to assess pain with every set of observations (**must be** at least daily) |
| **4-5** | **MODERATE** | Assess. Using guidelines, prescribe/give analgesia as appropriate for the patient. Review. |
| **6-10** | **SEVERE** | Assess. Using guidelines, prescribe/give analgesia as appropriate for the patient. Review. |

**Figure 35.3** Continued

it can cause bronchospasm and hypoxia with V/Q mismatch), followed where necessary by misoprostol 1000 mcg rectally.

Pharmacological measurements have little to contribute to the management of PPH caused by tissue or trauma. Treatment of 'thrombin'-related PPH is by replacement of specific clotting factors or increasing concentrations of other prothrombotic agents, and is discussed later in 'Transfusion of Blood and Blood Products'.

## Surgical treatments of postpartum haemorrhage

Genital tract trauma sufficient to cause major haemorrhage should be repaired in theatre where there is good lighting and access to appropriate anaesthesia.

Surgical treatments for PPH due to uterine atony include placement of an intrauterine balloon followed by inflation to prevent bleeding by inducing tamponade (e.g. the Bakri™ balloon (Figure 35.4)), a haemostatic 'brace' suture around the uterus (e.g. the B-lynch suture), hysterectomy and either external ligation of uterine or internal iliac arteries, or use of IR to embolize the uterine artery. The frequency with which these agents were used, in a series of 323 women in Scotland in 2010 with major haemorrhage, together with their 'success' rates (in terms of hysterectomy avoided) are shown in Table 35.3.[4] It should be noted that apparently superior success rates of one strategy compared with another cannot be firmly inferred from this series, since different strategies will have been used in different clinical scenarios. However, the fact that only 5% of women treated with an intrauterine balloon went on to need hysterectomy, together with its relative ease of placement are likely to account for the more than eightfold increase in use of the balloon since 2003. There has also been a threefold increase in the use of compression sutures over this time period. A systematic review of hysterectomy-sparing treatments for PPH (balloon tamponade, uterine compression sutures, arterial embolization, and uterine devascularization or arterial ligation) demonstrated efficacies of 84–92%, with no significant difference in efficacies.[38]

Although intrauterine balloon tamponade has not been subjected to formalized randomized controlled trials, the demonstration of a reduction in the need for arterial embolization and conservative surgical procedures after its introduction supports its use.[39] It works by applying pressure greater than systemic arterial pressure to the inside of the uterus. The RCOG endorses the use of intrauterine balloon tamponade as a first-line surgical intervention in women with bleeding due to uterine atony.[2] Balloon tamponade appears equally effective in resource poor settings.[40] A variety of balloon devices are suitable, including a Foley catheter, a Bakri™ balloon (Figure 35.4), a Sengstaken–Blakemore oesophageal catheter, a condom catheter, and the Rusch balloon (see Georgiou[41] for further details on use in practice). The Rusch balloon appears to have advantages in terms of size, cost and ease of use, although the Bakri™ balloon with its opening in the uterine cavity may allow earlier detection of continued bleeding. Regardless of the balloon used, it should be kept in place for at least 4–6 hours with most publications suggesting its removal by 48 hours.

The next most commonly used treatment for PPH is the haemostatic brace suture, as described by Christopher B-Lynch in 1997[42] (Figure 35.5). Again, there have been no large randomized trials comparing the haemostatic brace suture to alternative treatments. The UK Obstetric Surveillance System (UKOSS) cohort reported outcomes of 272 women needing second-line treatment for PPH (i.e. when drug treatment and/or uterine balloon tamponade had failed): uterine compression sutures were successful in 75% of the 199 women so treated.[43] Uterine necrosis and pyometra have been reported as complications, but these can be minimized with appropriate attention to technique and the use of a suture such as polynecaperone (Monocryl®) which degrades completely over 3 weeks, losing its tensile strength.[44] Again, the use of the B-Lynch suture and/or other compression sutures is endorsed by the RCOG.[2]

**Table 35.3** Frequency of use and 'efficacy' (hysterectomy avoided) of procedures used to treat major obstetric haemorrhage in Scotland in 2010

| Procedure | Number | % of total | % Success rate[a] |
|---|---|---|---|
| Intrauterine balloon tamponade | 81 | 21.5% | 95% |
| Haemostatic brace uterine suturing (e.g. B-Lynch) | 34 | 10.5% | 82% |
| Hysterectomy | 18 | 5.6% | 0 |
| Uterine artery embolization (interventional radiology) | 17 | 5.3% | 70% |
| Bilateral ligation of uterine or internal iliac arteries | 5 | 1.5% | 80% |

[a]Hysterectomy avoided.

The use of IR techniques is increasingly popular in the management of obstetric haemorrhage. Its use in placenta accreta has been described previously in this chapter. Bilateral uterine arterial embolization is appropriate when the uterus is thought to be the source of bleeding. Where the source of bleeding is unknown, or where it is likely to come from vaginal, cervical, or pelvic 'trauma', imaging can be useful to visualize the bleeding point, followed by embolization to the relevant vessel. Again, there are no randomized trials, and few series reporting long-term outcomes. Out of 19 women treated with embolization in the UKOSS series, 17 (89%) avoided hysterectomy.[43] These immediate success rates are similar to those from the Netherlands in a series of 114 women with arterial embolization, although 25% women ultimately underwent hysterectomy.[45] One series of 28 women with mean follow-up of 12 years, noted that all six who wished to become pregnant again did so and delivered successfully.[46] Another series demonstrated future successful pregnancy in all 16 women who wished another pregnancy after arterial embolization to treat PPH.[47]

Hysterectomy is the definitive treatment for PPH in women with uterine atony or uterine trauma. However, hysterectomy is life-saving in selected cases and should not be denied in an effort to preserve fertility. The Confidential Enquiry into Maternal and Child Health recommends that 'consider[ing] hysterectomy early' is an important component of effective management of PPH.[33] The RCOG guidelines endorse this advice, especially in cases of placenta accreta or uterine rupture, and suggest that a second consultant be involved in both the decision-making and the surgery.[2] UKOSS reviewed a series of 315 women undergoing peripartum hysterectomy in the United Kingdom.[48] The majority (53%) were performed because of uterine atony, with a further 38% performed because of placenta percreta, accreta, or increta. Eighty per cent of peripartum hysterectomies followed caesarean delivery. Complications included death (0.6%), need for intensive care unit

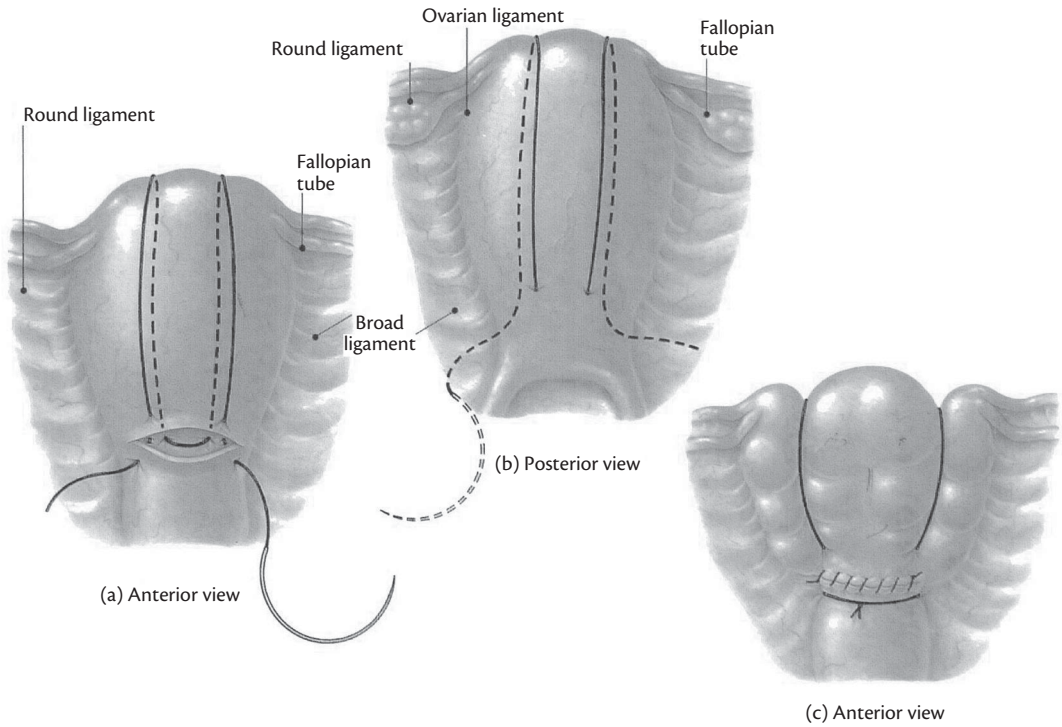

**Figure 35.5** B-Lynch suture.

Reproduced from Christopher B Lynch ***et al.***, 'The B-Lynch surgical technique for the control of massive postpartum haemorrhage: an alternative to hysterectomy? Five cases reported', *BJOG: An International Journal of Obstetrics & Gynaecology*, Volume 104, Issue 3, pp. 372–375, Copyright 1997, with permission from Wiley.

admission (80%), bladder damage (12%), ureteric damage (4.4%), ovary removal (5.7%), other further surgery (19.4%), and other severe morbidity (17%). There were no differences in complication rate comparing subtotal with total hysterectomy. Bladder damage was more likely in the presence of placenta accreta, and younger and multiparous women. Caesarean delivery and morbidly adherent placenta were noted as risk factors for peripartum hysterectomy in another systematic review.[49]

## Transfusion of blood and blood products

The term uterus has a blood flow of approximately 750 mL/min and therefore in the event of a massive haemorrhage, all obstetric units should have immediate access to O-negative blood. Blood transfusion is, however, not without its potential hazards,[50] specifically transfusion reactions, transfusion-related lung injury, and infection. Blood should not therefore be given without due consideration.[51] Furthermore, most obstetric patients are healthy prepregnancy and have no co-morbidities. They can usually therefore tolerate relative anaemia well and a haemoglobin of 7 g/dL is acceptable to most stable postpartum women. See Figure 35.6 for the Simpson Centre for Reproductive Health transfusion algorithm for stable postpartum women.

However, in the actively bleeding parturient, it is recommended that the haemoglobin be kept between 7 and 9 g/dL by transfusion.[52] Laboratory samples for a full blood count and clotting screen are useful only for baseline purposes as in a haemorrhage, the patient may have lost several circulating blood volumes before these results are to hand which will therefore not reflect the real-time picture. Some units may have near-patient testing devices like the HemoCue® (Figure 35.7) and a thromboelastograph (Figure 35.8) which will give very rapid haemoglobin[53] and clotting status respectively. Furthermore, the thromboelastograph will indicate which blood products are required to treat any coagulopathy which may be present although the reference ranges may be different in obstetric patients.[54]

A more detailed explanation of the thromboelastograph and its interpretation are available in Chapter 48.

Where a thromboelastograph is not available, it has been suggested from major trauma studies[52] that the platelet count should be maintained above 50 × $10^9$/L and prothrombin and activated prothrombin time within 1.5 times the mean control. Fibrinogen should be 1.5–2 g/L, higher than that recommended by the RCOG[55] of 1 g/L as most pregnant women have fibrinogen levels often greater than 4 g/L, so 1 g/L would seem excessively low. In fact, a fibrinogen level less than 2 g/L has a positive predictive value of 100% for severe PPH and is the only marker among those investigated to do so.[56] Fibrinogen can be given as fresh frozen plasma (FFP) 10–15 mL/kg or as cryoprecipitate (10 units). Recently there have been case reports of fibrinogen concentrate used in obstetric haemorrhage.[57] This has the advantages that it does not need to be thawed and can be given in small volumes thus reducing the volume load and the chances of pulmonary oedema.

A 1:1 transfusion ratio of blood:FFP: has been advocated following improved survival in military casualties in Iraq and Afghanistan.[58] Here the patients were aggressively treated with blood products along with early damage control surgery and avoiding the 'lethal triad' of hypothermia, acidosis, and coagulopathy. However, obstetric patients are of a different physiological milieu than soldiers, with a higher thrombotic potential than their male non-pregnant counterparts. The Association of Anaesthetists of Great Britain and Ireland (AAGBI) has currently advised against this 1:1:1 regimen in routine obstetric practice.[59]

Donor blood has been anticoagulated with acid citrate dextrose which chelates calcium, resulting in hypocalcaemia after massive transfusion. It is recommended that calcium chloride is given to maintain calcium levels above 0.9 mmol/L.[55]

## Cell salvage

The collection and re-transfusion of autologous blood from surgical sites has been well established in many specialities—orthopaedics, cardiac, vascular, and hepatobiliary surgery—for decades.[60] However, there has been a reluctance to embrace it in obstetrics because of the fears of amniotic fluid embolism and rhesus isoimmunization.

The cause of amniotic fluid embolism, now re-named anaphylactoid syndrome of pregnancy[61] is unknown. It is rare, occurring in approximately 1/50,000 births but with a high mortality (20%)[62]

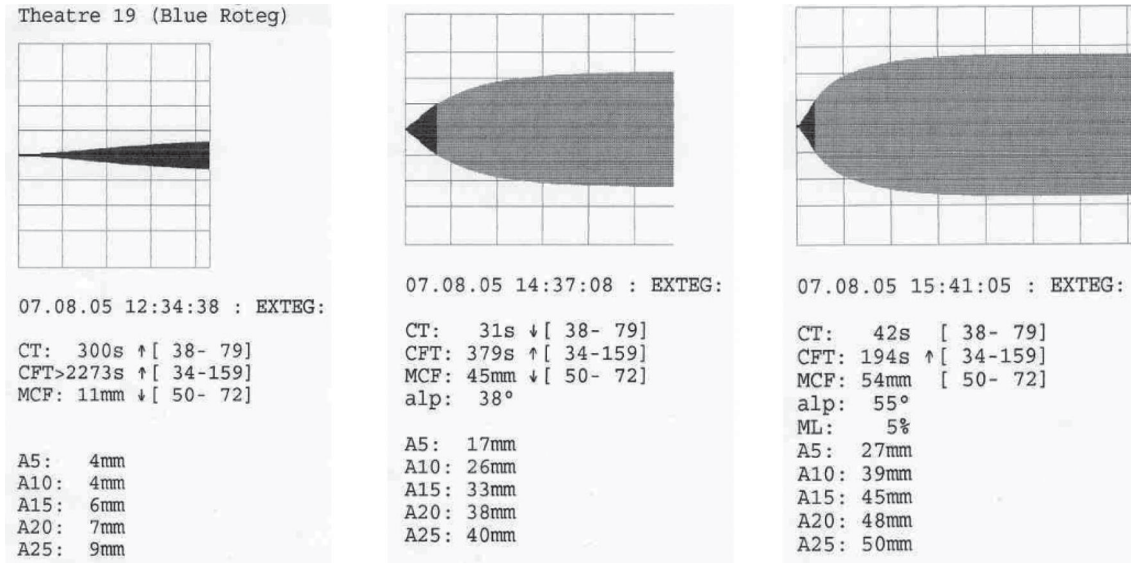

**Figure 35.8** Thromboelastograph in patient with disseminated intravascular coagulation (left) and subsequent normalization following treatment with fresh frozen plasma and platelets.

and accounted for 15 deaths in the most recent Confidential Enquiry into Maternal Deaths in the United Kingdom.[6] Previously, fetal squames and other debris were thought to cause the syndrome which resulted in cardiovascular collapse, hypoxia, and coagulopathy. More recently, it is thought that there is a systemic inflammatory response which results in release of endogenous inflammatory mediators.[63]

More detail about anaphylactoid syndrome of pregnancy can be found in Chapter 38.

When cell salvage was first introduced into obstetrics, a separate suction device was used to collect amniotic fluid and another introduced post delivery to collect maternal blood.[64] The cell saver machines have integral filters and when a leucocyte depletion filter (LDF) is used as well, the salvaged blood returned to the mother has similar levels of amniotic fluid contaminants as that seen in maternal blood after a normal delivery.[65] Recently, however, some units have abandoned the two-sucker approach and aspirate amniotic fluid as well as blood into the same suction device. There appears to be no increased risk of anaphylactoid syndrome with this approach[66] and it may be that this is the way forward as in some cases (e.g. placenta praevia or anterior fibroids), most of the blood is lost before delivery.

In 2011, there were case reports of severe hypotension with salvaged blood given with a LDF.[67,68] The mechanism of this was postulated to be bradykinin release, bradykinin being a potent vasodilator. An article in 2013 suggests that interleukin 6 may be the culprit if the blood has been filtered using subatmospheric pressures applied with a 50 mL syringe.[69] But neither theory explains why hypotension does not occur in the millions of patients receiving non-autologous blood which has been filtered through the LDF.[70] If severe hypotension does occur, the filter should be removed and the salvaged blood transfused without it. A SHOT (Serious Hazards of Transfusion) report should be completed.

Using the LDF has another practical disadvantage. The rate of blood flow through the filter is severely hampered by the fine mesh and is a major drawback in replacing blood in a rapidly haemorrhaging patient. Removing the filter speeds up re-transfusion rates significantly. It should be remembered that before the introduction of filters several hundred patients were transfused salvaged blood uneventfully and continue to do so in non-obstetric settings.

The cell saver machines cannot differentiate maternal from fetal cells and there can be transfusion of fetal cells from salvaged blood back to the mother. This may give rise to Rhesus isoimmunization in Rhesus-negative mothers who have Rhesus-positive babies with problems in subsequent pregnancies if anti-D is not given. However, the transference of fetal cells in cell salvage is of the same magnitude as occurs in a normal delivery.[71] The Kleiheur test done postnatally, and after the salvaged blood has been given, will detect how much anti-D needs to be given to prevent Rhesus isoimmunization. Transference of other alloantibodies has not given rise to any clinical problems following cell salvage (J. Faulds, personal communication).

One of the problems of cell salvage is the uncertainty of which patients would benefit from the process. In the 2007 SCASMM, Peacock and Clark identified all the Scottish women in that year who had had a loss greater than 2500 mL, or required a 5-unit transfusion of blood or coagulation products.[72] It would appear that worthwhile volumes of blood could be salvaged in those with placenta praevia, accreta, and abruption, pre-eclampsia, caesarean after induction of labour, and at exploratory laparotomy. However, a definitive study has yet to be done to confirm this. If clinicians are unsure about potential blood loss, the collect-only reservoir of the cell savage system can be used without the centrifuge, the more expensive part. This can easily be activated if blood loss becomes significant.

It must be remembered that there are no coagulation products in salvaged blood and FFP, cryoprecipitate, and platelet transfusions may be required.

NICE, the AAGBI, RCOG, and MBRRACE have all recently endorsed cell salvage in obstetrics. A large randomized trial is underway which will determine the role of cell salvage in reducing blood transfusion in obstetrics (SALVO, ISRCTN66118656).

## Women who refuse blood products

There are some parturients who refuse blood products due to religious beliefs.[34] They are at increased risk of dying with two such women dying in the last MBRRACE report.[6] The implications of their decisions regarding refusal of blood products should be discussed at length antenatally. The best place for this to be done is in the high-risk clinic or similar suitable environment. The partner should accompany the patient as they may have different views but must be made aware that the patient's wishes supersede theirs. Some women may request their religious advisor attend the clinic appointment also.

Haematinics must be prescribed and a full blood count should be checked at 32 and 36 weeks to ensure that their haemoglobin is optimized for delivery. Some may need intravenous iron or erythropoietin to bring the haemoglobin above 10 g/dL.[5]

Apart from impressing upon these women that they have a greater chance of dying compared to others, the exact nature of what they will accept in the event of a haemorrhage must be discussed and documented. Some adjuncts, if they have non-blood components (e.g. recombinant factor Vlla), and some techniques like cell salvage, may be acceptable. A useful chart is shown in Figure 35.9.

On admission to the delivery suite, all staff should be aware of the status of the patient. Senior medical staff should also be informed. If there is a haemorrhage, a consultant obstetrician and consultant anaesthetist should be called in a timely manner. The patient should be monitored for at least 4 hours postpartum so that any complications are diagnosed and managed early. Each hospital should have a group which liaises with organizations whose members refuse blood.

## Anaesthesia in obstetric haemorrhage

Neuraxial anaesthesia is relatively contraindicated in a patient who is actively bleeding as spinal or epidural anaesthesia causes sympathetic blockade with resultant vasodilatation and removes the compensatory vasoconstriction which would naturally occur in the presence of blood loss. General anaesthesia (GA) is the technique of choice with judicious use of induction agents to avoid vasodilation and hypotension. This is offset somewhat initially by the hypertensive stimulus of laryngoscopy. The use of volatile agents for maintenance of anaesthesia used to be notoriously associated with relaxation of the uterus but since the demise of

halothane this has not clinically been a problem and up to 0.46 minimum alveolar concentration of sevoflurane and isoflurane can be given without affecting uterine tone.[73] During a haemorrhage, if the patient is hypovolaemic and hypotensive, reducing the volatile will not necessarily lessen atony and increases the risk of awareness.

Unfortunately, haemorrhage often occurs unexpectedly in obstetrics and many patients who bleed will already have a spinal or epidural *in situ*. Provided the patient is kept well-filled, and comfortable, the anaesthetist may persevere with the regional technique. However, if the operation is prolonged and outlasts the spinal, or if there is pain or discomfort, there is no choice but to provide a GA. Further, a hypovolaemic hypotensive patient will feel faint and nauseous and a GA indicated for these reasons. Inducing GA can also be advantageous as it then frees the anaesthetist to proceed with insertion of arterial and CVCs and for the staff in theatre to communicate more frankly without the need to curtail discussion to prevent alarming the patient and partner.

Unless already *in situ*, two large-bore cannulae are indicated as well as use of the rapid infuser and cell saver if available. An arterial line and CVC are indicated in a massive haemorrhage. A second dose of antibiotic is necessary if blood loss exceeds 1500 mL. Perioperative thromboelastography and HemoCue® are invaluable to guide blood and coagulation product replacement in these circumstances. If there is evidence of fibrinolysis, tranexamic acid may be considered.

There are some cases where using neuraxial anaesthesia is controversial. One of these is for placenta praevia. This can potentially cause catastrophic bleeding and theoretically a GA should be given

for the reasons described above. However, if the placenta praevia is minor or posterior, bleeding is less likely and many experienced anaesthetists would use a regional technique. In a series of 350 consecutive placenta praevia cases, Parekh found that neuraxial anaesthesia even in the presence of considerable haemorrhage was not problematic and was associated with significantly less blood loss and transfusion.[74] Hong and colleagues[75] also demonstrated that epidural anaesthesia as opposed to GA resulted in less transfusion requirements in grade 4 placenta praevia patients. An alternative to epidural or single-shot spinal would be a combined spinal–epidural (CSE). This would allow longer surgical time if problems were encountered.

Another area where the choice of anaesthetic depends on anaesthetic experience is in the management of an elective caesarean with a placenta accreta. In many of these cases, internal iliac balloons are placed preoperatively. Some anaesthetists insert a CSE providing anaesthesia for insertion of the radiology catheters with the spinal component. The caesarean is then performed under epidural top-up, although if blood loss becomes excessive, conversion to a GA is advised (G. O'Sullivan, personal communication). This will work well if the bleeding from the adherent placenta is not excessive but many of these cases bleed torrentially despite the internal iliac balloons if the placenta starts to separate and the anaesthetic team may be stretched to cope with a nauseous anxious patient (and partner) rather than proceeding unhampered with resuscitation.

Patient choice should be taken into consideration when discussing anaesthetic techniques unless there is an overwhelming reason to choose one technique over another. In a case like placenta praevia and accreta, the patient and partner should understand that neuraxial anaesthesia can be initiated but GA may be necessary if complications arise. The partner's understanding that they should leave when requested must be determined from the outset.

Patients who have had a major haemorrhage will inevitably require level 3 (intensive) care. A period of ventilation will buy time for re-warming, reversing coagulopathy, and often righting fluid balance as one of the commonest causes for ITU admission is pulmonary oedema caused by over-generous fluid resuscitation in the early stages of haemorrhage.

## Simulation training for management of obstetric haemorrhage

Simulation training using 'drills' is an increasingly important component of quality improvement in obstetrics. Simulation training may either focus on the individual (e.g. MOET, ALSO) or the 'team' (PROMPT). There is some (weak) evidence that drills may improve team-working and identify knowledge and performance gaps.[76]

## Debriefing

The mortality and morbidity associated with major obstetric haemorrhage are considerable. Communication with the woman and her relatives is an important feature of the management of obstetric haemorrhage and appropriate management requires good team communication.

Once the immediate danger period has past, it is appropriate to conduct a formal debriefing with the woman and her relatives. This should include an accurate account of events, some explanation of 'why' this happened, 'why' any specific measures or treatments were undertaken, and 'what this means' for future health (including pregnancies). Regular morbidity reviews identify examples of good practice, and management that could be improved in the future. This should be fed back to staff who will also require some debriefing, both to help them come to terms with what has happened, and for educational purposes.

## Controversies in obstetric haemorrhage

Treatment modalities in massive obstetric haemorrhage have rarely been subjected to randomized trials, and it could therefore be argued that much of the accepted treatment lacks a robust evidence base. Many 'new' techniques and drugs are introduced by enthusiasts—in the presence of a life-threatening situation is it difficult to persuade such individuals to randomize to 'no treatment'. Some new treatments are described below.

### Recombinant factor VIIa

Factor VIIa is an important component of the clotting cascade—the recombinant form can be given intravenously. The RCOG advises: 'In the face of life-threatening PPH, and in consultation with a haematologist, rFVIIa may be used as an adjuvant to standard pharmacological and surgical treatments'.[2] A suggested dose is 90 mcg/kg, which may be repeated in the absence of clinical response within 15–30 minutes. Importantly, factor VIIa requires adequate concentrations of fibrinogen and platelets to be effective—consideration should be given to fibrinogen and/or platelet administration for those with fibrinogen below 1 g/L and platelets greater than $20 \times 10^9$/L. Patients who are hypothermic, hypocalcaemic, and acidotic will not respond to factor VII treatment either.[77] There have been recent reports of arterial thrombosis following the use of factor VIIa in non-obstetric patients.[78]

### Tranexamic acid

Although the RCOG does not endorse the use of tranexamic acid, there is weak evidence for its efficacy in PPH[79] and considerable evidence for its use in trauma.[80] In trauma usage, a dose of 1 g is given slowly intravenously and repeated if required after 8 hours. The WOMAN trial is currently addressing the role of tranexamic acid in obstetrics.[81]

### Cell salvage

The last controversy is the use of cell salvage, which is widely used, although there is no evidence it has any clinical benefit or cost-effectiveness (both in terms of reducing transfusion). A multicentre trial 'SALVO' is ongoing in the United Kingdom to address this issue, as described previously.

## Conclusion

Major obstetric haemorrhage remains a significant cause of maternal mortality and morbidity. Risk factors should be identified. Prompt and effective anaesthetic and obstetric intervention (ideally as part of a multidisciplinary team) significantly improves outcomes. Management includes pharmacological and surgical

techniques with frequent input from blood transfusion and intensive care services. IR is sometimes required. Research increasingly identifies effective and ineffective strategies in the treatment of this condition.

# CHAPTER 36

# Hypertension in pregnancy

John A. Anderson, Pierre-Antoine Laloë and Derek J. Tuffnell

## Introduction

Hypertensive disorders during pregnancy occur in women with pre-existing primary or secondary chronic hypertension, and in women who develop new-onset hypertension in the second half of pregnancy. Both carry risks for the woman and the baby. Although the rate of eclampsia in the United Kingdom appears to have fallen,[1] hypertension in pregnancy still caused 19 maternal deaths in the United Kingdom between 2009 and 2012 in the latest 2014 national report, 'Saving Lives, Improving Mothers' Care'.[2] Hypertensive disorders during pregnancy may also result in substantial maternal morbidity. A study reported that one-third of severe maternal morbidity was a consequence of hypertensive conditions.[3] A study from one region of the United Kingdom reported that 1 in 20 (5%) women with severe pre-eclampsia or eclampsia were admitted to intensive care.[4] Pre-eclampsia is associated with significant fetal mortality and morbidity, mostly as a result of prematurity. One in 20 perinatal deaths of deaths of infants without congenital abnormalities in the United Kingdom are associated with pre-eclampsia.[5]

## Spectrum of hypertensive disease in pregnancy

### Non-proteinuric hypertension

Women with normal blood pressure at the onset of pregnancy who subsequently develop hypertension without proteinuria after 20 weeks of gestation have gestational hypertension (GH). In itself, GH is less likely to cause significant morbidity than pre-eclampsia, but it pre-disposes women to the development of pre-eclampsia.

### Primary or secondary chronic hypertension

There is a group of women who have pre-existing, chronic, primary or secondary hypertension prior to conception. In the United Kingdom it is likely that the majority of these women are unknown to their general practitioner, midwife, or obstetrician (though rates are estimated at 0.6–2.7%)[6] and the diagnosis of underlying chronic hypertension is revealed at final postnatal follow-up. It is therefore difficult to truly identify patients with chronic pre-existing hypertension, from hypertensive patients in the antenatal clinic with GH. For this reason, women presenting with GH prior to 20 weeks are considered to have chronic hypertension. In excess of 95% of women with chronic hypertension will not have any underlying discoverable pathology, and therefore have essential hypertension. The remainder may have associated, proven cardiovascular, renal, or endocrine disease.[7]

Rising rates of obesity and increasing maternal age in the developed world are increasing the incidence of chronic pre-existing hypertension and GH.[8] These conditions are additional risk factors for subsequently developing pre-eclampsia.[9,10]

### Proteinuric hypertension

This encompasses pre-eclampsia and eclampsia; haemolysis, elevated liver enzyme levels, and low platelet count (HELLP) syndrome; and acute fatty liver of pregnancy (AFLP). They all may be considered as a continuum of the same disease at a cellular level and are more likely to result in harm than non-proteinuric hypertension. The careful management of women with moderate and severe proteinuric hypertension in the intra- and postpartum periods reflects this. It is also worth noting that HELLP and AFLP may not initially present with significant hypertension or proteinuria, though this may develop later.

## Definitions

About one in ten pregnancies in the developed world are affected by hypertension in pregnancy and this includes two relatively benign conditions (chronic and gestational hypertension) and a potentially dangerous one (pre-eclampsia).[11] Considerable debate has always surrounded the definition of the hypertensive disorders of pregnancy. Consequently broad clinical definitions are used, reflecting that much overlap occurs in the phenotypic presentations of conditions of hypertension in pregnancy.

Pre-eclampsia affects up to 1 in 20 pregnancies dependent on parity[12] and is characterized by placental dysfunction, and maternal vascular, neurological, renal, and hepatic dysfunction which may lead to hypertension, stroke, seizures (eclampsia), end-organ damage, haemorrhage, placental abruption, fetal growth restriction, and both fetal and maternal death. Rarely this disease may manifest itself as HELLP and AFLP.

Clinically differentiating the more benign conditions of chronic hypertension and GH from pre-eclampsia to predict outcome has been dependent on traditional, but non-specific, clinical markers such as blood pressure, urinary protein excretion, signs, and symptoms. The difficulty in identifying women with pre-eclampsia is underlined by the knowledge that HELLP and AFLP patients may not present with hypertension in the initial stages of the disease

and up to 20% of women with eclamptic seizures do not meet typical diagnostic criteria prior to their seizure event.[13] The lack of specificity makes the prediction and prevention of complications difficult.

Clinical definitions advocated by the National Institute of Health and Care Excellence (NICE)[14] have been used in an effort to provide consistency about the parameters to classify the condition in the United Kingdom. These depend upon the detection of hypertension, with or without proteinuria. However, these are crude proxy measurements of disease activity as both are signs of the condition rather than its cause or consequence. Clinically it is much more difficult to identify the more important consequences of pre-eclampsia such as cerebral oedema, glomerular damage, or basement membrane permeability.

### Hypertension

Pregnancy-related hypertension is currently defined in the United Kingdom as a sustained raised blood pressure of over 140/90 mmHg, with a diastolic blood pressure of 90 mmHg on two separate occasions or a single diastolic reading of 110mmHg, in a woman who is pregnant or in the puerperium (6 weeks postnatal).[15] Current guidance divides cases into:

- *Mild hypertension:* diastolic blood pressure 90–99 mmHg, systolic blood pressure 140–149 mmHg.
- *Moderate hypertension:* diastolic blood pressure 100–109 mmHg, systolic blood pressure 150–159 mmHg.
- *Severe hypertension:* diastolic blood pressure 110 mmHg or greater, systolic blood pressure 160 mmHg or greater.[16] This definition is used in the United Kingdom and by the American Society of Hypertension and Society of Obstetricians and Gynaecologists of Canada. The Society of Obstetric Medicine of Australia and New Zealand use a level of 170/110 mmHg for severe hypertension

### Significant proteinuria

Defined as 300 mg of protein excreted in 24 hours, or a urine protein:creatinine ratio greater than 30 mg/mmol.[16]

### Gestational hypertension

Raised blood pressure falling within the above-mentioned categories, without proteinuria or associated biochemical abnormalities developing after 20 weeks of gestation, is described as gestational hypertension (GH) and used to be termed pregnancy-induced hypertension (PIH). Raised blood pressure prior to 20 weeks is considered to be chronic underlying hypertension.

### Chronic hypertension

Chronic hypertension is hypertension that is present at the booking visit or before 20 weeks of gestation or hypertension requiring treatment when referred to maternity services. It can be primary or secondary in aetiology.

### Pre-eclampsia

Pregnant women with confirmed hypertension with significant persistent proteinuria (i.e. >300 mg on 24-hour urine collection or a urinary protein:creatinine ratio greater than 30 mg/mmol) are said to have pre-eclampsia.

In the United Kingdom, severe pre-eclampsia is considered to be pre-eclampsia with severe hypertension and/or with symptoms, and/or biochemical and/or haematological impairment. The Society of Obstetricians and Gynaecologists of Canada includes gestation of onset before 34 weeks, heavy proteinuria, maternal symptoms, signs of end-organ dysfunction, abnormal laboratory tests, or signs of fetal morbidity. The American Society of Hypertension includes gestation below 35 weeks, maternal symptoms, abnormal laboratory tests, or fetal morbidity. This generates difficulty in comparisons of outcomes in different settings. Eclampsia is a convulsive condition associated with pre-eclampsia.

## Epidemiology

Hypertension complicates between 6% and 12% of all pregnancies.[17] Around one in ten women will develop hypertension and over 4% pre-eclampsia in their first pregnancy[12] though most will have straightforward pregnancies and good maternal and neonatal outcomes.[1] Good care of hypertensive women in pregnancy involves minimizing risk in the antenatal period along with good surveillance and effective antenatal treatment. Timely intervention for delivery and multidisciplinary care in the face of severe disease or complications can minimize the morbidity and mortality for both mother and fetus. The hypertensive conditions of pregnancy can result in life-threatening multisystem pathology, affecting the nervous, hepatic, haematological, renal, and respiratory systems.

### Maternal morbidity and mortality

An estimated 63,000 women die worldwide as a consequence of pre-eclampsia and its complications with 98% of these occurring in the developing world.[18] In the United Kingdom, pre-eclampsia accounts for the second largest number of direct maternal deaths. There were 22 deaths in the triennium 2006–2008.[2] Of these, nine died of cerebral haemorrhage, five due to cardiac arrest due to uncontrolled eclamptic seizures, three from liver failure, two from multiorgan failure while in critical care, two from complications of AFLP, and one from an intra-abdominal haemorrhage of uncertain origin. In 20 cases their care was viewed as 'substandard' by the assessors. This was usually due to a failure to manage severe hypertension. The overall mortality rate has ranged from 0.66 to 0.83/100,000 maternities. The three predominant causes of death are cerebral events, pulmonary problems, or liver disease. The lack of a reduction in cerebral deaths has led to tighter recommendations for the control of hypertension with a gradual reduction in the recommendation to treat hypertension from 170/110 mmHg to the current recommendation of treating blood pressure above 150/100 mmHg and that a systolic blood pressure above 170 mmHg should be a medical emergency. A significant success has been the reduction in pulmonary deaths. This is predominantly due to fluid restriction regimens avoiding pulmonary overload leading to adult respiratory distress syndrome. Deaths from liver disorders have remained relatively constant.

### Severe pre-eclampsia

Determining the incidence of severe pre-eclampsia is difficult because of a lack of precision about exact criteria to differentiate between moderate and severe cases. In Yorkshire between 1999 and 2003, there were 1087 cases of severe pre-eclampsia in 210,631

maternities. This was a rate of 5.2/1000 maternities.[4] There were no maternal deaths in this series but 49 women (rate of 23/10,000 maternities) needed intensive care; Pulmonary oedema developed in 2.3% of cases, 0.55% of women required renal dialysis, and 4.3% of women had platelets below $50 \times 10^9$/L and an alanine aminotransferase (ALT) level over 70 IU/mL. Oliguria (defined as <80 mL/4-hour block for two consecutive blocks) occurred in 7.9% of cases.

### Fetal morbidity and mortality

Hypertensive disorders also carry a risk for the baby. In the most recent UK perinatal mortality report, 1 in 20 (5%) stillbirths in infants without congenital abnormality occurred in women with pre-eclampsia.[5] The contribution of pre-eclampsia to the overall preterm birth rate is substantial; 1 in 250 (0.4%) women in their first pregnancy will give birth before 34 weeks as a consequence of pre-eclampsia[12] and 8–10% of all preterm births result from hypertensive disorders.[19] Half of women with severe pre-eclampsia give birth preterm. Small-for-gestational-age babies (mainly because of fetal growth restriction arising from placental disease) are common, with 20–25% of preterm births and 14–19% of term births in women with pre-eclampsia being less than the tenth centile of birth weight for gestation.[20]

## Pathogenesis

Most research relating to the pathogenesis of hypertension in pregnancy relates to pre-eclampsia, largely because chronic hypertension, essential or otherwise, has its causes outside pregnancy, while GH on its own has a less severe impact on maternal or neonatal outcome, unless pre-eclampsia develops.

The pathogenesis of pre-eclampsia is unresolved but it is widely accepted that abnormal placentation is involved in the pathophysiology. The disease will begin to resolve following the delivery of the fetus and placenta, while pre-eclampsia can occur in the absence of fetal tissue, as occurs in a complete molar pregnancy, a condition in which pre-eclampsia is more frequent.

It has become increasingly apparent that the manifestation of pre-eclampsia in a given pregnancy is determined at the outset of pregnancy, when the trophoblast implants in the endometrium and invades to access the maternal spiral arteries arising from the myometrium. Normally the infiltration of fetal cytotrophoblasts act to trigger the maturation and remodelling of the spiral arteries from small-capacity, narrow vessels into high-capacity, wide vessels. The failure of this process is a consistent histological finding in the placentae of those pregnancies complicated by pre-eclampsia clinically. The balance of opinion is that the failure of the maturation of these spiral arteries and the subsequent placental ischaemia causes cytokines, interleukins, and growth factors to be released into the circulation, whose vasoactive properties can cause end-organ damage and lead to the clinical signs and symptoms of the disease. This would also support the observation that pre-eclampsia is an independent variable for maternal cardiovascular disease in later life.[21]

Research has been aimed at identifying these key vasoactive factors and several possible molecules have been identified. These include elements of the angiotensin pathway and tumour necrosis factor alpha. While alterations in these substances have been identified in pre-eclampsia, a definitive mode or pattern of causation has yet to be defined. This may reflect the complexity of the biochemical milieu surrounding pregnancy and pre-eclampsia and also the biochemical research difficulties in developing a valid animal model,[22] as pre-eclampsia only occurs in primates.

The most promising avenues have focused on the vascular endothelial growth factor (VEGF) family of cytokines, its receptors and variants. VEGF is one of the platelet-derived growth factor family and has several variants including VEGF-A, placental growth factor (PGF), and VEGF-B, VEGF-C, and VEGF-D. The main activities of all of these molecules are to promote the growth of blood or lymph vessels and modulate the behaviour of that growth. In the case of VEGF-A, this includes angiogenesis, lumen, and fenestration formation, while VEGF-B encourages the formation of the myocardium in the embryo. All the VEGF molecules act by activating specific, tyrosine kinase type receptors, which span the cell membrane of target cells. In pre-eclampsia, abnormal levels of VEGF have been implicated as predictive of pre-eclampsia.[23]

Soluble fms-like tyrosine kinase-1 (sFlt1) has also been implicated in the development of pre-eclampsia. This variant of the VEGF receptor (VEGFR)-1, which lacks the usual transmembrane and intracellular components, can bind to circulating VEGF and PGF, thereby reducing the free levels of these molecules and their subsequent biological activity to promote angiogenesis and placentation. Women with pre-eclampsia have increased amounts of sFlt1 and smaller amounts of circulating VEGF and PGF leading to theories that reduced levels of the former may lead to early renal manifestations of PET. *In vitro* and *in vivo* primate studies have demonstrated higher levels of sFlt-1 in hypoxic placentae.[24]

Similarly, endoglin (sEng), a version of the transforming growth factor beta co-receptor, is increased in pre-eclampsia and has been demonstrated to have some synergy with sFlt-1 in hepatic damage associated with pre-eclampsia.[25] It is becoming increasingly evident that the levels of these molecules can be elevated in women who will go on to become severely pre-eclamptic, weeks before any clinical manifestations.[26]

A hypothesized link to a longstanding observation has also been put forward as a consequence of these findings. Cigarette smokers are known to have a reduced rate of pre-eclampsia in comparison to the background population. Haemoxidase (HO)-1 is induced by the inhaled products of tobacco smoke as a probable stress response. The induction of HO-1, a stress response gene, promotes cellular protective measures, particularly against hypoxia, including the degradation of haem to biliverdin and carbon monoxide. Both biliverdin and carbon monoxide have been shown to reduce the production of sFlt1 and sEng.[27] Investigation into the possible role of statins in obstetrics to treat pre-eclampsia, via this mode of action, may reveal an effective therapy. Pilot work to assess the maternal-fetal safety and pharmacokinetic profile of pravastatin in patients at high risk of pre-eclampsia is also being studied in the United States.[28]

The mode of action of aspirin in reducing the rate of recurrence of pre-eclampsia has not been precisely elucidated but is likely to be a consequence of its selective antagonism of cyclooxygenase-1. A randomized control trial is prospectively studying the value of 81 mg daily aspirin for patients with high pre-eclampsia risk scores.[29]

Pre-eclampsia is more common in scenarios where there has been a reduced exposure time to paternal antigens prior to

conception. Classically pre-eclampsia presents more commonly in first pregnancies, though extends to first pregnancies to current partners and is more common in pregnancy following *in vitro* fertilization treatment with donor sperm.

## Antenatal risk assessment and risk reduction

Over 100 different methods of testing women antenatally to predict their risk of developing pre-eclampsia have been put forward over the last 60 years. These have included biochemical, physical, and epidemiological methods; however, none has proven singularly superior. It is still possible to counsel women to some extent in the preconceptual or early antenatal period regarding their risks of developing GH and most importantly pre-eclampsia.

All pregnant women in the United Kingdom will have a risk assessment performed as part of routine antenatal care, in order to identify those women at high risk of pre-eclampsia. Several risk factors are known and these have been incorporated into NICE guidance[30] and are summarized in Box 36.1.

In high-risk women, management involves increased antenatal surveillance. Clinicians should ensure women are aware of important symptoms and should have a lower threshold for investigation with symptoms or abnormalities on urinalysis or blood pressure assessment. The principal reason for this is the lack of a definitive diagnostic or screening test with sufficient positive predictive value. Whilst uterine artery Doppler does also predict women who are at increased risk, it is only appropriate in women who are already identified as at higher risk. Since all higher-risk women need aspirin, uterine artery Doppler does not alter clinical management and is therefore unwarranted in most cases.

**Box 36.1** Risk factors for the development of pre-eclampsia

**High risk factors**

- Hypertensive disease during a previous pregnancy
- Chronic renal disease
- Autoimmune disease such as systemic lupus erythematosus or antiphospholipid syndrome
- Type 1 or type 2 diabetes
- Chronic hypertension

**Moderate risk factors**

- First pregnancy
- Age 40 years or older
- Pregnancy interval of greater than 10 years
- Body mass index (BMI) of 35 kg/m$^2$ or greater at booking visit
- Family history of pre-eclampsia
- Multiple pregnancy

National Institute for Health and Clinical Excellence (2011) CG 107 Hypertension in pregnancy: the management of hypertensive disorders during pregnancy. Manchester: NICE. Available from www.nice.org.uk/CG107 Reproduced with permission. Information accurate at time of press. For up-to-date information, please visit www.nice.org.uk.

**Table 36.1** Antenatal risk factors for the development of pre-eclampsia

| Risk factor | Relative risk | Confidence intervals |
|---|---|---|
| Antiphospholipid syndrome | 9.72 | 4.34–21.75 |
| Previous history of pre-eclamptic toxaemia | 7.19 | 5.83–8.83 |
| Pre-existing diabetes | 3.56 | 2.54–4.99 |
| Multiple pregnancy | 2.93 | 2.04–4.21 |
| Nulliparity | 2.91 | 1.28–6.61 |
| Family history | 2.90 | 1.70–4.93 |
| Raised BMI | | |
| Before pregnancy | 2.47 | 1.66–3.67 |
| At booking | 1.55 | 1.28–1.88 |
| Age over 40 | 1.96 | 1.34–2.87 |
| Diastolic blood pressure >80 mmHg | 1.38 | 1.01–1.87 |

Adapted by permission from BMJ Publishing Group Limited., *The BMJ*, Risk factors for pre-eclampsia at antenatal booking: systematic review of controlled studies, Kirsten Duckitt, Deborah Harrington, volume 330, pp. 576–580, © 2005.

When discussing risk with individual patients, assessing the likelihood of pre-eclampsia is difficult and is more complex than a cumulative assessment of the risk factors listed above. Factors, such as family history of pre-eclampsia, can have a variable significance on risk assessment; one first-degree relative with a history of pre-eclampsia is significant, whereas two will increase these risk factors further. It is therefore possible to counsel women about their risk dependent on history and the strength of positive risk factors despite the difficulty of no definitive investigative testing. The relative risks of history factors and co-morbidities are outlined in Table 36.1.[31]

## Prevention of pre-eclampsia

### Antenatal aspirin

The only intervention shown to reduce the rate of pre-eclampsia is aspirin 75 mg daily. Therefore women at high risk of pre-eclampsia should be advised to take 75 mg of aspirin daily from at least 12 weeks of gestation. Although NICE recommends aspirin only from 12 weeks onwards, this is because firm evidence for its use has only been widely tested in randomized controlled trials from this gestation.[32] In theory and probably in practice it would have more effect if started as early in pregnancy as possible. Women at high risk include those with previous or current relevant obstetric history, or existing co-morbidities known to increase the risk of hypertensive disease of pregnancy.

Women who are at high risk or have a number of moderate risk factors should therefore be advised to take daily low-dose aspirin. The use of aspirin or non-steroidal anti-inflammatory drugs in obstetrics patients is not considered to increase the relative risk (RR) of complications for regional anaesthesia and requires no additional precaution.[33]

### Other 'preventative therapies'

Many drugs have been put forward as effective therapies for the prevention of pre-eclampsia in at risk women. However, only

aspirin is known to be effective. Despite anecdotal evidence, no robust evidence base exists for the use of nitric oxide donors,[34] progesterone,[35] diuretics,[36] fish/algal oils,[37] garlic oil,[38] antioxidants (vitamins C and E),[39] folic acid, or magnesium. Indeed, there is evidence that pharmacological doses of vitamins C and E are associated with an increased risk of adverse outcome.[40] Dietary salt reduction also has no evidence base to support it. High-dose folic acid (4 mg daily) is being studied in Canada to prospectively determine if it can lower the incidence of pre-eclampsia.[41] There were no suitable randomized control trials assessing the value of Chinese herbal medicine in pre-eclampsia in a Cochrane review, despite identification of 45 trials on the subject.[55]

Low-molecular-weight heparin (LMWH) should not be prescribed to reduce the risk of hypertension in pregnancy. However, women with conditions such as systemic lupus erythematosus and antiphospholipid syndrome, which not only carry an increased risk of pre-eclampsia, but are more likely to suffer thromboembolic disease or pregnancy loss, will be given LMWH to reduce these risks.[33]

Controversy still surrounds the use of dietary calcium supplementation antenatally to reduce the risk of hypertensive diseases in pregnancy. Trials have produced ambiguous results in varied populations making a definitive conclusion impossible. In women with a low dietary calcium intake, some preventative benefit has been seen; however, in women with good dietary calcium intake, no benefit is seen.[43] Nevertheless, the intervention is low risk, low cost, likely to be well tolerated, and holds little harm to mother and fetus. Thus, even modest benefits, would warrant the use of oral calcium supplementation. The case for its use remains to be proven.

No particular additional lifestyle advice for women at risk of, or suffering from, hypertension in pregnancy is required beyond that normally given to pregnant women regarding rest, exercise or the timing of maternity leave from work. Additional information can provide further indications to shape antenatal management.

## Diagnosis of pre-eclampsia

The primary method for the diagnosis of pre-eclampsia is the measurement of the blood pressure and the assessment of the urine for proteinuria. Other clinical signs have limited specificity for pre-eclampsia. The validity of methods used to assess the blood pressure and to quantify proteinuria in order to make the diagnosis is therefore very important.

### Assessment of blood pressure

Given the nationally defined thresholds for blood pressure measurement and categorization of hypertension in pregnancy, the accurate assessment of blood pressure is paramount in the screening of the pregnant population and for the diagnosis and risk assessment of hypertensive disease in pregnancy. The margin for error commonly introduced when measuring blood pressure in the pregnant and non-pregnant population has been widely documented either through mechanical or operator limitations. Strict validation protocols now exist for automatic blood pressure measuring devices for use within specific populations and clinical settings.[44] Similarly, inaccuracies introduced by operator error when using manual devices have led to the introduction of guidance for the use of manual devices.[45] Simple measures such as being aware of digit preference, where practitioners will round blood pressure readings up or down to the nearest 5 or 10 mmHg, will reduce inaccuracies. Use of standard sphygmomanometer cuffs will be inappropriate for up to a quarter of women who require a larger cuff to reduce the incidence of artificially elevated blood pressures and thus the over-diagnosis of hypertension. Similarly, use of the correct Korotkoff sounds to measure blood pressure will reduce over-diagnosis of hypertension when taking blood pressure manually. Using Korotkoff phase 5 rather than Korotkoff phase 4 will prevent over-diagnosis of diastolic hypertension, while keeping the rate of cuff deflation lower than 2–3 mmHg/s will also reduce this error.[46,47]

All women in the United Kingdom will have their blood pressure routinely monitored as part of their antenatal care. This will occur at midwifery-led appointments at home or in the community when the women first registers her pregnancy (typically just after finding out she is pregnant), and then at 16 and 25 weeks (for primigravid women), 28 (for all women), 31 (primigravidae), and then for all women at 34, 36, 38, 40, and 41 weeks of gestation. If the blood pressure readings gained at these visits are above the threshold of 140/90 mmHg as specified in the NICE guidance this will result in escalation of care, usually for a period of sustained blood pressure monitoring in an outpatient maternity day unit type setting.[48] Additional investigation will occur as per Table 36.2 dependent upon persistent increases in blood pressure and significant proteinuria.

**Table 36.2** Management of gestational hypertension and pre-eclampsia

| | Gestational hypertension | Pre-eclampsia |
|---|---|---|
| Admission to hospital | Only to control severe hypertension | Yes |
| Anti-hypertensive treatment | For moderate or severe hypertension to target of 80–100 mmHg diastolic and below 150 mmHg systolic | For moderate or severe hypertension to target of 80–100 mmHg diastolic and below 150 mmHg systolic |
| Measure blood pressure | Weekly in mild hypertension<br>Twice-weekly in moderate hypertension<br>Four times daily with severe hypertension until controlled | Four times daily or more if severe hypertension |
| Assessment of proteinuria | At each visit using automated assessment or PCR | Not necessary once diagnosis confirmed |
| Blood tests:<br>Full blood count<br>Renal function<br>Transaminases<br>Bilirubin<br>Electrolytes<br>Albumin | Not necessary with mild hypertension<br>As a baseline with moderate hypertension but do not repeat<br>Weekly if has had severe hypertension | Mild pre-eclampsia—twice-weekly<br>Moderate and severe pre-eclampsia check three times a week (though more frequent if abnormal) |

National Institute for Health and Clinical Excellence (2011) CG 107 Hypertension in pregnancy: the management of hypertensive disorders during pregnancy. Manchester: NICE. ### Assessment of proteinuria in hypertensive disorders of pregnancy

The differentiation and diagnosis of GH and pre-eclampsia and therefore the increased likelihood of more serious complications, is dependent upon the reliable and accurate diagnosis of significant proteinuria. This has traditionally been taken at a level of greater than 300 mg excretion in a 24-hour period. This level is endorsed in international guidelines. However, the accuracy of the quantification of proteinuria is vulnerable to collection and measurement error. By its very nature, the length of time required to undertake a 24-hour collection rules it out as a bedside test and a tool for immediate assessment at first presentation to secondary care. A widely used screening test is urine dipstick analysis, but good evidence has established that significant error exists in measuring proteinuria even when experienced staff read urinalysis strips.[49] To reduce inaccuracies of proteinuria measurement, use of an automated reagent-strip reading device is recommended by NICE guidance in secondary care settings.[30] However it should be stressed that this is still insufficient for absolute confirmation of significant proteinuria and formal quantification of proteinuria should be performed. The two approaches are either a 24-hour urine protein collection or a urinary protein:creatinine ratio. There is no evidence to suggest that this is necessary in the routine screening of the whole pregnant population. Urine protein:creatinine ratio requires a single urine sample that is sent for immediate biochemical analysis which allows for faster turnaround than a 24-hour urine collection. It is now recognized that this investigation is comparable to a 24-hour urine protein measurement.[50] Results of 300 mg of protein excreted in 24 hours, or a urine protein:creatinine ratio result greater than 30 mg/mmol, indicates significant proteinuria.

Further research to improve accuracy is still needed. Similarly convincing evidence, as to where the correct thresholds lie to determine prognostic significance (and thus influence management), remains to be discovered. Once the degree of hypertension and presence and quantity of protein are confirmed, the initial treatment regimens will follow the patterns outlined in Table 36.2.

## Symptoms of pre-eclampsia

The symptoms listed in Box 36.2 are commonly associated with pre-eclampsia but are by no means universal. Symptoms do not necessarily correspond with the objective severity of disease and subsequent maternal or fetal complications. Similarly, women may only have one of these symptoms and not the expected constellation. A woman with no symptoms can yet present with severe pre-eclampsia.

**Box 36.2** Symptoms of pre-eclampsia

- Severe headache
- Problems with vision, such as blurring or flashing before the eyes
- Severe pain just below the ribs
- Nausea and vomiting
- Sudden swelling of the face, hands, or feet.

Antenatally it is important that all pregnant women, especially those diagnosed with hypertension, are aware of the above symptoms and their significance. They must therefore be able to seek advice from a healthcare professional 24 hours a day, or if necessary, attend secondary care obstetric services directly should these symptoms manifest themselves.

## Antenatal care

### Gestational hypertension

Women with GH should have a full assessment carried out in secondary care by the obstetric team. They will need ongoing follow-up and care throughout and after the pregnancy. The risk factors of developing GH and pre-eclampsia are listed in Box 36.3.

Dependent on the severity of disease, obstetric units offering care and follow-up to these women should have the capability to offer admission to hospital, treatment, regular measurement of blood pressure, facilities for accurate testing for proteinuria, and blood tests as described in Table 36.2. Most women with non-proteinuric hypertension can and should be managed as outpatients.

Women who have been treated as inpatients for severe GH, which has then been subsequently stabilized, will usually be managed on an outpatient basis with regular reviews.[51] A recommended regimen of monitoring in these patients will include blood pressure and urine checks twice weekly, with weekly blood testing. Similarly, those women presenting with mild hypertension prior to 32 weeks, and those women with hypertension and increased risk factors for pre-eclampsia (see Box 36.3), should be offered increased outpatient monitoring, with blood pressure and urine check twice per week.

There is no evidence regarding the benefit of bed-rest in women with hypertension in pregnancy.[30]

### Pre-eclampsia

Women diagnosed with pre-eclampsia should usually be managed as inpatients.

The monitoring of pre-eclampsia requires regular blood pressure monitoring and relevant blood testing. Once the diagnosis of pre-eclampsia is confirmed by the presence of significant

**Box 36.3** Risk factors for developing gestational hypertension and pre-eclampsia

- Nulliparity
- Age 40 years or older
- Pregnancy interval of more than 10 years
- Family history of pre-eclampsia
- Multiple pregnancy
- BMI of 35 kg/m$^2$ or more
- Low gestational age at presentation
- Previous history of pre-eclampsia or gestational hypertension
- Pre-existing vascular disease
- Pre-existing kidney disease.

proteinuria there is little value to the ongoing monitoring of urinary protein excretion. The blood tests include a full blood count (FBC) to assess haemoglobin levels and platelets, liver function tests to monitor enzymatic changes, and renal function tests. Clotting tests to diagnose any developing coagulopathy are appropriate if there are abnormalities of platelet levels or liver function. There is no evidence of additional value to urate assessment. The advice from NICE is summarized in Table 36.2. Ongoing monitoring of physiological and biochemical markers should be organized, a plan made for management of hypertension, along with a plan for delivery. Ideally, thresholds in blood pressure or biochemistry should be should be specified to trigger an escalation in monitoring and management, including those which would warrant an expedited delivery.

If the likelihood of premature or urgent delivery is deemed significant due to severe hypertension, defined as hypertension which is refractory to first-line antihypertensives, concerns regarding fetal growth or well-being, or if a women has significant co-morbidities, then anaesthetic pre-assessment is indicated.

Women diagnosed with pre-eclampsia should be managed with an integrated care package. Due to the unpredictable nature of pre-eclampsia and the difficulty in anticipating which women will develop complications such as severe pre-eclampsia, eclampsia, and fetal complications, women must be fully assessed on a regular basis. When women are assessed, they need to be seen by professionals experienced in the management of pre-eclampsia, who have the facilities to measure blood pressure, test for proteinuria, and blood tests

## Antihypertensive treatment

The evidence available regarding the use of antihypertensives in pregnancy is limited due to a surprising lack of good quality clinical trial data relating to pregnant women, and the unwillingness of clinicians to use untried and untested newer antihypertensives. First-line treatment is labetalol. Labetalol has both non-selective β-adrenoreceptor antagonism and selective α-adrenoreceptor antagonism which together reduce systemic vascular resistance, reduce heart rates, and reduce the risk of arrthymias.[52] If commencing treatment for the first time, a graduated course of treatment should be commenced and titrated to control hypertension. A blood pressure with a systolic below 149 mmHg and between 80 and 100 mmHg diastolic should be aimed for, whilst avoiding profound and sudden drops in blood pressure. Labetalol is superior to other agents including methyldopa and other beta blockers such as atenolol in various studies demonstrating effectiveness in reducing hypertension while minimizing maternal and fetal side effects.[53–57] It also has a licence for use in pregnancy. Whilst some studies have suggested that particular drugs are associated with impaired fetal growth it is probably the lowering of blood pressure that drives this effect. Therefore it is likely that any drug which effectively lowers blood pressure will be associated with a reduction in fetal weight. A reasonable initial dosage for moderate hypertension is 200 mg orally two or three times a day.

In the more acute setting with severe hypertension, an initial dose of oral labetalol 200 mg is used when commencing antihypertensive treatment. If blood pressure has not started to fall within 20 minutes a repeat dose should be given. Rarely if a third dose fails to manage blood pressure, 50 mg of intravenous labetalol should be given. Again this should be repeated every 10–15 minutes, until the blood pressure is brought below 150/100 mmHg, but maintaining a diastolic above 80 mmHg to avoid fetal complications. Once this is achieved a labetalol infusion up to a maximum of 2 mg/min should be commenced.[30] In some settings, an arterial line for closer blood pressure monitoring and frequent blood sampling is inserted when intravenous antihypertensives are required, though this is uncommon in the United Kingdom.

If bolus doses of IV labetalol fail to bring hypertension under control then second-line treatments such as hydralazine or nifedipine can be used. In some settings nicardipine or urapadil are used. An initial dose of 10–20 mg of oral nifedipine is recommended. Note that oral nifedipine is recommended over sublingual nifedipine as the latter can cause precipitous falls in blood pressure. Modified- or slow-release preparations help reduce this phenomenon and are very useful in ante- or postnatal settings, but are less helpful in the acute situation. Rarely nifedipine can cause profound drops in blood pressure, leading to fetal compromise due to placental hypoperfusion and in severe cases this may necessitate delivery. Whilst there have been concerns about nifedipine and a possible interaction with magnesium sulphate, that does not seem to have been the case in the larger trials or in clinical practice.

Hydralazine is a very effective treatment when given intravenously. However, it is more commonly associated with profound reductions in blood pressure and tachycardia than other agents. A dose of 5 mg hydralazine can be given intravenously. Usually a fluid bolus of up to 500 mL crystalloid fluid should be given before or at the same time as the first dose of intravenous hydralazine prior to delivery. This is to avoid fetal compromise. Other agents are less commonly used in the United Kingdom but can be considered. Diazoxide 15mg intravenous is an arterial vasodilator and could be used as an alternative to hydralazine.

Nicardipine is an alternative calcium channel blocker that can be given parenterally. Intravenous nicardipine 10 mg over 5minutes may be given in severe hypertension.

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers are contraindicated antenatally as they are associated with congenital abnormalities. They may be considered postnatally.

In all cases it is important not to drop the maternal blood pressure precipitously. Stabilizing the maternal condition, thus preventing the secondary consequences of hypertension such as a cerebrovascular accident, remains the principal objective of treatment and supersedes any indication for delivery. A precipitous decision to delivery prior to maternal stabilization can lead to sudden physiological changes in response to anaesthesia and surgery with increased maternal and fetal complications. During administration of antihypertensive medication, ongoing critical care and fetal monitoring must be continued to track any response and modify treatment accordingly and identify any adverse outcomes for both mother and fetus.

## Timing of birth

Women with chronic hypertension or GH should not be advised to have elective delivery prior to 37 weeks due to the increased risks of the complications of prematurity and increased admission to special care baby services.[5] Only women with severe

hypertension above 160/110 mmHg, which is refractory to medical treatment, should be offered delivery prior to 37 weeks.[58–60] Delivery arrangements should be agreed between the woman, the obstetric team, the anaesthetic, and critical care teams in consultation with other professionals as required (cardiology, haematology, and neurology). When planning elective delivery it is important to ensure optimization of maternal blood pressure and to decide on the administration of corticosteroids with a possible 48-hour delay to optimize their effect.[61] If vaginal birth is planned, steroids are usually given before 34 weeks of gestation but if elective caesarean delivery is planned, then they are beneficial up to 38 weeks.

When women present with pre-eclampsia prior to 34 weeks, the aim should be to manage them conservatively. The blood pressure should be treated and stabilized, ideally avoiding same-day delivery, unless fetal or maternal risks from pre-eclampsia are critical. The main contraindication to delivery is the more serious consequences of prematurity in this group. However, prior to 34 weeks, women with pre-eclampsia will have hypertension increasingly refractory to antihypertensive treatment. They are also more likely to have worsening biochemical or haematological profiles or concern about fetal well-being. Even women with severe hypertension and pre-eclampsia should have their blood pressure stabilized and a plan to aim for delivery after 34 weeks as associated neonatal morbidity begins to decline. However, these decisions are multidisciplinary and must not be detrimental to the woman's well-being. The advantage of prolonging gestation is to the fetus alone.

Obstetric care plans should indicate clinical and investigation thresholds, which must be crossed to warrant elective delivery prior to 34 weeks. Mode of delivery should be agreed between the woman and obstetric team. A semi-planned caesarean delivery or induction may be offered. However, induction is less likely to result in labour and subsequent vaginal birth at earlier gestations. Before 32 weeks a caesarean delivery will probably be required. The multidisciplinary team should also be involved in decision-making, including the anaesthetic and neonatal consultants, who can provide maternal and neonatal support respectively, in the event of any associated morbidity.

Women with mild or moderate pre-eclampsia can be offered delivery from 34 weeks onwards and prior to 37 weeks, as clinically indicated by maternal or fetal condition. The neonatal risks are reduced after 34 weeks; however, they must be considered as their incidence does not drop below 10% until after the 36th week of gestation. After 37 weeks, once the diagnosis of pre-eclampsia is confirmed, obstetricians will usually advise women to deliver within 24–48 hours of confirmation of the diagnosis.

There is a 'grey' zone for women who have pre-eclampsia with mild or moderate hypertension between 34 and 37 weeks when the optimal timing of birth is not clear. Women who have pre-eclampsia with mild or moderate hypertension may progress to severe disease with its risks, but it is not clear whether these risks outweigh or should outweigh the risks of planned late preterm birth for the baby. Neonatal services are under constant pressure and planned preterm birth without clear benefit to either woman or baby would have costs. The HYPITAT study[62] in 2008 randomized women with GH and mild pre-eclampsia to induction of labour at 36 weeks versus expectant management and delivery as clinically dictated by changing symptoms. Of women who were randomized, 117 (31%) allocated to induction of labour developed poor maternal outcome (as measured by a range of composite outcomes, including severe hypertension and the development of HELLP syndrome) compared with 166 (44%) allocated to expectant monitoring (RR 0.71; 95% confidence interval (CI) 0.59–0.86; $P < 0.0001$). No cases of maternal or neonatal death were seen due to the limited size of the trial. Interestingly women randomized to induction of labour were probably less likely to require a caesarean delivery RR 0.75 (95% CI 0.55–1.04; $P = 0.085$). This is likely to be due to the decreased likelihood of these women developing more severe hypertensive disease.

Future randomized controlled trials are planned that compare policies of immediate planned birth between 34 + 0 and 36 + 6 weeks in women who have pre-eclampsia with mild or moderate hypertension with expectant management and birth for clinical progression.

## Intrapartum management

Women with pre-eclampsia should receive the same basic care in labour as all women and in particular they should have one-to-one midwifery care. Additionally, blood pressure should be monitored hourly in women with mild or moderate hypertension and more frequently in women with severe hypertension. Any antenatal hypertensive medication should be continued in labour with dose titration as per the clinical picture.

### Blood testing and analgesia

Haematological and biochemical testing in women with mild or moderate hypertension should be organized according to the antenatal criteria outlined in Table 36.2, even when considering neuraxial anaesthesia. This means that women with mild hypertension and no proteinuria do not need a platelet count or coagulation screen and are suitable for neuraxial anaesthesia barring other concurrent pathology or contraindication. There is evidence to avoid over-testing by only performing a thromboelastograph study if platelets are less than 100.[63]

### Decision about level of care (critical care levels)

Woman with severe hypertension or severe pre-eclampsia should be managed in a critical care setting with:

- close blood pressure monitoring
- continuous heart rate monitoring
- continuous oxygen saturation monitoring
- fluid balance
- fluid restriction
- intravenous access (2 × 16 G cannulae if possible)
- haematological and biochemical testing
- continuous fetal heart rate monitoring prior to delivery

Close blood pressure monitoring does not imply invasive blood pressure monitoring, though that may be required on occasions. Generally non-invasive blood pressure monitoring with checks at frequent intervals depending on the blood pressure reading is reasonable. One possible advantage of invasive monitoring is that it can also make repeated blood sampling more patient-friendly and especially if there is concurrent thrombocytopaenia.

A multidisciplinary approach to treating pre-eclampsia and severe hypertension is crucial and critical care is a vital part of management. Obstetric and midwifery teams are often proficient

in diagnosing, treating, and managing pre-eclampsia. They are also acutely aware of the complications which may arise due to the disease itself or iatrogenically, but will be unable to supply a full range of supportive care for these women. Anaesthetists on the labour ward are therefore ideally placed to offer this expertise and support to the woman and the team.

In order to manage complicated pre-eclampsia appropriately, the following recommendations are made to guide appropriate obstetric critical care support:[30]

- *Level 3 care (or intensive therapy unit (ITU) care)*—severe pre-eclampsia needing ventilatory or inotropic support or renal replacement therapy.
- *Level 2 care (or high dependency unit (HDU) care)*—step-down from Level 3 or severe pre-eclampsia with any of the following complications:
  - eclampsia
  - HELLP syndrome
  - haemorrhage (estimated blood loss greater than 1000 mL)
  - hyperkalaemia
  - severe oliguria
  - coagulation support
  - intravenous antihypertensive treatment
  - initial stabilization of severe hypertension
  - evidence of cardiac failure
  - abnormal neurological findings.
- *Level 1 care (routine delivery suite care)*—women with the following conditions:
  - Pre-eclampsia with mild or moderate hypertension
  - Ongoing conservative antenatal management of severe preterm hypertension
  - Step-down treatment after the birth.

## Fluid management and renal complications of pre-eclampsia

Fluid overload has been a contributory factor in deaths due to pre-eclampsia.[2] Whilst it is the case that the intravascular volume is depleted, the fact that the capillary membranes are more permeable can lead to fluid entering the tissues. This is exacerbated if there is excess fluid administration. Therefore women with pre-eclampsia should not be given volume expanders intrapartum. The one exception is if hydralazine or other potent vasodilators are the antihypertensives being used, prior to birth. The vasodilatation and drop in blood pressure can cause a reduction in placental blood flow and fetal compromise.

Where fluid management is problematic, intrapartum monitoring should include invasive arterial blood pressure but pulmonary artery flotation catheters are not recommended as there is a high reported complications rate (1/25 catheters inserted in a retrospective review of 100 cases of severe pre-eclampsia or eclampsia).[64] Central venous catheters can be used if fluid balance is difficult though interpretation of the information provided can be difficult.

Fluid restriction is undertaken to prevent pulmonary and cerebral oedema. The incidence of pulmonary oedema in pre-eclampsia is around 2%.[5] The synergy of left ventricular diastolic dysfunction, reduced colloid oncotic pressure of pregnancy, and increased capillary permeability make this a dangerous complication of pre-eclampsia.[65] The negative inotropic effect of the commonly used agent labetalol as well as injudicious fluid administration with oliguria also increase the risk of pulmonary oedema. Whilst no specific amount of total fluid input per hour can precisely be defined, it is recommended that clear guidance is given to avoid iatrogenic fluid overload. A regimen in current clinical use is 1mL/kg/h of fluids in total, up to a maximum of 80 mL/h. These can be given by the oral or intravenous route. Given that fluid restriction must take into account oral intake, intravenous crystalloid, magnesium sulphate, and labetalol infusions, careful fluid balance monitoring is vital. Ongoing fluid losses such as haemorrhage should be replaced appropriately. If oxytocin is to be continued post delivery it should be administered in small crystalloid volumes by syringe driver (e.g. 50 units in 50 mL 0.9% saline over 5 hours, i.e. therapeutic dose delivered of 10 units/hour). To facilitate fluid restriction, magnesium sulphate and labetalol should equally be given in a low-volume infusion (e.g. in a 50 mL syringe).

Oliguria is a common feature of pre-eclampsia in the peripartum and early postpartum period. However, this will usually resolve spontaneously with a marked diuresis 24–48 hours after delivery. Glomerular capillary endotheliosis is a classical histological appearance in association with pre-eclampsia. However, acute kidney injury is rare, with an incidence of less than 1/10,000 pregnancies. In pre-eclampsia, circulating volume may be reduced despite increased total body water so hourly monitoring of urine output is necessary, particularly with severe pre-eclampsia.

Postnatally, fluid restriction should be maintained. Urine output should be monitored and 4-hour blocks of urine output considered. If urine output is more than 80 ml in a 4-hour block, this should be considered acceptable. If two consecutive 4-hour blocks have less than 80 mL urine output, a fluid bolus should be considered. However, if the woman is already in positive balance by more than 750 mL then furosemide 20 mg intravenously may be given. If the woman is in less than 750 mL positive balance then crystalloid boluses of up to 250 mL should be given. This will resolve most cases of oliguria. If there is still no improvement in urine output then it would then be appropriate to seek the advice of a renal specialist, especially if there is also a raised serum creatinine. A central venous catheter may be useful here in guiding fluid management, though interpretation of the results can be difficult.

In the presence of pulmonary oedema, hypertension can be treated with a glyceryl-trinitrate infusion (5 mcg/min titrated up to response—maximum 100 mcg/min) as recommended by the European guidelines.[66] Such treatment should only be undertaken in the presence of invasive blood pressure monitoring in the ITU. Sodium nitroprusside is reserved only for resistant cases under expert supervision. The risk of cyanide toxicity, particularly for the fetus, makes sodium nitroprusside a short-term option only.

Massive haemorrhage, particularly placental abruption, which occurs more commonly in pre-eclampsia can, however, precipitate acute renal injury due to hypovolaemia. Whilst this may be

prevented with timely replacement of blood loss, there is a risk of renal problems even when blood loss is replaced. There is also the challenge of blood replacement leading to fluid overload and pulmonary oedema. In these cases, accurate measuring of blood loss with suction jar measurements and swabs weighting is mandatory. Treatment includes strict attention to electrolyte balance, particularly potassium and fluid balance. Rarely, if renal function does not return to normal or deteriorates, advice from renal physicians may be warranted, especially an assessment of whether dialysis is indicated, though this is rarely required in women who do not have pre-existing renal disease,

### Mode of delivery

As previously discussed, the ultimate cure for pre-eclampsia is delivery of the placenta. Intuitively, expediting delivery can therefore seem the most logical solution in treating poorly controlled pre-eclampsia with severe hypertension. However, stabilizing the mother should be a priority over delivery as failure to do this will increase maternal complications (e.g. stroke). Control of the blood pressure to target values of below 140–150 mmHg systolic and 80–100 mmHg diastolic, should be undertaken before the decision to deliver the fetus is made. For this reason the majority of caesarean deliveries for pre-eclampsia are category 2 according to the NICE classification with 'maternal or fetal compromise which is not immediately life-threatening'.[67] In the advent of eclampsia, in particular with fulminant pulmonary oedema or treatment-resistant seizures, it may occasionally be necessary to precipitate the delivery of the fetus before satisfactory blood pressure control can be gained.

Once the decision to deliver has been determined, the mode of delivery should be chosen. This should take into account the woman's wishes and the clinical circumstances. These include:

- hypertensive control
- symptoms
- complications such as HELLP syndrome
- eclampsia
- timing of magnesium sulphate administration
- fetal condition and likely outcome
- unit resource and staffing availability, both maternity and neonatal staff
- the prospects for a reasonably timely vaginal birth

The fetus will be monitored throughout labour regardless of gestation, due to the potentially reduced placental function associated with pre-eclampsia and due to the increased risk of complications, which may affect the fetus such as placental abruption.

There is no evidence supporting the limitation of the second stage of labour in women who have mild or moderate hypertension, but operative delivery is advised for those women with severe hypertension who have not responded to initial treatment in order to expedite delivery. Note that ergometrine should be avoided in the management of the third stage in hypertensive women due to its propensity to aggravate hypertension.

## Anaesthetic considerations

In the anaesthetic management of hypertensive diseases of pregnancy, the overarching goals are to ensure adequate tissue perfusion and oxygenation of parturient and fetus whilst treating hypertension to minimize maternal stroke risk. Providing effective analgesia in labour and optimal surgical conditions for caesarean delivery are integral to achieving these goals. There are a number of excellent reviews on this subject.[68,69]

### Labour analgesia

Epidurals are the analgesia of choice for labour in the pre-eclamptic patient. The reduction in pain afforded by an epidural prevents catecholamine surges and thus reduces the risk to the mother of stroke or cardiac events. There are advantages to the fetus and Jouppila et al. have shown that placental blood flow is increased in labour by epidural analgesia.[70] This is postulated to occur via decreased uterine vascular resistance which is secondary to the epidural-induced sympathectomy. Further, there is a lower threshold for obstetric interventions with pre-eclamptics and a working epidural can quickly facilitate these. It should be noted that oedema may be present over the lumbar spines and sacrum making insertion of neuraxial anaesthesia challenging.

In the United Kingdom, many obstetric units provide neuraxial anaesthesia to pre-clamptics with platelets down to $75 \times 10^9$/L based on the observed hypercoagulability seen in severe pre-eclamptics on thromboelastography.[71,111] A postal survey of obstetric anaesthetists from 1996 had already documented that 62% of responding anaesthetists would place epidural catheters in otherwise healthy patients with platelets counts as low as $80 \times 10^9$/L.[72] Some units advocate the use of platelet transfusion prior to regional anaesthesia if the platelet count is between 50 and $70 \times 10^9$/L.[72] Platelet transfusion for levels below $50 \times 10^9$/L prior to delivery may not only be indicated to perform neuraxial anaesthesia but may also be warranted prior to caesarean delivery to reduce the risk of postpartum haemorrhage. Some units would consider neuraxial anaesthesia at lower levels of platelet count especially if they are able to undertake platelet function testing. A careful risk:benefit analysis is required given the concerns of general anaesthesia (GA) in this group of women, due to the risk of surges in blood pressure or failed intubation with laryngeal oedema. Before the removal of epidural catheters in pre-eclamptics, a platelet count is warranted if the count has been low prior to insertion of the epidural or if there has been intervening haemorrhage.

### Neuraxial anaesthesia for operative delivery in the pre-eclamptic woman

In the absence of a contraindication to neuraxial anaesthesia, epidural and spinal anaesthesia are currently the anaesthetics of choice for caesarean delivery in pre-eclampsia. Contraindications to neuraxial anaesthesia are no different than in patients without pre-eclampsia/eclampsia, namely untreated coagulopathy including disseminated intravascular coagulation, seizure, pulmonary oedema requiring invasive ventilation, and lack of informed consent. Risk and benefit analysis for cases of eclampsia must be taken on a case-by-case basis by senior anaesthetists and obstetricians.

There have been retrospective and prospective studies with evidence to support the safe use of neuraxial anaesthesia[73–75] in severe pre-eclampsia. A number of studies have compared spinal and epidural anaesthesia in pre-eclamptics[76,77] and found that with spinal anaesthesia, blood pressure drops much less in pre-eclampsia than in healthy partunients.[78] In the context of neuraxial anaesthesia-induced sympathectomy with hypotension,

because of an increased sensitivity to vasopressors, ephedrine in small dose increments (3–6 mg) or phenylephrine (50 mcg) may be used. Anaesthetists should have a low threshold for inserting arterial lines as continuous blood pressure measurement will guide vasopressor use.

It is reassuring to know that no significant difference has been found in neonatal outcomes to date when comparing spinal and epidural anaesthesia in pre-eclampsia,[78] although this study by Aya et al.[78] was powered to find haemodynamic differences rather than differences in neonatal outcomes. Other advantages of spinal anaesthesia over epidural are that the former is usually quicker and less traumatic to perform and this may be pertinent when the platelet count is low. Further, some studies have shown that epidurals for caesarean delivery are not as effective as in normotensive patients and require higher conversion rates to spinals or GA.[77,79]

The current evidence thus supports the view that a single-shot spinal anaesthetic is recommended in the pre-eclamptic patient. Similar doses of intrathecal local anaesthetic should be used unless the fetus is premature, when a larger spinal dose is needed. Alternatively, a combined subarachnoid and epidural injection has been found to be a suitable technique. Low-dose subarachnoid bupivacaine (maximum 7.5 mg) with sufentanil in the sitting position followed by an epidural catheter insertion for titrating supplemental anaesthesia was studied prospectively in 30 severely pre-eclamptic parturients.[80]

### General anaesthesia in the pre-eclamptic

GA versus neuraxial anaesthesia has been the subject of a 2012 Cochrane review in which there were no differences found in terms of major maternal and neonatal outcomes.[81] The Cochrane review, however, was only able to retain data from 1793 women, of whom none died. There are two potential challenges for the obstetric anaesthetist managing the pre-eclamptic patient requiring a GA. Firstly, there is the risk of dramatic hypertension and cerebral haemorrhage upon direct laryngoscopy at induction and secondly there is the risk of the failed intubation in patients who are well known to have oedematous larynxes. [82] Neuraxial anaesthesia avoids both these potential complications.

However, GA is the recommended anaesthetic technique when patient oxygenation is at risk because of uncontrolled seizures (treatment-resistant eclampsia), or pulmonary oedema requiring invasive ventilation, or if severe coagulopathy is present. In the context of severe thrombocytopenia, the patient declining neuraxial anaesthesia or having disseminated intravascular coagulation, GA is unavoidable. On top of usual considerations for GA for obstetrics (see Chapter 22), considerations must be given to the conduct of a rapid sequence induction and intubation in the presence of hypertension. The use of the ramped position for pre-oxygenation should negate the risk of passive regurgitation and limit the rise in blood pressure seen at direct laryngoscopy by facilitating venous pooling in the lower limbs.

With the aim to secure the airway with a cuffed endotracheal tube, but without hypertensive response to direct laryngoscopy, two broad options are available, namely avoidance of direct laryngoscopy and obtunding the response to laryngeal manipulation with pharmacological options.

The choice of antihypertensives prior to laryngoscopy should be based on the anaesthetist's experience. Drug options include the use of intravenous alfentanil (10–20 mcg/kg 1 minute prior to induction), or remifentanil.[83] A remifentanil dose–response study of 75 parturients with severe pre-eclampsia found that the $ED_{50}$ of remifentanil as a bolus dose for attenuating a hypertensive response 90 seconds before induction was 0.59 mcg/kg.[84] A meta-analysis of remifentanil prior to induction, either as a 1 mcg/kg bolus or a 0.5 mcg/kg bolus followed by an infusion, found that remifentanil was effective in attenuating hypertensive response to laryngoscopy and that fetal base excess was statistically higher, although the clinical significance of the latter is unclear as Apgar values were similar.[85] The choice of opioid will be guided by the opioid onset time, the urgency of the caesarean delivery, and the fetal effects. Discussions about the merits of indirect laryngoscopy (e.g. AirTraq® and Glidescope®), optical stylets (e.g. Levitan FPS and Shikani Optical Stylet), and fibreoptic intubations to avoid hypertension are beyond the scope of this text, but may be increasingly relevant as new equipment is developed and studied.[86,87] Details of this equipment can be found in Chapter 26 on the difficult or failed obstetric airway.

The problem of failed intubation amongst pre-eclamptics is well known and steps must be taken to avoid a 'can't intubate, can't ventilate' scenario. Senior anaesthetists should be present at induction if at all possible and the difficult airway trolley (see Chapter 26 for an example of such a trolley) must be to hand including small endotracheal tubes (down to 5.5 mm). Induction and maintenance of GA, and use of intraoperative analgesia, is similar to that of healthy parturients. The use of magnesium sulphate infusion in pre-eclampsia does not seem to affect the reversal of non-depolarizing neuromuscular blockers in clinical practice, despite the theoretical risks to do so.

Extubation after GA in a pre-eclamptic patient is another potential challenge as there may be more mucosal swelling of the trachea in response to the presence of the endotracheal tube. There is nothing more frightening for an obstetric anaesthetist than to have a pre-eclamptic develop stridor on extubation. To avoid this and after positioning the patient in the sitting position, the cuff of the endotracheal tube should be deflated and if a leak is present, extubation can be performed but if there is no leak, signifying significant mucosal swelling of the trachea, it is better to re-inflate the cuff, re-administer GA, and transfer the patient to intensive care. Diuresis postpartum will result in a reduction of oedema including that of the mucosa and extubation should be subsequently uneventful.

## Uterotonics in pre-eclampsia

Oxytocin can cause haemodynamic changes in parturients, namely hypotension, so its dose is usually limited to 5 IU by slow intravenous injection post delivery.[88] Ergometrine is contraindicated in hypertension in pregnancy or with pre-eclampsia[89] because of its hypertensive effect and the consequent risk of cerebral haemorrhage.

## Postoperative care

Apart from the usual standards of postoperative care and postanaesthetic care,[90] Level 2 critical care (HDU care) is required particularly in the presence of invasive monitoring and oliguria.

Regular analgesia should be prescribed as paracetamol 1 g 6-hourly *per os* or *per rectum* only to avoid intravenous fluid bolus. Care should be taken to avoid non-steroidal anti-inflammatory

drugs (NSAIDs). In the presence of hypertension or pre-existing renal impairment, which pre-eclamptic patients have by definition, NSAIDs can lead to renal failure, papillary necrosis, or interstitial fibrosis.[91] Tramadol may be useful in this setting, particularly in breastfeeding mothers. If the patient has had a caesarean delivery under GA and no neuraxial opiate has been given, patient-controlled analgesia with opioid is necessary. Transversus abdominis plane (TAP) blocks have been shown to reduce morphine requirements postoperatively.[92] TAP blocks should probably be avoided in the presence of abdominal wall oedema or eclampsia owing to the risk of local anaesthetic toxicity.

Postoperative care includes continuation of magnesium sulphate infusion for 24 hours after the delivery or the last seizure in cases of eclampsia. Pre-eclampsia is a risk factor for thromboembolic disease so thromboembolic stockings should be in place and LMWH prophylaxis prescribed as soon as the platelets count is above $80 \times 10^9$/L.

## Complications and specific treatment

### Coagulopathy

Disseminated intravascular coagulation requires close coordination of care with involvement of the haematologists and blood transfusion specialists. Blood products including packed red calls, clotting factors (both cryoprecipitate and fresh frozen plasma), and platelets may all be required (see Chapter 35 and Chapter 48). Supportive haematological care benefits from point-of-care testing and some centres are developing thromboelastography-guided treatment plans.[93]

### Renal failure

Acute kidney injury should be treated with supportive treatment in the first instance. Cessation of all nephrotoxic drugs (e.g. NSAIDs and ACE inhibitors) should be undertaken. Strict management of the fluid balance with 250 mL crystalloid boluses in case of oliguria is currently recommended. There is no evidence for the use of dopamine in pre-eclampsia according to a Cochrane review.[94] Indications for renal replacement therapy are as per the usual clinical criteria: refractory hyperkalaemia, severe acidosis, refractory pulmonary oedema, or symptomatic uraemia.

### Pulmonary oedema and cardiac failure

Peripartum cardiac failure is a complication in around 3% of parturients with severe pre-eclampsia. It may be a direct complication of pre-eclampsia along with inappropriate fluid management. However an important differential to exclude is peripartum cardiomyopathy (see Chapter 41). Heart failure secondary to pre-eclampsia is characterized by left diastolic dysfunction and is managed with non-invasive respiratory support, fluid restriction, diuretics, antihypertensives, and careful fluid balance especially in cases of haemorrhage and/or pulmonary oedema. More severe cases will require Level 3 critical care with invasive ventilation, intravenous furosemide, intravenous morphine, and as discussed earlier all drug infusions should be in high-concentration/low-volume syringe drivers to minimize fluid intake. But typically, pre-eclampsia-induced cardiac failure resolves in the 24–48 hours after delivery, unlike peripartum cardiomyopathy. Transthoracic echocardiography can be used to differentiate between pathologies and aid appropriate management. Findings usually seen in pre-eclampsia-induced heart failure include left diastolic dysfunction, preserved ejection fraction, and left ventricular hypertrophy with a normal sized ventricle. In peripartum cardiomyopathy, there is more systolic dysfunction, reduced ejection fraction, minimal left ventricular hypertrophy, and a dilated ventricle.[95]

### Eclampsia

The 2009–2012 maternal mortality report[2] did not state whether any maternal deaths occurred from eclampsia per se. However, the overall incidence of eclampsia seems to be reducing. In 1992, the estimated incidence of eclampsia was 4.9/10,000 in the United Kingdom. In Yorkshire between 1999 and 2003, it was 3.89/10,000[5] and by the time of the UKOSS survey in 2005/2006, it was 2.75/10,000 cases.[1] Whilst this reduction in the level of eclampsia is consistent with the reduction achieved by using magnesium sulphate in severe pre-eclampsia, much of the reduction had happened before the widespread use of magnesium sulphate for prophylaxis. Therefore some of the reduction must be due to better management of pre-eclampsia in general.

Eclampsia is one of the well-known complications of pre-eclampsia. However, other neurological complications can occur including cerebral haemorrhage/stroke due to uncontrolled hypertension or seizures, encephalopathy, and amaurosis fugax. Loss of autoregulation and perfusion pressures due to pre-eclampsia can account for some of these complications. Thromboembolic disease may contribute to further morbidity as counterintuitively, pre-eclampsia is associated with a hypercoagulable state.

Women with a single typical eclamptic seizure in the first 24–48 hours after birth probably do not need neuroimaging. However, any focal neurological sign should be investigated in the context of hypertension in pregnancy but the syndrome of pre-eclampsia itself, AFLP, and treatment with magnesium sulphate may all serve to generate non-specific neurological symptoms such as confusion, memory loss, inattention, drowsiness, visual disturbance, and tremor. It can thus be difficult to differentiate these signs and symptoms from a focal neurological insult. Careful assessment must be made in consultation with obstetricians, anaesthetists, neurologists, and radiologists whether neurological imaging is required, how it would affect immediate management, and whether the woman is stable enough to move to the computed tomography (CT) or magnetic resonance imaging scanner. Usually the former is sufficient to rule out major neurological change. However, the decision for the final mode of investigation should rest with the neurology and radiological team. Women who have a seizure more than 48 hours after birth, even when there are no focal neurological signs, probably should have neuroimaging to exclude the risk of a cerebral event, especially cerebral venous thrombosis.

Attention to thromboprophylaxis must always thus be taken during antenatal admission due to moderate or severe disease and in the postnatal period if there is no concern about postpartum haemorrhage, low platelets, and the removal of epidural catheters.

#### Magnesium sulphate

Women who have had an eclamptic fit should be put in the recovery position or wedged if antenatal. The airway should be secured and high-flow oxygen given by a Hudson mask. They should receive intravenous magnesium sulphate. A 4 g intravenous bolus

should be given over 15–20 minutes with a further intravenous infusion over 24 hours of 1 g per hour.[96] Diazemuls,[97] phenytoin,[98] or lytic cocktail[99] (chlorpromazine, promethazine, and pethidine) are no longer recommended. These latter treatments, while stopping seizure activity, increase morbidity and mortality by complicating communication, obtunding the airway and masking symptoms of ongoing disease. Prior to the publication of the Eclampsia Trial Collaborative in 1995[96] there was much debate about the appropriate treatment of eclampsia. The trial established that women allocated magnesium sulphate had a 52% lower risk of recurrent convulsions (95% CI 37–64% reduction) than those allocated diazepam and a 67% lower risk of recurrent convulsions (95% CI 47–79% reduction) than women randomized to phenytoin. Women allocated magnesium sulphate were also less likely to be ventilated, develop pneumonia, or require critical care admission than those treated with phenytoin. The babies of women who had been allocated magnesium sulphate before delivery were less likely to require intubation at delivery or require admission to a specialist neonatal unit than the babies born to women treated with phenytoin.

Recurrent seizures should be treated with a 2–4 g bolus of magnesium sulphate given over 5 minutes.[96] In eclampsia, magnesium sulphate infusion should continue for 24 hours after the last seizure. Oral magnesium is not used in the management of pre-eclampsia or eclampsia—this route is reserved for use as a laxative only.

Women on magnesium sulphate should have additional observations to monitor the signs of magnesium toxicity. Regular neurological observations, including orientation and signs of confusion should be noted along with deep tendon reflexes. Pulse oximetry and respiratory rate should also be measured. Since magnesium is renally excreted, urine output should also be monitored. Usually it is not required to measure magnesium levels. But if the patient is confused, has absent reflexes, or urine output of below 0.5 mL/kg (of lean body mass) per hour then magnesium levels should be sent. The infusion should be stopped until the magnesium levels are available. Should magnesium toxicity be diagnosed, that is, levels greater than 5 mmol/L, the standard treatment for magnesium overdose is 10 mL of intravenous calcium gluconate 10%.

Consideration should also be given to commencing the same magnesium regimen in women with severe pre-eclampsia if birth is planned within 24 hours. Again, these women should be treated in a critical care setting. In 2002, the Magpie[100] trial followed up the success of the Eclampsia Collaborative trial group and examined the use of magnesium sulphate in women with pre-eclampsia. Almost 10,000 women in 33 countries were randomized and received allocated treatment. Women allocated magnesium sulphate had a 58% lower risk of eclampsia (95% CI 40–71) than those allocated placebo (40, 0.8%, vs 96, 1.9%) which equated to approximately 11 fewer women with eclampsia per 1000. In the magnesium sulphate arm, 24% of women complained of side effect symptoms compared to 5% of women recruited to the placebo arm. Maternal mortality was also lower among women allocated magnesium sulphate, though the confidence interval crosses unity, so it was not statistically significant, the trend is towards reduction in mortality (RR 0.55; 95% CI 0.26–1.14). For women randomized and receiving treatment before delivery, there was no clear difference in the risk of the baby dying (576 (12.7%) vs 558 (12.4%) RR 1.02; 99% CI 0.92–1.14).

The indications for magnesium are severe pre-eclampsia or mild or moderate hypertension and proteinuria with one or more of the following:

- symptoms of severe headache
- problems with vision, such as blurring or flashing before the eyes
- severe pain just below the ribs or vomiting
- papilloedema
- signs of clonus (≥3 beats)
- liver tenderness
- HELLP syndrome
- platelet count falling to below $100 \times 10^9$/L
- abnormal liver enzyme tests (ALT or AST rising to above 70 IU/L)

### Anaesthetic management following eclampsia

Delivery of the fetus becomes a priority after an eclamptic fit. However, stabilization of the mother should not be superseded by hasty delivery. Blood pressure control must be achieved as described previously and blood tests taken in anticipation of imminent delivery and possible neuraxial anaesthesia. Delaying delivery also allows time for recovery of maternal cerebral function so that explanation and informed consent can be done. This will also facilitate cooperation for neuraxial anaesthesia or pre-oxygenation prior to GA.

Randomized control trials are not feasible for a study of anaesthesia for delivery after eclampsia—case reports, expert opinion, and the rare retrospective review can give insight into appropriate management. One such review presented 66 'stable' eclamptic parturients who had caesarean deliveries.[101] Of these patients, two had intrathecal anaesthesia while 37 had epidural and the remaining had a GA. We must bear in mind that these 66 patients had a Glasgow Coma Scale score of 14 or 15 and are a 12.4% subset of the eclamptic patients seen in one South African centre over a 4.5-year period.

## HELLP syndrome

HELLP syndrome is a serious complication of pregnancy related to pre-eclampsia. It is characterized by *h*aemolysis, *e*levated *l*iver enzymes and a *l*ow *p*latelet count, thus generating the accepted acronym.[102]

### United Kingdom obstetric surveillance system definition

Diagnosis is based upon laboratory investigations including FBC, liver function tests, and blood film. Box 36.4 lists the diagnostic signs of HELLP.

Incidence estimates vary from 0.5 to 7.6/1000 deliveries and between 8% and 24% of cases with severe pre-eclampsia/eclampsia.[103,104] Although there have been reports that women with HELLP syndrome are more likely to be older, of white ethnicity, and multiparous,[105–107] and the majority, although not all, have signs of pre-eclampsia,[108] there is no current strong evidence to confirm or refute these risk factors.

UKOSS has completed a study of HELLP syndrome. A total of 210 women met the case definition from an estimated 799,003 pregnancies; 129 had evidence of haemolysis giving an incidence of 1.6/10,000

**Box 36.4** Signs of HELLP syndrome

- *Elevated liver enzymes*: defined as serum aspartate aminotransferase (AST) ≥70 units/L *or* gamma-glutamyl transferase (γ-GT) ≥70 units/L *or* alanine aminotransferase (ALT) ≥70 units/L
- *And low platelets*: defined as platelet count < $100 \times 10^9$/L
- *And either haemolysis*: defined by abnormal peripheral blood smear *or serum lactate dehydrogenase* (LDH) levels ≥ 600 units/L or total bilirubin ≥ 20.5 μmol/L
- *Or hypertension*, defined as a systolic blood pressure ≥ 140 mmHg or a diastolic blood pressure ≥ 90 mmHg *or* proteinuria, defined as 1 + (0.3 g/L) or more on dipstick testing, a protein:creatinine ratio of 30 mg/mmol or more on a random sample, or a urine protein excretion of 300 mg or more per 24 hours

maternities (95% CI 1.3–1.9) but in 79 cases there was no haemolysis, meaning they had ELLP, or no information about haemolysis. This gives an incidence of 1.0/10,000 maternities (95% CI 0.8–1.3).[109]

Previously HELLP was considered to be a discreet entity from pre-eclampsia. However, the overlap in some of the symptoms including the manifestation of hypertension at some point in the disease course in most women and the similarity in some of the biochemical changes along with shared placental histology and molecular biomarkers has led to an acceptance that HELLP lies within the same spectrum of disease as pre-eclampsia.

### Presentation

Women may present with oedema, headache, visual disturbance, and epigastric pain in a similar way to pre-eclampsia with additional symptoms of nausea, vomiting, and general malaise. However, they may also be asymptomatic.

To date, there is no robust evidence or data which can be used to formulate risk factors for the development of the HELLP syndrome. Therefore, in the pregnant population, the principal screening methods and measures are currently the same as those for pre-eclampsia.

### Management

Treatment overlaps with that of pre-eclampsia should hypertension develop. However, additional monitoring of liver function and symptoms is mandated as rare complications such as liver ischaemia, intrahepatic or subcapsular haemorrhage, and haematoma can occur. All of these complications pose a significant risk of mortality, though conservative management may be appropriate in the stable patient. Hepatological or hepatic surgical support input is required in unstable patients.

Debate exists regarding the optimal management of women with HELLP prior to 34 weeks of gestation, when the maternal and fetal status remains stable. Though this is rare, there is no clear evidence that active management (i.e. plan prompt delivery) or a 'watch and wait' policy of maternal and fetal monitoring with delivery upon signs of worsening HELLP results in best outcomes while minimizing harm. The earlier point that robust, accurately predictive risk factors to guide management have not been elucidated by the current evidence base complicates this.

There is no evidence that corticosteroids effectively manage HELLP syndrome, therefore, do not use dexamethasone or betamethasone for the treatment of HELLP syndrome (unless this is for the benefit of fetal lung maturation).

Thus the clinical management of HELLP syndrome is much the same as for other variants of severe pre-eclampsia. The maternal condition should be optimized, with haematological support (Chapter 48), then birth should be planned. It may be possible to defer for 48 hours for the benefit of antenatal corticosteroids for the fetus but that would require very close maternal monitoring for any signs of deterioration, particularly of renal function. After birth, the recovery of women with HELLP is often much slower than in women with more common pre-eclampsia. They will commonly need 5–6 days of HDU-type care to await the improvement of liver, renal, and haematological function. However, they rarely need significant amounts of treatment for hypertension.

## Acute fatty liver of pregnancy

### Background and epidemiology

AFLP is a rare but dangerous disorder which may present in combination with pre-eclampsia, is difficult to differentiate from HELLP, and is largely a diagnosis of exclusion. It is said to be more common in primigravidae and in pregnancies carrying a male fetus[110] and twins.[111] AFLP virtually always occurs in the latter part of the third trimester with an average gestational age of 37.5 weeks[112] and may only become clinically apparent after delivery.[113] The UKOSS survey of AFLP in 2005–2006[111] estimated the incidence at 5.0/100,000 pregnancies (95% CI 3.8–6.5/100,000). Case fatality was 1.8%—just one case. However, 60% of women needed critical care.

### Definition and diagnosis

Given the non-specific clinical and biochemical changes associated with AFLP, there is a necessity and a difficulty in differentiating non-pregnancy-related liver disease from AFLP. Many women will report persistent nausea and vomiting and these symptoms, while non-specific and unhelpful in pregnancy, may predate any biochemical change. Half of affected women might have hypertension, proteinuria, and oedema, alone or in combination. Accordingly, the Swansea criteria[114] have been developed and are widely accepted as the best international definition and set of diagnostic measures.[115] They are listed in Box 36.5.

The systemic complications of AFLP are due to fulminant hepatic failure and may include encephalopathy, acute kidney injury, infection, pancreatitis, haemorrhage, coagulopathy, and hypoglycaemia. Symptoms may vary and may not progress beyond nausea, vomiting, and epigastric pain but can rapidly deteriorate to encephalopathic symptoms such as restlessness, confusion, disorientation through to asterixis, seizures, psychosis, and ultimately coma. Other, non-hepatic complications are possible, including respiratory failure, sometimes requiring assisted ventilation,[116] gastrointestinal bleeding from gastric ulceration, and Mallory–Weiss tears as a consequence of excessive nausea and vomiting. Hepatorenal

**Box 36.5** Features of acute fatty liver of pregnancy

A patient must have six or more of the signs or symptoms, in the absence of other explanations, to be deemed to have the syndrome:

- Vomiting, abdominal pain
- Polydipsia/polyuria
- Encephalopathy
- Elevated bilirubin > 14 μmol/L
- Hypoglycaemia < 4 mmol/L
- Elevated urate > 340 μmol/L
- Leucocytosis > 11 × $10^9$/L
- Ascites or bright liver on ultrasound
- Elevated transaminases
- Elevated ammonia > 47 μmol/L
- Renal impairment creatinine > 150 μmol/L
- Coagulopathy (PT >14 seconds or APTT > 34 seconds), or microvesicular steatosis on liver biopsy

Reproduced from *GUT*, CL Ch'ng, M Morgan, I Hainsworth, JGC Kingham, volume 51, Issue 6, pp. 876–880, 2002, with permission from BMJ Publishing Group Ltd.

syndrome may eventually develop and cause kidney injury failure due to oliguria and acute tubular necrosis.

### Investigation

If AFLP is suspected, investigations should include a FBC, clotting profile, renal and liver function tests, and urate and a cross-match would be prudent.

### Imaging

Ultrasound and CT scans of the liver can be used for diagnosis, but the specificity and sensitivity of these tests are limited, may be insufficient to make a firm diagnosis and the likelihood of false negative results is high.[113] Imaging may show hepatic steatosis but, unfortunately, findings are inconsistent as the fat deposits are microvesicular and the liver can appear normal. Ultrasound imaging is a helpful, but not definitive, test as approximately 20% of the general population will demonstrate a hepatic echogenic appearance suggestive of fatty changes to the liver.

Liver biopsy is the gold standard diagnostic test but, given the potential for coagulopathy, biopsy should only be used where the diagnosis is unclear and where delivery will not be delayed. The characteristic findings on biopsy are of microvesicular fatty infiltration, fibrin deposition, and haemorrhage.

### Management

Care of patients with AFLP is centred on supportive care and should include careful monitoring for evidence of progressive hepatic failure, hypoglycaemia, and coagulopathy. This usually requires admission to areas that can provide high dependency levels of care. Some hospitals have dedicated high dependency facilities within delivery suites, but this is not universal. The local service setup and a multidisciplinary team approach will determine the most appropriate area for patient management. As treatment and disease progress, the situation may need review. The likelihood is that these women will suffer at least one organ failure, thus level two care should be considered as these women will be best cared for in a critical care setting. The required multidisciplinary team effort will involve the obstetricians and midwives initially, the anaesthetic team throughout, and the input, advice, and review by intensivists and physicians with gastroenterological or hepatological expertise.

A plan of care should include:

- ventilatory support if required
- attention to fluid balance
- fluid restriction to 80 mL/h
- regular monitoring of liver function tests, coagulopathy, haemoglobin, platelets and glucose, and renal function
- antihypertensive medication as required
- vitamin K
- intravenous vitamins $B_{1,2,3,6}$ and vitamin C
- delivery.

Spontaneous resolution usually follows delivery; however, liver damage can be sufficient to require liver transplant. Maternal deaths are caused by sepsis, haemorrhage, aspiration, renal failure, pancreatitis, and gastrointestinal bleeding. Although maternal mortality rates in the past approached 75%, an average mortality rate of 7% has been cited. Early diagnosis, prompt therapy, adequate supportive care, and a multidisciplinary approach are the key to a good outcome.

### Differentiating between HELLP and acute fatty liver of pregnancy

In both conditions women may or may not have significant hypertension. They may well have proteinuria. They will have abnormal liver function and commonly disordered renal function. However, in AFLP the liver disorder will be the primary dysfunction. The bilirubin level is likely to be higher and disordered coagulation will be more prominent. Platelets may still be reduced but the urate, if measured, will be significantly higher.

Hypoglycaemia is more common with AFLP. If the plasma ammonia can be measured it will be significantly higher with AFLP. The primary management is not different between the two conditions—stabilization of the mother and then delivery of the baby. However, the likelihood of deterioration of liver function with encephalopathy means that specialist hepatology involvement is more likely to be needed with AFLP.

Chapter 48 has a useful table to help in the differential diagnosis of HELLP, AFLP, and the rarer idiopathic thrombocytopenic purpura and haemolytic uraemic syndrome where presentation may be similar.

## Breastfeeding and anti-hypertensives

NICE Clinical Guideline 107 provides a comprehensive overall summary of antihypertensives suitable for use in pregnancy and the postnatal period.[30]

Women who are breastfeeding or expressing milk after birth should not be given diuretics for the treatment of hypertension. Suitable drugs are listed in Box 36.6.

**Box 36.6** Antihypertensives suitable for the breastfeeding mother as no known or documented evidence of adverse effects upon infants

- Atenolol
- Captopril
- Enalapril
- Labetalol
- Metoprolol
- Nifedipine

National Institute for Health and Clinical Excellence (2011) CG 107 Hypertension in pregnancy: the management of hypertensive disorders during pregnancy. Manchester: NICE. Available from www.nice.org.uk/CG107 Reproduced with permission. Information accurate at time of press. For up-to-date information, please visit www.nice.org.uk

There remains insufficient evidence to support the safe use of other antihypertensives such as angiotensin receptor blocking agents, amlodipine, and ACE inhibitors (other than enalapril and captopril) in the postnatal period.

## Gestational hypertension: postnatal follow-up and longer-term care

Women with GH should receive close monitoring of their blood pressure postpartum, with daily monitoring for 2 days and a further check between day 3 and day 5 as they are at risk of significant hypertension in the early postpartum period. Between 29% and 57% of women with hypertension will have normal blood pressure 3 days after delivery, rising to 50–80% by day 7.[117] Women with GH should continue antihypertensive medication, though this should be reduced if their hypertension falls below 130/80 mmHg. If antihypertensive treatment is modified postpartum, either as a change of dose or medication, additional monitoring should be in place as clinically indicated. Women who had mild antenatal hypertension may become more hypertensive postpartum and treatment is recommended if this increases to 149/99 mmHg or above.

Traditionally, women have continued to take the medication prescribed antenatally, except in the case of methyldopa, which should be changed to an alternative as soon as possible postpartum. This is in direct opposition to a Medicines and Healthcare products Regulatory Agency directive that methyldopa is the only recommended antihypertensive in the postnatal period,[118] due to its minimal excretion in breast milk. However, this directive does not take into account the significant increases in postnatal depression associated with methyldopa. Increasingly, obstetricians are acknowledging that more modern antihypertensives offer better blood pressure control, fewer side effects, are largely considered safe in breastfeeding, and complement recommendations on adult hypertension. Typically women will be changed from medications such as labetalol to slow-release formulations of nifedipine or ACE inhibitors which are safe postnatally, even for the breastfed infant.

A careful plan for postnatal care should be routine for women with GH who return home, with provision for home visits, medical review if warranted, a specified frequency of blood pressure monitoring, along with indications for stopping treatment and seeking medical review, should the degree of hypertension or clinical situation change while under community follow-up.

Women with GH who remain on antihypertensive medication postnatally should be reviewed 2 weeks after delivery in primary care. All women with GH require medical follow-up at 6–8 weeks after delivery.[30] There should be a check of the blood pressure and of the urine for protein. This will normally form part of the GP review common in most areas in the United Kingdom. If the blood pressure has not returned to normal, specialist review of the woman's blood pressure should be sought including potential discussion with cardiologists. In these situations, it is likely that a degree of chronic hypertension or subclinical causative pathology existed prior to pregnancy and this was not discovered until the first antenatal appointment, or the physiological stress of the pregnancy has revealed an underlying predisposition.[21]

## Pre-eclampsia: postnatal investigation, monitoring, and treatment

The cure for pre-eclampsia is delivery, as it probably removes the source of abnormal inflammatory cytokines released by the placenta. However, it may take several days or even weeks for maternal physiology to return to normal parameters for the healthy postnatal population. The proportion of eclampsia in the United Kingdom is higher among women who have delivered, possibly due to the mistaken perception that they are no longer at risk. Similarly, a small but significant number of women die due to complications, which are a direct result of pre-eclampsia and associated hypertension, including stroke, liver failure, and hepatic rupture. With this in mind, when reviewing women with pre-eclampsia postnatally, all practitioners should continue to ask about symptoms, specifically headache and epigastric pain/discomfort.

All women who have had pre-eclampsia should be closely monitored in the days following delivery, while they are an inpatient, with blood pressure monitoring performed at least four times per day. Women who have not received antihypertensive medication to treat their pre-eclampsia can expect monitoring on at least one occasion between day 3 and day 5. If this latest reading is elevated, blood pressure should continue to be monitored on alternate days until normal. If this persists at 1 week, medical review is indicated.[43]

Occasionally, women who have not required treatment antenatally will have postnatal hypertension above 150/100 mmHg, in which case antihypertensive medication is indicated to avoid complications. Women who have delivered, but required antihypertensive medication, should have their blood pressure monitored four times daily while an inpatient, and then every other day for up to 2 weeks, until they are normotensive and have stopped medication. If neither of these has occurred, medical review is indicated.[30]

Women who have required antenatal treatment should remain on treatment until their blood pressure falls below 140/90 mmHg and begin to titrate down antihypertensive treatment if their blood pressure falls below 130/80 mmHg. Again, after delivery, women who have been taking methyldopa should be switched to an alternate antihypertensive medication as soon as possible after delivery to avoid an unnecessary increased risk of postnatal depression.

As a general rule, clinicians caring for women in the puerperium whose blood pressure is 140/90 on several occasions, should consider commencing, or increasing antihypertensive medication. If women have a blood pressure reading of 150/100 mmHg, commencing or increasing treatment is recommended. Readings of 160/100 mmHg or above should prompt immediate referral to an obstetric unit and/or senior review. HDU and/or invasive monitoring should be considered.[117]

Women who had pre-eclampsia but are no longer symptomatic, whose blood pressure is below 149/99 mmHg (treated or untreated) and whose blood results are improving, may be transferred from the inpatient to the community setting with an appropriate plan for care. This should include information to the women regarding symptoms to watch out for, a defined team who will review the women in the community, and a plan of who should provide medical review if required. Reviews at 2 and 6–8 weeks should also be organized at this point as medically indicated. All women should receive a medical review at 6–8 weeks; those still on medication should be seen 2 weeks postnatally. If they still require medication at 6–8 weeks, specialist referral is warranted to investigate further causes of hypertension.[11,119,120] Similarly, these women will need specialist advice regarding the increased risk of pre-eclampsia in future pregnancies.[30]

All women with moderate or severe pre-eclampsia, especially those being stepped down from critical care need a postnatal check of biochemical and haematological indices of disease at 48–72 hours. If these are normal, further tests are not necessary; however, if they are improving but remain abnormal, these will need repeating at the 6–8-week postnatal review, unless clinically indicated in the interim.

All women with pre-eclampsia should have their urine checked using a reagent strip for proteinuria at 6–8 weeks. If proteinuria persists, a further test should be undertaken 4 weeks later and specialist renal review requested if this remains positive.

## Counselling of long-term risks and lifelong maternal health

It is important that women who have suffered pre-eclampsia in this pregnancy are informed of future risks to their health, both in future pregnancy and in later life.[30]

Women who have suffered an episode of GH or pre-eclampsia have an increased risk of developing cardiovascular disease, compared to the general female population, in later life. Given that there are familial and therefore genetic tendencies towards developing high blood pressure in pregnancy, this may represent a pre-existing propensity to developing cardiovascular disease in later life, compared to the background population. There is some evidence to suggest that pre-eclampsia may actually cause underlying vascular damage on a cellular level in some women and thus, increase their risk of developing pre-eclampsia.[121]

Later life complications include:[21,121]

- hypertension
- ischaemic heart disease
- cerebrovascular accident
- venous thromboembolism
- end-stage renal disease (increased but low absolute risk in women with no proteinuria at 8 week postnatal review).[122]

Thrombophilia screening is not recommended in postnatal women by NICE solely on the basis of an episode of pre-eclampsia.[30] There is some suggestion that some thrombophilic conditions predispose women to pre-eclampsia (including hyperhomocysteinaemia, prothrombin heterozygosity, anticardiolipin antibody positivity, factor V Leiden heterozygosity, and methylene tetrahydrofolate reductase (MTHFR) homozygosity), while others do not (factor V Leiden homozygosity, antithrombin III deficiency, protein C deficiency, protein S deficiency, lupus anticoagulant positive, and acquired activated protein C resistance), though the evidence for this is of mixed quality.[30] If this has been associated with a history of recurrent miscarriage, prematurity, or small-for-gestational-age fetus, then thrombophilia screening may be warranted.

Antenatal and intrapartum venous thromboembolism prophylaxis should be risk assessed as normal, as per guidance from the Royal College of Obstetricians and Gynaecologists.[123]

## Future pregnancy

The risk of GH in a future pregnancy ranges from about 1 in 8 (13%) pregnancies to about 1 in 2 (53%) pregnancies, while the risk of pre-eclampsia in a future pregnancy rises to approximately 1 in 6 (16%) pregnancies.[124–127] If their recent episode of pre-eclampsia was severe, or complicated by HELLP syndrome, or led to a pre-term birth prior to 34 weeks, this risk rises to 1 in 4 (25%) of pre-eclampsia recurrence in a future pregnancy. If a pre-term birth occurred before 28 weeks, the risk rises to 55%.[128] There is no evidence to suggest that an interpregnancy interval of 10 years increases the risk of pre-eclampsia.

## Conclusion

The hypertensive disorders of pregnancy cover a wide range of conditions, most of which are relatively mild with a low risk of complications for mother and baby. However, they are still an important cause of maternal and fetal mortality. They can present in a number of ways and require multidisciplinary care to achieve an optimum outcome. The more serious complications of eclampsia, hepatic, renal, and haematological abnormalities will commonly involve the care of the anaesthetic and critical care team and will present challenges to the provision of anaesthesia. A full understanding of the nature of the condition, its various presentations, complications, and ability to affect all organ symptoms will be important for obstetric anaesthetists. Anaesthetic care focuses on providing effective analgesia, safe surgical anaesthesia, and individually tailored supportive critical care to parturients with hypertensive diseases of pregnancy in a context of potentially fatal cardiovascular, pulmonary, cerebral, and haematological pathology.

CHAPTER 37

# Thromboembolic disorders in pregnancy

Salma Ballal and Ian A. Greer

## Introduction

Thromboembolism in pregnancy remains a major cause of direct maternal mortality in the Western world. It was the leading cause of death in the United Kingdom from 1985 and after dropping to third place with sepsis taking pole position in 2006–2008, thromboembolism has once more re-emerged as the most common cause of direct maternal death in the United Kingdom and Ireland in the latest 2009–2012 national maternal mortality report by MBRRACE-UK[1] (Table 37.1).

Deaths previously from thromboembolism were associated with failures in (1) obtaining objective diagnoses and investigating chest symptoms in at-risk women (often because of unfounded concerns such as radiation exposure for the fetus), (2) lack of provision of adequate thromboprophylaxis, (3) inadequate risk assessment, and (4) failure to ensure multidisciplinary care.[1]

The physiological changes of pregnancy, considered to be hormonally driven, are associated with alterations in the coagulation and fibrinolytic systems. There is an increase in procoagulant factors, such as factors VII, VIII, X, and von Willebrand factor, and a substantial rise in fibrinogen. The endogenous anticoagulant activity and fibrinolysis are suppressed, such as through reduced protein S and increased placentally derived plasminogen activator 2 inhibitor respectively. These changes lead to a physiological hypercoagulable state in pregnancy, which physiologically may prepare the body for the haemostatic challenge of delivery, but will also increase the risk of thrombosis during pregnancy. It is important to emphasize that thrombosis is usually a 'multi-hit' disorder and a single risk factor such as the procoagulant effects of pregnancy is rarely sufficient to cause a clinical event, rather events are more likely when multiple risk factors are present at the same time.

Thromboembolic events in pregnancy are spread across the three trimesters with over 50% of events occurring in the first 20 weeks of pregnancy.[2] However, the puerperium is the time of greatest risk with a relative risk of around 20-fold compared to the non-pregnant population. This is likely to reflect trauma to the pelvic vessels in the course of delivery causing endothelial damage. When this is added to the hypercoagulable changes of pregnancy, and venous stasis, which is also a feature of normal pregnancy, the three components of Virchow's triad, which underlies venous thrombosis will coexist, so increasing the risk. Indeed, in relation to postpartum events, around 80% occur in the first 3 weeks after delivery.[3]

Importantly, when compared to the non-pregnant population where distal deep vein thrombosis (DVT) is most common, most events in pregnancy are iliofemoral and left sided. This is thought to occur due to the compression of the left iliac vein by the right iliac artery which leads to decreased blood flow on the left side.

The relative risk of antenatal venous thromboembolism (VTE) is about fivefold higher than in non-pregnant women of the same age and this is increased further postpartum, but the absolute risk is low, with an overall incidence of VTE in pregnancy and the puerperium of 1–2/1000.[4–6]

## Risk factors for thrombosis in pregnancy

Pregnancy is itself a risk factor for thrombosis but it is important, given the multi-hit nature of the problem, for clinicians to be aware of additional risk factors (Table 37.2) that will increase that risk further.[3,10,12] A clear example of this is the dramatic increase in risk when immobility is combined with a body mass index (BMI) of 25 kg/m$^2$ or higher (Figure 37.1). The two most significant single risk factors in pregnancy for thromboembolism are history of previous VTE and thrombophilia.

### Previous venous thromboembolism

In pregnant women with a history of VTE, the risk of recurrence is increased three- to fourfold (relative risk 3.5; 95% confidence interval (CI) 1.6–7.8).[7] Recurrent events account for 15–25% of all thromboembolic events in pregnancy.

A previous single VTE can be provoked (e.g. combined contraceptive pill, pregnancy, trauma, immobility, surgery, and thrombophilia) or unprovoked, where no additional risk factor is apparent. Some of these women will require antenatal prophylaxis but all should receive postpartum prophylaxis, as this is the period of greatest risk.[8,9] Women with a history of an unprovoked or idiopathic, known thrombophilia or oestrogen-related VTE should be treated as a high-risk group and thromboprophylaxis should be recommended antenatally and for 6 weeks postpartum. A history of a VTE provoked by a risk factor that is no longer present in a woman with no other risk factors requires close observation antenatally with thromboprophylaxis commenced after delivery and continued for 6 weeks postpartum.[9]

For women on pharmacological thromboprophylaxis in pregnancy, the rate of recurrence has been reported to range from 0% to 2.4%.[10,11] However, the rate of recurrent VTE in women who

did not receive prophylactic anticoagulation has been reported to range from 2.4% to 12.2%.[12,13]

## Thrombophilia

Thrombophilia is also an important risk factor[10] and can be divided into heritable and acquired. Heritable thrombophilia is a positive finding in 20–50% of women who experience VTE during pregnancy and the postpartum period.[14,15] Although thrombophilia is a risk factor for VTE, performing a thrombophilia screen before commencing anticoagulant therapy is not routinely recommended as it will not influence the immediate management of acute VTE. Furthermore, although the results of genetic texts for heritable thrombophilia will be unaltered, such as for factor V Leiden, other investigations such as protein S are markedly altered by pregnancy, or the presence of thrombus (e.g. antithrombin) making such investigations less reliable, often confusing rather than clarifying the situation.

Women with multiple previous VTE, or a previous VTE and a problem such as antiphospholipid syndrome, are considered to be at a high risk of recurrence and may require higher doses of low-molecular-weight heparin (LMWH) in pregnancy. They are likely to be on long-term anticoagulation with warfarin prior to conception. An intermediate or treatment dose of LMWH is required throughout pregnancy and should be continued postpartum for a minimum of 6 weeks or until converted back to long-term warfarin.[9]

# Diagnosis of thromboembolism in pregnancy

The clinical diagnosis of DVT and pulmonary thromboembolism (PTE) is unreliable in pregnancy. Indeed, following objective testing only a minority of those with clinically suspected VTE will have the diagnosis confirmed.[12,16] Nonetheless, given the

**Table 37.2** Risk factors and their odds ratios for risk of venous thromboembolism in pregnancy[3,10–12]

| Risk factor | Adjusted odds ratios | 95% CIs |
|---|---|---|
| Previous VTE | 24.8 | 17.1–36 |
| Immobility:<br>If combined with BMI ≥ 25 | 7.7<br>62 | 3.2–19 |
| BMI > 30 | 5.3 | 2.1–13.5 |

Data from various sources (see references).

life-threatening nature of this condition, anticoagulant therapy should be commenced if there is a delay in obtaining objective testing unless there are strong contraindications to its use. The condition should be suspected during pregnancy where symptoms and signs are consistent with a possible VTE, such as dyspnoea, chest pain, haemoptysis, unilateral leg pain and swelling (especially on the left side), lower abdominal pain, low-grade pyrexia (a feature of thrombosis), and collapse.

Clinical probability assessment in pregnancy still has a role in pregnancy despite differing from the non-pregnant assessment. The LEFt rule reported on 194 suspected DVT cases in pregnancy looked at symptoms in the left leg (L), calf circumference difference of at least 2 cm (E for (o)edema), and first-trimester presentation (Ft) are the components of the LEFt rule. It was found that 0/89 with no component had DVT compared with 7/105 with one or more components.[17] Righini et al. assessed 157 pregnant women with suspected DVT; the diagnosis was confirmed in 11.7% of women with one or more LEFt component versus 0% in women with no components. Therefore the LEFt rule may be useful in excluding the diagnosis but meanwhile objective testing remains important.[18]

# Diagnosis of deep venous thrombosis in pregnancy

## Compression ultrasonography

Compression ultrasonography (CUS) of the entire proximal venous system is considered the optimal first-line diagnostic test for DVT in pregnancy.[19,20] If the initial ultrasound shows an abnormality in the popliteal or femoral veins, the diagnosis of proximal DVT is confirmed and therapeutic anticoagulation should be employed. As the majority of gestational DVTs are iliofemoral these are usually easily visualized confirming the diagnosis. Where the initial CUS is negative and where the clinician has ongoing suspicion of DVT then repeat ultrasound examinations on days 3 and 7 should be considered. Treatment should be stopped pending the repeat test. An apparently normal ultrasound examination in a patient with significant symptoms and signs or risk factors for VTE does not completely exclude a calf DVT.[19] Results from the recently published EDVIGE study found that following a single CUS for suspected DVT in pregnancy only 10.5% had the diagnosis confirmed. Of 177 women who had a negative CUS and who did not receive anticoagulation, only 1.1% (95% CI 0.3–4.0%) had a VTE on 3 months of follow-up.[21] In women reporting swelling of the entire leg with or without back, buttock, or flank pain, an iliac vein thrombosis should be suspected. Serial CUS of the proximal venous system is not helpful in the diagnosis of iliac vein thrombosis and pulsed Doppler of the iliac vein, magnetic resonance imaging (MRI), venography, or conventional contrast venography should be considered.[19,20]

## D-Dimer

D-dimer, a specific fibrin degradation product, has been extensively used in the exclusion of DVT in the non-pregnant population, but its use in pregnancy requires further studies and evaluation. Some authorities employ D-dimer measurements in pregnancy following the initial negative ultrasound scan, and where there is an elevated D-dimer a repeat ultrasound is performed. However, D-dimer levels increase in normal pregnancy as gestation advances. D-dimer levels will be outside the normal range at term and postpartum in most normal pregnancies. D-dimer levels also increase with complications such as pre-eclampsia, and abruption, which are themselves associated with an increase in risk for VTE.[8,19,20] Further, false-negative D-dimer results have been reported with VTE in pregnancy.[22] In view of these issues and because D-dimer assays have not been evaluated in prospective management studies, it is the authors' practice to proceed direct to CUS in women with suspected DVT, and repeat this as required rather than rely on D-dimer measurements.

## Venography

Venography is the gold standard test for the diagnosis and exclusion of DVT outside of pregnancy.[23,24] In pregnancy, concerns about *in utero* fetal exposure to ionizing radiation and potential teratogenicity and oncogenicity during testing have limited the use of venography and the number of studies involved. When venography is used with abdominal shielding the risk from radiation to the fetus is very low, and the fear of fetal irradiation is often overstated[25] (Table 37.3). For the majority of cases CUS is sufficient, particularly as over 70% of DVTs are iliofemoral in pregnancy. If difficulty is encountered in imaging possible pelvic thrombus then MRI venography can be safely used in pregnancy.

## Computed tomography scan venography

Computed tomography venography may be useful in detecting pelvic vein thrombosis but it is associated with significant radiation exposure to the fetus, and in practice is rarely required to make a diagnosis.[26]

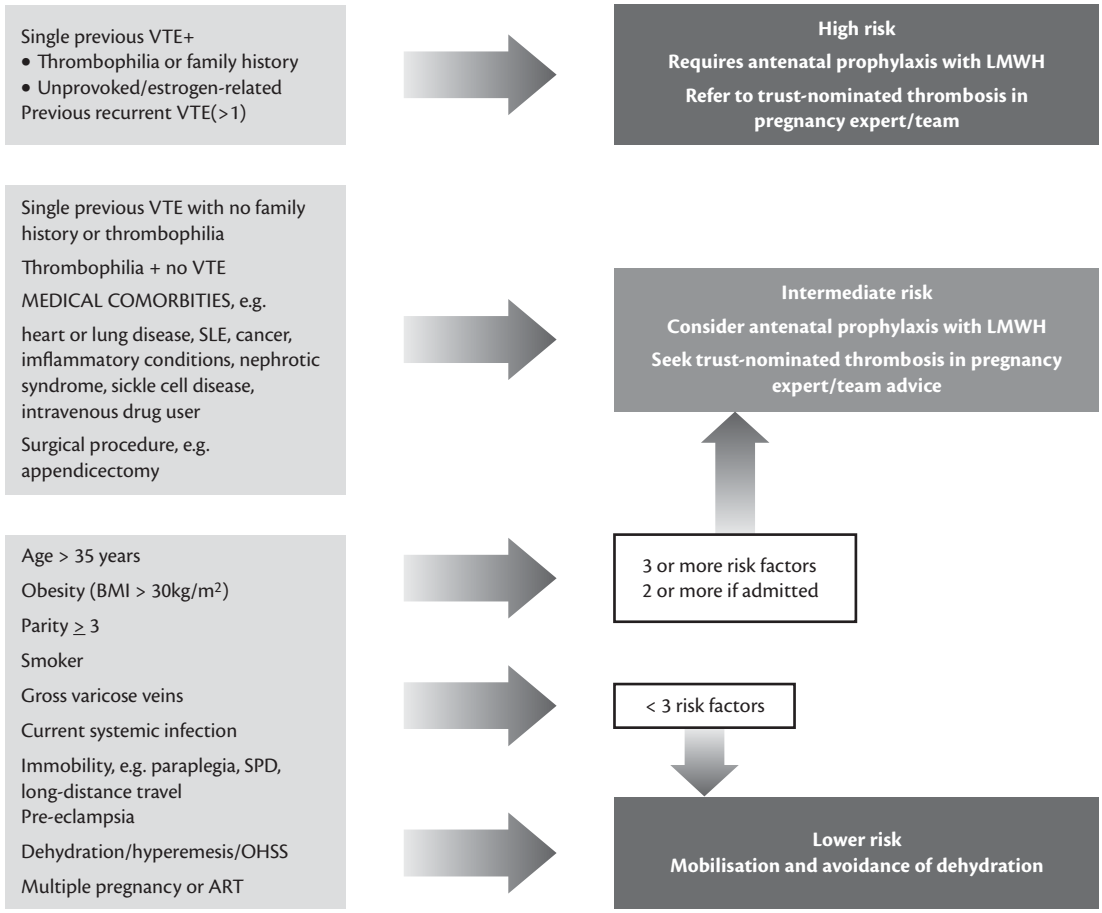

**Figure 37.1** Obstetric thromboprophylaxis risk assessment.

## Diagnosis of pulmonary thromboembolism

Firstly it is useful to note that the CUS is valuable in assessing women with suspected PTE in pregnancy, because the treatment of DVT and PTE is the same. Therefore specific chest imaging may be avoided with a positive diagnosis of DVT. However, it is also important to consider the role of specific thoracic imaging modalities and the electrocardiogram (ECG).

### Chest X-ray

In a pregnant woman with a suspected PTE who is haemodynamically stable, a chest X-ray (CXR) is valuable. It may identify other pulmonary disease such as pneumonia, lobar collapse, or pneumothorax. Pregnant women in general have low rates of pre-existing pulmonary disease and in over 50% of cases the CXR will be normal. Non-specific features of PTE on CXR include atelectasis, effusion, focal opacities, regional oligaemia, and pulmonary oedema. The radiation dose to the fetus from a CXR performed at any stage of pregnancy is negligible and a CXR should not be withheld from a pregnant woman with a potentially fatal condition.

### Electrocardiogram

The ECG is a non-specific investigation for the diagnosis of pulmonary embolus in pregnancy. In normal pregnancy the electrical axis of the heart changes, which can make the ECG lack specificity. The ECG may also be normal, however in massive pulmonary embolus features of acute right heart strain such as right bundle branch block, right axis deviation and peaked P-waves may be present. The classical $S_1$, $Q_3$, $T_3$ is infrequently seen. It is, however, valuable in relation to alternative cardiac diagnoses.

### Computed tomography pulmonary angiography and ventilation perfusion lung scan

The main techniques for objective diagnosis of PTE are ventilation/perfusion (V/Q) lung scan or computed tomography pulmonary angiography (CTPA). Local availability and guidelines may be the determining factor for which diagnostic technique is employed in pregnancy. In the non-pregnant population, the British Thoracic Society recommends CTPA as first-line investigation for non-massive PTE due to better sensitivity and specificity than V/Q lung scanning,[27] and also the possibility to identify other potential pathology contributing to the patients symptoms (e.g. aortic dissection). Furthermore, older non-pregnant patients with chest symptoms will often have co-morbid chest pathology so limiting the value of V/Q scans, but this is not usually the case in most young pregnant women.

When weighing up the risks and benefits of these techniques it is important to consider not only the diagnostic accuracy, but also the issue of radiation exposure in the context of diagnosis of PTE.

**Table 37.3** Estimated fetal radiation exposure with venous thromboembolism investigation

| Radiologic procedure | Radiation mGy |
|---|---|
| Bilateral venography without abdominal shield | 0.628 |
| Unilateral venography without abdominal shield | 0.314 |
| Limited venography | < 0.05 |
| Pulmonary angiography (femoral route) | 0.221–0.374 |
| Pulmonary angiography (brachial route) | < 0.05 |
| Ventilation lung scan: | |
| $^{133}$Xenon | 0.004–0.019 |
| $^{99m}$Tc-DTPA | 0.007–0.035 |
| $^{99m}$Tc-SC | 0.001–0.005 |
| Perfusion lung scan using $^{99m}$Tc-MAA: | |
| 3 mCi | 0.018 |
| 1–2 mCi | 0.006–0.012 |
| Chest radiograph | < 0.001 |

DTPA: diethylenetriamine penta-acidic acid, SC: sulphur colloid; Tc: technetium.

NB 1 Gy = 100 Rad. Threshold for fetal abnormality induced in *in utero* exposure is 100–200 mGy.

Concerns over radiation exposure for the fetus are often cited as reasons to avoid radiation-based investigation in pregnancy. However, the commonly employed investigations are not associated with high levels of fetal exposure (Table 37.3). In addition, it is important to take into account the clinical context—a potentially fatal disorder for the mother, and the fetus if the event is antenatal. CTPA is associated with less radiation exposure to the fetus than V/Q lung scanning in all trimesters of pregnancy. It has been estimated that the risk of fatal cancer to the age of 15 years is <1/1,000,000 after *in utero* exposure to CTPA and 1/280,000 following a perfusion scan.[19] Perhaps of more concern is that CTPA, while associated with a lower dose of radiation for the fetus than a V/Q scan, exposes the mother to a relatively high radiation dose of as much as 20 mGy to the thorax and in particular exposure of breast tissue is a concern, as calculations suggest a significant increase in lifetime risk of breast cancer.

Therefore, where available, V/Q scans are generally preferred in pregnancy because of the lower radiation dose to the mother, and the low incidence of co-morbid pulmonary problems that often reduce the value of such scans in the non-pregnant patient.[19] Further, during pregnancy, and especially if the CXR is normal, the ventilation component can often be omitted thereby minimizing the radiation dose for the fetus. Thus the authors generally prefer V/Q lung scanning over CTPA for the first-line investigation of PTE in pregnancy because of its high negative predictive value, low incidence of co-morbid pulmonary pathology, and lower radiation dose to the mother.

### Pulmonary angiography

Pulmonary angiography carries the highest radiation exposure (at least 0.5 mSv to fetus, and 5 –30 mSv to mother)[19] and should be used mainly in severe cases prior to embolectomy.

## Management of venous thromboembolism in pregnancy

### Initial assessment

In the initial assessment of the patient before commencing therapeutic anticoagulation for VTE, a full blood count, coagulation screen, urea, electrolytes, and liver function tests should be checked to exclude renal or hepatic dysfunction, which are relevant for anticoagulant therapy. As noted earlier, thrombophilia screening is not usually performed as many components of the thrombophilia screen are altered by both pregnancy (e.g. lower protein S) and the presence of thrombus (lower antithrombin), and because the results will not alter the acute management of VTE.

### Anticoagulants in pregnancy

#### Vitamin K antagonists

Warfarin is an oral anticoagulant that interferes with hepatic synthesis of vitamin K-dependent clotting factors, which leads to depletion of prothrombin, and factors VII, IX, and X with resultant anticoagulation. Warfarin crosses the placenta and is associated with an increased risk of fetal complications, specifically congenital malformations and an increased risk of pregnancy loss with first-trimester exposure. While congenital abnormalities are reported in up to 5%[8,28–32] of cases with first-trimester warfarin exposure, only a small number (<1%) develop the specific warfarin embryopathy (midfacial hypoplasia, limb hypoplasia, and stippled epiphyses).[33,34] There is some evidence to suggest that if the woman is taking a dose greater than 5 mg/day this is associated with a higher risk of congenital abnormalities.[32,35,36] In the third trimester, there is a significant risk of maternal and fetal bleeding if taken after 36 weeks, as the fetus is also anticoagulated. This is of particular concern at delivery. Warfarin can, however, be used in the postpartum period if required as there is no significant excretion in breast milk.

#### Low-molecular-weight heparin

Heparins remain the agents of choice for treatment and prophylaxis of VTE in pregnancy.[19,20] LMWHs have now largely replaced unfractionated heparin (UFH) for the immediate management of VTE in pregnancy. LMWH acts by inactivating thrombin and factor Xa without depleting circulating levels of clotting factors. It does not cross the placenta and is not present in breast milk in appreciable amounts, and in any event is orally inactive, so there is no risk of anticoagulation in the fetus or the newborn. There are now substantial data from randomized controlled trials in non-pregnant patients confirming that LMWH is more effective than vitamin K antagonists in preventing recurrent VTE and post-thrombotic syndrome without increasing the risk of serious bleeding events.[8,37] Furthermore, LMWH is more effective, has a lower risk of bleeding, and is associated with lower mortality than UFH in the initial treatment of DVT in non-pregnant patients.[8,19,38] Indeed, a meta-analysis of randomized controlled trials has shown equivalent efficacy of LMWH to UFH in the initial treatment of PTE.[8,38] While data on efficacy of LMWH in pregnancy are extrapolated from the non-pregnant, direct data on safety are available for pregnancy. A systematic review of LMWH in pregnancy has confirmed its safety and also describes efficacy consistent with the extrapolation from the non-pregnant in the management of acute VTE,[11] supported by further data from a large retrospective review of over 1000 pregnancies exposed to a

LMWH.[39] Heparin-induced thrombocytopenia (HIT) resulting in thrombosis, an immune-mediated reaction, is extremely rare with LMWHs and therefore in women only exposed to LMWH, platelet monitoring is unnecessary. Some patients may develop skin reaction similar to UFH with LMWH in the form of pruritic skin eruption or local irritation at the injection site. The incidence of this has been reported to range from 1.8% to 29%,[8] but in systematic reviews has been of the order of 2%.[11]

Compared with UFH, LMWH is associated with a substantially lower risk of HIT, haemorrhage, and osteoporosis.[11,14,40]

Although useful in monitoring UFH (see 'Unfractionated Heparin'), the activated partial thromboplastin time (aPTT) is not meaningfully changed in patients on LMWH and cannot be used to assess response to therapy. Monitoring anti-Xa levels for women on LMWH is no longer recommended[20] and is difficult to justify in pregnancy due to the satisfactory results with weight-based dosing and also because anti-Xa monitoring does not reliably predict either recurrent thrombosis or bleeding risk, at least in part because of variability in the assay.[8,20,41] There may be a case for monitoring levels at extremes of body weight (<50 kg and >90 kg), where compliance is in doubt, and in women with other complicating factors including renal disease, severe thrombophilia, and recurrent VTE (if LMWH therapy requires monitoring, the aim is to achieve peak anti-Xa activity, 3 hours post injection of 0.5–1.2 units/mL for women with VTE). Routine platelet count monitoring to identify HIT is not required in obstetric patients who have received only LMWH. However, if the obstetric patient is receiving LMWH after first receiving UFH, or if she has received UFH in the past, making HIT more likely, the platelet count should be monitored every other day from day 4 to day 14, or until LMWH is stopped, whichever occurs first.[42]

### Unfractionated heparin

UFH, as with LMWH, does not cross the placenta. It was used in the past for treatment and prophylaxis of VTE in pregnancy, but in contemporary practice it has been widely replaced by LMWH due to the evidence discussed earlier. Therefore, in current practice, UFH use has been limited to specific circumstances, such as women considered to be at high risk of haemorrhage who require thromboprophylaxis or treatment prior to delivery. Prophylactic UFH is administered subcutaneously in divided doses. If UFH is required in therapeutic doses it is administered either by an intravenous continuous infusion or subcutaneous injection twice a day. The aPTT is used to monitor UFH with the dose adjusted accordingly to maintain the aPTT in the therapeutic range. The effect of UFH can be limited by stopping the intravenous infusion and also by protamine sulphate, which cannot be so readily achieved with subcutaneous LMWH.

Any exposure to UFH is associated with an increased risk of HIT, which occurs in 3% of non-pregnant patients receiving UFH.[43] Long-term use of UFH has been associated with increased risk of osteoporosis and fractures.[44] Up to 30% reduction in bone density and approximately 2–3% vertebral fractures with long-term use has been reported.[45,46] Adverse skin reactions to UFH include bruising, urticarial rashes, vasculitis which can lead to skin necrosis, and well-circumscribed, erythematous lesions (because of a delayed type 4 hypersensitivity reaction).[8]

### Danaparoid

This heparinoid crosses the placenta in negligible quantities. Therefore there is no demonstrable fetal toxicity with maternal danaparoid use.[8] It has an anti-IIa and anti-Xa effects with a long anti-Xa half-life of about 24 hours. Danaparoid can be administered intravenously or subcutaneously. It is usually used in pregnant women who develop HIT or a skin reaction from heparin and require ongoing anticoagulant therapy. However, the quality of evidence available to support its safety is scarce and advice should be sought from experts in haemostasis and thrombosis.

### Fondaparinux

There are limited data on this anticoagulant as its use in pregnancy is relatively new. Fondaparinux is a pentasaccharide that acts, like heparins, by inhibiting factor Xa through enhancing the effect of antithrombin. In an *ex vivo* model, no placental passage of fondaparinux was demonstrated[47] but anti-Xa activity of about 10% of that in maternal plasma was found in the umbilical cord plasma in newborn infants of five mothers being treated with 2.5 mg during pregnancy.[48] It is recommended that the use of fondaparinux be restricted to those with severe adverse reactions to heparin such as HIT or who cannot receive danaparoid.[8]

### Oral anti-Xa and thrombin inhibitors

There are no significant data supporting the use of new oral direct thrombin inhibitors such as dabigatran, or the new anti-Xa inhibitors such as rivaroxaban, or apixaban in pregnancy. As they are orally active they are likely to cross the placenta with resultant fetal anticoagulation and risk of bleeding. These agents should be avoided in pregnancy at the present time[9] due to lack of safety data and also because a highly effective and safe alternative exists with LMWH although not as an oral preparation.

### Parenteral direct thrombin inhibitor

There are insufficient data to evaluate the safety of recombinant hirudin, and no published reports on the use of bivalirudin in pregnancy.[8]

### Thrombolysis during pregnancy

Thrombolysis reduces clot burden by breaking down fibrin. Thrombolytic agents include streptokinase, urokinase, recombinant tissue plasminogen activator, and anisoylated plasminogen streptokinase activator complex. These markedly enhance the conversion of plasminogen to plasmin, with resultant degradation of fibrin to fibrin degradation products. There is growing evidence on the use of thrombolytic agents in pregnancy.[8,49,50] Streptokinase, and probably other thrombolytic agents, do not cross the placenta.[51–54] No maternal deaths associated with thrombolytic therapy have been reported, and the maternal bleeding complication rate is approximately 6%, which is consistent with that in non-pregnant patients receiving thrombolytic therapy. Most bleeding events occur around catheter and puncture sites, and in pregnant women, from the genital tract. Currently, given the limited data on the safety and efficiency of thrombolysis in pregnancy, the use of these agents should be reserved for life-threatening maternal thromboembolism.[8]

## Treatment of acute venous thromboembolism

In pregnancy, it is recommended that the initial treatment of acute VTE is by a twice-daily dosage regimen of LMWH.[19] This is because of the recognized pregnancy-related alterations in the pharmacokinetics of LMWH, which is cleared by the kidney. However, there are growing data, mostly with tinzaparin, that once-daily dosing may be satisfactory (tinzaparin, 175 units/kg) and may be appropriate in the

initial acute treatment of VTE in pregnancy.[39,55] As there is greater experience with twice-daily dosing and the possibility of reduced anticoagulant activity towards the end of the 24-hour period due to increased renal clearance, the authors prefer a twice-daily dose in the initial treatment of acute VTE with enoxaparin (1 mg/kg twice daily) or dalteparin (100 units/kg twice daily) until the situation is stable, then converting if required to a once-daily regimen of (1.5 mg/kg enoxaparin or dalteparin 10,000–18,000 units once daily depending on body weight). There are other techniques that are also of value in the management of acute DVT in pregnancy. Leg elevation should be employed and graduated elastic compression stockings should be fitted to reduce oedema.

The prophylactic and treatment dose of LMWHs as recommended by the Royal College of Obstetrician and Gynaecologists is described in Table 37.4.

Treatment of DVT by thrombolysis can reduce post-thrombotic syndrome, but at the expense of increased bleeding.[37] In the non-pregnant patient, the current American College of Chest Physicians recommendation is to prefer anticoagulation over systemic thrombolysis, reserving consideration of the latter only to patients with all of the following criteria: iliofemoral DVT, symptoms for less than 14 days, good functional status, life expectancy of 1 year or longer, and low risk of bleeding.[37] Catheter-directed thrombolysis is considered the preferable approach. Because of the uncertainty regarding the balance of risks and concerns relating to major bleeding, in pregnancy anticoagulant therapy alone appears preferable to systemic thrombolysis unless there is massive occlusive iliofemoral DVT threatening leg viability through venous gangrene.

## Graduated elastic compression stockings

The woman should be encouraged to mobilize whilst wearing compression stockings, as in non-pregnant patients[37] this has been shown to reduce pain and swelling. Studies in non-pregnant patients have shown that early mobilization, with compression therapy, does not increase the likelihood of developing PTE.[56,57] This approach may also help prevent the development of post-thrombotic syndrome as there are some trial data from outside pregnancy to suggest that compression stockings started within 2 weeks of DVT and continued for 2 years reduce the likelihood of post-thrombotic syndrome by around 50% but does not impact on the frequency of recurrent VTE.[37] Although there are no data demonstrating an impact from compression stockings on clinical outcomes in gestational DVT, the effect of these stockings on the venous system in postpartum women has been studied, where they are associated with reduced diameter of the common femoral vein along with increased blood flow velocity.[58]

## Life-threatening pulmonary thromboembolism

A massive PTE is a serious, life-threatening obstetric and medical emergency that may be defined as a pulmonary embolus associated with haemodynamic compromise (systolic blood pressure <90 mmHg or a drop in systolic blood pressure of ≥40 mmHg from baseline for a period > 15 minutes), not otherwise explained by hypovolaemia, sepsis, or new arrhythmia. The collapsed, shocked pregnant woman requires rapid assessment by a multidisciplinary resuscitation team of experienced clinicians including senior obstetricians, anaesthetists, physicians, and radiologists. This situation needs a quick but thorough assessment and decision for treatment usually are made on an individual basis taking into account the available resources and expertise. The options include intravenous UFH, thrombolytic therapy, catheter-assisted thrombus removal, or surgical embolectomy. In the initial response, oxygen should be administered and circulatory support provided with intravenous fluids and inotropic agents as required. Intravenous UFH is the traditional method of heparin administration in acute VTE and remains the preferred treatment in massive PTE because of its rapid effect and extensive experience of its use in this situation. The aim is to prolong the a PTT by 1.5–2 times control. As anticoagulant therapy will not reduce the obstruction of the pulmonary circulation, there is a strong case for considering systemic thrombolytic therapy. An infusion of UFH can be given following thrombolytic therapy. If the patient is not suitable for thrombolysis or moribund, cardiothoracic surgeons should be consulted urgently with a view to emergency thoracotomy.

## Inferior vena cava filters

It is the authors' experience that inferior vena cava (IVC) filters are rarely necessary. In general, these should be restricted to women with proven VTE and who have continuing PTE despite

**Table 37.4** Prophylaxis and treatment dose of LMWHs in pregnancy

| Weight (kg) | Enoxaparin | Dalteparin | Tinzaparin |
|---|---|---|---|
| <50 | 20 mg daily | 2500 units daily | 3500 units daily |
| 50–90 | 40 mg daily | 5000 units daily | 4500 units daily |
| 91–130 | 60 mg daily[a] | 7500 units daily[a] | 7000 units daily[a] |
| 131–170 | 80 mg daily[a] | 10,000 units daily[a] | 9000 units daily[a] |
| >170 | 0.6 mg/kg/day[a] | 75 units/kg/day[a] | 75 units/kg/day[a] |
| High prophylactic (intermediate) dose for women weighing 50–90 kg | 40 mg 12-hourly | 5000 units 12-hourly | 4500 units 12-hourly |
| Treatment dose | 1 mg/kg/12 hourly antenatal; 1.5 mg/kg/daily postnatal | 100 units/kg/12-hourly or 200 units/kg/daily postnatal | 175 units/kg/daily (antenatal and postnatal) |

[a]May be given in two divided doses.

Data from the Royal College of Obstetrician and Gynaecologists.

adequate anticoagulation or where anticoagulation cannot be used. Temporary IVC filters can be considered in the perinatal period for large iliac DVT, but their value is uncertain. Each case requires individual assessment as there are hazards from filter placement including filter migration (occurring in >20%), filter fracture (around 5%), and IVC perforation (up to 5%), and lifelong anticoagulation may be required.

In the non-pregnant patient, filters reduce PTE, but increase DVT, and have no change in overall frequency of VTE.[8,19,37] It is important to note that temporary filters are sometimes not retrieved and so remain *in situ* in a proportion of patients.

Where a woman enters pregnancy with a filter *in situ*, her anticoagulation must be reviewed. Pregnancy substantially increases the risk of thrombosis, therefore in women with a filter in place who become pregnant, anticoagulation should be continued or restarted (with LMWH) as soon as pregnancy is diagnosed. Outside pregnancy, increasingly patients with filters in place do not remain on life-long anticoagulation, such as where the risk factor for thrombosis resolves. This is because of the risk of bleeding on long-term warfarin relative to the risk of thrombosis. With regard to anticoagulation of such women in pregnancy it is important to remember that LMWH does not carry the same risk of serious bleeding problems as long-term coumarin therapy. If she enters pregnancy on coumarin therapy then this should be switched to intermediate or treatment dose LMWH by 6 weeks' gestation to avoid the risk of warfarin embryopathy.

## Duration and intensity of maintenance treatment of venous thromboembolism

Women with antenatal VTE can be managed with subcutaneous LMWH for the remainder of the pregnancy. It is uncertain whether dose adjustment is required in pregnancy in relation to pregnancy-associated weight gain. It is the authors' practice to continue with the initial dose regimen throughout pregnancy for the majority of cases despite the pregnancy-associated weight gain (since LMWH does not cross the placenta and therefore the weight of the fetoplacental unit is not relevant).[8,19] It is not yet established whether the initial dose of LMWH can be reduced to an intermediate dose (75% of treatment dose) after an initial period of several weeks of therapeutic anticoagulation. However, this practice has been successfully employed outside pregnancy in patients with contraindications to coumarin therapy and in patients with underlying malignancy.[8] Although there have been no studies directly comparing these two types of dosing strategies in pregnant women, this type of modified dosing regimen may be useful in pregnant women at increased risk of bleeding or osteoporosis. For pregnant women with acute VTE, it is recommended that anticoagulants should be continued for at least 6 weeks postpartum and for a minimum total duration of therapy of 3 months.[8,19]

## Delivery in women on anticoagulant treatment for venous thromboembolism

For women on therapeutic anticoagulation, a planned delivery, either through induction of labour or elective caesarean delivery, may allow optimal timing of events and minimizes the risk of the woman from an unplanned delivery on full anticoagulation. Each case requires individual management depending on the thrombotic and bleeding risks.

The dose of LMWH should be reduced to a once-daily thromboprophylactic dose on the day prior to induction of labour or caesarean delivery. When a woman presents in labour on therapeutic LMWH, neuraxial anaesthetic techniques should usually be avoided for at least 24 hours after the last dose of LMWH due to the risk of neuraxial haematomas. In patients receiving prophylactic doses of LMWH, epidural anaesthetic techniques should usually be avoided for at least 12 hours after the last dose. A problem that frequently causes concern is where the thrombotic event occurs close to term with a consequently high risk of spontaneous labour. Consideration should be given to the use of UFH (since it can be relatively easily reversed using protamine sulphate and has a short duration of action) in this circumstance. If spontaneous labour occurs in women receiving therapeutic doses of subcutaneous UFH, assessment of the anticoagulant effect by the aPTT is required. Subcutaneous UFH should be discontinued 12 hours and intravenous UFH stopped 6 hours before induction of labour.

There is an increased risk of wound haematoma following caesarean delivery with both UFH and LMWH of around 2%.[9] For this reason, wound drains should be considered at caesarean delivery, and the skin incision should ideally be closed with staples or interrupted sutures to allow easy drainage of any haematoma.

A further thromboprophylactic dose of LMWH (enoxaparin 40 mg; dalteparin 5000 IU; tinzaparin 75 IU/kg) should be given by 3 hours postoperatively or more than 4 hours after a spinal anaesthetic or removal of the epidural catheter, if appropriate. The treatment dose should be recommenced around 12 hours after delivery.

## Postnatal anticoagulation

Heparin and warfarin are not excreted in breast milk and are satisfactory for use postpartum and when breastfeeding. In the authors' experience, most women prefer to use LMWH (which can be used with once-daily dosing postpartum) because they have become accustomed to its administration, and they appreciate the convenience of not having to attend clinics for monitoring of coumarin therapy when caring for a new baby. Before discontinuing treatment the ongoing risk of thrombosis should be assessed including a review of personal and family history of VTE. Thrombophilia screening should be discussed and arranged if required. Recently it has been reported that low-dose aspirin (LDA) can prevent recurrence of VTE in non-pregnant patients following completion of 6–18 months of anticoagulant therapy, with a low risk of bleeding.[58] These data do not suggest that LDA can replace therapeutic anticoagulation for VTE, but do suggest that where prolonged therapy is considered of benefit following completion of a full course of therapeutic anticoagulation, that LDA may be valuable. Nor do these data suggest that LDA can replace LMWH in pregnancy for women with a previous VTE. In view of the risk of VTE and its importance for maternal mortality and morbidity, LMWH, where there is now a substantial evidence base of efficacy and safety, remains the leading therapeutic option for secondary prevention of VTE in pregnancy.

## Conclusion

Although VTE remains a challenge in obstetric practice, an awareness of risk factors and use of thromboprophylaxis, along with objective diagnosis of possible events with prompt treatment, usually with LMWH, can reduce the burden of disease.

CHAPTER 38

# Amniotic fluid embolism (anaphylactoid syndrome of pregnancy)

John A. Anderson, Pierre-Antoine Laloë, and Derek J. Tuffnell

## Background

The definition of amniotic fluid embolism (AFE) has evolved since first being recognized as a cause of maternal death. Amniotic fluid and fetal debris in the maternal pulmonary circulation was initially described in 1926 by a Brazilian pathologist, RJ Meyer.[1] However, this Portuguese language publication received little attention. In 1941,[2] Steiner and Lushbaugh identified fetal squames and lanugo hair in the lungs of eight women who had collapsed and died shortly after giving birth. The term 'amniotic fluid embolism' was subsequently coined and born with it, the concept that women died from the physical emboli of fetoplacental material released into the maternal circulation by unspecified means. As a result, historical diagnosis has been pathological with the observation of fetal squames and hair in the maternal circulation postmortem. Attempts to histologically diagnose this condition in survivors have previously been attempted by aspirating maternal blood from pulmonary catheters in an effort to find histological evidence of fetal material, without much success.

More recently, the presence of amniotic fluid and fetoplacental material in the circulation of healthy pregnant women has been proven to occur regularly without resulting harm. Thus, the mere presence of amniotic fluid in the circulation as a cause of morbidity or mortality has been challenged. Focus has turned to an associated immunological cascade, which is now accepted to be the principal cause of the catastrophic pathophysiological sequelae and clinical features of AFE. Subsequently an alternative and more accurately descriptive name for AFE has been put forward by Clark et al.,[3] 'anaphylactoid syndrome of pregnancy'.

## Definition

The diagnosis of AFE is clinical and must be considered as part of the differential diagnosis and resuscitation of any acutely unwell or collapsed woman who is pregnant, peripartum, puerperal, or who has undergone any recent invasive uterine procedure. Symptoms or signs may be non-specific and include dyspnoea, reduced oxygen saturation, or coagulopathy. The UK Obstetric Surveillance System (UKOSS) uses defined criteria to determine if a patient had AFE (Box 38.1).[4]

Maternal collapse has many differential diagnoses (see later) and AFE should be considered. If, after investigation for other causes of sudden maternal collapse, no obvious cause is found, a diagnosis of AFE becomes likely. In the event of death, pathological findings of fetal material in the maternal circulation will confirm the diagnosis.

## Incidence

The incidence of AFE has not significantly changed over the last 5 years and is equal to approximately 2.0/100,000 in the United Kingdom.[4] Despite being very rare, there is some variation in the Western world with estimated incidences of 7.7/100,00 in the United States,[3] 3.3/100,000 in Australia,[5,6] and 6/100,000 in Canada[7], though it is worth noting that collection methodologies for these data vary between nations and uncertainties surrounding diagnosis complicate inclusion criteria. In the United Kingdom, mortality rates remain stable between triennia.[8]

## Mortality and morbidity

AFE is the seventh most common cause of all maternal deaths.[8] In the United Kingdom, it has accounted for over 90 deaths since 1985 and in the United States and Australia, it was responsible for between 7.5% and 27% of direct maternal deaths.[5,9] In the United Kingdom, it has fallen from the second to the fourth leading cause of direct death, accounting for 0.57 deaths per 100,000 maternities.[10]

In the developing world, maternal mortality rates are much higher overall, eclipsing the impact of this rare disease. However the importance of AFE in maternal mortality in the developed world demonstrates that improvements such as better antenatal and intrapartum care, which have improved maternal mortality rates in the 40 years until the 1990s, had little or no impact on AFE. Historically case mortality rates were reported as being in excess of 85%;[11] however, they are now within the range of 16.5–61% in the United Kingdom, Australia, and the United States [4,6,9] This is possibly as a result of advances in supportive critical care and clinical diagnosis of milder cases.[12] Perhaps more importantly, as underlined by Margarson, the high reported mortality

**Box 38.1** UKOSS case definition

**Summary**

- *Either*: a clinical diagnosis of AFE (acute hypotension or cardiac arrest, acute hypoxia, or coagulopathy in the absence of any other potential explanation for the symptoms and signs observed)
- *Or*: a pathological diagnosis (presence of fetal squames or hair in the lungs).

Adapted with permission from D. Tuffnell, M. Knight, F. Plaat., Amniotic fluid embolism – an update, *Anaesthesia*, volume 66, issue 1, pp. 3–6 Copyright © 2011 John Wiley & Sons.

of the 1979 review was from published cases, which should not be confused with the overall AFE mortality rate.[13] However, given the lack of change in the actual number of deaths, this improved survival may be due to a greater readiness to make a clinical diagnosis rather than a genuine reduction in case survival.

AFE carries significant risk for the fetus. Earlier evidence demonstrated that approximately half of the babies born to women who die of AFE will die, and up to 20% of babies born to women who survive AFE will die. Of the surviving infants, up to a third may suffer hypoxic ischaemic encephalopathy (HIE), a proportion of whom will go on to develop cerebral palsy.[14] The most recent information demonstrates that AFE carries with it a perinatal mortality rate of 135 per 1000 cases.[4]

## Pathophysiology

Historical theory underpinning AFE postulated multiple physical emboli of fetoplacental material leading directly to cardiorespiratory collapse (Figure 38.1). Multiple animal studies and biochemical research have failed to substantiate this theory, due to methodological considerations and conflicting results,[15] thus supporting the idea that the main mechanism of action in AFE is secondary to abnormal activation of multiple inflammatory markers and clotting cascades, unique to humans. Furthermore, the physical mechanisms have been hypothesized to include abnormal contractions, cervical tears, or the involvement of placental abruption. However, none have been proven. Indeed, the presence of amniotic fluid and fetal material in the uterine arteries of women undergoing routine obstetric procedures such as a caesarean delivery, who did not display signs of AFE, suggests further yet undiscovered mechanisms.

The observation of rapid circulatory collapse, fluid shift out of the intravascular space, and the invariable onset of consumptive coagulopathy and consequent cardiac and pulmonary complications are hallmarks of AFE. The underlying mechanism of this is thought to be an immune-mediated response to amniotic fluid or trophoblastic cellular components. A host of *in vitro* experiments have produced evidence of coagulant and humoral responses. Mediators such as prostaglandins, serotonin, proteolytic enzymes, leukotrienes, tryptase, and histamine have all been implicated.[12]

### Coagulation

Amniotic fluid has been shown to activate complement in certain situations and also causes cells exposed to it to externalize

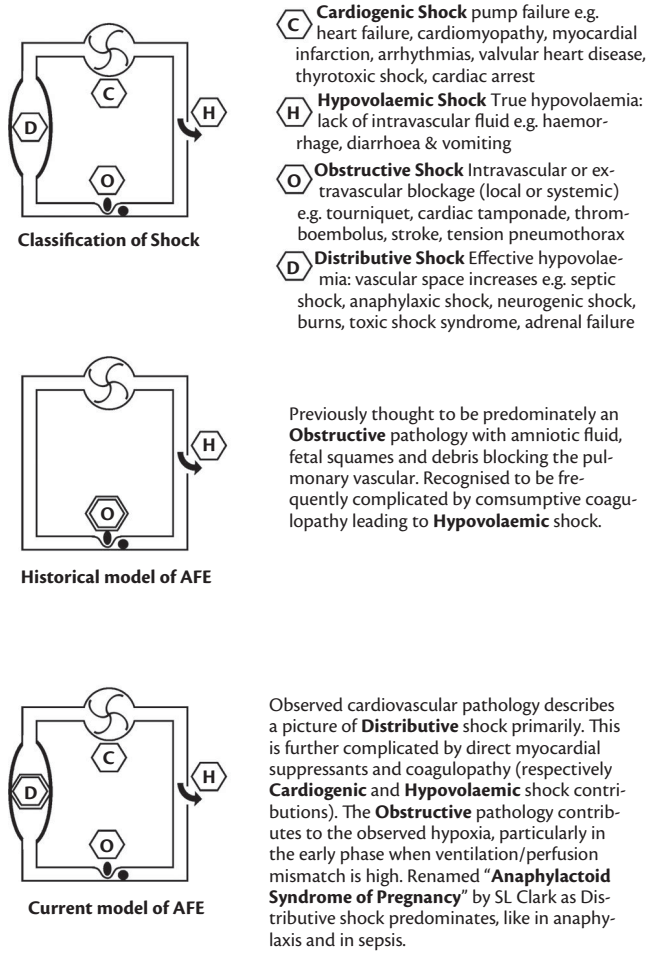

**Figure 38.1** Classification of shock with historical and current AFE models.

procoagulants such as phosphatidylserine and tissue factor. Fetal surfactant, present in amniotic fluid in increasing levels towards term, has a similar structure to thromboplastin and possesses some thromboplastic action. Cysteine protease, found in amniotic fluid and the amniochorion, can activate factor-X *in vitro*. Platelets will also irreversibly aggregate in amniotic fluid[16] and release platelet factor III. Amniotic fluid itself contains activated factors II, VII, and X. Stimuli to the clotting cascade at multiple points may well trigger the disseminated intravascular coagulation (DIC) and subsequent coagulopathy seen in AFE. Furthermore, amniotic fluid is known to contain high concentrations of anticoagulants such as thrombomodulin, annexin V, and tissue factor pathway inhibitor-2. Correlation between the ability of amniotic fluid to shorten plasma re-calcification time and amniotic fluid surfactant concentrations have been demonstrated.[16] It has also been observed that some patients entered into various AFE registers or case series did not have coagulopathy, while thought to have AFE. This may underline either the difficulty of final diagnosis, or variation in the disease, which would substantiate inconsistent findings in animal studies. One possible confounding explanation for this is that patients in whom coagulopathy was not observed tended to die, despite resuscitation measures, in the early phase of the disease. DIC may not have had time to develop. However, when caring for women who clinically are suspected to have suffered AFE, it must be assumed that a consumptive coagulopathy

is very likely to occur and can occur very early in the course of the disease.

### Humoral

Other biochemically active substances found in high levels in amniotic fluid include endothelin, a potent vasoconstrictor which will also reduce myocardial contractility, perhaps explaining the reduction in cardiac function seen in AFE cases and animal models. A variety of inflammatory markers such as cytokines, leukotrienes, and prostaglandins have also been implicated. Although performed in 30 pregnant goats, Hankins et al. conducted a carefully matched study with five study groups, including one group who had injectates of 5 μm filtered and boiled amniotic fluid.[17] The allantoic fluid group served as control group and showed that the volume of the injectate (2.5 mL/kg) was not a confounding factor, adding to the argument that humoral mediators are central to the pathology of AFE, much like in sepsis and other forms of distributive shock.

The presence of these substances in amniotic fluid and their production by the fetoplacental unit may be protective against episodes of fetomaternal haemorrhage and may play a crucial role in continuation of pregnancy. Animal studies include the observation that transgenic mice with low tissue factor concentrations have a 42% incidence of spontaneous mid-gestational miscarriage.

### Haemodynamic

Consequent to the humoral factors described in the previous section, the initial haemodynamic insult is probably due to pulmonary vasospasm, pulmonary hypertension, and right ventricular dysfunction resulting in profound hypoxia. In a reported case who underwent transoesophageal echocardiography in the hyper-acute setting (performed just after the return of spontaneous circulation near the end of an emergency caesarean section), acute right ventricular failure with prominent septal bulging from right to left was seen.[18] Physical embolization of the pulmonary microvasculature by fetoplacental material would have contributed to this clinical picture. This may be transient but may lead to a primary lung injury and acute respiratory distress syndrome (ARDS). Animal model work supports this as an early rise in pulmonary vascular resistance and extravascular lung water are seen in goats who had meconium-stained amniotic fluid injectates.[17] Early studies suggested that pulmonary hypertension was the prominent feature of the condition, thus requiring treatment with pulmonary vasodilators. Subsequent studies, which included invasive monitoring during the acute phases of the disease, demonstrated an initial period of pulmonary hypertension, which was less than previously thought and then left ventricular failure due to impaired left ventricular function. The initial right ventricular failure followed by left ventricular failure led Clark to suggest that AFE, pending survival of the initial phase, is a bi-phasic disease.[3] As the subsequent reduction in left-sided pre-load causes left ventricular failure and systemic hypotension, this aggravates the cardiogenic shock by reducing myocardial perfusion.[19] Figure 38.2 displays the biphasic response in terms of postulated contributions from the four causes of shock.

Reduced maternal cardiac output and hypoxia will lead to reduced oxygen availability to the fetus. Also, normal physiological uterine contractions will temporarily cut off uterine blood flow during labour. However, this is resumed during uterine relaxation. The concurrent release of catecholamines into the maternal circulation during the acute phase of AFE is thought to induce a tetanic pattern of contraction. Both of these factors may result in fetal distress.

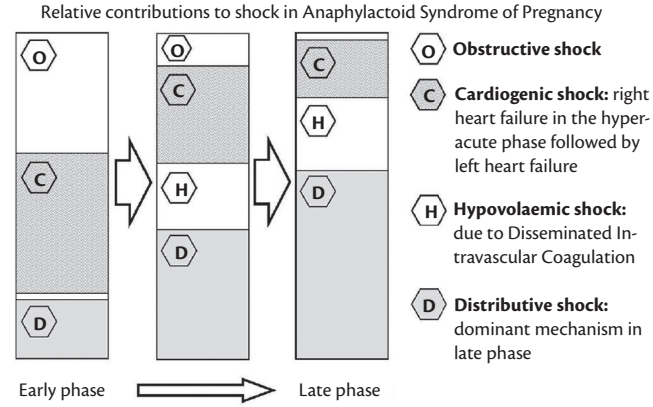

**Figure 38.2** Postulated contributions of types of shock seen in AFE with biphasic response.[3,17,19]
Data from various sources (see references).

## Sequelae

AFE carries serious consequences for both mother and fetus, including the following:

- Maternal: pulmonary oedema, ARDS, DIC, pulmonary embolus, haemorrhage, left cardiac failure, cardiac arrhythmias, cerebrovascular events, cardiorespiratory arrest, and death
- Fetal: fetal distress, HIE, learning difficulties, cerebral palsy, and intrauterine and neonatal death.

## Risk factors

The most recent, comprehensive review of cases within the United Kingdom was performed utilizing data collected by UKOSS, using the specific diagnostic criteria outlined previously. Box 38.2 lists the risk factors that were identified.

There was no association with other risks which were previously felt to predispose women to AFE.[3] These include ethnicity (however, black or ethnic minority women are more likely to die from AFE; this may reflect their overall poor outcomes in relation to all causes of maternal mortality), assisted vaginal delivery,

**Box 38.2** Risk factors for AFE

- Maternal age over 35 years old
- Induction of labour (relative risk (RR) 3.86, 95% confidence interval (CI) 2.06–7.31)
- Multiple pregnancy
- Caesarean delivery (RR 12.5, 95% CI 6.25–25.8).

Data from UK Obstetric Surveillance System.

placenta praevia, placental abruption, eclampsia, fetal distress, and hyperstimulation

Some observational studies have suggested that mothers carrying a male fetus are at higher risk of AFE. This could corroborate similar postulates that rhesus or ABO incompatibilities may be a factor in the development of AFE.[20]

One of the concerns about cell salvage in the obstetric setting has been the possibility that it could lead to AFE. That has not been the case either in the literature or clinical practice. Cell salvage should therefore not be seen as a risk factor for AFE (see Chapter 35).

## Presentation

Cases of AFE have been reported prior to labour, during and after normal labour, after instrumental delivery, and after caesarean delivery. Less commonly, AFE can occur during uterine evacuation and amniocentesis.

Maternal signs and symptoms may include dyspnoea, loss of consciousness, cough, wheeze, headache, chest pain, cyanosis, hypoxia, hypotension, cardiac arrhythmia, cardiopulmonary arrest, seizure and signs of heart failure, and/or pulmonary oedema (Box 38.3). Less specific symptoms may include premonitory feelings, restlessness, agitation, numbness, tingling and seizures. In many women, one of these presentations will quickly evolve into maternal collapse. As such, AFE should be at the forefront of any differential diagnosis when presented with this obstetric emergency. Fetal monitoring, if running, is likely to show fetal compromise.

## Immediate treatment

A working diagnosis of AFE should be considered in any women displaying any of the symptoms just described in the 'Presentation' section during labour and postpartum, or after any surgical evacuation of the uterus which cannot be explained by an alternative diagnosis. Clark and others have best summarized this as an ABCD approach to the collapsed pregnant with Airway, Breathing, Circulation, and Delivery being the key elements.[15,21] The patient must be wedged as a priority if still pregnant as aortocaval compression will worsen the cardiovascular collapse.

**Box 38.3** Consider AFE in the presence of:

- Acute fetal compromise
- Cardiac arrest
- Cardiac dysrhythmias
- Coagulopathy
- Hypotension
- Maternal haemorrhage (with evidence of early coagulopathy or cardiorespiratory compromise)
- Premonitory symptoms, e.g. restlessness, numbness, agitation, and tingling
- Seizure
- Shortness of breath.

### Call for help

Any maternal collapse requires the immediate expertise of senior obstetricians, midwives, anaesthetists at the bedside, and the support of critical care and haematology departments. Get help immediately.

### Ensure airway patency

In the event of collapse, gravid women's airways are at particular risk of airway compromise and of subsequent complications such as Mendelson's syndrome owing to delayed gastric emptying. Concerns regarding the airway changes of pregnancy are reviewed in Chapter 26. Cardiopulmonary resuscitation (CPR), should it be warranted, raises intra-abdominal pressure thus increasing the risk. Practitioners must maintain airway patency. Consider immediate intubation especially if the patient is still pregnant, requires CPR, or is at risk of cardiorespiratory collapse (e.g. profound hypoxia).

### Maintain oxygenation

In spontaneously breathing patients, apply high-flow oxygen (>12 L/min) via a non-rebreathing mask with a reservoir bag. As the gravid uterus displaces abdominal viscera, pulmonary functional reserve capacity typically decreases by 20% in pregnancy.[22] A progesterone-mediated physiological rise in respiratory rate throughout pregnancy, means that patients already have an increased minute alveolar volume despite typical 4 cm diaphragmatic displacement.[23] In the presence of respiratory distress, pregnant patients therefore have reduced compensatory mechanisms. The management of hypoxia must therefore be acutely and aggressively managed in proportion with the clinical picture. Symptoms (dyspnoea, collapse), signs (tachypnoea, cyanosis), and monitoring (pulse oximetry, arterial blood gas) should guide care. Invasive positive pressure ventilation via a cuffed endotracheal tube is required in cases of severe respiratory distress, or imminent or actual cardiorespiratory arrest. Consider the use of positive end-expiratory pressure, particularly in the presence of cardiogenic and non-cardiogenic pulmonary oedema.

### Cardiovascular support

Women with AFE are prone to sudden circulatory collapse secondary to acute right heart failure, left heart failure, cardiac arrhythmias, pulmonary embolism, and sudden fluid shifts associated with massive haemorrhage and/or disseminated intravascular coagulation. CPR must be started immediately in case of cardiac arrest.

Despite there being no robust evidence of benefit to the arrested mother, delivery should be expedited as a necessary adjunct to maximize the effectiveness of CPR. An accepted threshold within UK practice is that if CPR is proving unsuccessful after 3 minutes, action to deliver the fetus should be taken.[21] Perimortem caesarean delivery of a viable fetus is a time-critical intervention with reported fetal outcomes varying from 67% intact survival to 0% survival if the fetus is delivered respectively within 5, or beyond 35, minutes of maternal arrest.[3] However, this kind of intervention should be performed to aide maternal treatment, regardless of fetal condition, including fetuses which have already died *in utero*.

Continuous monitoring and aggressive management form the basis of personalized cardiovascular support of patients with AFE.

If still pre-delivery, a left lateral tilt remains indicated. Monitoring should include a continuous electrocardiogram (ECG) and invasive blood pressure in a suitable critical care environment, with urgent bloods taken for full blood count, coagulation, urea and electrolytes, and crossmatching. Cardiac output monitors and transoesophageal echocardiography may provide valuable information in the management of AFE-induced shock. Supportive care should be individualized and may include two large-bore intravenous cannulae, replacing intravascular fluid loss with crystalloid, colloid and blood products. Identified arrhythmias should be treated, with particular consideration of the possibility of abnormal electrolytes. Vasopressor, chronotropic, and/or inotropic support will be guided by cardiac output monitoring. The use of cardiopulmonary bypass, extracorporeal membrane oxygenation, and intra-aortic balloon pump devices have all been reported in the management of AFE-induced cardiovascular collapse.[24]

### Delivery of the fetus

If CPR is being performed, its success will be impaired by the gravid uterus making chest compression difficult and reducing cardiac venous return despite left lateral tilt. There is good evidence that pregnant women are more vulnerable to hypoxic brain injury in the event of circulatory collapse.[21] High-quality CPR is therefore paramount in preventing such injures should the women survive. To this end, if CPR has not been successful after 3 minutes, plans for immediate delivery should be made, with the aim of delivering by 5 minutes. CPR should not be interrupted wherever possible.

The fetus is also at risk, but this is of secondary concern to maternal well-being. The fetus is at risk of significant mortality or morbidity. The known UK case series cohort is small but suggests that survival is 50/50 if born to a dead mother, rising to over 70% if born to a live women.[15]

If instrumental delivery is not possible, an emergency caesarean delivery should be performed. Considerations of sterility and precise anatomical dissection are secondary, to expediting delivery, and an obstetrician will only need a scalpel. A modified Joel–Cohen or similar technique could be used, or whatever the clinician feels most comfortable with. To this end, a disposable scalpel should be on the resuscitation trolley in every clinical area that pregnant women can present.

Delivery of the fetus, though necessary, is likely to compound the problems presented by DIC. Haemorrhage is likely to ensue. The full armamentarium of postpartum haemorrhage treatments should be employed (see Chapter 35).

A significant proportion of women will need a hysterectomy (20%) and early recourse to hysterectomy is reasonable. The other systemic effects of AFE mean that early cessation of any haemorrhage is a priority to optimize maternal outcome.

## Intermediate treatment

### Correct hypoperfusion

Consider cardiac output monitoring, especially in the presence of pulmonary oedema, haemodynamic instability, or end-organ hypoperfusion. Liaise with obstetricians, intensivists, other anaesthetists, and cardiologists for ongoing support. These professionals are vital in planning continuing care should the woman survive the initial insult.

### Correct coagulopathy

Early transfusion of blood and blood products is often required in managing AFE. Liaise early with senior haematologists to prepare for and treat DIC with fresh frozen plasma, cryoprecipitate, platelets, and red blood cells. The aim of management should be to re-establish and maintain normal coagulation profiles. Point-of-care testing such as thromboelastography will help individualize care (see Chapter 48).

In the UKOSS survey of AFE, seven women with confirmed AFE were successfully treated with plasma exchange transfusion. It is believed that removal of cytokines, cellular debris, and coagulation by-products may moderate and shorten the impact of the humoral response. Any acidosis, hypocalcaemia, and hypothermia should also be corrected. Due to the small numbers of women involved we do not have definitive evidence of additional survival or reduced morbidity.

### Uterine tone

In instances of concurrent postpartum haemorrhage, whether this is in the presence of DIC or not, consideration must be given to the use of uterotonic agents in order to limit blood loss and maintain a circulating volume. Surgical options, including emergency hysterectomies, have been used when required.

### Further investigation

Obtain a chest X-ray. In many cases of AFE, the appearances of the chest X-ray of women show a shadowing consistent with ARDS, however this seems to improve within a short space of time.[14]

### Retrospective diagnosis

Classically, AFE was diagnosed by the presence of fetal squames found in maternal circulation postmortem; however, with AFE survival rates increasing, diagnosis is increasingly clinical. A maternal collapse can be caused by a number of differential diagnoses (see Box 38.4).[24–26]

In the immediate milieu surrounding the management of a maternal collapse due to any of the situations in Box 38.4, treatment will overlap regardless of diagnosis, and uncertainty should not delay treatment. After immediate resuscitation, diagnosis regains importance, some causes may require reversal through particular treatment. Diagnosis of AFE is principally one of exclusion. Thus an ECG should be performed (if not already done), and a repeat arterial blood gas, full blood count, and clotting profile are required along with liver function tests and serum electrolytes. An echocardiogram should be considered to exclude myocardial problems. Similarly a ventilation perfusion scan or computed tomography pulmonary angiogram will diagnose or exclude abnormalities such as a pulmonary embolism.

Zinc coproporphyrin and tryptase levels are not used in the diagnoses of AFE as conflicting results in their use to aid diagnosis have been published.

## Ongoing management

If not already involved, senior intensive care input is invaluable. After an episode of maternal collapse and successful resuscitation, transfer to intensive care is inevitable and the only treatment available for AFE is supportive. Failure to provide such care reduces survival. In such an environment women can be closely

monitored, using invasive techniques if necessary, and receive one-to-one nursing care, with the option of treatments for complications such as diuretics, inotropes, and steroids. The timing of movement to an intensive care unit should be discussed with the specialists involved and is likely to follow initial resuscitation. Some units may have the facilities and expertise to provide level one intensive care on the labour ward, but outreach support from intensivists is paramount.

Following initial fluid resuscitation inotropic support should be considered in the event of declining cardiac function.[10] Pulmonary artery monitoring will sometimes be necessary. Once the blood pressure has improved, fluid restriction may act to prevent iatrogenic overload. On the basis that AFE resembles an anaphylactoid process, use of adrenaline and hydrocortisone has been suggested. There is no supportive literature on this point.

## Documentation

Good documentation should be clear, concise, and contemporaneous where possible. High-dependency maternity charts improve care by prompting carers for important observations on a regular basis and collating results allowing trends and changes to be identified. Contemporaneous reporting of AFE and maternal collapse is also important, not only for the internal hospital risk reporting but for national data collection. Critical information will include possible precipitant factors, complications, resuscitation timing, and neonatal outcomes.

Nationally, if AFE is suspected or maternal collapse occurs, the case should be reported to UKOSS. This can be done online at http://www.npeu.ox.ac.uk/ukoss. If the woman does not survive, her death should be reported to the confidential enquiry (MBRRACE) which can be found at http://www.npeu.ox.ac.uk/mbrrace-uk.

## Conclusion

Despite being first recognized nearly 90 years ago, AFE remains an acute obstetric emergency which carries a high morbidity and mortality. The mainstay of treatment continues to be supportive care of all affected organ systems. The use of prompt supportive treatment, invasive monitoring, and individually tailored care of respiratory, cardiovascular, and haematological complications maximizes each woman's chance of survival and provides an increasing knowledge base about AFE. Multiprofessional expertise must be sought immediately when managing acutely unwell pregnant patients. Owing to thankfully low disease incidence, ongoing surveillance and reporting of all AFE cases to national registrars, such as UKOSS in the United Kingdom, remains a research priority for the benefit of families worldwide.

PART 9

# Systemic disease in pregnancy

# CHAPTER 39

# The obese parturient

Fiona C. Denison and Alistair Milne

## The global phenomenon of obesity

Obesity is defined by the World Health Organization (WHO) as a body mass index (BMI) greater than 30 kg/m$^2$ (Table 39.1).[1] Although obesity has been prevalent throughout human history, the rising prevalence of obesity in developed and more recently in developing countries[2] is a relatively recent phenomenon. The exponential rise in obesity across the world ('globesity') has prompted the WHO to describe it as one of the most important global health problems today, estimating that by 2020, two-thirds of the global burden of disease will be due to non-communicable diseases associated with diet.[1,3]

The aetiology of obesity is complex and multifactorial with increasing urbanization,[4] social deprivation,[5,6] greater use of sugar-sweetened drinks and edible oils, a reduction in physical activity, increase in sedentary lifestyle, and developmental exposure to endocrine disruptors[7] being some of the factors implicated in causing the current global epidemic.

Amongst developed countries, recent estimates for the prevalence of obesity amongst adults are 26% in England,[8] 24% in Canada,[9] and 36% in the United States.[10] In developing countries, the prevalence of obesity is also rising with more women than men being obese.[2,11] In 2008, overweight and obesity were estimated to affect 1.6 billion adults worldwide. Although more recent data suggest a slowing or levelling out of obesity prevalence in some countries (including the United States),[10] the prevalence continues to rise rapidly in other countries. By 2030, it is therefore estimated that 1.12 billion adults will be obese and a further 2.16 billion will be overweight.

The incidence of maternal obesity lags behind that of the general population, primarily due to the relationship between obesity and impaired fertility and age at peak prevalence of obesity. Despite this, maternal obesity is now the commonest pre-existing morbidity in pregnant women in the United Kingdom with an estimated one in five pregnant women being obese.[12,13] In the United States, given that one in three women are obese,[10] the prevalence of obesity in pregnancy is even higher.

Obesity is associated with increased risk of maternal and offspring morbidity and mortality antenatally, intrapartum, and postnatally (Table 39.2).[14–17,156–162] Although it has been suggested that limiting maternal weight gain during pregnancy may reduce the excess maternal and offspring risk associated with maternal obesity (Table 39.3),[18] this is debated and there is currently insufficient evidence to recommend any particular intervention or weight gain targets.[19]

Women with pre-gravid obesity also have higher rates of coronary artery disease, non-alcoholic fatty liver, diabetes mellitus, hypertension, gallbladder disease, and depression. The offspring of obese mothers are at greater risk of long-term health problems including early-onset obesity and hypertension.[20]

From a practical perspective, maternal obesity poses significant technical challenges including availability of appropriate equipment and practical issues such as moving and handling. All anaesthetists and obstetricians, from those with a special interest in high-risk obstetric anaesthesia and obstetrics, to those covering the delivery suite out of hours, will therefore inevitably encounter maternal obesity.[21] It is therefore essential that all clinicians have the knowledge and expertise to manage the anaesthetic implications of maternal obesity and its obstetric complications during pregnancy and labour.

## Physiological changes of obesity

### The respiratory system

Obesity has several significant effects on lung function. The most marked of these is the change in functional residual capacity (FRC) which decreases in an exponential manner with increasing BMI.[22] This is due to a mass effect of adipose tissue on the chest wall, abdomen, around the viscera, and diaphragm. In the obese, this decreased FRC encroaches on the closing volume which leads to the closure of small airways during normal breathing and is associated with ventilation/perfusion mismatch, leading to reduced oxygen saturation.[23] Figure 39.1 shows the effect of obesity on lung volumes. The decrease in FRC also means that obese patients are breathing in the less compliant part of the pressure volume curve. Increased effort is required to overcome the respiratory system elasticity at these reduced lung volumes.[24] Residual volume usually shows little change, therefore expiratory reserve volume is significantly decreased. Total lung capacity shows a small decrease with increasing BMI.[25]

Compliance of the respiratory system also decreases, partly due to a decrease in chest wall compliance. This is again due to adipose tissue loading on the chest wall, abdomen, and diaphragm.[26] A decrease in lung compliance may also be the result of an increased pulmonary blood volume,[25] along with the reduction in FRC.

Forced expiratory volume in 1 second ($FEV_1$) is often reduced in morbid obesity, but the $FEV_1$/forced vital capacity ratio is often normal, thereby showing a mild restrictive defect.[26] However Lazarus et al. found an obstructive pattern that worsened with increasing BMI.[27] These factors result in an increased work of breathing in a population who have ventilation/perfusion mismatch causing reduced oxygen saturations. The obese patient is also well recognized to have increased oxygen consumption.[28]

**Table 39.1** Classification of body mass index according to World Health Organization criteria

| Classification | Body mass index (kg/m²) |
|---|---|
| Underweight | <18.5 |
| Normal weight | 18.6–24.9 |
| Overweight | 25.0–29.9 |
| Obesity I | 30.0–34.9 |
| Obesity II | 35.0–39.9 |
| Obesity III | ≥40.0 |

Reprinted from *Obesity: Preventing and managing the global epidemic*. Report of a WHO Consultation (WHO Technical Report Series 894), WHO, p. i–xii, Copyright (2000).

Obesity can lead to obesity hypoventilation syndrome and is also associated with sleep apnoea. These two conditions share many physiological and pathological features. Abnormal ventilatory drive, hypoventilation, and hypoxia lead to pulmonary vasoconstriction, which can in turn result in pulmonary hypertension.[26] This can exacerbate the cardiovascular pathology of obesity discussed in the following section.

## The cardiovascular system

Obese patients have an increased blood volume and cardiac output in response to the increased metabolic requirements of excess fat. Cardiac output increases by 50 mL/min for every extra 100 g of fat.[29] This can lead to left ventricular dilatation, hypertrophy, and diastolic dysfunction. Systolic dysfunction may also occur due to fat deposition in the myocardial fibres. Left ventricular afterload is also raised due to increased peripheral resistance.[30] Pulmonary hypertension related to obesity hypoventilation syndrome can lead to the right ventricle being affected in a similar way. The above changes can lead to heart failure, and are collectively the changes of obesity cardiomyopathy.[31,32] Obese subjects have double the risk of heart failure of those with a normal BMI.[33] The increase in cardiac workload that leads to obesity cardiomyopathy is exacerbated by the increase in plasma volume and cardiac output that occurs in pregnancy, further reducing cardiovascular reserve.

Obesity is also a risk factor for hypertension[34] and coronary heart disease.[35] A significant number of asymptomatic obese patients have ischaemic changes on their electrocardiogram. Echocardiography may be used as an assessment of myocardial function in these patients,[36,37] but quality of scans is often poor due to the increased layers of adipose on the chest wall. Gestational hypertension and pre-eclampsia are also more common in the obese.[38]

Obese women are more susceptible to supine hypotensive syndrome in late pregnancy and require to be carefully positioned. Tsueda et al.[39] described obesity supine death syndrome in the super morbidly obese non-pregnant patient, where death on lying supine probably occurs due to a combination of aortocaval compression causing a sudden reduction in venous return, coupled with hypoxaemia, resulting in cardiac arrest.

**Table 39.2** Risks of obesity in pregnancy

| Problem | Level of increased risk |
|---|---|
| Miscarriage[156,157] | 1–3-fold |
| Fetal abnormality (spina bifida, heart defect, omphalocele)[158] | 2–4-fold |
| Iatrogenic preterm birth[159,160] | 1.5–2-fold |
| Gestational diabetes[14,16] | 4-fold |
| Venous thromboembolism[161] | 3–4-fold |
| Pre-eclampsia[57] | 2-fold |
| Induction of labour[14,16] | 2-fold |
| Caesarean section1[4,16] | 2-fold |
| Postpartum haemorrhage[16] | 1–2-fold |
| Infection (wound, urinary tract, genital tract)[16] | 2-fold |
| Stillbirth[162] | 1–5-fold |
| Maternal death[107] | Increased |

Data from various sources (see references).

**Table 39.3** Institute of Medicine recommendations for weight gain during pregnancy, by pre-pregnancy BMI

| Pre-pregnancy BMI | BMI (kg/m²) | Total weight gain range (lbs)/(kg)[a] |
|---|---|---|
| Underweight | <18.5 | 28–40/12.5–18 |
| Normal weight | 18.6–24.9 | 25–35/11.5–16 |
| Overweight | 25.0–29.9 | 15–25/7–11.5 |
| Obese (includes all classes) | ≥30.0 | 11–20/5–9 |

## The gastrointestinal system

Obese patients have an increase in residual gastric contents[40] and hiatus hernia is common. Coupled with the hormonal changes of pregnancy that lead to an increased risk of gastro-oesophageal reflux, it is probable that the obese are at higher risk of pulmonary aspiration of gastric contents.

## The endocrine system

An increased BMI is the strongest risk factor for developing type 2 diabetes mellitus,[41] and gestational diabetes mellitus (GDM) is more common in the obese.[42]

# Pharmacology

## Pharmacokinetics

Despite the current prevalence and increasing rate of obesity, pharmacokinetic data in obesity is available for a very limited number of drugs.

The obese do not simply have an increased amount of fat. They also have an increase in lean body weight which can be as much as 40% of their excess weight.[43] This means that drug doses based on

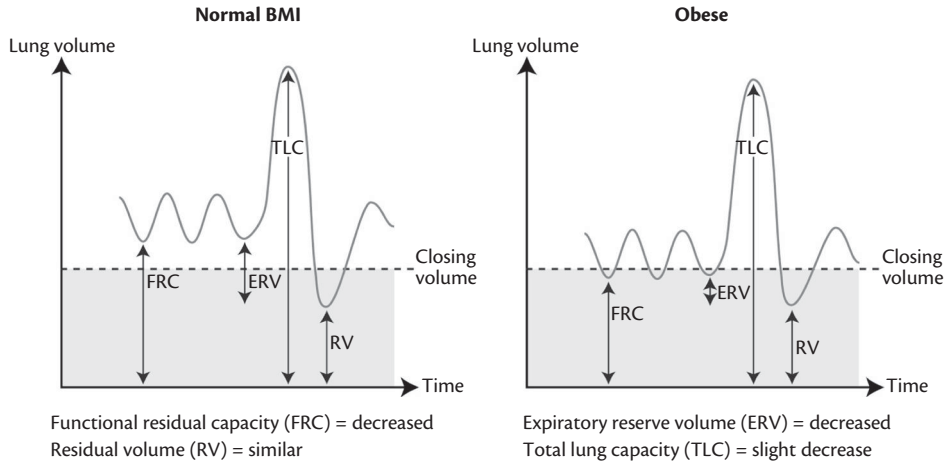

**Figure 39.1** The effect of obesity on lung volumes. A decreased functional residual capacity (FRC) encroaching on closing volume is largely at the expense of a decreased expiratory reserve volume (ERV).

their ideal body weight may result in under-dosing. Calculation of lean body weight is not routine in clinical practice, although equations exist to allow its estimation.[44] Due to its relationship with cardiac output, lean body weight is important in the early distribution kinetics of drugs.[45] Therefore a morbidly obese patient with an increased lean body weight and cardiac output will require an increase in initial dosing of some drugs.

The volume of distribution (Vd) is a determinant of drug loading-dose selection.[46] The Vd of a drug can be significantly altered in obesity, dependent on its hydrophilic or lipophilic nature. Hydrophilic drugs do not widely distribute into fat, and their Vd is therefore more dependent on ideal body weight. Total body weight has much more of an influence on lipophilic drugs that distribute extensively into fat.[47] This, however, is a generalization that does not hold true for all drugs, nor even all drugs of a similar group. Information should always be sought for a specific drug, if it is available. Wurtz et al.[48] discuss calculating ideal body weight and then using a 'dosing weight correction factor'—a fraction of the difference between actual and ideal body weights—to achieve a weight on which to base antimicrobial dosing. This correction factor differs dependent on the lipophilic or hydrophilic nature of the antibiotic in question. With no correction factor employed in the morbidly and super morbidly obese, therapeutic tissue levels of antibiotics are often not achieved.[49]

Plasma protein binding is another determinant of Vd. Drug binding to albumin does not appear to be affected by obesity. However, data as to whether drug binding to $\alpha_1$-acid glycoprotein is affected has been contradictory.[46]

Selection of a maintenance dose regimen is primarily determined by drug clearance. Varying hepatic and renal changes have been postulated to result in changes to drug clearance in the obese. Some have shown changes in clearance suggesting an increase in cytochrome P450 activity, others an increase in phase II conjugation pathways such as glucuronidation and sulphation.[46] Glomerular filtration has been shown to increase in some studies, yet decrease in others.[50] Again, data on the effects of obesity on drug clearance is very limited, although clearance does increase proportionately with increasing lean body weight.[51] Changes in clearance may be the result of obesity itself, or a result of disease processes associated with obesity.

### Pharmacodynamics

Morbid obesity can alter the pharmacodynamic profile of some drugs. For example, the morbidly obese patient with sleep apnoea can be very sensitive to the side effects of opiates, resulting in increased episodes of hypoxia. This effectively narrows the therapeutic window of the drug.

Further information on specific drugs can be found in the general anaesthesia section of this chapter.

## Obesity and pregnancy

Maternal obesity is associated with increased risk of short- and long-term morbidity and mortality for both mother and offspring. Some of this excess morbidity is due to significant pre-existing morbidities such as essential hypertension and GDM.[52,53] However, much of the disease burden is due to increased risk of complications, such as pre-eclampsia, developing *de novo* during pregnancy due to maternal obesity. These complications in isolation have implications for obstetric and anaesthetic management.

### Pre-existing morbidity

Obesity is associated with higher risk for pre-existing medical complications including chronic hypertension, type 2 diabetes, non-alcoholic fatty liver disease, and asthma.[15] For chronic hypertension, the incidence is 12-fold higher in a study of 117 severely obese women compared to normal weight control by term (24% vs 2%, respectively).[54] Pre-existing medical complications increase the risk of developing pregnancy-specific morbidities such as pre-eclampsia during pregnancy. Due to greater utilization of healthcare resources, pre-existing and *de novo* onset of disease have substantial resource implications for healthcare providers.[55]

### *De novo* morbidity during pregnancy

Maternal obesity increases the risk of hypertensive disorders of pregnancy. In nulliparous women, the risk of gestational hypertension is estimated to be 2.5 times greater for obese and 3.2 times greater with severe obesity.[56] For pre-eclampsia, the risk doubles for each 5–7 kg/m$^2$ increase in weight over normal[57] being 1.6 times and 3.3 times higher in obese and severely obese women,

respectively.[56] In women with pre-existing essential hypertension, the risk of developing pre-eclampsia is up to 25%.[58]

Pre-eclampsia causes significant maternal morbidity and is the most common indication for medically indicated pre-term delivery by caesarean delivery. Diagnosis of pre-eclampsia depends on an accurate measurement of blood pressure, which can be challenging in obese women. To measure blood pressure correctly, it is essential that an appropriately sized cuff be used with the cuff bladder encircling at least 80% of the arm. In obese women, this can be difficult due to increased upper arm circumference. The maximum upper arm circumference for which a standard and large cuff can be used is 28 cm and 48 cm, respectively.[59] In women with a BMI greater than 30 kg/m$^2$, a recent study demonstrated that 44% needed a large cuff with this rising to 100% in women with a BMI greater than 40 kg/m$^2$.[60] Even for some women, a large cuff may still be too small. Although the thigh cuff can be used up to a maximum arm circumference of 52 cm, it is not available in all settings and the brachial artery is often obscured after bladder inflation due to the width of the cuff. Given that there is a direct relationship between upper arm circumference and maternal BMI during pregnancy,[61] the diagnosis of pre-eclampsia and other hypertensive disorders and their subsequent anaesthetic management will be affected if the correct cuff size is not used. The Pre-eclampsia Community Guidelines (PRECOG) guidelines therefore advise a different size of cuff depending on arm circumference (Table 39.2).[62] The diagnosis of hypertensive disorders of pregnancy is often further complicated in obese women due to the presence of co-morbidities such as pre-existing hypertension, renal compromise, non-alcoholic fatty liver, and diabetes which can mask diagnostic signs. This diagnostic uncertainty can prove challenging to the anaesthetist particularly when delivery by caesarean section is required.

GDM is also much more common in obese women. Although as a single risk factor, obesity has a low predictive value, the unadjusted odds ratio (OR) for developing GDM for overweight, moderately obese, and severely obese were estimated as being 1.97 (95% confidence interval (CI) 1.77–2.19), 3.01 (95% CI 2.34–3.87), and 5.55 (95% CI 4.27–7.21), respectively.[63] Although the evidence base is lacking, recent UK national guidelines[64,65] recommend that women with GDM should be delivered by term and that induction of labour should be considered if spontaneous labour does not occur. GDM is an independent risk factor for caesarean delivery and many obese women with GDM will therefore require anaesthetic input intrapartum.[66]

Maternal obesity is also associated with increased risks of 'minor complications' of pregnancy with higher BMI during the first trimester (BMI ≥ 30 kg/m$^2$ compared with BMI < 25 kg/m$^2$) including symphysis pubis dysfunction (OR 3.97; 95% CI 2.19–7.18), heartburn (OR 2.65; 95% CI 1.42–4.94), and chest infection (OR 8.71; 95% 2.20–34.44) and with drugs used to treat these complications including Gaviscon® (OR 3.52; 95% CI 1.78–6.96). Although for an individual woman the burden of disease may be relatively low, at a population level, the burden is substantial due to these conditions being relatively common.

## Pregnancy after bariatric surgery: obstetric implications

Bariatric surgery is recognized as the most effective treatment for weight loss in morbidly obese patients.[67] For many women it may be the only way to attain healthy BMI, achieve better regulated hormones, and improve fertility. Pregnancies conceived following bariatric surgery have a reduced risk of GDM, pregnancy-induced hypertension, and pre-eclampsia.[68] However, these benefits need to be balanced by the increased risk of preterm and small-for-gestational-age births[69] and nutritional deficiencies[70] in women. Women with a history of bariatric surgery should therefore be regarded as a high-risk group during pregnancy regardless of their BMI.[69]

Women should be advised to avoid pregnancy during the acute weight loss phase, that is, 1–2 years postoperatively due to increased risks of nutritional deficiencies.[71] Whether conception during the acute weight loss phase is associated with increased risk of adverse pregnancy outcomes is less certain. Although earlier studies suggested an increased risk of premature birth and spontaneous miscarriage in pregnancies conceived within 2 years of a gastric bypass, more recent studies have failed to demonstrate an excess in maternal and perinatal complications.

The three most common bariatric surgical procedures are laparoscopic adjustable gastric banding, laparoscopic sleeve gastrectomy and laparoscopic Roux-en-Y bypass. Laparoscopic adjustable gastric banding is a restrictive procedure that comprises of a silicone band that encircles the proximal stomach, creating a pouch at the top of the stomach. This is connected by a fine-bore tube to a subcutaneously placed port, attached to the abdominal muscle. The band's inner surface has the ability to be inflated thus exerting pressure on the stomach and restricting the passage of food from the proximal stomach to the larger part of the stomach. The band inflation or decompression is carried out by injecting or withdrawing saline solution through the port using a syringe and Huber needle.

Laparoscopic sleeve gastrectomy is a restrictive procedure which involves surgical stapling along the longitudinal reservoir of the stomach following the line of the lesser curve from the cardiac sphincter to the pylorus. This provides a stomach sleeve of approximately 150 mL capacity. The fundus and greater curve of the stomach are then surgically removed.

The laparoscopic Roux-en-Y bypass is both a restrictive and malabsorptive procedure. It involves fashioning a small gastric pouch of 20–50 mL capacity; the remainder of the stomach is detached and left *in situ*. Approximately 150 cm of the small intestine is surgically bypassed so that food from the gastric pouch empties into the jejunum. The small pouch restricts the amount of food the patient is able to consume and the intestinal bypass of the duodenum provides the malabsorptive effect.

Both restrictive and malabsorptive bariatric surgery are associated with nutritional deficiencies due to a combination of malabsorption, food intolerances, and poor dietary intake. Maternal weight and nutritional status should therefore be assessed at the beginning of pregnancy for women who have had bariatric surgery and identified deficiencies should be treated and monitored.[72] Complications of bariatric surgery such as bowel obstruction, anastomotic leak, and band erosion can be difficult to diagnose because they may present with nausea, vomiting, and abdominal pain which are common features of pregnancy. Early and continuous engagement of bariatric surgeons is therefore recommended throughout pregnancy. Even after bariatric surgery, many patients remain obese and are therefore at increased risk of developing GDM during pregnancy. Patients with malabsorptive procedures will experience dumping following ingestion of the normal

glucose used for the oral glucose tolerance test. This is caused by hyperinsulinaemia and hypoglycaemia and manifests clinically as nausea, vomiting, bloating, and diarrhoea. Alternative tests such as a fasting blood glucose or a 2-hour postprandial blood sugar between 24 and 28 weeks may need to be used to diagnose GDM.

### Pregnancy after bariatric surgery: anaesthetic implications

Restrictive and malabsorptive gastric procedures, coupled with the anatomical distortion of the stomach in pregnancy, may put parturients at even higher risk of delayed gastric emptying. They should be treated as having a full stomach at all times. The nutritional deficiencies that occur after bariatric surgery can result in anaemia due to iron and vitamin $B_{12}$ deficiency and electrolyte disturbance. Reduction in fat-soluble vitamin absorption can lead to vitamin K deficiency and therefore potentially coagulopathy.[73] Recommendation that pregnancy should be delayed for at least 12–18 months post bariatric surgery may not avoid many of these issues. Iron, vitamin $B_{12}$, and vitamin K deficiencies are often present several years after surgery.[74] Non-steroidal anti-inflammatory drugs should be avoided due to the increased risk of marginal ulceration in post-bariatric surgery patients.[75] Whilst bariatric surgery may result in a significant loss of excess weight, many patients will still be morbidly obese. Therefore all the problems related to obesity remain.

## Anaesthetic management of the obese parturient

### Assessment of the obese parturient: the anaesthetic clinic

All women with a BMI over 40 kg/m$^2$ should be seen prior to labour and delivery by an anaesthetist.[76] Early assessment allows for review of current management of any co-morbidities, further investigations to be carried out, and involvement of other specialties as appropriate in a timely manner. Reduced exercise tolerance may signal a decreased cardiorespiratory reserve and the need for further investigations to aid assessment. Symptoms of sleep apnoea should be investigated as the use of continuous positive airway pressure can reduce hypoxaemic episodes and prevent right ventricular failure.

Airway assessment can identify the potentially difficult airway. The increased incidence of failed intubation in the obstetric population is well recognized—approximately 1:250 compared to 1:2000 in the general population.[77] The risk of difficult intubation in the morbidly obese parturient has been reported to be as high as one in three.[78] Whilst difficult intubation in the non-pregnant obese patient is also high (15.5% by Juvin et al.[79] with BMI > 35 kg/m$^2$), it is worth noting that a low incidence of significant problems has been reported when there is involvement of senior experienced personnel.[80] Neck circumference is more predictive of difficult intubation than BMI in the morbidly obese.[81]

Assessment of ease of venous access is also useful. Peripheral cannulation can be aided by the use of ultrasound where veins are neither visible nor palpable, but in those with extremely difficult access a central venous line may be required.

Examination of the patient's back will give an early indication as to the ease with which neuraxial analgesia or anaesthesia may be established. In those without a palpable midline or spinous processes, ultrasound (Figure 39.2) may be a useful tool to aid neuraxial analgesia or anaesthesia.

Early assessment of the morbidly obese pregnant patient in the clinic environment also allows explanation of available options. Challenges faced in terms of neuraxial analgesia, and neuraxial and general anaesthesia can be discussed. This will help with managing the mother's expectations, and allow anaesthetic involvement at an early stage of labour should she wish it. An anaesthetic plan should be discussed and documented.[76]

Preparation for the morbidly obese parturient involves many considerations, including equipment. Firstly, a clinic area equipped with patient transport chairs, chairs, and examination couches suitable for morbidly obese patients must be available. Beds must be large and robust enough for the patient. Some delivery suite beds will have a weight limit of around 180 kg, which is also the approximate limit for standard operating tables. Bed hydraulic adjustments must be able to operate effectively. Bariatric operating tables have an upper weight limit of around 450 kg and have appropriate side adjusters to alter the table width. Consideration will need to be given to the method of tilting the patient safely to minimize aortocaval compression. This may involve the use of additional side supports attached to the operating table, or straps to hold the patient in place. Patient hoists and hover mattresses will be necessary for patient movement. Bed mattresses must be specifically designed to minimize the risk to pressure areas. Calf compression stockings and inflatable compression boots must be of appropriate sizes.

Blood pressure cuff should exceed the circumference of the arm by 20% in order to read accurately. However, the extremely conical shaped upper arm that some morbidly obese patients have may still make upper arm non-invasive blood pressure recording impossible. A forearm blood pressure cuff could be used, but their accuracy is not as reliable. Singer et al. found that the differences between forearm and upper arm systolic and diastolic blood pressures were within 20 mmHg in 86% and 94% of patients, respectively in non-obstetric, non-obese subjects.[82] Forearm blood pressures are higher. This would be a useful temporizing measure in an emergency situation, but an arterial line would be preferable, especially in a group where arterial blood gases may be beneficial and venous access poor for peripartum blood samples.

Long spinal epidural needles and combined spinal–epidural (CSE) kits will need to be available. The distance between skin and epidural space increases in a linear fashion with increasing BMI.[83,84] However, Hamza et al.[85] found that—despite this correlation—very few parturients had an epidural space deeper than 8 cm.

Equipment should be available to help achieve optimal patient positioning for intubation. Several commercially available wedge-shaped pillows exist for this purpose (see Figure 39.3). If using these wedges, elevating blocks may require to be secured onto arm boards to bring the board level up to that of the patient's shoulders on the wedge. An ultrasound machine may be helpful to attain peripheral or central intravenous access, or to assist with surface skin marking prior to neuraxial anaesthesia. Equipment may be necessary to suspend or lift the fat pannus to aid surgical access.

Staffing levels will also need to be considered. Extra staff will be required to care for the morbidly obese parturient. Moving

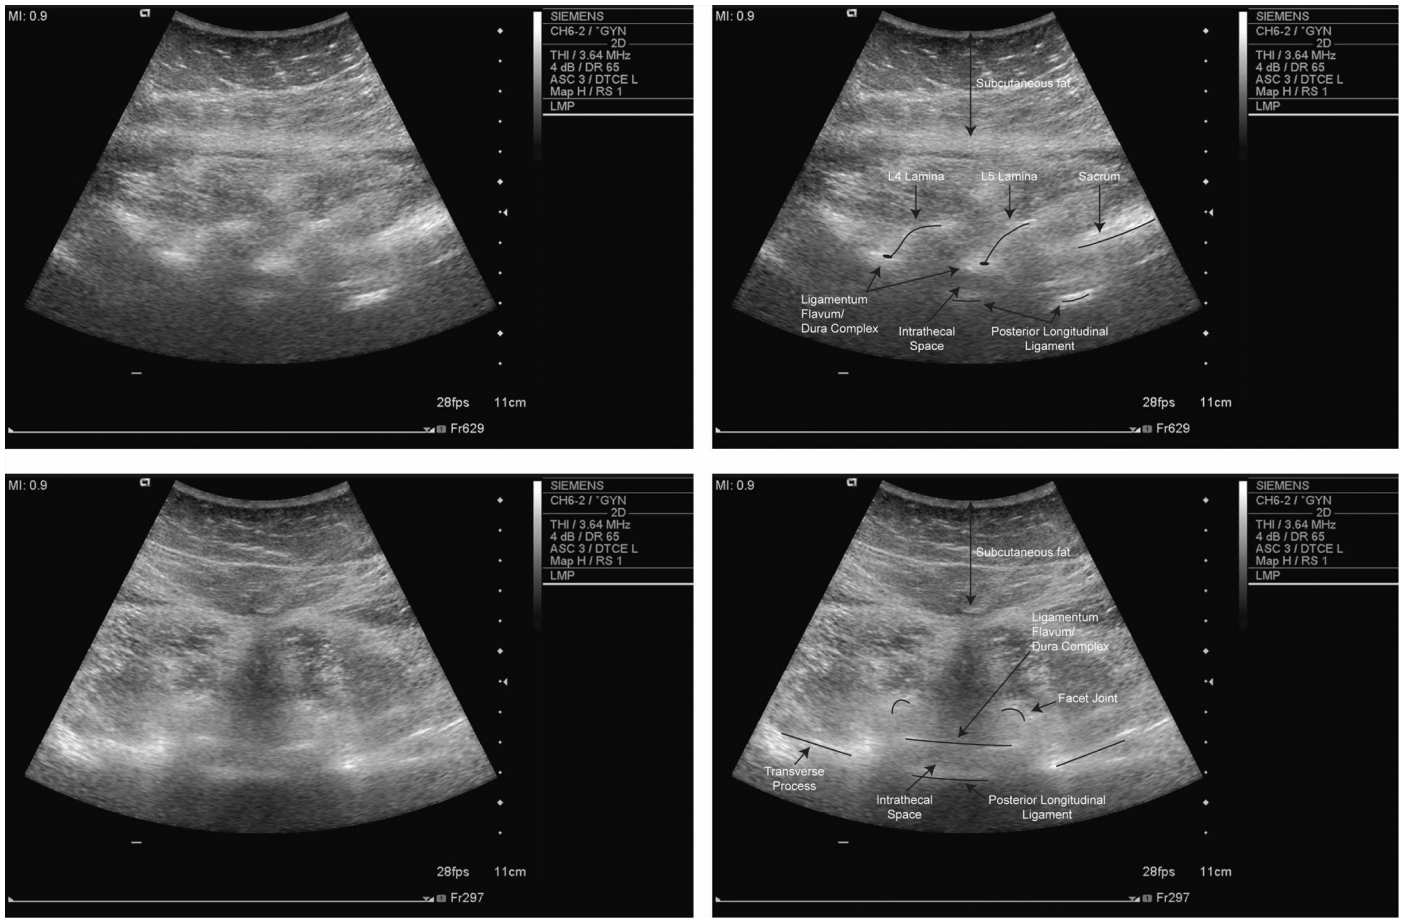

**Figure 39.2** Epidural ultrasound images in a patient with BMI > 40 kg/m$^2$. Top left: paramedian view. Bottom left: transverse view. Right: images repeated with landmarks identified. Note the much poorer quality images obtained in the obese patient compared with those often published from non-obese subjects, due to the layer of subcutaneous fat.

patients may require extra personnel, and those operating hoists need to be familiar with them. Theatre, anaesthetic, and obstetric staffing numbers will all likely need to be increased to assist with the increased technical complexity of morbidly obese patients.

## Anaesthetic management in labour

Entonox® and opioids are readily available forms of pain relief in most delivery suites. Both of these have been shown to increase the incidence of hypoxaemia in the morbidly obese[86] and often provide suboptimal analgesia.[87,88]

Epidural analgesia is not only more effective, it also allows conversion to anaesthesia for instrumental or caesarean delivery in a patient population where establishing neuraxial anaesthesia *de novo* could take considerable time and general anaesthesia carries significantly increased risks.

Placement of an epidural catheter can be very challenging and time-consuming in the morbidly obese with more attempts required to site the epidural than in a patient of normal body habitus. Once in place, there is a higher failure rate and an increased likelihood of requiring resited.[54,89] The lack of bony landmarks and increased skin to epidural space distance no doubt contribute to this. Identification of the midline is difficult and any small errors in needle direction will only be magnified by the increased distance traversed by the needle to reach the epidural space. Taking the patient to theatre where the lighting is optimal, the theatre bed rigid, and skilled help is available can all make the insertion easier. Sitting the patient with her pannus between her knees, heels together, and with the table slightly tilted backward to promote her bending forward may also facilitate opening up the lumbar interspaces. Placing the morbidly obese patient on her side for neuraxial block placement is not helpful as the skin folds fall over the midline.

The use of ultrasound imaging to aid epidural insertion can be of great benefit. Ultrasound is used to identify the midline, desired interspace, depth of the epidural space, and needle direction required. Skin surface markings are made to identify needle insertion points and standard techniques then used to insert the epidural. Studies have shown the use of ultrasound to reduce the number of needle punctures and the number of different levels attempted to insert an epidural.[90] They have also shown a decrease in pain scores and an increase in patient satisfaction.[91,92] Vallejo et al. found that ultrasound use prior to epidural insertion for labour analgesia significantly reduced the number of initial attempts taken by first-year trainees and the number

of replacements required thereafter.[93] Figure 39.2 shows ultrasound images from a parturient with a BMI greater than 40 kg/m$^2$. A curved probe is best suited for the obese subject. Real-time insertion is difficult due to the needle and ultrasound beam being parallel rather than perpendicular to each other, so the needle is not easily visualized. Technology is now available that will indicate the needle position on the real-time ultrasound image even when the tip is not visible. This uses multiple position sensors embedded in the probe and needle. Other technologies use a magnetic field and the ferromagnetic properties of the needle to delineate its position on the ultrasound image.

Once successfully inserted, epidurals in the morbidly obese require careful management. Skin to epidural space distance can be altered by a change in patient position.[85] Moving from a sitting, flexed position for insertion to an upright position can result in an indrawing of the catheter at the skin. Carefully sitting the patient upright prior to fixation of the catheter will mean that movement of the catheter occurs inward at the skin rather than the catheter being pulled back out of the epidural space if the change in position is made after fixation. There is increased mobility of the skin over the lumbar spine due to the intervening fat pad. This, coupled with the increased depth from skin to epidural space, means that any movement on the bed could result in the catheter being pulled back out of the space.[94,95] Leaving an increased length of catheter within the epidural space would seem to be a sensible idea. The higher failure rate of epidurals in the morbidly obese dictates that careful attention must be paid to these women and the functioning of their epidurals throughout labour especially as the obstetric intervention rate in obese women is high and the epidural may be needed for anaesthesia.

Remifentanil patient-controlled analgesia (PCA) is a method used for labour analgesia that has become more prevalent in recent years. Epidural analgesia results in lower pain scores than remifentanil PCA.[96,97] However, some studies have shown remifentanil PCA to be similar to epidural analgesia in terms of patient satisfaction.[98] Its use in the morbidly obese must be undertaken with extreme caution. Remifentanil is a potent respiratory depressant. Virtually all studies report patient desaturation with its use,[99] and it has been associated with several incidents of respiratory[100,101] and cardiorespiratory arrest.[102,103] Van de Velde[104] noted that if all studies reporting respiratory side effects are combined, 32% of patients using remifentanil experience some degree of respiratory depression. There is currently no significant data available regarding remifentanil PCA use in the morbidly obese. Its unlicensed use in a subgroup of patients who already have an increased risk of respiratory complications and a narrowed therapeutic window when using opiates should only be undertaken after considerable thought and discussion. If a dosing regimen based on body weight is used, it is imperative that this is based on lean body weight and not total body weight. Due to the pharmacokinetics of the drug, dosing based on total body weight could result in significant overdosing in the morbidly obese. The strict implementation of written local monitoring standards is essential. A recent report highlighted compliance of these in one unit to be 70%, falling to 10% after withdrawal of supervision by their acute pain team.[105] Meticulous attention should therefore be paid to ensure that monitoring—including the continuous presence of an appropriately trained midwife—is instigated appropriately and continues throughout PCA use.

## Caesarean delivery

### Obstetric issues

There are many factors to consider in the morbidly obese parturient undergoing caesarean delivery. This is a patient population which is at increased risk of morbidity and mortality, both from a global obstetric[11] and anaesthesia-specific perspective, particularly when under general anaesthesia.[106] The 2007 Confidential Enquiries into Maternal and Child Health (CEMACH) report highlighted these increased risks, especially of difficult intubation and aspiration.[107] Wound asepsis is very important as maternal obesity is an independent risk factor for wound infection and subsequent complications including panniculus necrosis.[108] The limited available data suggest that use of prophylactic antibiotic before caesarean delivery,[109] maintaining normothermia intraoperatively and closure of the subcutaneous space if it is greater than 2 cm,[110] may help reduce the incidence of postoperative wound complications. Specific surgical equipment including longer retractors, malleable copper retractors or circular self-retaining rigid or flexible retractors may be required to facilitate access to the pelvis in an obese woman.

### Neuraxial anaesthesia for caesarean delivery

An established and effective labouring epidural can be used to provide anaesthesia for delivery. Care should be taken as standard doses of local anaesthetic may produce a higher block in the obese[111] as both the intrathecal and epidural space are reduced with the deposition of adipose tissue. If an epidural is not already *in situ*, then a CSE should be considered. Firstly, the epidural needle can act as a longer introducer needle for the spinal needle compared to the introducers that accompany the normal length spinal needles. With the increased depth required in the obese, the flexible spinal needles often bend but will be unable to do this within an epidural needle. Secondly, a single-shot spinal (SSS) in the morbidly obese is often less predictable. It can result in a higher block[112,113] although other studies have found no correlation between BMI and anaesthetic block height.[114,115] Further, the rapid onset of the sympathetic block due to spinal anaesthesia in the obese can result in catastrophic hypotension when combined with the aortocaval compression caused by fetus and fat pannus and too high a block resulting in intercostal muscle blockade along with the decreased FRC of the obese parturient can lead to hypoxaemia. Therefore using a smaller than normal spinal dose in the first instance can provide a block to appropriate height with less hypotension and the epidural component can be used if that block height was not achieved. Another advantage of the CSE is that augmentation or prolongation of the block is obviously also possible with an epidural catheter *in situ* if operative time is prolonged as is common in the morbidly obese.

However, a SSS with a normal dose is preferred by some operators in the obese parturient. But meticulous care must be taken with positioning and the judicious use of vasopressors to prevent high block and hypotension respectively. The rationale for a SSS is that if the epidural catheter cannot be passed in the CSE technique

then one must rely only on the smaller spinal dose with the potential that this will wear off if surgery is prolonged and a general anaesthetic becomes necessary. The two-space technique has been advocated to allow placement of the epidural catheter followed by a SSS in a lower space but in modern practice this is almost obsolete and one could argue that one was fortunate to site the spinal, much less the epidural in the two-space technique in the morbidly obese. The decision of which neuraxial technique to use depends on individual expertise and familiarity with either technique.

Appropriate patient positioning on the operating table is vital. Some super morbidly obese patients will be unable to lie horizontally, even with a left lateral tilt. Indeed, Tsueda et al.[39] described two cases of 'obesity supine death syndrome' in super morbidly obese patients who had cardiovascular collapse when lying supine. A parturient who cannot lie supine, or who cannot lie supine when their fat pannus is manipulated, will not tolerate a caesarean delivery under neuraxial anaesthesia. The ability of the super morbidly obese parturient to tolerate this should be tested towards the end of pregnancy to allow updated and informed anaesthetic and obstetric plans to be made.

The operating table itself should, as discussed earlier, be suitable for the patient's weight, have robust side extenders available, and have side supports and straps for securing the patient when tilted.

The patient should also be positioned on the table in the ideal position for intubation, as the need for conversion to general anaesthesia may arise. This will often be a ramped position (discussed later). This position can obviously lead to significant effects on the spread of spinal anaesthesia when using hyperbaric bupivacaine and so this must be considered when establishing a block. Positioning for surgical access may involve methods for elevating the fat pannus if a Pfannenstiel incision is planned. This can involve moving and taping the pannus in a cephalad direction. Some women will not tolerate this, however, due to cardiorespiratory compromise. A method of suspending the pannus vertically will be required in these cases.

Blood pressure monitoring may require an arterial line. This should be inserted prior to neuraxial anaesthesia to allow for careful monitoring during onset of the block and when positioning the patient supine.

Obese patients have a higher incidence of postpartum haemorrhage which is mainly due to uterine atony and increased technical challenges of operating on the obese parturient. Intraoperative blood loss may be significant, so consideration should be given to the use of Syntocinon® infusion and cell salvage.

## General anaesthesia for caesarean delivery

The risks of general anaesthesia in the morbidly obese parturient are significant. Antacid prophylaxis should be used to decrease the risk of pneumonitis from gastric acid aspiration in this population who are known to have increased residual gastric contents. Sodium citrate has been shown to significantly increase gastric pH when given shortly before induction.[116] A recent meta-analysis of ranitidine versus proton pump inhibitors showed ranitidine to be more effective in reducing the volume of gastric acid secretions and increasing gastric pH.[117] A combination of antacids plus $H_2$ antagonists has been shown to significantly reduce the risk of gastric pH of less than 2.5 compared with antacids alone,[118] therefore many will choose to use this combination.

The immediate increased risks of difficult and failed intubation in the pregnant and obese populations are well recognized, as mentioned earlier. Each patient undergoing general anaesthesia should have an intubation plan made. This may be a rapid sequence induction (RSI) ideally involving senior, experienced personnel with close attention paid to the factors discussed below, or it may be an awake fibreoptic intubation if the risks of an RSI are felt to be too great.

If planning a RSI, close attention should be paid to factors that can delay the time to onset of critical hypoxia at induction of general anaesthesia. FRC, metabolic rate, and alveolar oxygen concentration are the factors which have the greatest effect on this time. The morbidly obese parturient has a significantly reduced FRC. They also have a significantly increased metabolic rate. Oxygen consumption is approximately 250 mL/min in the normal BMI patient at rest. This increases to approximately 330 mL/min in the term parturient.[119] In the morbidly obese at rest, an oxygen consumption of up to 453 mL/min has been reported.[28] Figures for the morbidly obese parturient at term are not readily available, but would be assumed to be significantly elevated. Increasing oxygen consumption from 250 to 400 mL/min reduces the time to 50% oxygen saturations by around 40%.[120] Jense et al. investigated the time to 90% saturations after the onset of closed airway apnoea in preoxygenated patients with normal BMI versus the morbidly obese. These times were 364 seconds in the normal BMI group versus 163 seconds in the morbidly obese group.[121] Alveolar oxygen concentration can be optimized prior to induction by careful preoxygenation with 100% oxygen. Using 90% oxygen has been shown to halve the time to critical hypoxia compared to using 100%, with an open airway during apnoea.[120] Attention to maintaining a patent airway with 100% oxygen during the apnoeic phase of RSI will also significantly increase the time to critical hypoxia. This is due to the fact that during the apnoeic phase the rate of oxygen extraction from the alveoli is tenfold that of carbon dioxide reaching the alveoli. This quickly creates a reduction of intrathoracic pressure if the airway is obstructed which rapidly reduces the partial pressure of oxygen remaining in the lungs still further. An open airway allows bulk movement of oxygen to the lungs and prevents this reduction of intrathoracic pressure. Studies using a physiology simulator have shown the time to 50% saturations as 66 minutes with open airway apnoea and 100% oxygen compared to 8 minutes with a closed airway.[122]

Preoxygenation in a 45° head-up position has also been shown to significantly increase the time to desaturation in the obese non-pregnant population.[123] However, Baraka et al.[124] found no difference with the head-up position in the pregnant population. When severe hypoxia does develop, the oxygen saturation decreases extremely rapidly at a rate of approximately 30% per minute.[120]

Appropriate positioning prior to induction of anaesthesia is vital, both to optimize position for laryngoscopy and to aid respiratory function. Figure 39.3A shows poor positioning for induction of general anaesthesia. Figure 39.3B shows a better, ramped position. This position, with horizontal alignment of the sternum and external auditory meatus is an optimized position for laryngoscopy.[125] The ramping also helps improve respiratory function by moving the weight off the chest wall and diaphragm, increasing the FRC. This may result in an increased time to hypoxia at induction.

Many drugs used in the management of the morbidly obese parturient undergoing general anaesthesia have altered pharmacokinetics as discussed earlier.

- Thiopental—induction doses should be adjusted for lean body weight. Peak plasma concentrations are reduced in the obese due to their increased cardiac output.[126] Thiopental is highly lipid-soluble, which results in an increased volume of distribution in the obese. Clearance is also significantly increased.
- Suxamethonium—dosing should be based on total body weight. The morbidly obese have an increase in both extracellular fluid volume and pseudocholinesterase activity, both of which determine the duration of action of the drug.[127]
- Non-depolarizing neuromuscular blockers—dosing should be based on ideal body weight. Both vecuronium[128] and rocuronium[129] duration of action is significantly increased in the obese when dosing is based on total body weight. Most studies also show the same for atracurium,[130] although Weinstein et al. showed no difference in the recovery times of obese surgical patients.[128] However, it would seem sensible to also base atracurium dosing on ideal body weight.
- Volatile anaesthetic agents—the lipid solubility of isoflurane is greater than that of sevoflurane which is again greater than desflurane. However, the clinical effects that these differences produce in the morbidly obese are the relevant factors. Torri et al.[131] found the difference between the wash out curves of isoflurane and sevoflurane only statistically significant in the first 60 seconds after discontinuation of the agents. This was after surgical procedures significantly over an hour in length. Some studies have shown no difference in time to follow commands and extubation when comparing sevoflurane with desflurane in the morbidly obese, if anaesthetic concentration is carefully titrated.[132] Others have shown a significantly more rapid time to obeying commands and extubation using desflurane—and higher oxygen saturation on arrival to the post-anaesthetic care unit.[133] Emergence and both early and intermediate recovery—for at least 2 hours postoperatively—have been reported as more rapid with desflurane than isoflurane in morbidly obese patients.[134]
- Remifentanil—dosing should be based on lean body weight. Pharmacokinetics are not significantly different in the obese. Dosing based on total body weight results in significantly increased blood levels of the drug in obese patients.[135]
- Opiates—fentanyl dosing should be based on lean body weight.[45] Dosing of longer-acting opiates such as morphine and diamorphine must be carefully titrated due to the risk of respiratory depression and upper airway obstruction in the morbidly obese. Respiratory physiological changes in this group of patients along with the increased occurrence of sleep apnoea make opioid-induced hypoxia much more likely to occur.[136,137]

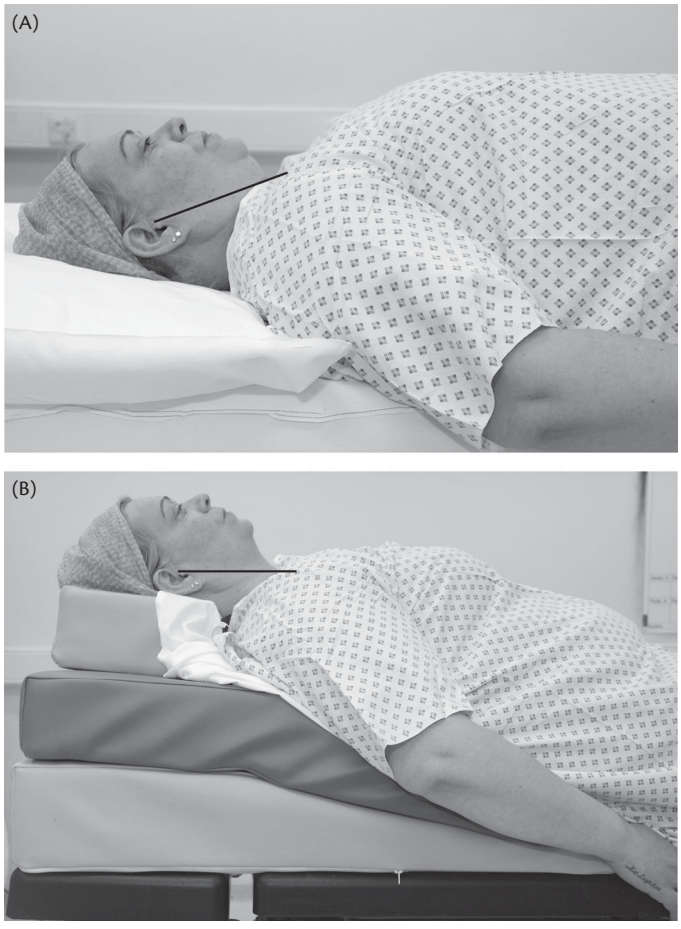

**Figure 39.3** Optimal positioning for tracheal intubation. (A) A single pillow provides a poor position. (B) Horizontal alignment of the sternum and external auditory meatus provides an optimized position for laryngoscopy. This is achieved with the use of wedges.

The incidence of respiratory complications has been reported to be significantly higher at tracheal extubation than at intubation.[138] One-third of events reported to the 4th National Audit Project into major complications of airway management in the United Kingdom occurred during emergence or recovery.[139] The most common of these events was airway obstruction. The morbidly obese are in a higher risk category for problems occurring at extubation. They are more sensitive to the side effects of opiates and at an increased risk of airway obstruction. Decreased FRC and increased metabolic rate will lead to more rapid desaturation should a problem occur and there is an increased risk of difficult intubation should reintubation be required. As such, all patients should have an extubation plan made. The Difficult Airway Society published guidelines for the management of tracheal extubation in 2012.[140] These highlight the need to optimize patient and other factors—such as location and assistance—prior to extubation. The threshold for delaying extubation if any factors are not optimized should be low, as extubation is an elective procedure

## Postoperative analgesia

This would ideally result in manageable pain levels with minimal side effects—such as drowsiness and respiratory depression—and would allow the patient to breathe deeply to minimize atelectasis and mobilize early to minimize risks of deep venous thrombosis.

If a CSE technique has been used intraoperatively, consideration should be given to running an epidural infusion in the early postoperative period. This not only provides optimal analgesia and minimize opiate-related side effects, it will also provide a method of re-establishing anaesthesia should this be necessary in the early postoperative period when the morbidly obese are at a

higher risk of complications such as postpartum haemorrhage.[141] Multimodal analgesia with non-opiate analgesics should be used if appropriate. This will have a morphine-sparing effect.[142,143]

If intrathecal or epidural opiates are used, appropriate regular postoperative monitoring of adequacy of ventilation, oxygenation, and level of consciousness should be in place.[144] Morbid obesity is a risk factor for respiratory depression from neuraxial opiates. In one study of 856 patients, all of the eight patients who suffered respiratory depression were markedly obese.[145] If available, neuraxial diamorphine has been reported as having an improved side effect profile compared with morphine in terms of pruritis and drowsiness.[146] Intravenous morphine is associated with higher pain scores than neuraxial morphine after caesarean delivery,[147] and is well known to cause respiratory depression and sleep-disordered breathing[137] However, morphine PCA after gastric bypass surgery in the morbidly obese has been reported as safe and effective.[148]

Several different local anaesthetic blocks have been used in an attempt to provide improved analgesia and reduce opiate requirements postoperatively, such as ilioinguinal–iliohypogastric nerve blockade and transversus abdominis plane (TAP) blocks. Bilateral ilioinguinal nerve blockade after caesarean delivery has been shown to reduce opiate requirement in the first 24 hours postoperatively,[149,150] but other studies have shown no significant difference between this technique and wound infiltration.[151] TAP blocks are a more recent technique shown by meta-analysis to reduce postoperative morphine consumption in analgesic regimens that exclude neuraxial morphine.[152] In the morbidly obese patient, the landmark technique—identifying the triangle of Petit—would prove difficult. The ultrasound approach, while also more difficult in the morbidly obese, may be better suited which allows accurate placement of local anaesthetic into the correct tissue plane.

A multimodal postoperative analgesic approach with the aim to minimize intravenous opiates would seem sensible, although vigilant, appropriate monitoring is probably the most vital ingredient in avoiding postoperative respiratory complications in the morbidly obese.

## Postoperative care

There should be a low threshold for the morbidly obese to be cared for in a high dependency or intensive care area postoperatively, with continuous monitoring. This is especially so after general anaesthesia when the risk of postoperative respiratory failure is elevated.[81] Any morbidly obese patient with sleep apnoea or a history suggestive of this should be cared for in a high dependency unit postoperatively. A high level of medical and nursing care is required with close attention to detail in order to minimize increased risks in the morbidly obese from many postpartum complications such as haemorrhage, deep venous thrombosis, and wound infection.[89,108,153]

Obesity is a significant risk factor for venous thromboembolism and warrants particular consideration. All women should have an assessment of risk factors for venous thromboembolism in the antenatal period. This assessment should be repeated at any hospital admission or on development of any new risk factors. Detailed guidelines from the Royal College of Obstetricians and Gynaecologists describe this risk assessment.[154] A BMI greater than 30 kg/m$^2$ is one of a range of risk factors. All women with a BMI of over 40 kg/m$^2$ should be offered 7 days of low-molecular-weight heparin (LMWH) post delivery, even after a normal delivery and in the absence of other risk factors.[154] Dosing of LMWH is calculated on patient weight.

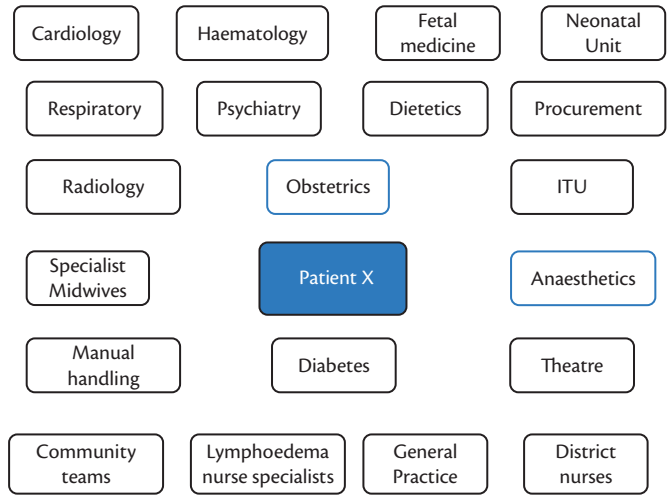

**Figure 39.4** The multidisciplinary team involved in the care of one super morbidly obese patient in our institution.

Many of the equipment and staffing needs mentioned earlier are equally as relevant in postpartum patient care, such as appropriate mattresses to minimize pressure area risk, patient hoists, appropriately sized calf compression stockings, inflatable boots, and blood pressure cuffs.

The postpartum period provides women with a unique opportunity to lose weight to reduce the risk of adverse pregnancy outcome in a subsequent pregnancy and also improve maternal health. To facilitate this and to enable pregnancy spacing, it is therefore important that obese women are given appropriate contraceptive advice postpartum. Although the overall quality of the evidence is low, a 2013 Cochrane review demonstrated that most studies do not demonstrate an association between maternal BMI and effectiveness of hormonal contraceptives.[155]

## Conclusion

The care of the morbidly obese parturient is truly a multidisciplinary affair which must be coordinated by a named consultant obstetrician. Figure 39.4 lists the different specialities involved in the care of just one super morbidly obese patient in our institution. This care involves a high level of communication and great attention to detail in all aspects of patient management. Continuity of care from the anaesthetic team, from prenatal assessment through to postnatal care, will aid optimum patient management. It can aid peer group discussion through a lead anaesthetist to gain consensus opinion on patient care. This will not only help to provide optimum patient care, but will also help to manage patient expectation, especially in the super morbidly obese patient where differing opinions may exist in terms of their management.

CHAPTER 40

# Moderate to complex congenital heart disease

Daryl P. Dob, Elspeth E. Pickering, and Michael A. Gatzoulis

## Introduction

Children born with congenital heart disease no longer face the prospect of early death and a poor quality of life. In fact, most neonates with moderate to complex congenital heart disease have a survival rate to adulthood of over 80%.

The ratio of adults to children with congenital heart disease is increasing, due to better surgical repairs, and longer survival with a better quality of life. In the Western world, there are more adults than children alive with congenital heart disease. This remarkable medical effort has allowed young women with congenital heart disease to mature to an age where they wish to have babies of their own.

Early generations of women, palliated with the Mustard or Senning intra-atrial switch repairs, have shown it is possible to face the cardiovascular challenges of pregnancy and survive. Consequently, more women with congenital heart disease are taking on possibly the greatest cardiovascular challenge of a woman's life—pregnancy and childbirth.

In Europe, maternal death occurred in 0.5% of mothers with congenital heart disease compared with 0.007% in the normal population.[1] As the number of women with congenital heart disease is predicted to grow by 25% in the next decade[2] and more women with congenital heart disease become pregnant, a better understanding of moderate to complex heart disease, different surgical repair procedures, and residual anomalies is paramount. We will examine the management of parturients with transposition complexes (both classical and congenitally corrected), tetralogy of Fallot, the Fontan circulation, Eisenmenger's syndrome, and congenital aortic stenosis, taking into consideration the effect of pregnancy, labour, delivery, and anaesthesia on each circulation.

## History

The development of neonatal and paediatric cardiac surgery and cardiology represents one of the greatest medical advances of the last century. This achievement began in the 1930s when the first closure of a patent ductus arteriosus (PDA) was carried out by Robert Gross in Boston. In 1944, Alfred Blalock and Helen Taussig began to palliate babies with their shunt from the aorta to the pulmonary artery which increased pulmonary blood flow.

In 1953, John Gibbon performed the first surgery using a heart–lung bypass machine or pump oxygenator as it was originally known. Quickly after this, repair of Fallot's tetralogy became possible in 1954, and for the first time palliation of transposition of the great arteries was performed in the 1960s by Mustard in Canada and Senning in Sweden. The Jatene arterial switch was performed in 1976 in Brazil and popularized by Professor Sir Magdi Yacoub throughout the 1970s and 1980s in London, United Kingdom.

This was followed by palliation of even more complex congenital heart disease. For the first time babies with univentricular circulations could be palliated with an atriopulmonary or cavopulmonary connection and grow up with the Fontan circulation, a revolutionary idea to separate oxygenated and deoxygenated blood and increase systemic arterial saturations, accepting the loss of the hypoplastic right ventricle.

With more babies growing to adulthood, the understanding of moderate to complex congenital heart disease, the surgical repairs to treat it, and the residual defects left after surgery are paramount to allow safe passage through pregnancy and delivery.

## The role of prepregnancy counselling and the high-risk anaesthetic clinic

In line with the top ten recommendations of the 2006–2008 Confidential Enquiries into Maternal and Child Health report published in 2011,[3] pre-conception counselling is essential. Issues such as risks of mortality and morbidity may be understandably difficult to approach, but need and can be handled sensitively. Accurate documentation is important.

The following factors should be specifically considered: a poor functional class before pregnancy (New York Heart Association (NYHA) functional class higher than II), cyanosis, impaired systemic ventricular function (ejection fraction < 40%), left heart obstruction (mitral valve area < 2 $cm^2$, aortic valve area < 1.5 $cm^2$, or left ventricular outflow tract peak blood pressure gradient > 30 mmHg before pregnancy), or a preconception history of adverse cardiac events such as symptomatic arrhythmia, stroke, transient ischaemic attack, and pulmonary oedema. The expected cardiac event rate with none, one, or more than one of these factors is 5%, 27%, and 75% respectively.[4–6]

Multidisciplinary working is essential to ensure a safe outcome for mothers and babies. A regular clinic which allows the mother with congenital heart disease to see her obstetrician, cardiologist, midwife, anaesthetist, intensivist, and neonatologist is paramount.

## Normal cardiac configuration

In order to understand the circulations and physiology of moderate to complex congenital heart disease it is important to have a logical understanding of the connections in the normal heart. To do this we have divided the normal circulation into seven features.[7,8]

Figure 40.1 shows a schematic drawing of the normal circulation and the features are described as follows:

1. Venoatrial concordance, that is, all (right and left) veins (systemic and pulmonary) are connected to the corresponding atria normally.
2. No atrial septal defect (ASD).
3. Atrioventricular concordance, that is, the atria are normally connected to the corresponding ventricles (right atrium to right ventricle, etc.).
4. No valvular abnormalities between the atria and the ventricles.
5. No ventricular septal defect (VSD).
6. Ventriculoarterial concordance, that is, the ventricles are connected normally to the corresponding great arteries.
7. No semilunar valvular abnormalities and no connections between the great vessels such as PDA.

Knowledge of these features allows a logical means of communication about different surgical repairs and their residual effects on each circulation.

## Physiological changes of pregnancy in the normal cardiovascular system

Systemic vascular resistance is reduced due to peripheral vasodilatation mediated by progesterone, oestrogen, and prostacyclin, as well as low-pressure arteriovenous connections in the placenta. In the normal circulation, central venous and pulmonary artery pressures are unchanged during pregnancy, although central venous pressure is increased during labour and may remain elevated for a few hours postpartum. Blood volume also increases throughout pregnancy and is 45–50% greater than prepregnancy values by term. This represents an increase in both red cell volume and plasma volume. The increase in plasma volume is relatively greater, resulting in physiological anaemia. Cardiac output increases steadily until 20 weeks of gestation when it is maintained at 40–50% above normal until term. This is due to an increase in both stroke volume and heart rate. In labour, cardiac output may increase by a further 25–50% with an additional increase of 15–30% during contractions. It remains elevated for a few hours after delivery. Aortocaval compression by the gravid uterus can lead to reduced venous return, cardiac output, and uterine blood flow. Autotransfusion of blood from the placenta also occurs during the third stage of labour.

Functional residual capacity steadily decreases as pregnancy continues. This, in combination with the increasing oxygen demands of the growing fetus, means arterial oxygen desaturation occurs faster than in the non-pregnant state.[9]

## Transposition of the great arteries

Transposition of the great arteries is the commonest cyanotic congenital heart disease seen in neonates.[10] In the presence of an intact ventricular septum, cyanosis is seen on the first day or so of life, when the ductus arteriosus usually closes.

### Pathophysiology

In transposition of the great arteries there is ventriculoarterial discordance. This is a feature 6 type abnormality in the classification of cardiac configuration previously described. Figures 40.2

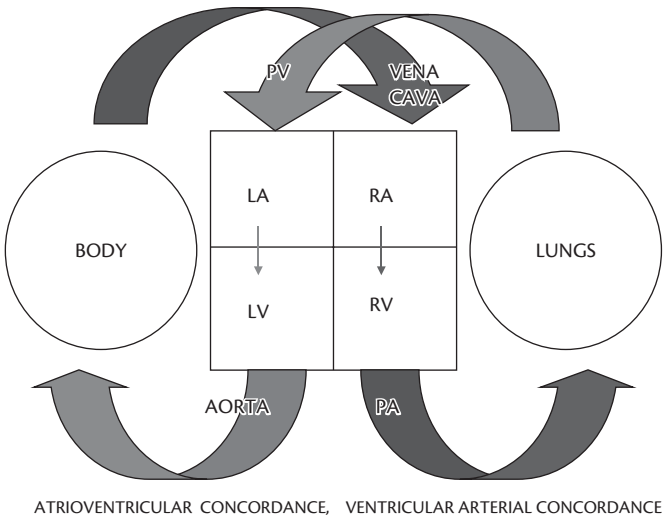

**Figure 40.1** (See colour figure section). The normal configuration.
Reprinted from *International Journal of Obstetric Anesthesia*, Volume 19, edition 3, D.P. Dob, M.A. Naguib, M.A. Gatzoulis, A functional understanding of moderate to complex congenital heart disease and the impact of pregnancy. and 40.3 demonstrate the lesion. The aorta and pulmonary artery are incorrectly connected to the left and right ventricles respectively. There is still normal atrioventricular concordance (feature 3). The aorta is connected to the right ventricle and the pulmonary artery to the left ventricle. If there is no connection between pulmonary and systemic circulations this pattern is incompatible with life as the pulmonary circulation receives all the oxygenated blood and the systemic circulation none, that is, there are two completely separate circuits and the patient is severely cyanosed.

Neonates usually survive because mixing between the two circulations allows oxygenated blood to pass through to the systemic circulation. Blood mixes in the heart via a VSD (in >50% of cases), an ASD, or outside the heart via the ductus arteriosus. The ductus arteriosus allows oxygenated blood from the aorta to cross to the pulmonary arteries.

For patients with a large VSD or PDA, high flow through the pulmonary circulation eventually leads to pulmonary hypertension and reversal of flow (Eisenmenger's syndrome—see later). These patients then have differential cyanosis, in which oxygenated blood from the left ventricle entering the pulmonary artery crosses the PDA because of pulmonary hypertension, supplying the lower body with more oxygenated blood than the ascending aorta, leaving them with a blue upper body and head and a pink lower body.

## Management

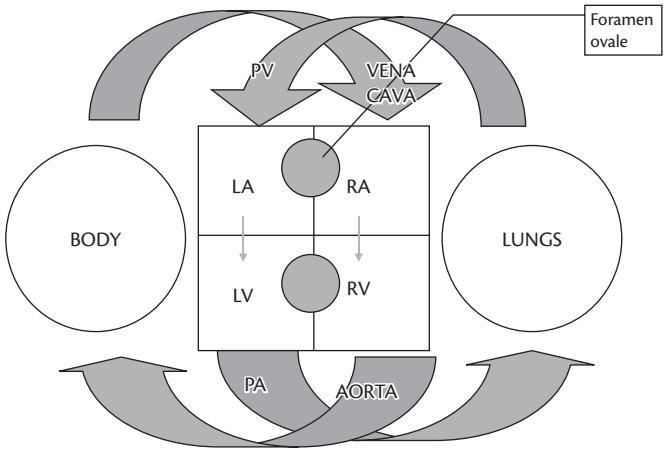
### Rashkind atrial balloon septostomy

Early management in cyanotic babies includes prostaglandin $E_1$ to maintain the patency of the ductus arteriosus and a Rashkind atrial balloon septostomy. This procedure creates a sizeable ASD to improve oxygenation until surgery can be performed.[11] It is performed by passing a catheter through the foramen ovale, blowing a balloon up then pulling the catheter back through, creating the defect. A Blalock–Hanlon surgical atrial septectomy is effectively the same as the Rashkind procedure but carried out as an open operation for infants presenting later when the septum is too thick for balloon septostomy.[12]

### Atrial switch (senning or mustard) procedure

From the 1960s to the 1980s repairs concentrated on switching blood flow at atrial level, because arterial switch operations were technically too difficult. Atrial switching was achieved with an atrial baffle, so that deoxygenated blood could be channelled through to the left ventricle and round to the pulmonary circulation, while oxygenated blood could be channelled into the right ventricle (systemic ventricle) to go around the systemic circulation. The inferior vena cava and the superior vena cava are transected and connected to a trouser shaped baffle which conducts the venous blood across to the mouth of the mitral valve. This allows the deoxygenated blood to be pumped around the pulmonary circulation by the subpulmonary (morphological left) ventricle. Oxygenated blood from the lungs returns via the four pulmonary veins into the left atrium. From here it is channelled across to the mouth of the tricuspid valve and into the right ventricle. This allows oxygenated blood to be pumped through the aorta around the systemic circulation, by the subaortic (morphological right) ventricle. These are known as Senning and Mustard repairs and represent physiological rather than anatomical repair. The Senning procedure, in which an atrial baffle was fashioned from autologous tissue, was first described in 1959.[13] This was followed by the Mustard procedure in 1964 where the baffle used was made of synthetic material[14] (Figure 40.4). The 30-year survival rate after atrial switch repair (Mustard or Senning) is 80%.[15]

During surgery for insertion of the atrial baffle, the sinus node may be damaged or compressed, leading to arrhythmia.[16] Pregnancy carries a 20% risk of arrhythmia especially supraventricular tachycardia. This is usually related to the presence of atrial scar tissue, in addition to the physiological changes of pregnancy.[17]



1. Natural large ASD 2. Pulmonary stenosis with VSD 3. ASD and VSD with Eisenmengers (reverse flow)

Tachycardia is often more haemodynamically compromising, because of the systemic right ventricle. The presence of artificial tissue, atrial scarring, and complex anatomy makes treatment of arrhythmias by radiofrequency ablation and pacemaker insertion challenging.[18–20]

Baffle obstruction is an infrequent late complication. Obstruction of the superior vena cava is more common than that of the inferior vena cava. Jugular engorgement with facial oedema (superior vena caval syndrome) is usually a late sign indicating obstruction of both superior and inferior venae cavae.[21] Baffle obstruction can be managed by percutaneous balloon dilatation, stent insertion, or occasionally surgical refashioning of the baffle.[22]

Pulmonary hypertension occurs in 7% of patients with Mustard or Senning repairs. Predisposing factors include operation at more than 2 years of age, shunts prior to repair, raised pulmonary pressures, and pulmonary venous baffle obstruction.[23] Some patients with transposition of the great arteries have a degree of pulmonary hypertension at presentation because the left ventricle pumps blood into the pulmonary circulation generating a high pressure, particularly in patients with a large VSD. The most common cause of pulmonary hypertension after baffle procedure is pulmonary venous obstruction secondary to pericardial baffle constriction. The incidence has been reduced since the use of polytetrafluoroethylene baffles.[24]

Women with Mustard or Senning atrial switch repairs for transposition of the great arteries used to represent the majority of patients with moderate to complex congenital heart disease attending high-risk obstetric clinics. This has changed as more women present following an arterial switch operation performed in the 1980s, as this became the operation of choice for transposition of the great arteries. [25] (See 'Arterial Switch (Jatene) Procedure'.)

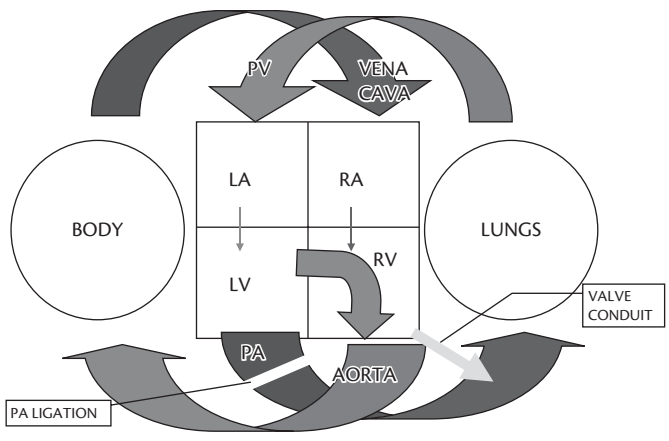

**Figure 40.5** (See colour figure section). Rastelli procedure. The large red arrow represents the Dacron tunnel from the left ventricle to the aorta. The blue arrow represents the valved conduit from the right ventricle to the pulmonary artery. The pulmonary trunk is transected and sewn up.

Reprinted from *International Journal of Obstetric Anesthesia*, Volume 19, edition 3, D.P. Dob, M.A. Naguib, M.A. Gatzoulis, A functional understanding of moderate to complex congenital heart disease and the impact of pregnancy. Part I: The transposition complexes, pp. 298–305, Copyright (2010), with permission from Elsevier.

## Rastelli procedure

This operation is performed in patients with transposition of the great arteries, VSD, and pulmonary stenosis. Oxygenated blood is directed through the VSD to the aorta using a tunnel made of Dacron® (Figure 40.5). After inserting a large ventricular septal patch, the pulmonary valve is over-sewn and the right ventricle connected to the pulmonary artery via a valved conduit.[26] The Rastelli procedure is a low-risk operation, but later conduit replacement operations are required for most patients. This can be done with low risk.[27] The perceived advantage of this repair is that the systemic ventricle is the left ventricle. In one series, early deaths were related to conduit compression and sepsis, while late deaths were related to residual VSD and infections.[28] The Réparation à l'Etage Ventriculaire (REV; literally repair of the ventricular floor)[29] can be used to dissect off the aorta and pulmonary trunk and change them round without using a valved conduit from the right ventricle. This has the advantage of not having to operate again to replace the conduit. The modified Nikaidoh operation can also be used to dissect off the main arteries in bulk along with the morphologically correct valves and the coronary arteries. These repairs are currently producing good survival and reoperation free numbers but longer follow-up is required.[30]

## Arterial switch (Jatene) procedure

The arterial switch procedure (Figure 40.6) was first attempted by Mustard and Senning in the 1950s but was unsuccessful due to early technical problems with cardiopulmonary bypass in small babies. The first successful cases were described in 1976 by Jatene in Brazil and by the 1980s the arterial switch procedure became the operation of choice for transposition of the great arteries.[31] It leaves the patient with a repair that is closer to the normal anatomy, in that the aorta and pulmonary artery are connected to the correct ventricles. The advantages are that the left ventricle now becomes the systemic pumping chamber, and the mitral valve becomes the systemic atrioventricular valve.

The operation is technically demanding as the coronary arteries must be dissected off the pulmonary trunk and re-implanted on to the neo-aorta, without being stretched or kinked.

Coronary events may occur in 7% of patients. They are the main cause of early morbidity and mortality in the postoperative period. They are often related to abnormal coronary anatomy. Kinking, torsion, or extrinsic compression by biological glue are some of the causes of early coronary events and require immediate surgical revision. Late coronary events are uncommon and they are mostly due to progressive intimal thickening due to abnormal coronary blood flow or stretching of the coronary arteries with normal growth.[32] Coronary function must be assessed regularly following surgery, aiming for early diagnosis.[33] This prevents sudden cardiac death due to coronary obstruction.

Ideally the arterial switch operation should be performed before the left ventricle becomes adjusted to the lower pulmonary pressures and thus potentially unable to support the systemic circulation. Left ventricular function may deteriorate gradually after arterial switch operation in patients with transposition of the great arteries with an intact ventricular septum,[34] functional impairment can be observed as early as 2 weeks of life.[35] Pulmonary artery banding is used before surgery to prepare the left ventricle to take over as the systemic ventricle. Unfortunately this is not always successful and left ventricular failure may still

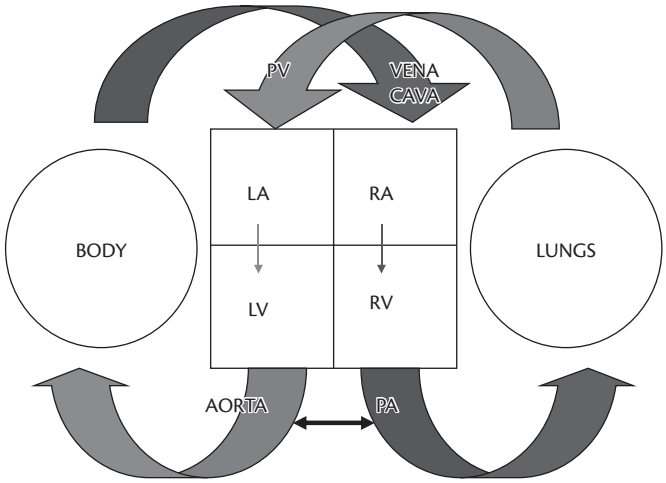

**Figure 40.6** (See colour figure section). Arterial switch (Jatene) procedure. Aorta and pulmonary artery switched to the correct ventricle (represented by the black arrow). The coronary arteries are transected with a 'button' of pulmonary artery wall and re-implanted into the neo-aorta, which was the old pulmonary artery.

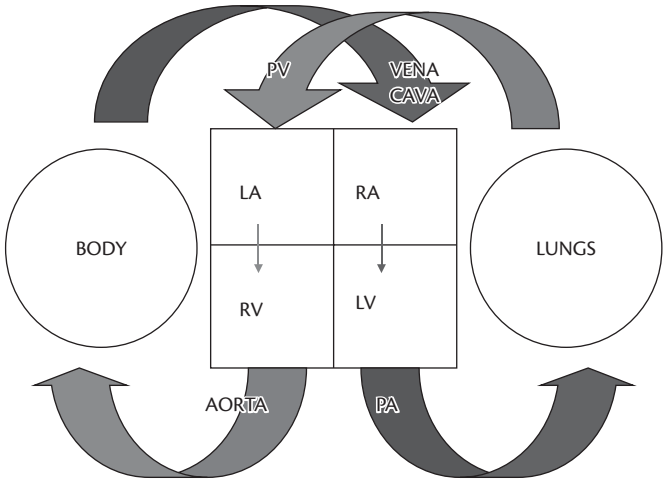
develop.[36–38] Right ventricular outflow obstruction is the most common late complication of arterial switch procedures. The obstruction can occur at the level of the right ventricle in the form of infundibular stenosis or more commonly in the supravalvular area at the level of the pulmonary artery.[39–41] The mechanism is not clear, but the pulmonary artery may be stretched with growth. In 10% of cases it can be severe enough to require intervention.



ATRIOVENTRICULAR DISCORDANCE, VENTRICULAR ARTERIAL DISCORDANCE
(Double discordance) (essentially normal circulation with systemic RV)

**Figure 40.7** (See colour figure section). Congenitally corrected transposition of the great arteries showing double discordance.

Survival rate after the Jatene arterial switch operation can be as high as 96% after 23 years and freedom from reoperation as high as 81.9%.[42] Factors associated with increased mortality include complex transposition of the great arteries, associated cardiac lesions, major intensive care unit events, and re-operation.[43] Patients with arterial switch procedures are now entering early adulthood and increasing numbers are attending high-risk obstetric clinics.[25]

### Congenitally corrected transposition of the great arteries

This is an uncommon condition with an incidence of about 1% of all forms of congenital heart diseases.[44] These patients have two abnormalities that nearly correct each other in terms of physiology. They have ventriculoarterial discordance (feature 6, as in patients with classic transposition of the great arteries) but they also have atrioventricular discordance (feature 3), which means they have a natural intra-atrial switch leaving them with an essentially normal circulation in terms of oxygenation (Figure 40.7). However, they have a systemic right ventricle with all the concerns previously discussed. Associated lesions are also common and have an impact on outcome, namely VSD, Ebstein's anomaly of the tricuspid valve (which is the systemic atrioventricular valve), subpulmonary stenosis, and acquired complete heart block.

Since oxygenation is normal at birth, congenitally corrected transposition of the great arteries may present later in life than classic transposition, usually with cardiac failure.[45,46] The median age of death is 40 years, with a 10-year survival of 64–83% from the time of diagnosis, depending on associated anomalies. The main cause of death is heart failure due to the systemic right ventricle.[47–49]

Medical management of congenitally corrected transposition should be aimed at treating complications such as heart failure and arrhythmias. Permanent pacing for complete heart block may be required and biventricular pacing may have an advantage in selected patients.

Surgical treatment such as valvuloplasty or valve replacement for pulmonary stenosis with VSD closure may be required. Pulmonary artery banding increases left ventricular pressure and shifts the interventricular septum to the right. This reduces tricuspid regurgitation and right ventricular dysfunction.

A double-switch procedure (Figure 40.8), in which an arterial switch procedure is combined with an atrial switch procedure, may be used for selected patients, on occasion in preparation for pregnancy. In the atrial switch procedure, the intra-atrial baffle directs oxygenated blood from the left atrium across to the left ventricle, and deoxygenated blood to flow across from the right atrium to the right ventricle. Then the aorta and pulmonary arteries are switched so that the aorta is now connected to the left ventricle and pumps oxygenated blood around the systemic circulation. The right ventricle is connected to the pulmonary artery and pumps deoxygenated blood round to the lungs.[50–52]

## The parturient with transposition complexes

### Pregnancy

Although the arterial switch procedure is now the gold standard for treatment of transposition of the great vessels, atrial correction was performed regularly until the 1980s and many such patients present to antenatal clinics. They can present with a multitude of

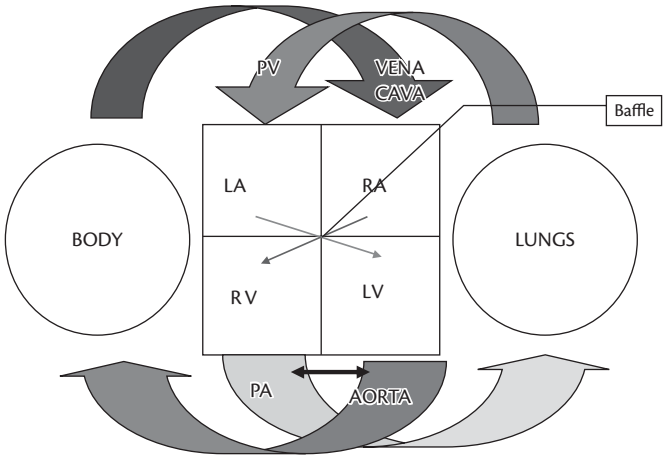

**Figure 40.8** (See colour figure section). Double-switch procedure—an intra-atrial switch is combined with an arterial switch to give a near normal circulation to repair congenitally corrected transposition of the great arteries.
Reprinted from *International Journal of Obstetric Anesthesia*, Volume 19, edition 3, D.P. Dob, M.A. Naguib, M.A. Gatzoulis, A functional understanding of moderate to complex congenital heart disease and the impact of pregnancy. Part I: The transposition complexes, pp. 298–305, Copyright (2010), with permission from Elsevier.

problems during pregnancy.[47,53] The most common and potentially life-threatening is right (systemic) ventricular failure or dysfunction. This can be secondary to the pregnancy-induced increase in cardiac output, heart rate, and plasma volume.[53] Strain on the systemic morphological tricuspid valve leads to annular dilatation and subsequent regurgitation, so worsening ventricular failure. Labour puts further strain on the weaker right ventricle. This particular complication can occur any time during pregnancy and delivery.[54]

Patients with more than moderate to severe systemic right ventricular dysfunction should be discouraged from becoming pregnant (and given appropriate contraception) as there is a risk to themselves and a risk of incomplete cardiovascular remodelling even after successful pregnancy, which ultimately compromises their prognosis. It is sometimes necessary to make therapeutic improvements such as baffle reconstruction, before contemplating the demands of pregnancy.

Once pregnant, the woman must be watched carefully for systemic ventricular failure as cardiac output increases with gestation. She will need frequent review by her cardiologist and obstetrician. Cardiac output rises to a peak at around 20 weeks and must then be sustained for the rest of the pregnancy. This is often the time when systemic ventricular failure and pulmonary oedema occur. They can be managed medically. Occasionally, in very severe cases surgical intervention, such as baffle reconstruction, is necessary.

If the woman can sustain the increased ventricular workload, it is a good sign that her circulation is robust. However, if there are signs of decompensation, such as arrhythmias, pulmonary oedema or even simply fatigue, then admission to hospital for bed rest is essential. Delivery should be considered if the gestational age allows.

Mothers with transposition complexes can present with haemodynamically significant arrhythmias, which need to be dealt with promptly. Both DC cardioversion and adenosine are safe and should be offered in any patient with haemodynamic compromise. Beta blockers may convey some protection in arrhythmia control and prevention of recurrence. Patients with a history of arrhythmia should be counselled for catheter-based ablative procedures, which in the right environment and for well selected patients may prevent arrhythmia recurrence during pregnancy.

As gestation progresses, functional residual capacity decreases and respiratory function worsens. This is greatly improved after delivery, so the needs of the mother must be weighed against the needs of a premature fetus. Consultation with the neonatologists is very helpful. Risks to the fetus are associated with poor maternal functional class before pregnancy or maternal cyanosis, left heart obstruction as outlined, maternal age less than 20 or over 35 years, maternal smoking, and treatment with anticoagulants.[55,56]

For patients with congenitally corrected transposition of the great arteries, potential problems in pregnancy include dysfunction of the systemic right ventricle with low cardiac output, increased systemic atrioventricular valve regurgitation with heart failure, atrial arrhythmias, and atrioventricular block. Occasionally, surgery to repair the circulation such as the double-switch operation, may have to be performed prior to conception. The rate of fetal loss is increased.

## Labour and delivery in patients with transposition of the great arteries

In the transposition complexes there is a trend towards vaginal delivery and instrumental second stage. If pregnancy is well tolerated and systemic ventricular function is unimpaired, then it is possible to wait for spontaneous labour. A low-dose neuraxial technique can be used for labour analgesia to reduce pain and cardiovascular stress. A traditional epidural or a combined spinal–epidural (CSE) technique that maintains haemodynamic stability[57] are both appropriate. In the CSE technique, 1 mL of plain 0.25% bupivacaine with fentanyl 25 mcg is injected intrathecally and epidural 10–15 mL boluses of 0.1% bupivacaine with fentanyl 2 mcg/mL may be given half-hourly at the request of the patient.[58–60] If systemic ventricular function is good, and the woman appears well in labour, then it is sensible to use non-invasive monitoring: blood pressure, electrocardiography, and pulse oximetry. If systemic ventricular function deteriorates then intra-arterial continuous blood pressure monitoring is useful. It is important to remember that if a Blalock–Taussig shunt has been performed, pulsations in the radial artery may not be present on the operated side. Central venous pressure monitoring is rarely needed unless progress is poor. Pulmonary artery catheterization (PAC) to ascertain pulmonary capillary wedge pressure is not used as a routine, because of technical difficulties in getting through the heart to the pulmonary artery, particularly in an atrial switch (Mustard or Senning) repair and the induction of arrhythmias as the PAC is floated.

In past decades, general anaesthesia was regarded as the mainstay for caesarean delivery in moderate to complex heart disease. It is now rarely used for delivery in mothers with transposition complexes. The presence of a full stomach with delayed gastric emptying in labour necessitates tracheal intubation, which leads to a stress response.[61] It is possible to modify traditional general anaesthesia induction techniques, for example, using high doses of short-acting opioids such as fentanyl, alfentanil, or remifentanil

to allow smoother induction. This may help to avoid ventricular depression and hypotension in congenital heart disease but the baby may suffer respiratory depression after birth and need naloxone to counteract residual opiates in the circulation. General anaesthesia tends not to be used for caesarean delivery in women with transposition complexes.

The increased haemodynamic stability associated with low-dose sequential CSE[62,63] or incremental spinal anaesthesia, [64] or *de novo* epidural anaesthesia, has made neuraxial anaesthesia acceptable for caesarean delivery in women with moderate to complex congenital heart disease. Following intrathecal hyperbaric bupivacaine 5 mg with diamorphine 300 mcg, block height is assessed and carefully increased with 5 mL epidural boluses of plain 0.5% bupivacaine/levobupivacaine or ropivacaine 7.5 mg/mL with or without epinephrine 5 mcg/mL, so as to increase block height to a level necessary for surgery. Unfortunately, postdural puncture headache after intrathecal catheter placement for continuous spinal anaesthesia may be troublesome in obstetric patients.[65]

The blood pressure can be maintained with vasopressors and inotropes. Phenylephrine 25–50 mcg, metaraminol 0.5–1 mg, or epinephrine 5 mcg are useful and can be given in repeated doses. Epinephrine is particularly useful for severe hypotension, as it not only provides vasoconstriction, but positive inotropy and chronotropy. Intra-arterial continuous blood pressure monitoring is a useful guide to vasopressor therapy, but not always necessary for robust circulations. Central venous pressure monitoring may also be useful, but not always necessary. Women with transposition complexes tend to suffer systemic ventricular failure, and small doses of furosemide (5–10 mg) may be given at the time of delivery, to help mobilize and eliminate the extra plasma volume built up during pregnancy. Using these techniques it is possible to deliver babies safely by caesarean delivery and for the mother to be awake to enjoy the experience.

# Tetralogy of fallot

## Pathology

First described in 1888 by the French physician Etienne-Louis Arthur Fallot,[66,67] tetralogy of Fallot is a common cyanotic congenital heart disease with an incidence of 10% of all reported congenital heart diseases.[68] It is characterized by four components (Figure 40.9):

1. Large VSD.
2. Right ventricular outflow tract obstruction: the severity may vary but it is almost universally at subvalvular level. It is often associated with an abnormality in the pulmonary valve itself. This obstruction causes a right-to-left shunt, a reduction in blood flow to the pulmonary artery, and subsequent cyanosis.
3. Overriding aorta: the aorta receives blood from both the right and left ventricles through the VSD.
4. Right ventricular hypertrophy: progressive right ventricular outflow tract obstruction results in right ventricular hypertrophy which adds to the obstruction and worsens the condition.

Prognosis for patients who do not undergo surgical repair is poor; the most common causes of death are pulmonary haemorrhage, brain abscess, and thromboembolic complications.[69] In 1945, the first surgical treatment for tetralogy of Fallot was performed by Alfred Blalock.[70] This was followed by the first intracardiac repair in 1954, and 1 year later, the first repair using a pump oxygenator by Kirklin.[71] Palliation of tetralogy of Fallot with systemic to pulmonary shunts such as the Blalock–Taussig shunt has been the accepted standard for symptomatic neonates and infants.[72] The Blalock shunt procedure involves fashioning a conduit from the subclavian to the pulmonary artery to increase blood flow to the lungs and bypass pulmonary stenosis. Indications for palliative treatment include cyanotic spells or persistent profound arterial desaturation, very young age, or unfavourable pulmonary arterial anatomy.[73,74]

## Surgical repair

Primary repair of tetralogy of Fallot is routinely performed in stable patients aged 6 months or older with suitable pulmonary artery anatomy. Optimal timing for repair remains somewhat controversial, varying between 6 months and 2 years, although currently many surgeons are considering primary neonatal repair.[75,76] Repair involves relieving the right ventricular outflow obstruction and closure of the VSD.

Several complications may follow surgical repair. Up to 80% of patients develop a degree of pulmonary regurgitation.[77] This is made worse by factors that elevate pulmonary artery pressure. Although well tolerated in early life, pulmonary regurgitation may lead to right ventricular dilatation and failure, reduced exercise capacity, arrhythmia, and sudden cardiac death in the long term. The pulmonary valve may eventually need replacement.[78,79]

Aortic valve regurgitation may also occur and is mainly caused by dilatation of the aortic root secondary to increased aortic blood flow before surgical repair. Intrinsic abnormalities of the aortic wall also predispose to aortic root dilatation and secondary aortic regurgitation.[80,81] Other postulated causes are lack of support due to a septal defect and retraction of the surgical patch.[82]

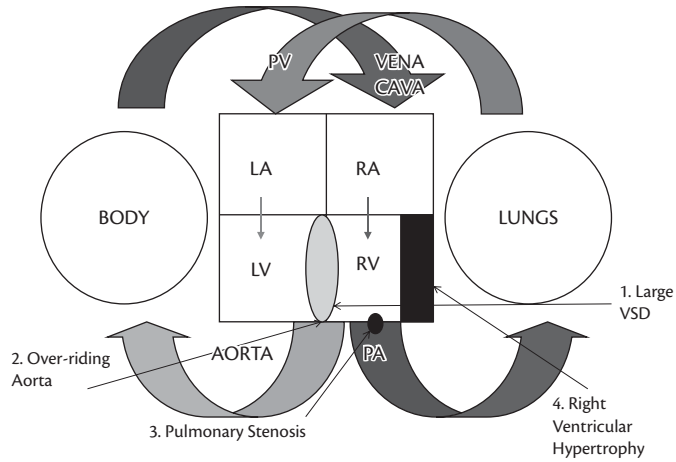

**Figure 40.9** (See colour figure section). Fallot's tetralogy. The purple colour represents mixed oxygenated and de-oxygenated blood.

Dob, M.A. Gatzoulis, A functional understanding of moderate to complex congenital heart disease and the impact of pregnancy. Part II: Tetralogy of Fallot, Eisenmenger's syndrome and the Fontan operation, pp. 306–312, Copyright (2010), with permission from Elsevier.

Further problems after repair include residual or recurrent right ventricular outflow obstruction, right ventricular dilatation, and residual VSD. Atrial and ventricular arrhythmias can also occur. Ventricular arrhythmias are the most common cause of sudden late cardiac death after repair of tetralogy of Fallot.[83]

### Pregnancy

Before the introduction of surgical repair, few patients with tetralogy of Fallot reached childbearing age and thus successful pregnancy was uncommon. The haemodynamic burden of pregnancy combined with residual cardiovascular lesions after repair result in a 7% reported incidence of complications. The most important is progressive dilatation of the right ventricle and ventricular failure, in some patients. The circulation should be reviewed with particular reference to severe right ventricular outflow tract obstruction, severe pulmonary regurgitation, and pre-existing right ventricular dysfunction.[84] Other complications include atrial and ventricular arrhythmias, thromboembolism, progressive aortic root dilatation, and endocarditis.[85] There is a 6% incidence of fetal congenital anomaly, including heart disease and pyloric stenosis. Intrauterine growth restriction and spontaneous fetal loss due to low maternal cardiac output may also occur.[86] Early admission to hospital for rest and control of associated complications should be discussed and a plan for delivery agreed and documented. Close follow-up, repeat echocardiography, and treatment of associated complications such as heart failure, arrhythmias, or deterioration of NYHA class is paramount. Preterm delivery should be considered if clinical right ventricular failure and decompensation occur.

### Labour and delivery

Vaginal delivery with epidural analgesia is becoming more common, with forceps or ventouse extraction to shorten the second stage. Low-dose epidural or CSE analgesia for labour works well and can avoid haemodynamic instability.[60] If caesarean delivery is planned, low-dose combined spinal with incremental epidural anaesthesia,[62] or incremental *de novo* epidural or incremental spinal catheter anaesthesia[64] are both suitable. If the regional technique fails or there is a life-threatening emergency, general anaesthesia may be necessary. Invasive blood pressure monitoring is useful, but central venous pressure monitoring should be considered carefully, as the information gained can be difficult to interpret and is not always needed. Prophylaxis against thromboembolism and bacterial endocarditis should be considered and postpartum high-dependency care is advised.

## Eisenmenger's syndrome

### Pathology

Victor Eisenmenger, an Austrian physician, first described this syndrome in 1897, but it was Paul Wood who named it after him and gave us our current understanding of the condition in 1958.[87] It is important as 5–10% of patients with congenital heart disease develop some degree of pulmonary arterial hypertension, which in turn affects functional class and survival prospects.[88]

In patients with intracardiac shunting (ASD or VSD), blood usually flows from left to right, as the pressure on the left side is approximately four times higher. When this shunting is prolonged, exposure of the pulmonary vasculature to systemic arterial pressure leads to progressive changes in the microvasculature causing increased pulmonary vascular resistance. A wide variety of mediators is released, resulting in vasoconstriction and vascular remodelling. The pressure in the pulmonary circulation rises and eventually equals, or, in certain circumstances, exceeds systemic pressures.[89] Figure 40.10 demonstrates that when the pressure on the right side of the heart has increased to equal systemic pressure, a significant amount of blood flows across the VSD from right to left. This dilutes well-oxygenated blood arriving from the lungs with deoxygenated blood, which has completely bypassed the lungs. In pulmonary hypertensive crisis, the pressure on the right side of the heart rises even higher, resulting in more deoxygenated blood entering the systemic circulation, worsening cyanosis (Figure 40.10).

When the shunt reverses from right to left, usually in teenage years or early adulthood, chronic cyanosis and secondary erythrocytosis develop. Some patients with Eisenmenger´s syndrome have minimal cyanosis at rest but desaturate profoundly with exercise. General symptoms are usually non-specific and may include breathlessness, fatigue, chest pain, and syncope.[90]

Cerebrovascular accidents result from low oxygen delivery to the tissues, paradoxical embolism, or cerebral abscess. Haemoptysis is also common and may be caused by pulmonary infarction or rupture of a pulmonary vessel, although this is not usually a terminal event. There is also a risk of hepatic and renal impairment and bacterial endocarditis. Arrhythmias are common and may lead to sudden cardiac death. Although exercise limitation and exertional dyspnoea may remain stable for years, poor exercise capacity identifies patients at risk of dying and in need of hospitalization. Congestive cardiac failure is a late ominous sign.[91,92]

### Management of Eisenmenger's syndrome

Eisenmenger's syndrome affects many systems and effective management spans a wide variety of treatments.[93–95] Ventricular failure

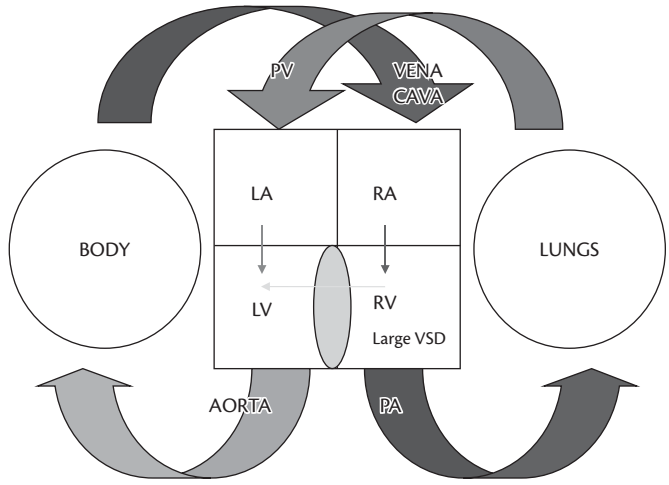

**Figure 40.10** (See colour figure section). Eisenmenger's circulation. The purple colour represents mixed oxygenated and de-oxygenated blood.
Reprinted from *International Journal of Obstetric Anesthesia*, Volume 19, edition 3, M.A. Naguib, D.P. Dob, M.A. Gatzoulis, A functional understanding of moderate to complex congenital heart disease and the impact of pregnancy. Part II: Tetralogy of Fallot, Eisenmenger's syndrome and the Fontan operation, pp. 306–312, Copyright (2010), with permission from Elsevier.

and associated arrhythmia must be treated promptly. Cyanosis leads to secondary erythrocytosis and blood viscosity increases.[96] As blood viscosity increases, flow and potentially oxygen transport may decrease, leading to symptoms of the 'hyperviscosity syndrome' (headache, loss of concentration, muscle weakness, and fatigue). There is increased risk of cerebrovascular accident[97] and myocardial ischaemia associated with hyperviscosity syndrome. It used to be routinely treated with venesection. However, repeated venesection although useful for primary erythrocytosis, has been shown to result in chronic iron deficiency, microcytosis, and increased whole-blood viscosity in congenital heart disease and so actually increases the risk of cerebrovascular accidents.[98]

Symptoms of iron deficiency are similar to those of hyperviscosity syndrome. In fact, the majority of patients with Eisenmenger's syndrome and chronic secondary erythrocytosis do not exhibit symptoms of overt hyperviscosity and do not require phlebotomies.[99] Iron deficiency should be treated with oral iron supplementation because anaemia limits exercise tolerance and increases the risk of stroke.[100,101] Large intrapulmonary thrombi, occurring in up to a quarter of patients with Eisenmenger's syndrome, may require anticoagulation. Conversely coagulation disorders may occur and must be corrected.

Over the last decade, there has been much interest in pulmonary vasodilators often referred to as pulmonary arterial hypertension-specific therapies. Prostacyclin, produced by vascular endothelium, is a short-acting vasodilator and an inhibitor of platelet aggregation. Prostacyclin analogues, such as epoprostenol, have been shown to improve functional residual capacity and oxygen saturation, and to reduce pulmonary vascular resistance providing both haemodynamic and symptomatic improvement. [102] Patients treated with epoprostenol for up to 3 years live longer than those receiving standard therapy.[103] Endothelins are powerful vasoconstrictors produced by vascular endothelium; competitive antagonists of endothelin-1, such as bosentan, are effective vasodilators. Sildenafil, a selective phosphodiesterase-5 inhibitor, results in increased nitric oxide levels and pulmonary vasodilatation.[104] Both these classes of drug have been used in the management of pulmonary hypertension in Eisenmenger's syndrome, and they are joined by ambrisentan and tadalafil.[105] In the acute situation, inhalation of nitric oxide itself may reduce total pulmonary vascular resistance in 30% of patients.

Heart and lung transplantation or lung transplantation with repair of the defect is the only surgical treatment.[106] However, it is a remote option only in highly selected patients, and there are currently major problems with shortage of donor organs. Currently, the results of the pulmonary arterial hypertension-specific therapies mentioned above have improved oxygenation and quality of life so much that the decision to offer heart transplantation to patients with Eisenmenger's syndrome is now even more challenging. Nevertheless, short-term survival for patients undergoing single or bilateral lung transplant is 70–80% at 1 year while long-term results are less favourable with only 50% surviving 4 years. Heart and lung transplant recipients have a 1-year survival of 60–80% and a 10-year survival less than 30%.[107,108] Life expectancy without transplantation in Eisenmenger's syndrome may be up to 20 years.[109]

## Pregnancy

Although maternal morbidity has decreased significantly over the past decade compared with previous decades, it still remains extremely high.[110] This change is due to the availability of pulmonary artery hypertension specific therapies mentioned previously. In the case of patients with pulmonary artery hypertension due to congenital heart disease, the mortality rate in a large British study was 28%[111] (from 36% in a previous study[112]), with the majority of deaths occurring within the first month after delivery due to right heart failure. In patients with pulmonary artery hypertension secondary to congenital heart disease, the systemic vasodilation induced by pregnancy together with the increase in cardiac output may enhance right-to-left shunting, exacerbating pre-existing hypoxia and leading to further pulmonary vasoconstriction. Additional stress occurring during labour and delivery, when hypercarbia and acidosis may lead to an acute increase in pulmonary hypertension, can also lead to refractory right heart failure, the main cause of postnatal death in women with pulmonary arterial hypertension due to congenital heart disease.

The spontaneous abortion rate is up to 40% and surviving infants suffer from intrauterine growth restriction.

Pregnancy prevention or early termination is the preferred measure for improving long-term survival. Combined oral contraceptives carry an increased risk of thrombosis while progesterone only contraceptives have a high failure rate. Laparoscopic sterilization carries the risk of general anaesthesia. Intrauterine coil and subdermal devices offer good safety and efficacy profiles and compare favourably with sterilization. Sterilization of the male partner may be an alternative.[113,114]

## Labour and delivery

For the patient who opts to continue pregnancy, coordination of a multidisciplinary team consisting of obstetrician, midwife, cardiologist, anaesthetist, intensive care physician, neonatologist, and social worker is essential. Antenatal counselling is very important and should be carried out in a multidisciplinary forum. Accurate records are necessary, because discussions, particularly those involving mortality, are often forgotten in the aftermath of subsequent events. Early detection and treatment of pregnancy-induced complications is important. The most common is ventricular failure.[115] Patients are usually admitted to the hospital early in the third trimester for bed rest and supplemental oxygen. The use of anticoagulation is controversial, but should be considered on an individual basis.

The pulmonary vasodilators mentioned earlier may be used, with the exception of endothelin antagonists, which are contraindicated in pregnancy because of concerns about teratogenicity. Inhaled nitric oxide may be useful, particularly during the peripartum period.

To allow a planned delivery, most patients with Eisenmenger's syndrome are delivered by elective caesarean delivery, frequently between 30 and 34 weeks, when the infant is viable and before major maternal decompensation ensues. *De novo* incremental epidural, low-dose sequential CSE,[62,116] or incremental spinal anaesthesia[64] are useful, as both allow slow titration of block height with minimal effects on the peripheral circulation, sometimes without the need for vasoconstrictors. Care must be taken not to reduce the systemic vascular resistance too much with the neuraxial technique such that the shunt from right to left worsens. Fluid balance must be meticulous to prevent excessive fluid overload or hypovolaemia both of which will affect shunting. If general anaesthesia is used, transoesophageal echocardiography

and invasive monitoring are easier to perform. High-dose opioids may be used to obtund the stress response to tracheal intubation.

Prophylaxis against deep venous thrombosis and infective endocarditis are imperative.[117] All mothers with Eisenmenger's syndrome should be cared for in a high dependency or intensive care unit for at least 48 hours, and close monitoring for 7–10 days is recommended

## Fontan procedure

### Pathology

First described in 1971 by Francis Fontan for the treatment of tricuspid atresia,[118] the Fontan procedure is now used in the treatment of most congenital heart defects which feature a single functional ventricle, a configuration that cannot be refashioned into a biventricular circulation.[119] Figure 40.11 shows the circulation of a patient with tricuspid atresia and a functional single ventricle.

The Fontan procedure separates pulmonary and systemic circulations, therefore normalizing the oxygen content of systemic blood. It involves either a direct connection between the systemic venous return and the pulmonary artery (the total cavopulmonary connection (TCPC)) or via the right atrium (atriopulmonary connection or classic Fontan circulation), bypassing the right ventricle.[120] This has the advantage that deoxygenated blood is oxygenated in the lungs and does not mix with deoxygenated systemic venous return in the single ventricle. Because the right ventricle is hypoplastic and, after the Fontan procedure, disconnected from the lungs, pulmonary flow must come from the remaining kinetic energy of the systemic circulation driven by the single ventricle. Therefore high venous pressures are usually required. The two circulations are separated and systemic oxygen saturation is high, while the single ventricle (left and hypoplastic right together) promotes flow only through the aorta (Figure 40.12).

Early versions of the Fontan procedure involved connecting the right atrium directly to the pulmonary artery with a valved conduit. This was called the atriopulmonary Fontan or classic Fontan procedure. Unfortunately, with time these versions resulted in sluggish, turbulent, and diminished blood flow through the lungs. Furthermore the relatively underdeveloped pulmonary vasculature was not ready to accept the venous blood flow, and back pressure on the venous system inevitably built up. This caused multiple complications such as right atrial dilatation, pleural effusions, ascites, liver venous engorgement, cirrhosis, and protein-losing enteropathy.

Marc de Leval developed the concept of the modern TCPC.[121] This is now completed in stages to avoid overburdening the developing pulmonary circulation.

After palliation such as a modified Blalock–Taussig [122] shunt to increase pulmonary blood flow, the first stage is to perform a bi-directional Glenn shunt operation.[123] This involves transecting the superior vena cava from the right atrium and connecting it to the right pulmonary artery. In this operation the venous blood from the upper body, head, and neck, flows passively through the lungs via the right and left pulmonary arteries (bi-directional), becoming oxygenated and returning to the left atrium. The inferior vena cava is still connected to the right atrium and so deoxygenated blood from the lower body still mixes in the single ventricle with the oxygenated blood from the lungs. The blood pumped out has an overall oxygen saturation of about 85–90%. This is an improvement on the previous oxygen saturation of about 80%, and allows the pulmonary blood vessels to accommodate a higher blood flow than before. The final stage of the procedure is to complete the TCPC. This involves transecting

the inferior vena cava, and connecting it to the pulmonary artery. This means that oxygenated and deoxygenated blood are completely separated, and arterial oxygen saturations reach 94–100%. The completely oxygenated blood is pumped out of the aorta by the single ventricle. It delivers oxygen to the body and then returns via the superior and inferior venae cavae directly to the pulmonary artery through the lungs, using the remaining kinetic energy of the single ventricle pump.

To overcome the problems of turbulent flow, the inferior vena cava is transected and connected to a conduit or 'tunnel' which takes blood through to the pulmonary artery, without eddying through the atrium. This allows smooth laminar blood flow.

In the early period after this operation, the problem of high venous back pressure can still occur. It is possible to make a small hole or 'fenestration' in the tunnel. If pulmonary venous pressure rises, then deoxygenated blood can vent out of the tunnel into the right atrium. This stops the venous pressure rising too high, at the expense of deoxygenated blood shunting through to the single ventricle. Although this slightly reduces systemic arterial saturation, it is worth it to allow the pulmonary vasculature time to recover from bypass surgery. At a later age it is possible to close the fenestration, usually with a catheter technique. In more recent times, the tunnel has been placed outside the right atrium forming an extracardiac conduit, with a small fenestration connected to the atrium.

In children with slightly better developed right ventricular morphology, the 'one-and-a-half ventricle' approach can be used. In this operation, the pulmonary trunk is not transected and the right ventricle is sealed up and allowed to pump blood from the inferior vena cava through the lungs, while the superior vena cava deoxygenated blood goes directly to the lungs through the bi-directional Glenn shunt. Long-term results are good and these patients may avoid the cyanosis and other venous back-pressure problems seen with the TCPC, because the small right ventricle provides some useful kinetic energy for the pulmonary blood flow.[124] Figure 40.13 shows a TCPC which is the modern version of the older atriopulmonary connection or classic Fontan procedure. The superior vena cava is transected and the top part connected to the right pulmonary artery. Subsequently, the inferior vena cava is connected to the underside of the pulmonary artery confluence either with an intra-atrial baffle or more recently with an extracardiac conduit. The proximal pulmonary artery is then transected and sewn up. All the systemic venous blood is thus directed to the lungs and all the oxygenated blood from the lungs travels through the pulmonary veins to the left atrium and into the single ventricle, then to the aorta (as there is no connection of the ventricle with the transected pulmonary artery). This oxygenated blood supplies the systemic circulation and is returned via the venae cavae to repeat the cycle.

The great advantage of the Fontan procedure that the oxygenated and deoxygenated blood are completely separated comes at a price; there is sluggish blood flow through the lungs, driven only by the remaining kinetic energy of the single ventricle pumping blood round the entire circuit. Venous return and pulmonary flow are particularly vulnerable to any extrinsic compression of the veins, for example, by positive pressure pulmonary ventilation, aortocaval compression, or pneumoperitoneum for laparoscopy.[125]

Survival following the Fontan operation is 85–98% at 1 month, 97% at 1 year, 94% at 5 years, and 90% at 10 years.[126–129]

## Complications of a fontan circulation

Complications after the Fontan procedure are common and relate to increased venous pressure congestion and low cardiac output.[130,131] Exercise tolerance is reduced mainly due to impaired

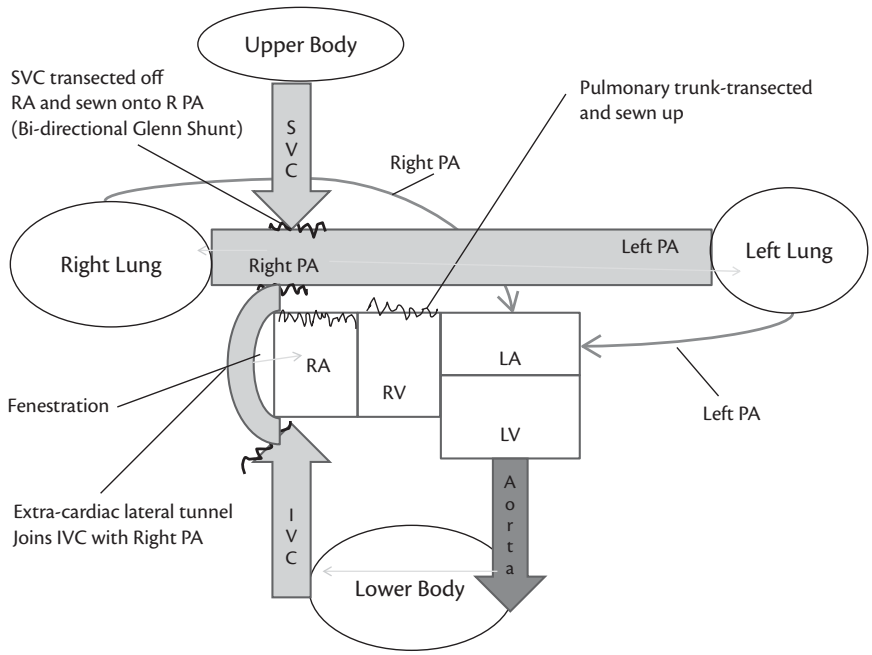

**Figure 40.13** (See colour figure section). Total cavopulmonary connection (TCPC) in detail with extracardiac lateral tunnel and fenestration (the modern Fontan). The superior vena cava is transected and connected to the right pulmonary artery. This is known as a bi-directional Glenn shunt and is usually the first part of the palliation. Subsequently, the inferior vena cava is transected and connected to the underside of the pulmonary artery confluence with an extracardiac conduit. The proximal pulmonary trunk is then transected and sewn up.

ventricular function and difficulty in increasing preload. The common ventricle can become dilated, hypertrophic, and hypocontractile. This is caused by the congenital malformation itself, previous surgery, or the very abnormal working conditions at the various stages of palliation before and after a Fontan operation. Low to moderate exercise training may improve cardiopulmonary fitness and should be preceded by exercise testing with electrocardiography.[132] Unfortunately atrial arrhythmias occur in up to 45% of patients and are due to incorporation of the atrial wall in the repair, causing atrial dilatation and hypertrophy. The sinoatrial node, its arterial supply, or its innervations may also be injured at the time of Fontan surgery.

Protein-losing enteropathy secondary to increased venous pressure is a serious complication of Fontan surgery occurring in 3–13% of late survivors. Protein loss results in hypoalbuminaemia and clinical features of oedema, pleural effusion, ascites, immunodeficiency, and hypocalcaemia.[133,134] Treatment includes a low-salt, high-calorie, high-protein diet with medium-chain triglyceride supplements, diuretics, steroids, heparin, protein infusions, and octreotide (synthetic somatostatin).

Thromboembolic complications have a major impact on long-term prognosis. There is also evidence to suggest an increased risk of intracardiac thrombus formation in patients with the Fontan circulation, which is associated with an increased risk of systemic thromboembolism, not necessarily eradicated by warfarin or aspirin therapy.[135]

### Pregnancy

Modified Fontan procedures have improved the long-term survival of patients with single-ventricle physiology, who are now reaching childbearing age. The combination of chronic hypoxaemia before palliation and chronic venous congestion afterwards may influence ovarian function resulting in menstrual cycle disorders and infertility.[136] For those who do become pregnant the most common obstetric complications are preterm rupture of membranes, and premature delivery between 26 and 33 weeks. There is a significant risk of neonatal death and postpartum haemorrhage. Arrhythmias, most commonly supraventricular, complicate at least 26% of pregnancies mostly in those with atriopulmonary connection (the older type of Fontan operation.)[137]

### Labour and delivery

It is important to avoid dehydration, which may reduce central venous pressure and blood flow through the cavopulmonary connection to the lungs. Avoidance of aortocaval compression by the gravid uterus and thromboprophylaxis are equally important. Since negative intrathoracic pressure helps draw venous return around the pulmonary circulation, it is important to avoid positive pressure ventilation, which will decrease pulmonary blood flow and thus cardiac output. The use of low-dose epidural analgesia or sequential low-dose CSE anaesthesia is preferred to general anaesthesia.

Any form of pneumoperitoneum for laparoscopic procedures will decrease venous return and should be avoided.

## Left ventricular outflow tract disorders

Obstructive lesions of the left ventricular outflow tract can occur at three different levels. The aortic stenosis may be subvalvular, valvular, or supravalvular aortic stenosis. Subvalvular and valvular aortic stenosis are more commonly found in males than females. In fact, valvular congenital bicuspid aortic stenosis is four times less common in women than men.

Many women with aortic stenosis will have had a repair during childhood. This is commonly done by the Ross procedure.[138] The stenotic aortic valve is removed and replaced by the native pulmonary valve, with the allograft valve taking the place of the pulmonary valve. This puts the allograft under less pressure.[139,140]

Pregnancy is usually well tolerated in women with isolated mild to moderate aortic obstruction and good left ventricular function. However, women with severe aortic stenosis may be at risk from 20 weeks of gestation onwards as cardiac output has increased by as much as 50%, and this increase must be sustained for a further 18–20 weeks if possible. Women who are pregnant with severe aortic stenosis are at risk of angina, left ventricular failure, and pulmonary oedema as well as sudden death.

It is possible that these symptoms occur for the first time in pregnancy, and management of severe congenital aortic stenosis will depend on the individual mother's needs and her gestation. In pregnancy, because of increased cardiac output, transvalvular pressure gradients measured by echocardiography are not as useful as valve area measurements. Mild aortic stenosis has a valve area of more than 1.5 $cm^2$, moderate 0.8–1.5 $cm^2$, and severe aortic stenosis a valve area of less than 0.7 $cm^2$. Severe aortic stenosis gives a transvalvular pressure gradient of more than 50 mmHg in the non-pregnant state and more than 80 mmHg in pregnancy. If the gradient falls without treatment this may indicate left ventricular failure and prompt immediate action.[60]

Medical treatment is aimed at reducing heart rate to allow better ventricular ejection and coronary filling. Beta blockers may be used in conjunction with bed rest and oxygen therapy to allow the fetus to grow.

If the mother's condition deteriorates and the fetus is not mature enough for delivery, aortic valve balloon dilatation can be considered. It does, however, carry the risk of severe aortic regurgitation, embolism, and cardiac tamponade. Nevertheless, in severe aortic stenosis it may be used as a bridging device to prolong the pregnancy and mature the fetus to a stage where it can be delivered and a definitive aortic valve replacement performed.[141]

Cardiopulmonary bypass during pregnancy carries a high risk of death to both mother (15%) and fetus (19–33%), so definitive aortic valve replacement during pregnancy should only be undertaken in the most exceptional circumstances. Heparinization for cardiopulmonary bypass also carries the risk of placental bleeding.

If, however, the fetus is viable, it can be delivered by caesarean delivery and then aortic valve replacement carried out under cardiopulmonary bypass after delivery, usually with the same general anaesthetic.

Beating heart aortic valve replacement and catheter aortic valve replacement are alternative strategies for these mothers.

## Conclusion

Women with moderate to severe congenital heart disease are now presenting to maternity services with increasing frequency; they pose additional risks to themselves and their offspring during pregnancy and the peripartum period. Better awareness of underlying anatomy, physiology, and common complications together with a multidisciplinary approach including expertise in obstetric

anaesthesia can improve the chances of safe delivery for both mother and baby and allow this growing patient population to reach their full life potential.[142]

## Acknowledgements

We would like to acknowledge the clinical contributions of our colleagues at Chelsea and Westminster Hospital and the Royal Brompton Hospital, London, particularly Dr M.A. Naguib in Rotorua, New Zealand, and the teamwork which makes it possible to look after this challenging, but rewarding, population of patients.

# CHAPTER 41

# Acquired heart disease

Linzi Peacock and Rachel Hignett

## Introduction

In the United Kingdom, recent maternal mortality reports highlight cardiac disease as the leading cause of maternal death.[1,2] (see Table 37.1 in Chapter 37). Similarly, the Centers for Disease Control and Prevention (CDC) report cardiovascular diseases as the commonest cause of maternal death for 2006–2009 in the United States.[3] The European Registry on Pregnancy and Heart Disease (ERPHD) has recently published mortality rates of 1%, over 100 times the background rate of death, for women with structural heart disease (congenital, ischaemic, cardiomyopathy, and valvular).[4] Morbidity is also increased in women with cardiovascular disease which causes 3.3% of severe maternal morbidity.[5]

Heart disease affects approximately 1% of pregnant women in the United Kingdom.[6] Although congenital heart disease (CHD) accounts for 75–82% of heart disease in pregnancy in the Western world, numbers of women dying from CHD form the minority.[1,2] The majority of cardiac deaths are due to acquired heart disease (AHD) which is increasing due to factors such as obesity, older maternal age, hypertensive disease, and diabetes mellitus becoming more prevalent in the female reproductive population.[7] Table 41.1 shows the rise in cardiac deaths over the triennia in the United Kingdom from 1994 to 2008. Women with CHD are usually diagnosed prior to pregnancy enabling them to have counselling and optimization of treatment before conception. In contrast, many women with AHD present for the first time during pregnancy.

In the 'Saving Mothers Lives' report 2006–2008,[2] 53 women died of heart disease which was associated with or worsened by pregnancy. Of these 53 deaths, 50 were in women with acquired cardiac disease. A further eight deaths which occurred in women with cardiac disease were classified as *late* deaths. The leading causes of cardiac death were sudden adult death syndrome (SADS), myocardial infarction (MI), mostly as a consequence of ischaemic heart disease (IHD), dissection of the thoracic aorta, and cardiomyopathy (Table 41.1). Worldwide, the ERPHD demonstrated the highest rates of maternal mortality in patients with cardiomyopathy.[4] In 'Saving Mothers Lives' 2006–2008, there were no deaths attributable to rheumatic heart disease (RHD). This is in stark contrast to resource-limited countries which have a significant disease burden in pregnancy due to RHD.

In addition to maternal and neonatal morbidity and mortality, there are many other factors which need to be taken into consideration in a woman known to have cardiac disease either prior to or during pregnancy. Pregnancy may accelerate disease progression in the mother, and may alter her life expectancy after pregnancy. The baby may be at risk of being born with cardiac defects. Drug regimens will need to be monitored and adjusted to avoid teratogenicity, and to accommodate the physiological changes encountered in pregnancy. Finally, invasive therapeutic and investigative procedures may need to be undertaken antenatally.

Early identification of heart disease in pregnancy will enable prompt referral to a specialist multidisciplinary team consisting of cardiologists with expertise in cardiac disease in pregnancy, obstetricians, and obstetric anaesthetists. This team will stratify risk, and will plan antenatal, intrapartum, and postnatal care accordingly.

This chapter will focus on the general principles of management of women with AHD in pregnancy, and will look in detail at IHD, arrhythmias, cardiac transplantation, aortic pathology, cardiomyopathies, valvular heart disease, and infective endocarditis (IE).

## General principles

### Risk assessment

All patients with known cardiac disease should have pre-pregnancy counselling undertaken by a cardiologist with an interest in pregnancy or by an obstetric physician. This advice should commence in adolescence for those with CHD and at the time of diagnosis for women with acquired cardiac disease.

The 2006–2008 triennial report[2] states that *all* women who died from MI and IHD had identifiable risk factors for IHD, and 60% of all the cardiac deaths occurred in women who were classified as overweight or obese. This has led to the recommendation that women with risk factors for IHD (i.e. diabetes, hypertension, obesity, a family history of IHD, and > 35 years old) should receive pre-pregnancy counselling.[8] Women should also be assessed for risk factors for IHD at booking of antenatal care. These recommendations were made in the 2003–2005 Confidential Enquiries report and were re-iterated in the 2006–2008 Confidential Enquiries report as lessons have not yet been learnt.[2,8]

The European Society of Cardiology (ESC) has produced comprehensive guidelines for the management of women with cardiac disease in pregnancy.[9] These guidelines include the modified World Health Organization (WHO) classification of maternal cardiovascular risk (Table 41.2). This classification is applicable to women with both CHD and AHD. It is based on the New York Heart Association (NYHA) classification (Box 41.1) of diagnosis and disease severity. In 2013, the ERPHD demonstrated a strong correlation between WHO risk classification and cardiac,

**Table 41.1** Causes of maternal death from heart disease in the United Kingdom from 1994 to 2008

| Type and cause of death | 1994–96 | 1997–99 | 2000–02 | 2003–05 | 2006–08 |
|---|---|---|---|---|---|
| *Acquired* | | | | | |
| Aortic dissection | 7 | 5 | 7 | 9 | 7 |
| Myocardial infarction (MI) | 6 | 5 | 8 | 12 | 6 |

| Total | 39 | 35 | 44 | 48[c] | 53 |

[a]Twelve late deaths reported in 2003–2005.

[b]Two late deaths reported in 2006–2008.

[c]Includes one woman for whom information or cause was not available.

Reproduced from Confidential Enquiry on Maternal and Child Health, Saving mothers iives: reviewing maternal deaths to make motherhood safer 2006–2008, *BJOG: An International Journal of Obstetrics and Gynaecology*, 118, pp. 1–203, Copyright 2011, with permission from Centre for Maternal and Child Enquiries (CMACE), BJOG, and Wiley.

obstetric, and fetal outcome in its series of 1321 consecutive pregnancies from mainly developed nations.[4] The ESC recommends that all women with cardiac disease are risk assessed against the modified WHO criteria (Table 41.2 and Table 41.3).

**Box 41.1** New York Heart Association Classification of Heart Disease

- NYHA class I No limitation to physical activity
- NYHA class II Slight limitation to physical activity
- NYHA class III Marked limitation to physical activity
- NYHA class IV Symptoms at rest

Reprinted from *The Journal of Heart and Lung Transplantation*, 28, 6, Stevenson LW, Pagani FD, Young JB, Jessup M, Miller L, Kormos RL, Naftel DC, Ulisney K, Desvigne-Nickens P, Kirklin JK, INTERMACS profiles of advanced heart failure: the current picture, pp. 535–541, Copyright (2009) with permission from Elsevier.

Women will have their antenatal care planned based on this assessment of risk (Table 41.3). Women with class 1 disease are usually treated as low-risk peripartum. It is recommended that women with class 2 disease should be referred to a multidisciplinary team consisting of cardiologists, obstetricians, and obstetric anaesthetists and should be seen each trimester. Class 3 and 4 disease require much closer surveillance, with assessment and management by the multidisciplinary team every 2–4 weeks.

The Royal College of Obstetricians and Gynaecologists (RCOG)[10] recommend that a formalized multidisciplinary care plan is agreed at 32–34 weeks of gestation (Figure 41.1). This should include consideration of mode of delivery, plan for optimal pain relief in labour, mechanisms to avoid and treat atonic postpartum haemorrhage (including safe drug regimens), postpartum care, thromboprophylaxis, and personnel named to oversee labour and delivery.

## Physiological changes in pregnancy

Major cardiovascular system (CVS) physiological changes begin to occur from the earliest stages of pregnancy.[11]

- Cardiac output (CO) increases by 30–50% by the end of the second trimester to accommodate the rapidly growing fetoplacental unit. This is achieved by an increase in stroke volume (SV), and to a lesser extent due to some increase in heart rate (HR) later in pregnancy.
- Blood volume will also increase significantly by 50–70% by the end of the second trimester. Red cell mass increases by up to 40%: as the increase in plasma volume is proportionately greater, red cell concentration is diluted which commonly results in physiological anaemia.
- Systemic vascular resistance (SVR) and blood pressure (BP) fall, due to maturation of placental development and circulating vasodilators, to a nadir between the 20th and 32nd week. SVR and BP rise again to early pregnancy levels at term.
- Inferior vena caval compression by the gravid uterus causes a positional reduction in CO from the middle of pregnancy.
- Pregnancy is a hypercoagulable state.
- Drug metabolism may be altered in pregnancy which may require alteration of dose or drug regimen.

Most healthy women are able to adapt easily to these physiological changes, but women with significant heart disease may develop

**Table 41.2** Modified WHO classification of maternal cardiovascular risk: application

| WHO classification of maternal cardiovascular risk |
|---|
| *WHO I* |
| ◆ Uncomplicated, small or mild<br>• pulmonary stenosis<br>• patent ductus arteriosus<br>• mitral valve prolapse |
| ◆ Successfully repaired simple lesions (atrial or ventricular septal defect, patent ductus arteriosus, anomalous pulmonary venous drainage) |
| ◆ Atrial or ventricular ectopic beats, isolated |
| *WHO II conditions* (if otherwise well and uncomplicated) |
| ◆ Unoperated atrial or ventricular septal defect |
| ◆ Repaired tetralogy of Fallot |
| ◆ Most arrhythmias |
| *WHO II–III* (depending on individual) |
| ◆ Mild left ventricular impairment |
| ◆ Hypertrophic cardiomyopathy |
| ◆ Native or tissue valvular heart disease not considered WHO I or IV |
| ◆ Marfan syndrome without aortic dilatation<br>◆ Aorta < 45 mm in aortic disease associated with bicuspid aortic valve |
| ◆ Repaired coarctation |
| *WHO III* |
| ◆ Mechanical valve |
| ◆ Systemic right ventricle |
| ◆ Fontan circulation |
| ◆ Cyanotic heart disease (unrepaired) |
| ◆ Other complex congenital heart disease |
| ◆ Aortic dilatation 40–45 mm in Marfan syndrome<br>◆ Aortic dilatation 45–50 mm in aortic disease associated with bicuspid aortic valve |
| *WHO IV* (pregnancy contraindicated) |
| ◆ Pulmonary arterial hypertension of any cause |
| ◆ Severe systemic ventricular dysfunction (LVEF < 30%, NYHA III–IV) |
| ◆ Previous peripartum cardiomyopathy with any residual impairment of left ventricular function |
| ◆ Severe mitral stenosis, severe symptomatic aortic stenosis |
| ◆ Marfan syndrome with aorta dilated > 45 mm<br>◆ Aortic dilatation > 50 mm in aortic disease associated with bicuspid aortic valve |
| ◆ Native severe coarctation |

**Table 41.3** Modified WHO classification of maternal cardiovascular risk: principles

| Risk class | Risk of pregnancy by medical condition |
|---|---|
| I | No detectable increased risk of maternal mortality and no/mild increase in morbidity |
| II | Small increased risk of maternal mortality or moderate increase in morbidity |
| III | Significantly increased risk of maternal mortality or severe morbidity. Expert counselling required. If pregnancy is decided upon, intensive specialist cardiac and obstetric monitoring needed throughout pregnancy, childbirth and the puerperium. |
| IV | Extremely high risk of maternal mortality or severe morbidity; pregnancy contraindicated. If pregnancy occurs termination should be discussed. If pregnancy continues, are as for class III. |

new symptoms or worsening of pre-existing symptoms as they struggle to adapt cardiovascularly. Further dramatic physiological changes occur in labour and during delivery which may cause or worsen cardiac decompensation.[11] CO increases by 10% in labour due to autotransfusion of up to 500 mL blood with each contraction, and catecholamine release due to pain. Further increases in CO are seen in the second stage: in addition to autotransfusion and catecholamine release, pushing by the mother contributes to a further increase in CO. CO peaks by up to 80% immediately after delivery due to autotransfusion and sudden relief of aortocaval compression. CO falls to pre-labour levels 1 hour after delivery. Cardiovascular physiology does not return fully to prepregnancy levels until 3–6 months postpartum.

## Cardiovascular investigations in pregnancy

### Electrocardiogram

Twelve-lead electrocardiograms (ECG) are usually normal, but may differ from the non-pregnant ECG due to the effect of the gravid uterus on heart position:

- Up to 15° left axis deviation
- Non-specific ST-segment and T-wave changes
- Relative tachycardia
- Left ventricular (LV) hypertrophy
- Q wave and inverted T wave in lead III
- Attenuated Q wave in AVF
- Supraventricular and ventricular ectopic beats.

### Exercise testing

Exercise testing provides an objective measurement of functional capacity as well as assisting in the diagnosis of IHD and exercise-induced arrhythmias. Unlike some more invasive tests, there is no radiation exposure, but there is an increased false-positive rate in non-pregnant women.[11] Exercise testing is recommended prior to pregnancy in women with known heart

| Cardiac diagnosis | …….. | Please circle agreed plan |

| | Contraceptive plans discussed **Yes / No** | |

Please inform the consultant obstetrician on call if there is departure from planned management or if unexpected clinical situations develop in women with cardiac disease.

**Figure 41.1** Clinical management plan for delivery.
Reproduced with kind permission from Ms Gubby Aiyida, FRCOG, Chelsea and Westminster Hospital, London.

| Examples of clinical situations | Consider the following: |
|---|---|
| Spontaneous labour and recent thromboprophylaxis use (e.g. LMWH/warfarin) | Inform anaesthetist asap |
| | D/W consultant anaesthetist on call |
| An epidural can be given more than 12 hours after prophylactic dose or more than 24 hours after therapeutic dose, or earlier at the discretion of the anaesthetist | For additional advice, contact ……. |
| | …….. |
| | via switchboard, or obstetricians listed overleaf |
| Need for syntocinon augmentation in labour | Use double-strength syntocinon but halve rate to reduce total volume of fluids given (this decision needs to be taken at consultant level) |
| Syntocinon as prophylaxis against postpartum haemorrhage | Low-dose infusion (12 mU/minute): use either 5 i.u. in 50 ml at 7 ml per hour or 10 i.u. in 500 ml at 36 ml per hour Continue for 4 hours (longer if concerns) |
| Postpartum haemorrhage | Inform anaesthetic and obstetric consultants on call |
| | For uterotonic, misoprostol 600 micrograms rectally is preferred, but monitor for hyperpyrexia |
| | Avoid hemabate or high-dose syntocinon |
| | Consider use of compression suture |
| | Consider use of intrauterine balloon (antibiotic cover is recommended) |
| | Strict input/output charts to be maintained |
| | Consider central access or arterial monitoring |
| Preterm labour | Atosiban (tractocile) is the first-line Mx Do not use ritodrine or salbutamol |
| Pacemaker | Do not use unipolar diathermy Beware pacemaker in unusual places (e.g. abdominal wall) when performing caesarean section |
| | De-activate implantable defibrillators |

Please seek advice from a consultant if there are concerns or if clarification is required on clinical management.
*The RCOG is grateful to Ms Gubby Ayida FRCOG (Chelsea and Westminster Hospital) for permission to use this clinical management plan.*

**Figure 41.1** Continued

disease as it can aid risk assessment.[9] The ESC Task Force recommends performing submaximal tests to reach 80% of the predicted maximal HR in asymptomatic pregnant patients with suspected coronary vessel disease.

### Echocardiography

Due to the hyperdynamic circulation in pregnancy, echocardiograms should be interpreted by cardiologists with expertise in caring for women with cardiac disease in pregnancy. Confusion may arise, for example, where cardiac impairment is not appreciated due to an apparently normal ventricular cardiac function (which should be hyperdynamic). Stenotic valve lesion severity may also be misinterpreted: increased velocity due to higher CO in pregnancy will increase peak gradients across valves.

## Cardiac interventions in pregnancy

Interventions maybe required in pregnancy for diagnosis and treatment of disease. Cardiac catheterization for diagnosis of coronary artery disease is safest if performed in the second trimester. By this time, organogenesis is complete and the fetal thyroid is inactive. Fetal irradiation can be minimized by shielding the abdomen, by using the brachial artery or radial artery approach and by limiting duration of fluoroscopy.[12]

Cardiac surgery is very rarely performed during pregnancy, and is a last resort after other modes of management have failed. Cardiac surgery during pregnancy carries mortality rates of 6%. This is comparable to non-pregnant women undergoing similar procedures.[13,14] Fetal mortality is very considerable with rates of 20–30%,[14–16] and survivors have significant late neurological morbidity in childhood principally as a result of preterm delivery.[9,12] Maternal risk is higher if surgery is emergent, if the mother has significant co-morbidities, and if surgery is for aortic dissection and pulmonary embolectomy (compared with a lower risk for valvular surgery). Surgery at delivery and postnatally is known to substantially increase maternal risk.[17]

The optimum timing of cardiac surgery for the fetus is in the second trimester.[9] If surgery is planned after 28 weeks the fetus is usually delivered by caesarean delivery (CD) immediately prior to cardiac surgery. Between 24 and 28 weeks of gestation, cases are risk assessed on an individual basis. Risk to the baby may be reduced by giving steroids prior to surgery for fetal lung maturation, monitoring of uterine contractions and fetal HR if possible, use of prophylactic tocolytics, and employment of high-flow, high-pressure, pulsatile, normothermic cardiopulmonary bypass.[17]

## Aims of intrapartum care

After monitoring and optimization of disease in pregnancy, the multidisciplinary team should formalize a plan for mode of delivery.

Fundamentals of intrapartum care in women with cardiac disease include:

1. Minimization of cardiorespiratory stress. In general, a vaginal delivery with incremental epidural analgesia and assisted second stage (i.e. delivery by low cavity forceps or ventouse) will be advised. Assisted second stage will reduce the cardiorespiratory stress in the mother associated with pushing. Effective incremental epidural analgesia will minimize catecholamine release due to the pain of labour. Planned CD is usually reserved for those with obstetric indications or very severe disease. These include severe aortic stenosis, severe pulmonary hypertension, intractable heart failure, acute or chronic aortic dissection, and a significantly dilated aortic root where the physiological stress of a vaginal birth would be very high risk. Advantages of a vaginal delivery compared with CD include a reduction in blood loss, reduced risk of infection, reduction in pulmonary complications, lower risk of venous thromboembolic complications, and reduced stress response.
2. Avoidance of aortocaval compression.
3. Optimization of fluid balance.
4. Use of invasive monitoring in those with significant disease. Invasive arterial BP monitoring prior to epidural insertion, neuraxial anaesthesia (NA) or general anaesthesia (GA) will enable rapid detection of cardiovascular instability in those women with WHO class 2 to 4 disease.
5. Provision of aspiration prophylaxis.

## Anaesthesia for caesarean delivery

Underlying disease and disease severity, preference of the anaesthetist, and choice of the mother will influence mode of anaesthesia, and use of invasive monitoring.

Over recent years, NA has been increasingly advocated for use in women with cardiac disease.[18] Compared with GA, NA is associated with less blood loss, avoids the CVS response to intubation, and avoids the cardiac depressant and vasodilating effects of GA agents. In a study published in 2003[19] of 125 voluntary reports of women with heart disease in pregnancy, 38% of emergency CD and 62% of elective CD were performed using NA. In addition to the usual considerations of use of NA in pregnancy, it is particularly desirable to use a technique which allows for titration of anaesthesia and therefore optimization and stability of haemodynamics in women with heart disease. The most familiar options are:

- Slow epidural top-up
- Combined spinal–epidural (CSE) with a low-dose spinal component for haemodynamic stability[20]
- Continuous spinal anaesthesia technique[21] via a spinal catheter is used in some centres, but this is an unfamiliar technique to most anaesthetists and has been associated with a high incidence of postdural puncture headache.

Whichever NA technique is used care should be taken to:

- Induce anaesthesia slowly to minimize haemodynamic instability
- Control hypotension due to vasodilatation. Phenylephrine is useful in stenotic valve lesions as tachycardia is avoided; ephedrine is useful in regurgitant lesions where a relative tachycardia is beneficial
- Carefully control fluid balance.

Where GA is the preferred technique, CVS stability can be achieved by using a 'cardiac' type GA:

- Hypertensive response to intubation should be obtunded, for example, by the use of 1–2 mg of intravenous alfentanil, or 0.5 mcg/kg intravenous remifentanil.
- Induction agent carefully titrated.
- Avoidance of tachycardia (which will increase myocardial work) and large swings in BP.
- Transoesophageal echocardiography (TOE), if available, is very useful in giving accurate information about ventricular filling and ventricular function. However, this requires the patient to be anaesthetized.
- Analgesia should be optimized to reduce circulating catecholamines. Epidural analgesia may be advantageous in reducing cardiac preload and afterload. Alternatively intravenous opiates and transversus abdominis plane (TAP) blocks may be used.

Invasive monitoring is beneficial in moderate- or high-risk cases: most commonly invasive arterial blood pressure (IABP) monitoring. Central venous pressure (CVP) monitoring may also be required, for example, where inotropic support is anticipated. There are some caveats for the use of CVP monitoring in pregnant women both with and without cardiac disease:

- CVP measurement may be an unreliable guide as to the fluid status of the patient especially in women with pregnancy-induced hypertension.
- Central venous catheter (CVC) tip may not lie in the desired position in the superior vena cava due to anatomical abnormalities or variations.
- Right-sided heart pressures may not accurately reflect left-sided pressures depending on the underlying disease.
- CVC tip may precipitate dangerous arrhythmias.

## Drugs used in the management of atonic postpartum haemorrhage

Standard drugs used in the management of atonic postpartum haemorrhage have profound CVS effects:

- Syntocinon® causes a sudden fall in SVR and causes a compensatory tachycardia and increase in CO. In women with significant heart disease, 2–5 IU should be given by infusion over 15–30 minutes to minimize these CVS effects.

- Ergometrine: smooth muscle contraction causes vasoconstriction and hypertension. Contraindicated in women with significant heart disease.
- Carboprost: causes smooth muscle contraction leading to pulmonary hypertension, bronchospasm, shunting, hypoxaemia, hypertension, and pulmonary oedema. Generally contraindicated in women with significant heart disease.
- Misoprostol: may cause pyrexia and shivering. Can be used in heart disease but some concern if pyrexia and shivering occur because of increased $O_2$ consumption.

Where drug therapies are limited due to significant heart disease, early recourse to surgical interventions such as B-Lynch uterine compression sutures, Bakri/Rusch uterine tamponade balloons should be used. (See Chapter 35 for more details of these techniques.)

### Postnatal care

Women with moderate- or high-risk disease should be cared for on a high dependency unit (HDU) for 24–48 hours after delivery. HDU care will enable more frequent observation of vital signs, use of invasive monitoring, and optimization of analgesia. The majority of deaths in women with cardiac disease occur postnatally due to lapses in the intensity of monitoring, fluid shifts which may precipitate cardiac failure, and poor analgesia which results in catecholamine surges.

## Ischaemic heart disease

### Epidemiology

IHD is rare in women of childbearing age.[22] The incidence of acute MI in pregnancy has been estimated at 1.3–6.7/100,000 births in population-based studies[23–25] although a recent UK Obstetric Surveillance System (UKOSS) study reported a lower incidence of only 0.7 cases/100,000 maternities.[26]

MI is a rare event in pregnancy with devastating consequences for both mother and baby. Maternal mortality due to MI has fallen from 37% in the 1980s but rates remain high at 5–11%.[23,24,28] Mortality is twice as high in women diagnosed with an acute MI during the peripartum period compared to the antepartum or postpartum periods.[28] During the 1990s, fetal mortality was reported as 21–34%:[27,29] again more recent data records a fall to 9%[28] with most deaths occurring in association with maternal death.

In the 2006–2008 Confidential Enquiries report,[2] six women died from acute MI and five deaths were attributed to chronic IHD where no acute MI was recorded. Death in these cases was presumed to be the consequence of arrhythmia or heart failure.

Acute coronary syndrome (ACS) is often a new diagnosis in pregnancy. The recurrence of ACS in pregnancy is unknown. In the European Registry only one patient out of 20 who had previously had an MI suffered a new ACS event whilst pregnant,[3] whilst five new cases occurred in previously well women.

The majority of MIs occur in the latter half of pregnancy or in the puerperium.[26]

### Risk factors

Pregnancy increases the risk of acute MI by three to four times.[23,24] The physiological changes of pregnancy with increases in blood volume, stroke volume, and HR, increase myocardial oxygen demand, whilst the physiological anaemia and reduction in diastolic BP reduce myocardial oxygen supply.[30] Thus pregnancy can result in worsening of known IHD but may also reveal disease in previously well women.

The risk factors for MI in pregnancy are similar to those in the general population:

- Hypertension.
- Obesity.
- Diabetes mellitus.
- Family history of MI.
- Advanced maternal age significantly increases the risk of MI. In the UKOSS report, the mean age of women suffering MI was 37 years compared to the mean age in the control group of 29 years.[26] This study found that for every year increase in maternal age the odds of MI increased by 30% whilst James et al.[24] found the risk of MI was 30 times higher in women over 40 compared to those under 20. This is of particular concern as maternal age is rising in developed countries due to the tendency of mothers to delay the age at which they start to have children,[31] and the use of *in vitro* fertilization. UKOSS is currently conducting a study of pregnancy at advanced maternal age. This study is looking at mothers aged 48 years and older to establish the characteristics, management, and outcomes, and to estimate the risk of adverse events attributable to advanced maternal age.
- Smoking has been shown to increase the risk of MI in pregnancy eightfold[24] which is in contrast to non-pregnant female smokers in whom this risk is increased twofold.[32] It may be that the hypercoagulable state of pregnancy and the increase in vascular reactivity[29] compound the risk of acute MI in women who smoke.
- Thrombophilia.
- Several obstetric complications are associated with an increased risk of MI. Endothelial dysfunction is involved in both the pathogenesis of pre-eclampsia and cardiovascular disease. Haemorrhage is associated with a hypercoagulable response[33] which may increase the risk of coronary artery thrombosis.[24] The association of haemorrhage with increased risk of MI may also be due to the use of ergot alkaloids, such as ergometrine, to treat uterine atony. These drugs are well known to cause coronary vasospasm and have been implicated in cases of acute MI.[34] Postpartum infection, mulitparity, and blood transfusion are also associated with an increased risk of MI.[24,28]

### Pathophysiology

The underlying pathology for MI in pregnancy differs from that in the general population where atherosclerotic disease with subsequent plaque rupture and thrombus formation predominates.

Information regarding coronary anatomy has been collated in several reviews of MI in pregnancy. These have shown that atherosclerotic disease ± thrombus accounted for only 40–50% of cases of pregnancy-related MI.[26,28,29] Coronary dissection, which is rarely seen outside pregnancy, accounted for 16–27%, coronary thrombus without atherosclerosis accounted for 6–21%, and normal coronary arteries were documented in up to 29%.[26,28,29] Anterior wall MIs occurred more commonly than inferior or lateral.[24,26]

Coronary dissection is the primary cause of MI in the peripartum period. Spontaneous coronary dissection in pregnancy is thought to result from hormonal and haemodynamic changes.[35] Excess progesterone results in biochemical and structural changes in the vessel wall that persists for up to 3 months postpartum.[36] These changes combined with the elevated shear forces from the increased blood volume and CO of pregnancy result in a greater susceptibility to dissection.

Coronary thrombosis without evidence of atherosclerosis may occur as a consequence of the hypercoagulable state of pregnancy, whilst coronary vasospasm may be responsible for the MIs that have been observed in patients with normal vessels.

## Diagnosis

The diagnosis of acute MI or ACS in pregnancy or the puerperium is the same as the non-pregnant state and consists of a history of chest pain associated with ECG changes and cardiac enzyme rise. Troponin levels may be higher in women with pre-eclampsia but they do not reach the threshold for diagnosis of ACS out with pregnancy.[11] In the UKOSS study,[26] all the women presented with typical symptoms of MI except for two who developed ECG changes whilst undergoing CD. However, there is concern that pregnant women may present with atypical symptoms such as abdominal or epigastric pain, vomiting, and dizziness, and symptoms may be attributed to pregnancy per se resulting in a failure to consider ACS.[2]

The differential diagnoses of ACS in pregnancy are acute pulmonary embolism, aortic dissection and pre-eclampsia. Echocardiography (Echo) may be a useful diagnostic tool to differentiate between these diagnoses. Coronary angiography is both diagnostic and allows treatment simultaneously.

## Management

### Pregnancy

- There are no guidelines advising women who have suffered an ACS on how long to defer pregnancy. In general, 1 year is felt to be an appropriate length of time as this allows full recovery, cardiac remodelling,[11] 12 months of dual antiplatelet therapy for those with drug-eluting stents, and full preconception stress testing. The ESC advocates that pregnancy can be considered in the absence of ongoing cardiac ischaemia and LV dysfunction.[9]
- For women who suffer ST elevation MI (STEMI) during pregnancy due to coronary thrombosis, primary percutaneous coronary intervention (PCI) is preferred to thrombolytic therapy as the initial mode of treatment provided that therapy is started promptly. Although thrombolysis using tissue plasminogen activator (which does not cross the placenta) has been used successfully,[37] subplacental haemorrhage can occur. Haemorrhage may be catastrophic particularly if thrombolysis is used in the first few weeks postnatally.[38] STEMI due to coronary dissection can also be treated by PCI whilst thrombolysis may aggravate it. All reports of stenting during STEMI in pregnancy have been with bare metal stents.[9] The safety of drug-eluting stents is unknown in pregnancy and requires prolonged use of dual antiplatelet treatment. There are case reports of the use of clopidogrel in pregnancy.[39,40] However, its safety is uncertain. The ESC advises that it should only be used when absolutely necessary and for as short a duration as possible.
- For patients with non-STEMI with intermediate- and high-risk features (i.e. raised cardiac biomarkers and ST segment changes) PCI should be considered, whilst those who are more stable can be managed medically.[9]
- Beta blockers, nitrates, calcium channel antagonists, and low-dose salicylates (e.g. aspirin 75 mg) can be used safely in pregnancy but angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), and statins are contraindicated. There is no safety data on glycoprotein IIb/IIIa inhibitors in pregnancy and as such they are not recommended.

### Labour

- The mode of delivery is determined by obstetric considerations and the clinical status of the mother. Vaginal delivery with assisted second stage and slow incremental epidural analgesia is the preferred mode. Despite these recommendations, CD occurred in 60% of women with IHD/MI in the European Registry which was the highest rate for all the cardiac conditions studied.[4]
- Slow incremental epidural analgesia attenuates the progressive rise in CO that occurs during labour, and allows for haemodynamic stability by slow initiation of pain relief. Addition of epinephrine to local anaesthetic mixtures should be avoided.
- Cardiac medication such as aspirin and beta blockers should be continued throughout labour.
- The third stage should be managed actively with an infusion of Syntocinon® (e.g. 2–5 IU of Syntocinon® infused over 15–30 minutes).
- A woman with known IHD should receive supplemental oxygen and have continuous ECG, pulse oximetry, BP, and cardiotocography monitoring throughout labour.
- Invasive BP monitoring should be instituted in women with LV dysfunction.
- Postnatal care should be undertaken in the HDU.
- Haemodynamic goals are:
  - reduction of cardiac workload and myocardial oxygen demand
  - avoidance of tachycardia
  - SVR should only be allowed to fall slowly and modestly to prevent reflex tachycardia and to maintain coronary perfusion
  - avoidance of aortocaval compression.

### Caesarean delivery

- For operative delivery, slow-onset NA with either incremental epidural or low-dose spinal component CSE allow for haemodynamic stability.[41] A standard single-shot spinal is relatively contraindicated as this produces a rapid sympathetic block with resultant hypotension and tachycardia.
- GA should be reserved for those women with a contraindication to neuraxial block such as the use of dual antiplatelet agents, or for women who are unable to lie flat due to congestive cardiac failure. Rapid sequence induction should be modified with opioids or beta blockers to obtund the pressor response to laryngoscopy and use of invasive BP monitoring is advised.
- Good postoperative analgesia is necessary to reduce pain-induced catecholamine surges. This should be provided with intrathecal or epidural opiates if NA has been used, or a combination of patient-controlled opioid analgesia and TAP blocks if the patient has undergone GA.
- Postoperatively, women should be monitored on a HDU for 24–28 hours and should receive cardiology input.
- Women who are not breastfeeding can start statins and ACE inhibitors postnatally as required.

## Arrhythmias

Arrhythmias during pregnancy are common and may manifest for the first time or recur more frequently. Premature atrial and ventricular beats occur in up to 59% of pregnant women investigated for palpitations,[42] whilst sinus tachycardia is observed in 39% of healthy women during the third trimester.[43] Although sustained tachyarrhythmias are rare (2–3/1000),[44] symptomatic exacerbation of paroxysmal supraventricular tachycardia (SVT) is common and occurs in 22–44% of women during pregnancy.[45]

The majority of arrhythmias are benign and occur in women who are otherwise healthy and have a structurally normal heart. In these circumstances, advice on managing symptomatic episodes and reassurance is sufficient. However, arrhythmias may have serious implications. Silversides et al. observed that arrhythmia recurrence during pregnancy resulted in a significant increase in the risk of adverse fetal events, in particular prematurity,[45] and arrhythmias are a predictor of an adverse cardiac event during pregnancy in women with structural heart disease.[46] Whilst no deaths have been documented from a primary arrhythmia in the United Kingdom, 20% of the cardiac deaths (ten deaths) in the 2006–2008 Confidential Enquiries[2] report were attributed to sudden adult/arrhythmic death syndrome (SADS) where a primary arrhythmia was presumed to be the cause of cardiac arrest.

### Pathophysiology

There are a number of cardiovascular adaptations that occur during pregnancy that are thought to result in the increased incidence of arrhythmias in pregnancy (Box 41.2). Pregnancy may also affect the trigger for arrhythmias as most tachycardic episodes are initiated by ectopic beats. These occur more commonly in pregnancy and may contribute to the increased frequency of arrhythmias.[47]

**Box 41.2** Pathophysiological mechanisms responsible for arrhythmias during pregnancy

- Elevated heart rate: modifies the effective refractory period and the velocity of conduction
- Reduced potassium levels
- Increased sympathetic tone
- Increased intravascular volume results in mechanical stretch of atria and ventricles which can unveil an arrhythmogenic focus
- Direct effect of hormones on cardiac excitability
- Increased number of myocardial alpha adrenoceptors due to oestrogen

### Diagnosis

The most common symptom reported is palpitations. Shortness of breath and chest pain may occur with relatively minor arrhythmias in late pregnancy. Syncope and presyncope may reflect underlying cardiac disease, but may also be attributed to a fall in BP due to peripheral vasodilatation particularly in the second trimester.[48] Patient enquiry should focus on any family history of arrhythmias or sudden death as these may be an indicator of hereditary cardiac disease.

It is important to attempt to diagnose the type of arrhythmia as this will determine appropriate treatment as well as providing prognostic information. Investigations should aim to establish whether any underlying cardiac disease exists, or whether there are underlying systemic disorders such as thyroid disease, pulmonary embolism, or sepsis.

Resting ECG is often unremarkable but may reveal a delta wave due to pre-excitation in Wolff–Parkinson–White (WPW) syndrome. Holter monitors, event recorders, or implantable loop recorders in conjunction with an accurate patient diary may all be used in pregnancy. Echo should be performed to diagnose structural and functional heart disease. Exercise ECG may be performed with care taken to avoid exceeding the woman's normal exercise capacity whilst tilt-table testing is avoided beyond 24 weeks of pregnancy due to supine hypotension from inferior vena cava (IVC) compression. Electrophysiological studies are usually delayed until after delivery.[11]

### General principles of treatment

Antiarrhythmic drugs are required in a minority of cases where there have been severe symptoms or significant haemodynamic compromise. Digoxin can be used for ventricular rate control but does not prevent recurrence. Beta blockers, class I antiarrhythmics, and sotalol should be used with caution with right ventricular (RV) or LV impairment and amiodarone is only used if all other drugs have failed.[9]

DC cardioversion may be used for women who are haemodynamically compromised by sustained tachyarrhythmia. DC cardioversion can be used safely in all stages of pregnancy as the amount of current reaching the fetus is small.[44]

## Arrhythmias associated with structural and congenital heart disease

Supraventricular and ventricular arrhythmias requiring treatment develop in up to 15% (mean 5%) of patients with CHD during pregnancy.[49] In the European Registry, supraventricular arrhythmias occurred most commonly in patients with valvular heart disease, whilst ventricular arrhythmias were most common in patients with cardiomyopathy.[4] Where a patient has repaired CHD the prevalence of arrhythmias increases with age and is the result of surgical scarring, the underlying lesion, and ageing. Patients who have undergone atrial surgery or who have RV impairment are particularly vulnerable to atrial flutter.

### Supraventricular tachycardia

The majority of episodes of paroxysmal SVT (PSVT) occur during the third trimester of pregnancy, labour, delivery, or postpartum.[48] Atrioventricular (AV) node re-entry tachycardia and AV re-entry tachycardia involving an accessory pathway can be treated with vagal manoeuvres, or intravenous adenosine. Adenosine is the first-line drug for terminating PSVT with doses of 6–12 mg successfully terminating 89% of episodes[50] although up to 24 mg has been used. Metoprolol is an alternative. Intravenous verapamil may cause fetal distress secondary to maternal hypotension.

Prophylactic treatment is only required when symptoms have been intolerable or haemodynamic compromise has occurred. Digoxin and metoprolol are first-line agents followed by sotalol, flecainide, and propafenone.[9] AV nodal blocking agents are contraindicated in patients with WPW as this can result in uncontrolled conduction down the accessory pathway resulting in maternal compromise.

Catheter ablation should only be considered during pregnancy for drug refractory or poorly tolerated arrhythmias. Women with a preceding history of SVT should be considered for catheter ablation prior to pregnancy. If this does not occur then the decision to stop or continue prophylactic medication should be made on an individualized basis following careful consideration of the risks versus the benefits.

### Atrial flutter/Atrial fibrillation

Atrial fibrillation (AF) and atrial flutter (AFl) are rare in pregnancy unless there is structural heart disease, hyperthyroidism, or electrolyte disturbance. Serious haemodynamic compromise to the mother and fetus may occur, particularly in women with valvular heart disease. Management is as the same as for non-pregnant patients with cases involving haemodynamic compromise being treated with DC cardioversion. Amiodarone is avoided due to fetal toxicity. It is preferable to attempt either electrical or chemical cardioversion in patients acutely as this avoids the need for anticoagulation. Flecainide may be used to cardiovert women with structurally normal hearts, whilst alternatives include beta blockers such as atenolol and sotalol, verapamil and procainamide. Digoxin may be used for rate control. Where AF/AFl is present for more than 48 hours, anticoagulation should be considered.

### Ventricular tachycardia

Ventricular tachycardia (VT) is rare in pregnancy. In healthy women, the most common cause of VT in pregnancy is due to idiopathic RV outflow tract tachycardia. It originates from the RV outflow tract just below the pulmonary valve and may cause ectopic beats, bigeminy or short runs of non-sustained VT. VT occurring in women with structural heart disease or ventricular dysfunction is associated with an increased risk of sudden cardiac death.[51] VT results in hypotension with subsequent reduced coronary perfusion and ischaemia resulting in VF. New onset of VT in the last month of pregnancy or in the early postpartum period should alert clinicians to the possibility of peripartum cardiomyopathy.

Irrespective of the underlying cause for VT, DC cardioversion should be performed in all women who are haemodynamically compromised. In those who are stable, lidocaine, procainamide, sotalol, and amiodarone may be considered. In patients with stable polymorphic VT, electrolytes should be corrected including magnesium and any precipitating drugs should be stopped. Temporary overdrive pacing may be required. Amiodarone, verapamil, and cardioselective beta blockers may be used for prophylaxis. Automatic implantable cardiac defibrillators (AICDS) have been used successfully in pregnancy[52] and should be considered where drug treatment for VT fails and for women surviving a cardiac arrest. Catheter ablation may be used when drug therapy fails.

In women with a family history of sudden death arrhythmogenic disorders, long QT syndrome (LQTS) should be considered. This occurs in both autosomal dominant and recessive forms. The risk of cardiac events is significantly increased in the postpartum period in such women but not during pregnancy and delivery.[53] LQTS may also be acquired as a result of certain drugs, electrolyte imbalance and metabolic conditions. If untreated the annual mortality is 1–2%. It is associated with an increased risk of polymorphic VT (torsades de pointes) which unless self-terminating may degenerate to ventricular fibrillation (VF). Beta blockers and occasionally cardiac pacing are used as prophylaxis. If the QT interval is greater than 550 ms or a patient survives a cardiac arrest then an implantable defibrillator should be inserted.

Many drugs used in theatres and anaesthetics are capable of either prolonging the QT interval directly, or predispose or exacerbate QT prolongation secondary to haemodynamic changes. In particular hypertension, bradycardia, tachycardia, hypoxaemia and electrolyte disturbances should be avoided in patients at risk.

- Terbutaline and ritodrine which are used to arrest preterm labour or for tachyphylaxis should be avoided.
- Oxytocin as a bolus of 10 units intravenously prolonged the QTc at 1 minute in normal women with a return to normal at 3 minutes.[54] Thus oxytocin should be administered as an infusion of 5 units over 20 minutes in women with LQTS for the prevention of postpartum haemorrhage.
- Antibiotics: macrolides should be avoided, and the quinolone group and antifungals fluconazole and ketoconazole may have variable effects on QTc.
- Antiemetics: ondansetron, granisetron, and droperidol should be avoided. Cyclizine can be used safely.[55]
- Volatile agents: all volatile agents prolong the QTc.[56] However, volatile agents have been used successfully in patients with LQTS receiving beta blockers.[55] In general, reference books tend to advocate the use of isoflurane over sevoflurane although there are very few studies comparing the safety amongst volatile anaesthetics. Propofol does not have any effect on the

QT interval thus total intravenous anaesthesia may be used although this may not be feasible in an emergency situation.

- Phenylephrine has been used successfully in LQTS patients with hypotension secondary to neuraxial blockade. Ephedrine should be avoided due to sympathomimetic effects.
- Some anaesthetists recommend omission of epinephrine from the epidural solution. This is not a universally accepted practice.[55]
- An up-to-date list of drugs to be avoided or used with caution in patients with LQTS can be found at http://www.crediblemeds.org

### Bradyarrhythmias

Bradyarrhythmias are rare in pregnancy and usually have a favourable outcome in the absence of underlying heart disease. Sinus bradycardia may occur secondary to supine hypotension or the Valsalva manoeuvre. First-degree AV block can occur without underlying heart disease. Second-degree AV block is more commonly associated with drugs or structural heart disease and may result following repair of tetralogy of Fallot or a ventricular septal defect. Women with isolated congenital complete heart block usually have a favourable outcome and rarely require insertion of a permanent pacemaker. Permanent pacemaker insertion is reserved for symptomatic women with complete heart block and ideally should be performed after the first trimester with shielding of the uterus to minimize irradiation of the fetus.

### Sudden Adult/Arrhythmic Death Syndrome

SADS is defined as sudden unexpected cardiac death (i.e. presumed fatal arrhythmia) where all other causes of sudden collapse are excluded including a drug screen for stimulants. SADS is a pathological diagnosis and includes those unexplained cases with a morphologically normal heart by both gross and histological examination.[2] The incidence of SADS appears to be rising with ten deaths recorded in the 2006–2008 Confidential Enquiries report. Six of the ten women had booking BMIs ranging from 30 to 45 kg/m$^2$ and obesity has been suggested as a potential risk factor. Cardiac hypertrophy is associated with obesity in the absence of hypertension, and both obesity and cardiac hypertrophy are risk factors for arrhythmia and sudden cardiac death.

## Management of pregnant women with arrhythmias

### Pregnancy

- Women with a history of arrhythmias should have preconception review by a cardiologist to discuss the risks of pregnancy.
- The use of antiarrhythmic drugs should be reviewed to optimize dose and to select drugs which are safe to take in pregnancy.
- Anticoagulant medication may need to be altered as warfarin is contraindicated in the first trimester.
- Catheter ablation should be considered prior to pregnancy in women with a history of SVT.
- Women with pacemakers tolerate pregnancy well and the presence of an AICD is not a contraindication to pregnancy nor does pregnancy increase the risk of major AICD complications or frequency of discharge.[52]

### Labour

- The mode of delivery is determined by obstetric considerations. Vaginal delivery is preferred and the decision on whether to allow maternal expulsive efforts during the second stage should be decided on a case-by-case basis. Expulsive efforts can cause reflex bradycardia but can also increase circulating catecholamine levels and thus trigger an arrhythmia.
- Women with a history of arrhythmias should have continuous ECG monitoring as well as pulse oximetry and regular BP measurements during labour.
- Neuraxial analgesia is recommended for women who are symptomatic or have haemodynamic compromise due to arrhythmia. Slow incremental epidural analgesia preserves maternal haemodynamic stability and minimizes the increase in circulating catecholamines.
- Phenylephrine is the vasopressor of choice for those with tachyarrhythmias whilst ephedrine should be used for women with bradycardia.

### Caesarean delivery

- Low-dose spinal component CSE or *de novo* slow incremental epidural may be preferred for CD as single-shot spinal results in rapid reduction in SVR with resultant reflex tachycardia.
- Syntocinon® should be given by slow intravenous infusion to avoid tachycardia.
- Following delivery women should continue to be monitored in a high dependency setting for a minimum period of 24 hours.

## Cardiac transplantation

The number of cardiac transplants performed in children and women of childbearing age is increasing.[57] Survival rates at 1 year and 5 years are 84% and 85% respectively (conditional on 1-year survival).[57] The commonest reason for heart transplantation in these groups is viral cardiomyopathy although the number of people being transplanted for CHD is increasing. Combined heart–lung transplants occur more frequently than solitary heart transplants. The majority of recipients have the underlying aetiology of CHD, idiopathic pulmonary artery hypertension, and cystic fibrosis.[58] Many women who have undergone cardiac transplantation regain normal functional status and may desire children. In general, pregnancy is well tolerated in cardiac transplant recipients provided the functional status of the patient pre-pregnancy is good.[59] The incidence of graft rejection during pregnancy and the postpartum period is unaltered and despite the use of immunosuppressant drugs the incidence of birth defects is similar to the general population.[58] The most frequent maternal complications are thought to be secondary to immunosuppressive therapy and include hypertension, pre-eclampsia, and infection.[60] Episodes of acute allograft rejection are usually mild and do not require treatment.[59] Fetal complications include preterm delivery and low birth weight.[60,61]

### Pathophysiological changes of pregnancy after cardiac transplantation

The transplanted heart lacks autonomic and somatic innervation. As a result the baseline HR is 100–120 beats per minute. Drugs acting via the vagus nerve such as atropine have no effect whilst indirectly acting vasopressors may have unpredictable effects. Phenylephrine is the vasopressor of choice. Directly acting sympathomimetics such as isoprenaline reliably produce inotropy and chronotropy. The denervated heart responds to the increased cardiovascular demands of pregnancy by atypical adaptive mechanisms. An increase in stroke volume occurs in response to higher CVP and intravascular volume, and a delayed increase in HR and contractility occur in response to circulating catecholamines from the adrenal medulla. The denervated heart is therefore more susceptible to hypovolaemia.

Multivessel coronary artery occlusion develops in 30% of cardiac transplant recipients at 3 years and 50% at 5 years.[62] Due to the lack of innervation episodes of myocardial ischaemia are silent and paroxysmal dyspnoea may be the only symptom.

### Management

#### Pregnancy

- All cardiac transplant patients should have a recent Echo and cardiac catheterization report as these provide assessment of ventricular function, the extent of atherosclerosis and permits endomyocardial biopsy to assess rejection.
- Exercise tolerance during pregnancy should be recorded at every visit as this may be the only indication of cardiac ischaemia.
- Regular monitoring of blood concentrations of immunosuppressants is required as the increase in blood volume may necessitate an alteration to their dose.
- Patients should have regular BP assessment due to the risk of hypertension and pre-eclampsia.

#### Labour

- The mode of delivery is determined by obstetric indications with vaginal delivery being preferred.
- All staff need to take particular care with asepsis for all procedures including examinations due to the increased risk of sepsis secondary to immunosuppression.
- Cardiac transplant patients generally tolerate the haemodynamic changes of labour and delivery well.[63] Although central venous and pulmonary artery pressure monitoring may be useful for assessing intravascular volume and gauging fluid therapy, the risks from introducing infection may outweigh any perceived benefit.[64] Intravascular volume should be maintained with intravenous hydration and avoidance of IVC compression.
- Patients should have continuous ECG, pulse oximetry, and regular BP monitoring throughout labour.
- Additional steroid cover may be required for patients receiving higher doses.
- Epidural anaesthesia is advocated during labour and delivery to minimize the hyperdynamic cardiovascular responses that may occur.[65] Camann et al.[65] had recommended the avoidance of epinephrine containing local anaesthetics due to concerns of increasing the HR further. However, this has been used without any untoward effect.[64]

#### Caesarean delivery

- Epidural or low-dose spinal component CSE is preferred over single-shot spinal for operative delivery as this allows a slower onset of block, and therefore more haemodynamic stability.
- Antibiotic prophylaxis should be given for all operative deliveries
- Phenylephrine is recommended for treating hypotension.
- Patients should be monitored for 24–48 hours post delivery in a high dependency area.

## Aortic disease and aortic dissection

Due to hormonal changes in pregnancy and up to 6 months postpartum, aortic dissection may occur both in women with and without underlying vascular disease. Approximately one-half of aortic dissections in women below 40 years of age are pregnancy related.[66] Aortic dissection can occur at any time during pregnancy and the puerperium but more than half of dissections occur during the third trimester. Aortic dissection is a devastating condition: the mortality rate associated with pregnancy is 25%.[67]

### Risk factors

- Acute or chronic hypertension. This is usually, but not always present when aortic dissection occurs
- Collagen vascular diseases:
  - Marfan syndrome (MFS)
  - Ehlers–Danlos (ED) syndrome type IV
- Bicuspid aortic valve
- Previous repair of aortic coarctation.

#### Marfan syndrome

Medical literature traditionally quotes the risk of aortic dissection in women with MFS as 1% in pregnancy even in the absence of dilatation of the aortic root.[9] This is mainly based on case reports and retrospective studies. A recent prospective study of 199 pregnancies in 69 women with MFS did not document any aortic dissections even in the 14 women who started pregnancy with an aortic root diameter between 45 and 51 mm.[68] This study also evaluated the aortic root diameter with echocardiography regularly during 55 pregnancies in 35 women. Aortic root diameters are known to increase by up to 1 mm in normal women in pregnancy. In women with MFS, slightly more aortic root dilatation was seen which did not entirely return to baseline postnatally.[68] Pregnancy may therefore have long-term implications for women with MFS.[68] Women who have aortic root diameters greater than 40 mm prior to pregnancy, or who are seen to have progressively increasing aortic root diameters during pregnancy, are thought to be at significantly increased risk of aortic dissection and need careful monitoring during pregnancy.[9] In women who have already undergone aortic root replacement, aortic dissection may still occur in the native aorta.

Mitral valve prolapse and regurgitation may progress in pregnancy with signs and symptoms of heart failure and arrhythmias.[9]

### Ehlers–Danlos syndrome Type IV

ED syndrome Type IV carries a very high risk of morbidity and mortality in pregnancy compared to the other nine ED subtypes. Type IV is transmitted as an autosomal dominant syndrome. In the general population, type IV EDS is very rare with an incidence of 1/50,000–1/100,000.[69]

Morbidity and mortality in pregnancy may occur due to:

- Spontaneous rupture and dissection of large vessels, including the aorta, even in the absence of vessel dilatation
- Uterine rupture
- Vascular fragility puts women at risk of postpartum haemorrhage.

### Bicuspid aortic valve

Congenital bicuspid aortic valve occurs in the general population with a rate of 1–2%. A high proportion of patients with bicuspid aortic valves will have some degree of aortic root dilatation whether or not there is dysfunction of the valve.[70] However, the risk of aortic dissection is less compared with women who have MFS: women with bicuspid valves are considered WHO class IV when aortic dilatation is greater than 50 mm.[9] Aortic dilatation may occur in the distal aorta which makes conventional imaging with echocardiography less reliable.

## Pathophysiology of aortic dissection

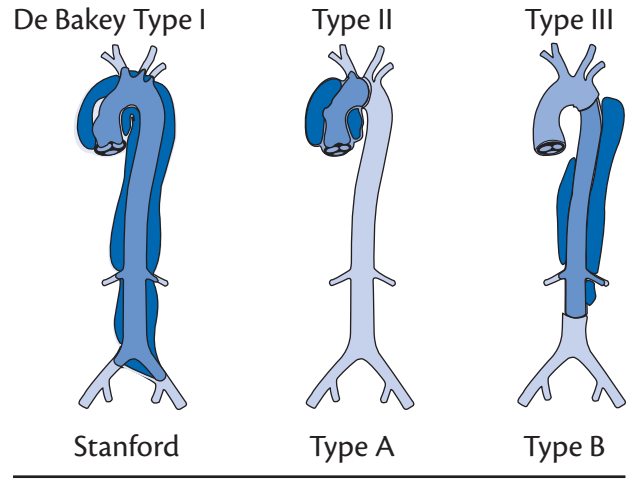
Progesterone causes changes in vascular collagen. Dissections occur if tears in vascular intima and adventitia propagate and create a false lumen. In the aorta, dissection may extend proximally and or distally. Signs and symptoms of aortic dissection are due to ischaemia and infarction of end organs (such as limb ischaemia, cerebrovascular accident (CVA), renal hypoperfusion) as dissection interrupts arterial supply. Vessel rupture may occur into the pericardium, abdomen, thoracic cavity and mediastinum. If dissection occurs proximally through the aortic arch, interruption of blood supply to organs supplied by the aortic arch will occur causing CVA, myocardial ischaemia and infarction, aortic regurgitation, pericardial tamponade, upper limb ischaemia, bronchial compression and recurrent laryngeal nerve palsy.

## Classification of aortic dissection

Aortic dissection may be classified as Stanford type A (i.e. involving the ascending aorta with or without involvement of the descending aorta: DeBakey types I and II) and Stanford type B (i.e. involving the descending aorta distal to the origin of the left subclavian artery only: DeBakey type III) (Figure 41.2). Most dissections occurring in pregnancy are type A (78.9%).[71]

## Presentation

A typical presentation of acute aortic dissection is a woman presenting with severe chest pain radiating through to the back. 'Saving Mothers' Lives' urges medical staff to thoroughly investigate women who need strong opiates for analgesia for chest pain.[2] Other symptoms depend on the location and extent of the dissection and presence of aortic rupture, but may include:



**De Bakey**

| | |
|---|---|
| **Type I** | Originates in the ascending aorta, propagates at least to the aortic arch and often beyond it distally. |
| **Type II** | Originates in and as confined to the ascending aorta. |
| **Type III** | Originates in the descending aorta and extends distally down the aorta or, rarely retrograde into the aortic arch and ascending aorta. |

**Stanford**

| | |
|---|---|
| **Type A** | All dissections involving the ascending aorta, regardless of the site of orgin. |
| **Type B** | All dissections not involving the ascending aorta. |

- Differential BP measurements in the arms and legs
- Ischaemic limbs
- CVA
- Dyspnoea
- Myocardial ischaemia and infarction
- Signs of acute aortic regurgitation
- Signs of pericardial tamponade
- Lower abdominal pain.

## Investigations

The gold standard for diagnosis is computed tomography (CT) or magnetic resonance (MR) angiogram[72] (Figure 41.3). These imaging modalities will reveal the location and extent of dissection. Abnormalities on chest X-ray (CXR), ECG, and Echo may point to the diagnosis before confirmation by CT or MR. CXR may reveal a widened mediastinum, signs of heart failure due to acute aortic incompetence, pericardial and pleural effusions, or may appear normal. ECG may reveal ST segment elevation due

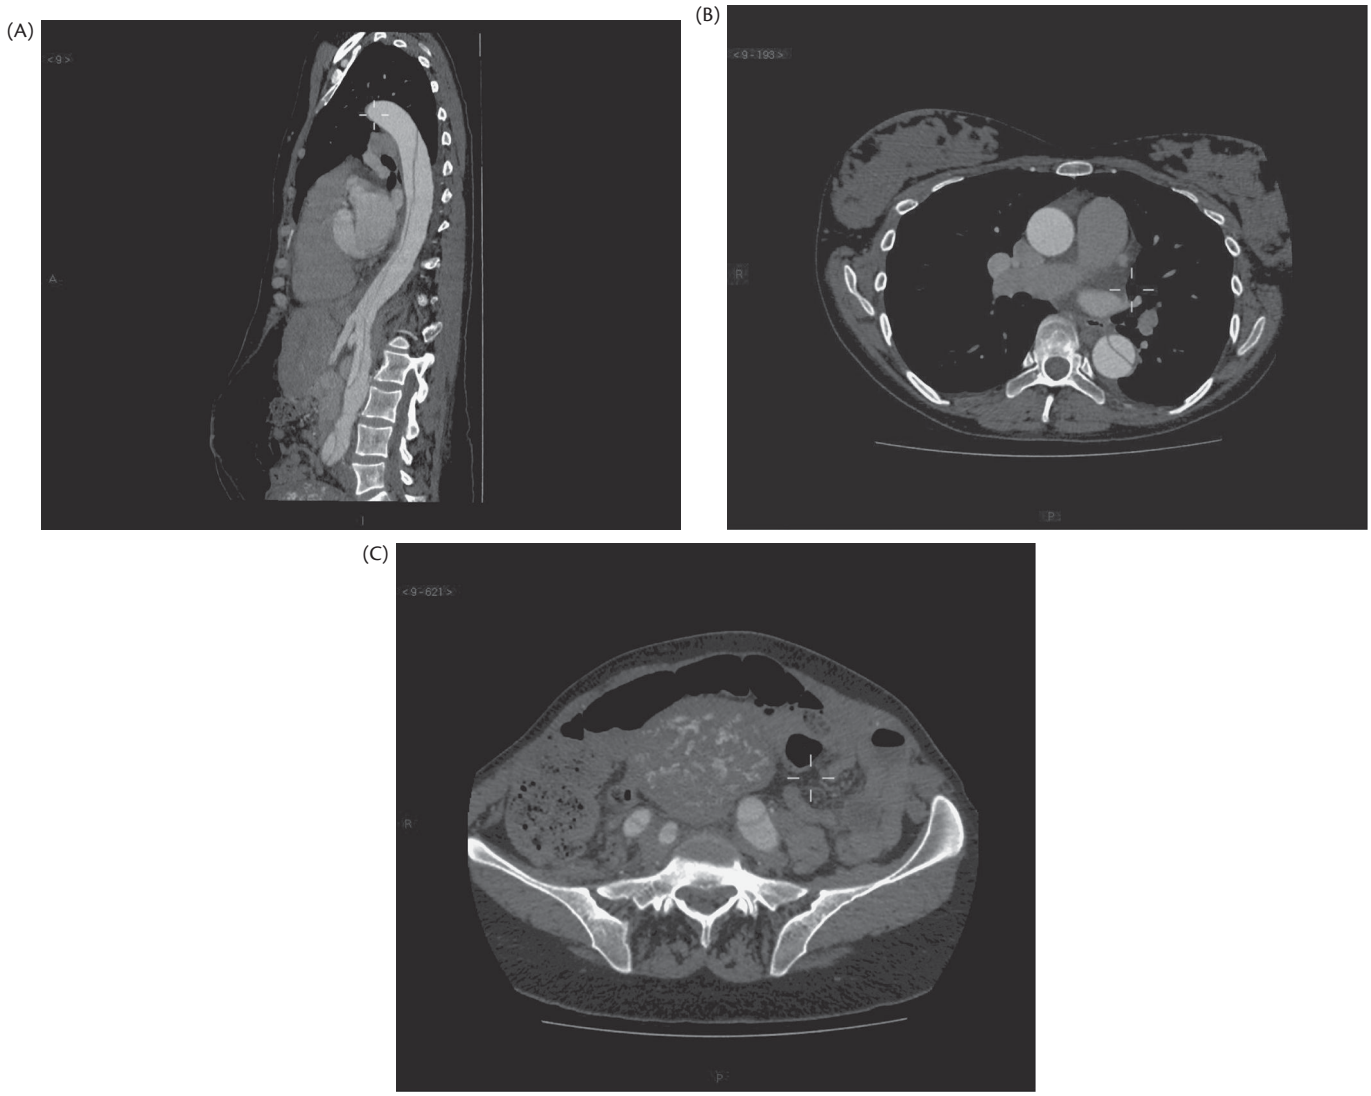

**Figure 41.3** Computed tomography angiogram (CTA) of thoracic dissecting aneurysm. (A) Sagittal CTA showing dissection flap extending down from thoracic to abdominal aorta. (B) Axial image from CTA thorax. (C) Axial CTA image showing flap extending into both common iliac arteries with top of postpartum uterus. Thanks to Dr. Hamish Ireland for the CTA Images of the aortic dissection.

to acute myocardial ischaemia and infarction. Echocardiography may reveal a widened aortic root and dissection flap if dissection has occurred in the proximal aorta, pericardial effusion, and aortic regurgitation. TOE will enable imaging of the descending aorta.[72]

## Management of women with aortic disease in pregnancy

Women who have very significant aortic dilatation (>45 mm in MFS, >50 mm associated with bicuspid aortic valves) prior to pregnancy are advised to avoid conception until surgical repair has been carried out.[9] Women with underlying aortic pathology, require frequent assessment of aortic diameter with echocardiography and good control of BP throughout pregnancy. The ESC guidelines[9] recommend that women with MFS are treated with beta blockers in pregnancy: this has been shown to limit aortic dilatation and reduce the risk of dissection. Celiprolol is specifically recommended in women with ED type IV.

Over 60% of patients with MFS may have dural ectasia: up to 90% may be asymptomatic. Patients with EDS may also be at risk of dural ectasia.[73] If this is moderate or severe, narrowing of the epidural space may make the risk of dural puncture unacceptably high. In addition dural ectasia may make the spinal dose difficult to estimate as CSF volume may be increased.[74] MRI evaluation of the lumbar spine should be considered to assist diagnosis.

Intrapartum management aims to limit cardiovascular stress by controlling maximal BP and rapid swings in BP. The ESC taskforce recommends controlled vaginal delivery with incremental epidural analgesia and assisted second stage for women with MFS and aortic diameters between 40 and 45 mm.[9]

If women with MFS have an aortic diameter greater than 45 mm, elective CD is recommended due to the high risk of aortic dissection.

An early elective CD should be planned for all women with ED type IV.

Both during labour and delivery, invasive BP monitoring enables accurate control of BP.

### Management of women with aortic dissection in pregnancy

Women who suffer aortic dissection in pregnancy require immediate aggressive control of BP to limit further dissection. Acute type A aortic dissections require surgical correction. Definitive surgical management of the dissection will be undertaken with or without CD depending on gestation.[62] Where aortic rupture and organ malperfusion have not occurred, type B dissections are usually treated conservatively.[71]

## Cardiomyopathy

Cardiomyopathy (CMP) is encountered rarely in pregnancy.[9] CMP may be inherited (hypertrophic cardiomyopathy (HCM), some types of dilated cardiomyopathy (DCM), arrhythmogenic RV cardiomyopathy, LV non-compaction cardiomyopathy, and some restrictive cardiomyopathies) or acquired. CMPs may be of toxic, infiltrative, ischaemic, and idiopathic aetiology. The symptoms of CMP overlap with normal symptoms of pregnancy, especially in the later stages of pregnancy, which can make diagnosis difficult.

The commonest forms of CMP encountered in pregnancy in the United Kingdom are peripartum cardiomyopathy (PPCM), DCM, and HCM. Both PPCM and DCM are acquired LV cardiomyopathies.

### Peripartum cardiomyopathy and dilated cardiomyopathy

PPCM and DCM may manifest in similar ways in pregnancy, but DCM may be pre-existing or may present early in pregnancy when CVS physiological changes cause cardiac decompensation. In contrast, PPCM presents at the end of pregnancy or within 5 months after delivery. The Heart Failure Association of the European Society of Cardiology Working Group on PPCM (2010) have suggested an alternative definition of PPCM to include idiopathic heart failure occurring due to LV systolic dysfunction which presents towards the end of pregnancy or in the months following pregnancy.[75] Seventy-eight per cent of PPCM cases occur 4 months postnatally, compared with 9% in the last month of pregnancy.[75] LV dilatation is not necessarily present in PPCM in contrast to DCM.

#### Incidence and aetiology

The limited data available regarding the incidence of PPCM suggests that the incidence varies widely in different populations ranging between 1/300 (Haiti) and 1/4000 (United States) pregnancies.[75] Whilst the aetiology of PPCM is unknown, possible causes include:

- Viral infection
- Inflammation
- Autoimmune
- Haemodynamic stress of pregnancy
- Prolactin (excessive production)[76]
- Genetic predisposition.[76]

In contrast to PPCM where aetiology is speculative, the cause of DCM may be identified in up to 50% of cases as:

- Infections (e.g. viral)
- Connective tissue diseases
- Haematological (e.g. sickle cell anaemia)
- Endocrine (e.g. thyroid disorders)
- Drugs (e.g. alcohol)
- Nutritional deficiencies
- Kawasaki
- Ischaemic
- Arrhythmogenic RV CMP
- Muscular dystrophy
- Metabolic (e.g. haemochromatosis).

**Box 41.3** Risk factors for peripartum cardiomyopathy

- Older or very young maternal age
- Black ethnicity
- Multiple gestations
- Increasing parity
- Obesity
- Family history
- Smoking
- Diabetes mellitus
- Prolonged use of beta agonists
- Hypertension

#### Risk factors

The risk factors for PPCM are listed in Box 41.3.

#### Diagnosis

Presentation of PPCM and DCM in pregnancy may be insidious, or may be due to an acute decompensation causing florid cardiac failure. This may be difficult to differentiate from the normal symptoms of pregnancy. However, progressive exertional dyspnoea, paroxysmal nocturnal dyspnoea (PND), orthopnoea, recumbent cough, tachypnoea, and auscultatory chest signs are rarely features of a normal pregnancy.[77]

A typical presentation might include the following signs and symptoms:

- Fatigue, lassitude
- Progressive exertional dyspnoea, orthopnoea, PND
- Cough
- Wheeze (which may confuse the diagnosis with asthma), bilateral basal crepitations
- Tachypnoea
- Hypoxaemia
- Peripheral oedema
- Chest pain
- Palpitations, tachycardia, arrhythmias
- Raised JVP
- Gallop rhythm

- Hepatomegaly
- Embolic phenomenon due to pulmonary emboli or due to emboli secondary to mural thrombus.

### Investigations

- CXR: typically will reveal cardiomegaly and pulmonary oedema. Pulmonary effusions may be seen.
- ECG: likely to show tachycardia. May reveal dysrhythmias. ST segment, T-wave changes, Q waves, and ventricular ectopic beats are common. Left bundle branch block is present in up to 50% of cases.[78]
- Echo will demonstrate reduced LV systolic function with an ejection fraction (EF) less than 45%, usually with global cardiac dilatation. Mitral regurgitation is often seen.[78] Echo will also detect intracardiac thrombus.

### Management

This will depend on the stage of pregnancy. Immediate management is focussed on stabilization of the mother's cardiac function and is the treatment of heart failure:[9,79]

#### *Pregnancy*

- Oxygen therapy to optimize oxygen saturation. Non-invasive ventilation may be required.
- Diuretics such as 20–40 mg furosemide intravenously for treatment of pulmonary congestion (which may reduce placental blood flow).
- Nitrates, nifedipine, hydralazine (to reduce afterload) where systolic BP is adequate.
- Anticoagulation in prophylactic or treatment doses (if very poor EF less than 35%, if cardiac thrombus is present or the patient is in persistent AF).
- Antiarrhythmics for AF or atrial flutter (digoxin) or careful rate control with cardioselective beta blockers in women whose CO is preserved.
- ACE inhibitors and ARBs are used postnatally (ACE inhibitors and ARBs are teratogenic early in pregnancy, and may cause fetal hypotension and reduced fetal renal blood flow later in pregnancy).
- More intensive therapies may be needed: inotropic support, counter-pulsation intra-aortic balloon device, ventricular assist devices, and sometimes cardiac transplantation.
- Bromocriptine, which blocks prolactin release, is a potential novel therapy which has reported some success in case reports and one randomized pilot study for postnatal treatment.[80]

#### *Labour*

- Depending on response to treatment, mode of delivery will be planned by the multidisciplinary team. Delivery will relieve the physiological burden of pregnancy on the mother's CVS. If the mother's cardiac failure can be stabilized, vaginal delivery with assisted second stage and early incremental epidural pain relief will usually be planned.[5]
- Invasive arterial BP monitoring would be useful prior to epidural insertion.

#### *Caesarean delivery*

- CD would be needed for women with obstetric indications, who are fully anticoagulated or in whom stabilization of heart failure cannot be achieved.[9]
- For women who are not fully anticoagulated, anaesthesia for CD may be provided by a low-dose spinal component CSE, or a slow incremental epidural. Both techniques are titratable and preserve myocardial contractility and reduce afterload. Invasive arterial BP monitoring should be used before commencement of anaesthesia.
- GA will be needed for women who are unable to lie flat.

### Prognosis for PPCM

In data from the United States, Turkey, and Haiti, between 23% and 41% of women regain normal LV systolic function.[75] This is more likely if EF at diagnosis is higher. Mortality rates for PPCM are not known in Europe, but worldwide, mortality rates of between 10% and 16% at 6 months after diagnosis have been reported.[75] It is strongly advised that women undergo preconception counselling prior to subsequent pregnancies. Limited studies suggest that there are very significant risks in future pregnancies even if LV function has returned to normal.[9,75,28] Subsequent pregnancy is not advised if LV EF was less than 25% at diagnosis, or where LV EF has not normalized.[5,22] Where LV function has normalized, risks include a 26% chance of developing cardiac failure, and 9% risk of persistent fall in LV EF of more than 20%. In women whose LV function has not normalized, there is a 50% chance of worsening cardiac failure, 42% chance of persistent fall in LVEF greater than 20%, and a 25% risk of maternal death.[11]

## Hypertrophic cardiomyopathy

### Incidence and aetiology

Ninety per cent of HCM is familial and is inherited in an autosomal dominant pattern.[81] The prevalence of HCM is 1/500.[82] HCM consists of asymmetrical hypertrophy of the LV and interventricular septum which causes diastolic LV dysfunction, atrial and ventricular arrhythmias and left ventricular outflow tract obstruction (LVOTO). Systolic LV dysfunction may also occur and mitral regurgitation may be present with LVOTO. When LVOTO occurs the cardiomyopathy may be termed 'hypertrophic obstructive cardiomyopathy'.

### Presentation

Many patients with HCM are asymptomatic, but symptoms may include chest pain, dyspnoea, arrhythmias (atrial and ventricular), presyncope and syncope (due to LVOTO), heart failure, and sudden death which may present at any age.

### Management

#### *Pregnancy*

- HCM is usually well tolerated in pregnancy: the risk of pregnancy correlates well with NYHA class before conception,[9,81] degree of LVOTO, and presence of arrhythmias.
- For women deemed to be very high risk before embarking on pregnancy, surgery may be an option to reduce LVOTO.
- Beta blockers should be continued in women who take them prior to pregnancy. Beta blockers may be started in pregnancy for symptoms or where LVOTO is significant or if interventricular septal thickness is greater than 15 mm.[9]

- Some women with HCM may have implantable cardiac defibrillators for prevention of ventricular arrhythmias and sudden death. Rates of cardiac events in HCM are similar in pregnant and non-pregnant patients: pregnancy does not appear to alter disease progression.[81]

#### *Labour*

- In low-risk cases, a vaginal birth may be considered.
- Tachycardias (which will reduce LV diastolic filling, thereby reducing LV preload and increasing LVOTO), and sudden decreases in preload (e.g. due to Valsalva during expulsive efforts and significant blood loss) and afterload should be avoided.
- The degree of LVOTO needs to be considered before using neuraxial analgesia and anaesthesia as these may be relatively contraindicated.
- A pure alpha agonist such as phenylephrine is the vasopressor of choice as tachycardia and increased contractility are to be avoided.[81]
- Fluid balance needs to be carefully maintained.
- Assisted delivery should be considered for women with significant LVOTO to avoid reduction in venous return and CO due to the Valsalva manoeuvre.[83]
- Syntocinon® for active management of the third stage should be given slowly over 15–30 minutes by infusion.

#### *Caesarean delivery*

- CD is indicated for women with obstetric indications, decompensated heart failure, and symptomatic LVOTO.[81]
- LVOTO, if severe, would favour GA as sudden falls in SVR and BP can be avoided.[83]
- GA would be required for women who cannot lie flat due to decompensated heart failure.
- Syntocinon® for active management of the third stage should be given slowly over 15–30 minutes by infusion.

## Valvular heart disease

Most valvular heart disease in pregnancy in resource-rich countries is due to CHD. This is in contrast to resource-limited countries where the majority of valvular heart disease is acquired due to RHD.[9] The UK triennial Confidential Enquiries into Maternal Deaths have stressed the importance of evaluating non-UK born residents from resource-limited backgrounds early in pregnancy for signs of valvular heart disease.[8]

In general, right-sided lesions are better tolerated than left-sided lesions, and due to the physiological changes which occur in pregnancy, regurgitant lesions are better tolerated than stenotic lesions for the following reasons:

- Rapidly increasing CO leads to higher peak gradients across stenotic valves which causes higher upstream pressures in the heart.
- The relative tachycardia in pregnancy increases oxygen demand to the myocardium.
- A fixed stenotic lesion will limit the heart's ability to increase CO.
- The lowered SVR and increase in HR in pregnancy are beneficial for regurgitant lesions and conversely detrimental to stenotic lesions.

### Aortic stenosis

Aortic stenosis (AS) may present for the first time during pregnancy. Usually mild to moderate AS is well tolerated in pregnancy. In contrast, severe AS poses a high risk with heart failure occurring in 10% and arrhythmias in 3–25%.[9] Death is rare in developed countries.

#### Aetiology

In resource-rich countries, AS is most frequently congenital due to a bicuspid aortic valve. In contrast, in resource-limited countries, AS is usually due to RHD. More than 50% of women who have a bicuspid valve will have associated abnormality and dilatation of the aorta whether the bicuspid valve causes haemodynamic compromise or not:[70] women with bicuspid valves should have careful monitoring of aortic diameter during pregnancy. Anatomically, AS may be supravalvular, valvular, or subvalvular.

#### Presentation

Women may present for the first time during pregnancy as the stenosed aortic valve struggles to cope with the increasing CO, HR, and reduction in SVR in pregnancy. A woman with AS may present with:

- Dyspnoea
- Angina
- Presyncope or syncope
- Signs and symptoms of cardiac failure
- Sudden death may occur.

Typical signs of AS are:

- Slow rising pulse
- Narrow pulse pressure
- Heaving apex beat
- Ejection systolic murmur heard loudest at the upper right sternal edge with carotid radiation.

#### Investigations

- ECG: may reveal LVH, left axis deviation, lateral ST segment depression in severe disease.
- CXR: may show signs of cardiac failure.
- Echo: will diagnose valve lesion, and severity, associated pathology such as dilated aortic root and enables assessment of cardiac function. Due to the increase in CO in pregnancy, pressure gradients across the valve will increase which may be misleading. For this reason, valve area is used to categorize severity where a normal valve area is 2.6–3.5 $cm^2$. Mild AS is greater than 1.5 $cm^2$, moderate AS 1.0–1.5 $cm^2$, and severe AS less than 1.0 $cm^2$.[84]

#### Management

##### *Pregnancy*

- Tachycardia should be avoided: beta blockers may be very useful to slow HR enabling increased LV filling, increased coronary

perfusion and limiting oxygen demand. Diuretics are required for heart failure. For symptomatic and severe disease medical treatment will include bed rest and oxygen therapy aiming to prolong gestation.

- Surgical management for severe disease not responding to medical therapy is either by means of percutaneous valvuloplasty or more rarely aortic valve replacement.

#### *Labour*

- Assisted vaginal delivery with slow early incremental epidural analgesia is the preferred option. Good epidural analgesia will limit the work of labour minimizing tachycardia and surges in CO.
- Careful monitoring should be undertaken with continuous ECG, $SaO_2$, and non-invasive BP.
- Invasive monitoring with IABP ± CVP is useful for moderate and severe disease.
- Care after delivery should be either intensive therapy or high dependency.
- Haemodynamic goals are:
  - avoidance of aortocaval compression
  - maintenance of sinus rhythm. Tachycardia should be avoided. Bradycardia should also be avoided to prevent falls in CO
  - optimization of LV filling by keeping the woman well filled
  - avoidance of sudden falls in SVR.

#### *Caesarean delivery*

- CD is planned for women who have severe disease and especially those who are symptomatic in the third trimester, or for those with obstetric indications.
- Traditionally GA has been used for severe AS,[19] but there are increasing numbers of case reports which have safely used neuraxial techniques either with low-dose CSE or slow incremental epidural.[85]
- Invasive monitoring is essential for moderate or severe disease. IABP is very useful ± CVP. If the patient undergoes GA, TOE is useful if available.
- For GA, CVS response to induction should be obtunded with either alfentanil or remifentanil.
- Syntocinon® bolus during the third stage should be avoided. An infusion of 2–5 units over 20–30 minutes will limit CVS changes. Ergometrine and carboprost are contraindicated.
- As with vaginal deliveries, women with significant AS after CD should be cared for in a level 2 or 3 area.
- Haemodynamic goals are as listed earlier under 'Labour'.

## Mitral stenosis

Significant valve stenosis may lead to left atrial dilatation with risk of AF, pulmonary hypertension, and RV hypertrophy and dilatation. Women who are most at risk include:

- Moderate or severe MS. Risk of death of up to 3%.[9] Women with severe disease are WHO class IV. Pre-pregnancy counselling should advise against pregnancy.
- Women who decompensate during pregnancy either due to poor tolerance of physiological burden or development of AF.
- Pulmonary hypertension with peak systolic pressure greater than 50 mmHg.

### Aetiology

In both the developed and the developing world, mitral stenosis (MS) is usually due to RHD.

### Presentation

Women may present for the first time during pregnancy especially during the second and third trimesters as CO peaks and SVR falls to a nadir. Symptoms and signs are those of left- and-right sided heart failure including:

- Fatigue, lethargy
- Dyspnoea, PND, orthopnoea
- Cough
- AF
- Systemic embolism (from AF and or dilated LA)
- Chest pain
- Haemoptysis (with pulmonary hypertension)
- Pleural effusions, peripheral oedema, hepatomegaly, ascites
- Symptoms of compression by LA: hoarse voice (recurrent laryngeal nerve compression), dysphagia (oesophageal compression)
- Typically a mid-diastolic rumbling murmur is heard on auscultation.

### Investigations

- ECG: may show bifid p waves due to LA enlargement. AF may be present
- CXR: may reveal enlarged LA, cardiac failure, prominent pulmonary arteries
- Echo: valve area is used to assess severity in pregnancy where an area of 4–6 $cm^2$ is normal, less than 1.5 $cm^2$ indicates moderate disease, and an area of 1.0 $cm^2$ or less indicates severe disease. Degree of gradient across the valve, and pulmonary hypertension are used as prognostic indicators.

### Management

#### *Pregnancy*

- Prevention of tachyarrhythmia and aggressive treatment of AF using beta blockers. Digoxin may be used as a second-line drug treatment or DC cardioversion if drug treatment fails.
- Diuretics will treat fluid overload due to heart failure.
- Low-molecular-weight heparin (LMWH) is required for AF or LA dilatation.
- Bed rest and $O_2$ therapy may enable a woman to reach a more desirable gestation.
- Surgical intervention for poorly controlled severe disease may be life-saving. Percutaneous balloon valvuloplasty may be offered if the valve looks amenable, that is, absence of significant valve regurgitation and a pliable valve. Mitral valve replacement is rarely performed in pregnancy.

### *Labour*

- Assisted vaginal delivery with early slow incremental epidural is usually advised for women with mild disease or women with more severe disease who are NYHA 1 or 2 and without pulmonary hypertension. Otherwise planned CD is advised.[9]
- Monitor continuously in labour with ECG, $SaO_2$, non-invasive BP.
- Invasive BP ± CVP are useful for moderate or severe disease.
- After delivery, care should take place in a level 2 or 3 area.
- Haemodynamic goals:
  - avoid aortocaval compression.
  - incremental epidural analgesia will reduce the work of labour by limiting increases in CO and HR due to pain and Valsalva. Epidural analgesia is useful in the immediate postpartum period to reduce preload.
  - prevention of fluid overload. A dose of diuretic should be considered at the time of delivery to offset the effect of autotransfusion. Venous return should be maintained by avoiding aortocaval compression. Excessive fluids should be avoided.
  - maintain sinus rhythm and avoid tachycardia. AF should be treated promptly.
  - avoid rapid reductions in SVR. If vasoconstriction is required, phenylephrine is rapidly titratable, and does not cause tachycardia.
  - avoid factors likely to increase pulmonary arterial pressure: give $O_2$, avoid acidosis, hypercarbia, and pain.

### *Caesarean delivery*

- CD is planned for women who have severe disease, that is, those who are NYHA class 3 or 4, and for those with pulmonary hypertension, or for women with obstetric indication.
- Invasive monitoring is essential for moderate or severe disease. IABP is very useful ± CVP.
- If NA is used, low-dose spinal component CSE or slow incremental epidural provide slow-onset titratable anaesthesia.
- If the patient undergoes GA, TOE is useful if available.
- For GA, cardiovascular response to induction should be obtunded with either alfentanil or remifentanil.
- Syntocinon® bolus during the third stage should be avoided. An infusion of 2–5 units over 20–30 minutes will limit cardiovascular changes. Ergometrine and carboprost are contraindicated.
- As with vaginal deliveries, women with significant MS after CD should be cared for in a level 2 or 3 area.
- Haemodynamic goals are as listed earlier under 'Labour'.

## Aortic and mitral regurgitation

Both aortic and mitral regurgitation (AR and MR) are usually well-tolerated in pregnancy unless regurgitation is severe or of sudden onset. The reduction in SVR and tachycardia in pregnancy favour regurgitant lesions.

### Aetiology

- AR and MR may be both congenital and acquired.
- AR may be due to bicuspid valves, dilated aortic root (e.g. MFS), IE, aortic dissection, and RHD.
- MR may be due to mitral valve prolapse, RHD, after valvuloplasty, IE, and functional due to LV dilatation.

### Presentation

Both conditions may present with dyspnoea, and signs and symptoms of heart failure. AR may present with angina due to reduction in coronary blood flow. MR may present with palpitations due to AF in association with dilatation of the LA.

Typical signs of AR are:

- collapsing pulse
- wide pulse pressure
- high-pitched early diastolic murmur at upper left sternal edge especially in expiration with woman sitting forward.

A typical sign of MR is:

- pan-systolic murmur radiating to apex.

### Investigations

- Both conditions should be investigated with ECG, CXR, and Echo.
- ECG: may show LVH for both valve lesions. Ischaemia may be seen in AR, and AF in MR.
- CXR: both conditions may lead to cardiomegaly and signs of cardiac failure. In MR, a dilated LA may be seen.
- ECHO: Doppler will enable quantification of severity of valve regurgitation.

### Management

#### *Pregnancy*

- Regular monitoring of cardiac function should be undertaken.
- Medical management is the mainstay of treatment in pregnancy:
  - heart failure is treated with diuretics
  - hydralazine and nitrates may be necessary to reduce afterload.

#### *Labour*

- Assisted vaginal delivery with incremental epidural analgesia is planned for women with significant disease. Good epidural analgesia will limit increases in SVR due to pain and Valsalva manoeuvre.
- Haemodynamic goals:
  - Relative tachycardia and lowered SVR are the physiological goals to reduce valve regurgitation
  - Aortocaval compression should be avoided
  - SR should be maintained.

#### *Operative delivery*

- If GA is needed, cardiac depression should be minimized.

### Prosthetic heart valves

Women with prosthetic heart valves should be referred for cardiology assessment early in pregnancy. In general, women with well-functioning tissue valves do well in pregnancy. In contrast, the risk of mortality with mechanical valves is 1–4%.[86] This risk of valve thrombosis is low for tissue valves and generally women are not anticoagulated. The risk of valve thrombosis is much higher with mechanical valves and lifelong anticoagulation is required. The risk of valve thrombosis is higher again in pregnancy due to hypercoagulability.[87]

Anticoagulation poses risks to both the mother and baby:

- Risk of bleeding from the placental bed
- Fetal loss (one-third with warfarin. Dose dependent)
- Embryopathy in 5–6% fetuses with warfarin between 6 and 12 weeks gestation. Dose dependent
- Fetal bleeding in second and third trimester.[9]

Unlike warfarin, heparin does not cross over the placenta to the fetus: therefore there are no fetal risks. However, the risk of mechanical valve thrombosis is 25% with unfractionated heparin compared with warfarin. Most women will therefore be maintained on LMWH anticoagulation during pregnancy, with monitoring of peak anti-factor Xa levels and also trough levels, as guided by expert haematology advice, in high-risk women. Unfractionated heparin is reserved for situations where rapid reversal of anticoagulation is needed. Consensus guidelines do not exist for optimal anticoagulation regimes in pregnancy. Each patient should therefore be referred for specialist advice early in pregnancy and an individual plan for optimal anticoagulation made on a case-by-case basis.[88] Multidisciplinary planning for labour and delivery will be required. Unless there are obstetric indications for CD, vaginal delivery will usually be the preferred option. To limit the risks of maternal haemorrhage at delivery, and haematomas associated with neuraxial block, induction of labour is often planned to enable step-down or rapid reversal of anticoagulation. UKOSS are currently investigating the outcomes of pregnancy in women with mechanical heart valves.

## Infective endocarditis

In contrast to resource-limited countries where RHD is common, resource-rich countries have a very low incidence of IE in pregnancy: 1/100,000 pregnancies.[9] The main at-risk group in resource-rich countries are intravenous drug misusers where IE may occur on normal heart valves. IE may be associated with diseased or prosthetic heart valves, septal defects, shunts, baffles, and AVMs. The risk for these groups rises to 0.5%.[9] The main causative organism in pregnancy is *Streptococcus*. Mortality rates are very high in pregnancy with up to 33% of mothers dying.[9] The major complications are due to heart failure precipitated by acute valvular regurgitation, and embolic disease.

IE is diagnosed in the same way as in non-pregnant patients, and is treated with long-term antibiotics. Surgical treatment is reserved for patients whose medical treatment has failed.

Routine antibiotic prophylaxis for the prevention of IE, for women with valve disorders or other predisposing heart lesions, is not required for women undergoing obstetric procedures. These include urinary catheterization, amniocentesis, chorionic villus sampling, normal vaginal delivery, instrumental vaginal delivery, and CD.[89]

## Conclusion

Heart disease is a leading cause of maternal death throughout the world. In many resource-rich countries it is the most common overall cause of maternal mortality: the vast majority of these deaths are due to AHD. AHD is also a significant cause of severe maternal and fetal morbidity. As risk factors for AHD become more prevalent in women of reproductive age, mortality and severe morbidity may increase. However, the majority of pregnant women even with the most severe types of AHD achieve safe deliveries. Assessment, treatment, and detailed peripartum plans agreed by a multidisciplinary team, consisting of cardiologists, obstetricians, and obstetric anaesthetists, are fundamental to a safe approach to pregnancy in women with AHD. Most women will undergo a vaginal delivery: in this instance an early incremental epidural will reduce the cardiorespiratory work of labour. Where operative delivery is undertaken, slow-onset NA is becoming a more accepted approach even in severe cardiac disease.

In stark contrast to patterns of cardiac disease in the Western world, RHD is still highly prevalent in developing countries. Without the same available resources, many more women are dying in pregnancy as a result of their cardiac disease compared with women in developed countries.

## Acknowledgement

Thanks to Dr Hamish Ireland for the CT angiography images of the aortic dissection.

# CHAPTER 42

# Respiratory disease

Wendy H. L. Teoh

## Cystic fibrosis

### Epidemiology and prevalence

Cystic fibrosis (CF) is a fatal autosomal recessive genetic disease involving chloride channels, affecting 1/2500–3200 live Caucasian births. CF was first distinguished from coeliac disease in 1938 when the autopsy studies of malnourished infants revealed 'cystic fibrosis of the pancreas'. Previously regarded as a uniformly fatal childhood disease, it has transitioned to a chronic, progressive disease of adults.[1] Since genetic identification in 1989 and improvements in diagnosis and therapeutic advances, CF sufferers have attained significant gains in quality of life, pregnancy, and longevity. The median survival age of patients with CF is now 38 years and increasing.[2] Declines in newborn CF incidence from 1975 to 2009 have been reported consecutive to the availability of prenatal diagnosis in France[3] and Australia.[3,4]

### Genetics

The cause of CF is a mutation in a single gene on chromosome 7, that encodes the cystic fibrosis transmembrane conductance regulator (CFTR).[5,6] CFTR functions as an adenosine triphosphate- and cyclic adenosine monophosphate (cAMP)-dependent chloride channel that is found at the apical border of epithelial cells lining most exocrine glands. Clinical CF is associated with mutations in the *CFTR* gene (of which the most common mutation among Caucasians, DeltaF508, was identified in 1989[7]) where epithelial cells are unable to alter chloride permeability in response to changes in cAMP, decreasing the water content of various secretions, and resulting in increased viscosity and luminal obstruction. Organs that express CFTR in their epithelial cells are affected, notably the airways (including sinuses and lungs), gastrointestinal tract (including pancreas and biliary system), the sweat glands, and the genitourinary system.

### Clinical manifestations

Pulmonary disease is responsible for more than 90% of the morbidity and mortality in patients with CF[8] stemming from the inability to clear thickened and inspissated mucus from the airways. Chronic airway obstruction with decreased forced expiratory volume in 1 second ($FEV_1$) and peak expiratory flow (PEF), and increased residual volume is seen. Colonization with *Pseudomonas aeruginosa, Staphylococcus aureus, Haemophilus influenza, Stenotrophomonas maltophilia,* and other Gram-negative organisms commonly occurs. *Burkholderia cepacia* and *Aspergillus fumigatus* are associated with high morbidity and mortality. Recurrent bacterial infections result in dilation of the conducting airways and bronchiectasis.[9] With disease progression, there is destruction of parenchyma and loss of pulmonary arterial vascular cross-sectional area. Ventilation/perfusion inequality results in chronic hypoxaemia, an increase in pulmonary vascular resistance (PVR), pulmonary hypertension, and cor pulmonale. Spontaneous pneumothorax is prevalent in older patients and those with more severe pulmonary impairment ($FEV_1$ of <40% predicted).[10]

Non-respiratory manifestations of CF include exocrine pancreatic deficiency, malabsorption, failure to thrive, fat-soluble vitamin deficiencies, recurrent pancreatitis, CF-related diabetes mellitus, hepatobiliary cirrhosis and portal hypertension, intestinal obstruction, increased gastroesophageal reflux, infertility, obstructive azoospermia, and salt-losing syndromes.

### Diagnosis

Diagnosis is based on sweat chloride measurements greater than 60 mEq/L plus the following characteristic clinical symptoms: presence of chronic obstructive lung disease (cough, chronic purulent sputum production, exertional dyspnoea) or a family history of CF. Chronic pansinusitis is universal. Malabsorption responsive to pancreatic enzyme treatment is evidence of exocrine insufficiency associated with CF. Obstructive azoospermia confirmed by testicular biopsy is also strong evidence of CF. Other laboratory findings include *CFTR* genotype with two known CF mutations, and nasal potential difference testing to detect CFTR dysfunction.[2]

### Impact of pregnancy on cystic fibrosis

With improvement in clinical care and longer survival of patients with CF, pregnancy has become commonplace. Deterioration of pulmonary function occurs as CF patients may be unable to meet the required increases in pregnancy-associated minute ventilation and oxygen uptake. Blood volume and cardiac output increments precipitate right heart strain, congestive heart failure, and pulmonary hypertension in those with moderate-to-severe pulmonary disease.

Of 20 pregnancies from 18 women with CF during the period 1995–2009, all women delivered live births apart from one therapeutic abortion. Three mothers either died or required lung transplantation after pregnancy (range 2.5–8.0 years).[11] Factors associated with poor outcome in pregnant CF patients are weight gain less than 4.5 kg, forced vital capacity (FVC) less than 50% predicted, pulmonary colonization with *B. cepacia*, frequent pulmonary infections, diabetes mellitus, malnutrition, and pancreatic insufficiency.[12,13]

Despite these negative effects, pregnancy can be managed without a persisting decrement in lung function beyond what may be

expected in non-pregnant CF.[14] Successful pregnancy outcome has even been reported in a CF patient following heart, lung, and renal transplant.[15]

With the increasingly positive outcomes for people with CF, it is likely that more couples will chose to pursue pregnancy, cognisant of the risks and longer-term issues for mother, child, and family. Successful outcomes for mother and child can be achieved with appropriate multidisciplinary care. The process begins prior to conception and requires frequent monitoring of the mother's respiratory status, level of glycaemic control and obstetric well-being. Overall long-term survival appears unaffected[16] but intensive health monitoring, more frequent use of intravenous (IV) antibiotics, and hospitalization[17] is evident in pregnant CF patients (due to respiratory exacerbations, diabetic treatment, supplementary nutrition, etc.).[18] A multidisciplinary team of providers is optimal to address the variety of issues that arise in such a pregnancy.

## Impact of cystic fibrosis on pregnancy

The incidence of intrauterine growth retardation, low birth weight infants, and preterm labour and delivery is increased for women with CF, especially those with the worst pulmonary, nutritional, and pancreatic function.[19,20] $FEV_1$ less than 60% predicted and body mass index (BMI) less than 20 $kg/m^2$ were significant predictors of fetal complications.[11] A recent review of 523 pregnancies in 401 women showed 83.1% of 516 pregnancies resulted in live births, of which 24% delivered preterm; miscarriage occurred in 6.3% and therapeutic abortion in 10% of pregnancies.[21]

## Medical management

Comprehensive care at adult subspecialty centres decreases hospitalization, and improves morbidity and mortality. Respiratory management includes chest physiotherapy with postural drainage: breathing exercises, high-frequency chest compression with an inflatable vest, and airway oscillation with a flutter valve are less time-consuming and do not require trained personnel. Adrenergic agonists (e.g. salbutamol) can be used for bronchial hyper-reactivity; bronchodilator therapy is considered if patients have an increase of 10% or more in $FEV_1$ in response to an inhaled bronchodilator. Chronic suppressive antibiotic therapy with aerosolized tobramycin[22] and oral azithromycin[23] decreases exacerbations of CF. The abnormal viscosity of airway secretions is due primarily to neutrophils and their degradation products. DNA released from neutrophils forms long fibrils that increase viscosity. Recombinant human deoxyribonuclease 1 (dornase alfa (Pulmozyme®)) cleaves this DNA, and increases sputum clearance, reduces air trapping,[24] improves $FEV_1$, and decreases pulmonary exacerbation rate.[25] Inhaled aztreonam lysine is also beneficial for chronic airway *Pseudomonas aeruginosa*.[26,27] Hypertonic saline acutely increases mucociliary clearance and has emerged as a safe and inexpensive adjunct therapy.[28] CF patients have a significant inflammatory component with asthma or asthma-like symptoms and benefit from oral or inhaled glucocorticoids. Continuous supplemental oxygen is the only medical therapy effective in treating pulmonary hypertension and improving right ventricle performance.[29] After lung transplantation, 1- and 5-year survival rates of 89% and 71% respectively have been reported, with the presence of diabetes not associated with a worse outcome.[30] Antithymocyte globulin induction therapy confers a significant survival benefit in CF patients undergoing lung transplantation and reduces rejection.[31] Nasal polyps, hypertrophy, and hyperplasia of nasal/sinus mucosa may benefit from use of decongestants or topical glucocorticoids, saline irrigation, and surgical drainage of sinonasal passages.

## Obstetric management

The primary issue is whether pregnancy is advisable, dependent on pregravid CF maternal health. CF is the first genetic disorder for which universal screening of preconceptional or prenatal patients became a component of standard prenatal care. Carrier screening facilitates risk assessment for prospective parents to have an affected offspring, although there remains a small residual risk for carrying a mutation even with a negative screening result.[32] There has been a modest reduction in the live-birth prevalence of CF since the introduction of newborn screening.[33]

## Anaesthetic management

CF sufferers have usually established long-term relationships with their respiratory physicians or CF specialists, are familiar with their disease, and have knowledge of healthcare systems. These strengths should be harnessed by the obstetric anaesthetist, and management decisions made in tandem with the CF parturient's multidisciplinary care team throughout the delivery and perioperative period. Neuraxial anaesthetic techniques are promoted to avoid airway instrumentation and exacerbating risk of pulmonary complications.

### Preoperative assessment and optimization

A thorough pulmonary evaluation is indicated. The interview should elicit the history of CF, disease progression, presence of cough, quality and quantity of mucus production, frequency of respiratory infections and airway reactivity, wheezing and response to bronchodilators, and functional exercise capacity. It is perfectly acceptable to order a chest radiograph, and a recent one is crucial to diagnose pneumothorax, pneumonic processes, or bullous disease. Lung hyperinflation is evidenced by diaphragm flattening, prominence of the retrosternal space, and kyphoscoliosis in late disease. Bronchovascular markings, initially present in upper lobes, progress to the lower lobes later in the disease process. Peribronchial cuffing and parallel-lined 'tram tracks' will be seen with bronchiectasis and cyst formation. Chest computed tomography may be helpful to delineate the extent of bronchiectasis, but does not correlate with exercise tolerance, and may appear worse than the patient's actual physical capabilities.[34] Baseline arterial blood gas analysis should be performed looking for $CO_2$ retention. Pulmonary function testing typically shows an obstructive pattern: increased ratio of residual volume to total lung capacity and decreased forced expiratory flow at 25–75% of lung volume. Greater reductions in $FEV_1$ and $FEV_1$/FVC ratio epitomize disease progression. Late findings of increased PVR, right ventricular hypertrophy, and cor pulmonale indicate advanced and decompensated CF, with great mortality. The perioperative management of patients with CF also encompasses a pancreatic and hepatobiliary evaluation. Coagulopathy resulting from vitamin K deficiency or general malnutrition should be excluded with prothrombin time and partial thromboplastin time. Aspiration prophylaxis is imperative due to increased incidence of gastroesophageal reflux disease (GORD) in CF patients. Glucose intolerance is rife and may require escalating insulin therapy.

### Issues affecting labour and vaginal delivery

Labour pain relief from neuraxial anaesthesia should aim to provide adequate analgesia, prevent maternal hyperventilation to limit the increased work of breathing, avoid high thoracic motor blockade that will impair the CF parturient's cough reflex and ability to expectorate thick secretions, and include avoidance of respiratory depression (e.g. parenteral opioids). Intrathecal opioids have been used successfully[35] but should be monitored closely for respiratory depression. Continuous lumbar epidural analgesia (avoiding a high block) with dilute bupivacaine solutions is ideal.[36–38] Continuous pulse oximetry monitoring and supplemental oxygen therapy are advisable due to the high incidence of hypoxaemia in CF patients.

### Issues regarding caesarean delivery

Neuraxial anaesthesia techniques (e.g. single-shot spinal, combined spinal–epidural (CSE), or epidural top-up) are ideal in minimizing postoperative pulmonary complications, with the same treatment goals as outlined above for labour and vaginal delivery. However, if general anaesthesia cannot be avoided, the increased risk of aspiration (from GORD) and bronchospasm need to be factored into the anaesthetic plan. The goal would be to have a parturient with minimal respiratory depression and full recovery of airway reflexes at the end of surgery and anaesthesia. Nasopharyngeal airways should be avoided due to sinonasal disease including sinus polyps. A rapid sequence induction should be preceded by non-particulate antacids and $H_2$ antagonists. CF is an obstructive process, and prolonged expiratory times may be necessary, as well as humidification of inspired gases and minimization of peak airway pressures to reduce the risk of barotrauma and pneumothorax. Nitrous oxide should be used with caution because of the increased risk of pneumothorax formation with positive pressure ventilation, as well as the likely presence of multiple blebs. Volatile anaesthetic agents produce bronchodilation and may be preferable in CF patients to total IV anaesthesia techniques. Adjunctive pain medications should be administered for post-caesarean delivery (CD) analgesia (e.g. non-steroidal anti-inflammatory drugs, IV paracetamol to reduce opioid-related respiratory depression). Bilateral transversus abdominis plane blocks are useful in reducing morphine consumption following CD under general anaesthesia.[39] Before extubation, consider lung recruitment manoeuvres to avoid atelectasis and endotracheal suction to mobilize secretions. The patient should be extubated fully awake, and high dependency care for 24 hours to monitor respiratory function is necessary. Immediate postoperative chest physiotherapy may be beneficial to some patients.

# Asthma

## Definition

Asthma is derived from the Greek word *aazein* meaning 'to pant' and was first used in 450 BC by Hippocrates to describe a condition characterized by spasms of breathlessness. The present Global Initiative for Asthma (GINA) definition of asthma covers a triad of airway pathology (chronic airway inflammation), disordered airway function (reversible airway obstruction and airway hyper-responsiveness), and typical symptomatology.[40]

## Epidemiology and prevalence

Asthma is the most common respiratory disorder to complicate pregnancy. The burden of asthma in pregnancy is increasing worldwide,[41] with European estimates of at least 4% of women having asthma, and at least 8% of women in antenatal clinics in the United Kingdom having asthma.[42] From 1976 to 2001,the prevalence of asthma in the United States has risen from 3% to 8.8%[43] and is 12% in Australia.[44]

## Genetics

Genes and environmental exposures interact to influence the risk of asthma susceptibility and severity; implicated genes indicate pathways for therapeutic intervention and provide insight into mechanisms of asthma severity progression.[45] Two large meta-analyses of asthma susceptibility identified four chromosomal regions that were consistently associated with development of asthma in ethnically different individuals: loci in the *ORMDL3* gene region of 17q21, interleukin (IL)-1 receptor-like 1 isoform 1 (*IL-1RL/IL-18R*) on chromosome 2q, thymic stromal lymphopoietin (*TSLP*) on 5q22, and *IL-33* on chromosome 9p24.[46,47] Genetic variants in the major histocompatibility complex gene region (human leucocyte antigen region) on chromosome 6p21 indicated asthma susceptibility in Asian populations.[48] Pharmacogenetic genome-wide screens also identified two correlated genetic variants in the glucocorticoid-induced transcript 1 (*GLCCI1*) gene that related to decreased response to inhaled glucocorticoids.[49]

## Pathophysiology

The underlying mechanisms involve (a) airway smooth muscle (ASM)-related bronchial hyper-responsiveness, (b) airway inflammation, and (c) remodelling changes in airway epithelium. This occurs against a backdrop of various genetic, environmental, biochemical, and immunological host characteristics affecting asthma phenotype and severity.

Changes in ASM contractile properties or impaired function of relaxant receptors play an important role in the development of bronchial hyper-responsiveness. G-protein coupled receptor (GPCR)-associated calcium responses in ASM can be modulated by a variety of inflammatory stimuli like tumour necrosis factor gamma, IL-13 (a T-helper type 2 (Th2) mediator in allergic asthma), or IL-1b.[50] Vagal and sympathetic factors directly modulate airway tone. Asthmatic ASM is infiltrated by both mast cells (mast cell myositis) and T lymphocytes but apparently not eosinophils. Mast cell migration is further induced by the production of various chemotactic mediators secreted by the ASM itself, which is closely related to the ASM inflammatory microenvironment.[50] This complex relationship between ASM cells and inflammatory cells is postulated to be a possible way for ASM to organize inflammation.

Placental growth factor (PlGF) and its receptor vascular endothelial growth factor receptor 1 (VEGFR1) play an important role in pathological conditions related to angiogenesis, vascular leakage, and inflammation. PlGF and its receptor VEGFR1 were found to be up-regulated in allergic asthma, playing a proinflammatory role by inducing tissue oedema, increasing tissue neutrophilia and the production of IL-17.[51]

Asthmatic bronchial remodelling is characterized by various structural changes, including abnormal epithelium, subepithelial

membrane thickening, alteration of the extracellular matrix deposition, neoangiogenesis, mucus gland hypertrophy, and increased ASM mass.[52] Inflammatory oedema and mucous plugging exacerbate airflow limitation and progressively impair the response to bronchodilator therapy. Recent evidence suggests that the increased ASM mass is the key feature of bronchial remodelling in asthma because of its association with a more severe asthma phenotype, and correlates with a decrease in lung function.[50] The airway remodelling, thickening, and aberrant communication between the injured airway epithelium and the pulmonary mesenchyme contributes to disease chronicity and refractoriness to corticosteroids.[53] Genome-wide association studies of asthma provide strong evidence of the biological importance of pathways that communicate epithelial damage to the adaptive immune system, ultimately leading to airway inflammation. Moreover, cytokines derived from epithelial cells such as TSLP and IL-33 are thought to promote the TH2 response through activation of receptors such as IL-1RL1 on cell types such as mast cells, TH2 cells, and regulatory T cells.[45]

## Diagnosis

Many patients with asthma during pregnancy will already be known asthmatics. A new diagnosis of asthma is usually suspected on the basis of characteristic symptoms (wheezing, chest tightness, cough, shortness of breath), temporal relationships (fluctuating intensity, worse at night) and triggers (e.g. allergens, exercise, and infections). Chest auscultation may reveal wheezing (but its absence does not exclude it) and a prolonged expiration phase.

The most common differential diagnosis is dyspnoea of pregnancy, which can occur in early pregnancy in approximately 70% of women. This breathlessness is differentiated from asthma by its lack of association with cough, wheezing, or airway obstruction. Other differential diagnoses include GORD, allergic rhinitis with chronic cough from postnasal drip, bronchitis, pneumonia, pulmonary oedema, and pulmonary embolism.[54]

Spirometry reliably demonstrates airflow obstruction, and is the diagnostic tool of choice.[55] The diagnosis of asthma is confirmed by a reduced $FEV_1$ with greater than 12% improvement after inhalation of a short-acting bronchodilator like salbutamol, or by an increase of greater than 10% of predicted $FEV_1$ post salbutamol.[55,56] The peak expiratory flow rate (PEFR) is another commonly used pulmonary function parameter. Peak flow meters are designed for monitoring asthma control and should not be used as diagnostic tools in the office because of significant variability in their reference values for predicted peak expiratory flow measurements. Current National Asthma Education and Prevention Program (NAEPP) guidelines suggest classifying degree of asthma severity in patients not on controller medication and degree of asthma control in patients on controller medication. Assessing severity or control involves determining the frequency of daytime symptoms, night-time symptoms, activity limitation, frequency of rescue therapy, and $FEV_1$.[57]

In patients with normal pulmonary function, methacholine testing is often performed to confirm bronchial hyper-reactivity. However, methacholine testing is not recommended in pregnancy due to lack of available safety data. If reversibility of airway obstruction cannot be elicited after bronchodilator therapy, yet has a clinical picture consistent with asthma, the parturient should be empirically treated for presumed asthma until methacholine testing can be performed postpartum.[58] Skin testing for allergens is recommended for most non-pregnant patients with persistent asthma[55] to help identify potential triggers such as mites, animal dander, mould, and cockroachs, for which specific environmental control instructions can be given; however, it is not recommended in pregnancy as it is associated with systemic reactions and anaphylaxis. As an alternative, pregnant patients with persistent asthma may undergo blood testing for immunoglobulin E antibodies to specific allergens.[58]

## Effects of pregnancy on asthma

### The rule of thirds

Most women with asthma experience a change in their disease control while pregnant. One-third of women will improve, one-third will worsen, the remainder will remain unchanged. These changes are unpredictable from woman to woman and from pregnancy to pregnancy,[59,60] necessitating careful regular review of asthma during pregnancy. While exacerbations may occur at any time during gestation, they appear to be more common in the late second trimester. This 'one-third hypothesis' of worsening asthma stemmed from a large prospective study of 330 parturients in the 1980s whose symptoms of wheeze and sleep and activity limitation due to asthma were significantly increased between 29 and 36 weeks' gestation.[61] Exacerbations of asthma during labour and delivery can be predicted by severity: Women with mild asthma had an exacerbation rate of 12.6% and hospitalization rate of 2.3%; those with moderate asthma had an exacerbation rate of 25.7% and hospitalization rate of 6.8%; and severe asthmatics had exacerbation of 51.9% and hospitalization rate of 26.9%.[62]

### Risk factors for asthma exacerbations during pregnancy

Atopy, sinusitis, and gastroesophageal reflux may also worsen in pregnancy, exacerbating asthma. Other risk factors for asthmatic exacerbations include inadequate prenatal care, obesity, and inhaled corticosteroids nonadherence.[63,64] The use of medication have profound effects on the course of asthma. One study found that asthma severity during pregnancy is similar to severity in the year before pregnancy, provided patients continue to use their prescribed medication. If women discontinue medication, even mild asthma becomes significantly more severe.[65] Respiratory tract viral infection is another culprit.[64] Pregnant women and those with asthma are certainly two groups with significantly increased susceptibility to infection with influenza strains, including seasonal and H1N1 influenza[66,67] due to a reduced production of interferon gamma and IL-10 from peripheral blood mononuclear cells and attenuation of antiviral and regulatory immunity,[68] which can be significantly improved by vaccination.[69] During the H1N1 pandemic in the United States, 7% of hospitalized patients were pregnant and 22% of these women had asthma. In total, 9% of all admissions to intensive care units (ICUs) and 16% of all deaths were among pregnant women, indicating that both the prevalence of illness and its severity is increased with pregnancy.[66,70–74]

### Assessment of asthma severity

Different benchmarks have been used to assess asthma severity, be it clinical symptoms or pharmacological therapeutic requirements, therefore leading to variations in reported studies. Women with severe exacerbations in pregnancy have significantly lower asthma-specific quality of life, which may be a more

sensitive measure of limitations due to asthma than symptoms alone.[75] Teeter[76] found that asthma symptoms correlated poorly with objective measures of airway obstruction $FEV_1$ and PEF, as post-treatment improvement in those parameters were not seen despite a subjective improvement in asthma symptoms. This reinforces the recommendation to measure airway obstruction objectively when assessing adult patients with chronic asthma.

Juniper and colleagues[77] described an overall improvement in methacholine airway responsiveness (dose change required to lower $FEV_1$ by 20%) in 16 parturients in the second trimester compared with preconception or postpartum values, with an associated improvement in clinical asthma severity as indicated by a reduction in minimum medication requirements. However, this did not result from better asthmatic control, as both symptoms and spirometry remained unchanged during pregnancy. They found no relationship with serum progesterone or oestriol concentrations, suggesting that other non-hormonal factors may also contribute to the improvement during pregnancy.[78]

### Mechanisms for changes in asthma during pregnancy

Hormonal involvement, altered immune function, and fetal-sex have been proposed as mechanisms in pregnancy-related changes in asthma.

#### *Hormonal factors*

Physiological factors that may improve asthma during pregnancy include higher levels of circulating cortisol, increased production of bronchodilating prostaglandins, and increased progesterone with advancing gestation that contributes to increased minute ventilation and cAMP-induced relaxation of ASM. Factors that may worsen asthma during pregnancy are decreased sensitivity to beta-adrenergic agonists, increased production of bronchoconstricting prostaglandins, and reduced sensitivity to circulating cortisol due to binding of steroid hormones (e.g. progesterone) to cortisol receptors. Juniper's work showed that increasing levels of progesterone in pregnancy does not play a central role in attenuating airway hyper-responsiveness in asthmatics.[77] Data has emerged that progesterone may actually worsen asthma by aggravating eosinophilic airway inflammation by enhancing systemic IL-5 production, and increasing bronchial hyperreactivity.[79] Thus, effects of pregnancy on asthma appear to involve factors *other* than direct hormonal effects on ASM.

#### *Non-hormonal factors*

Alterations in the maternal immune system during pregnancy such as a suppression of cell-mediated immunity may contribute to changes in asthma. Pregnancy-induced increases in regulatory T-cell prevalence was found to be absent in asthmatic pregnancies that interfere with physiological intrauterine growth.[80] In a study of 208 pregnant women, asthmatic atopic women with pets in the home during pregnancy were found to have lower percentages of regulatory T cells than atopic women who did not have pets.[81] Others have also found that lymphocyte activation of CD4 and CD8 T cells and the number of natural killer T cells were found to be blunted in pregnancy.[82] As lymphocyte activation characterizes bronchial asthma, these pregnancy-associated immunological alterations may explain why some mothers experience an improvement in their asthma.

Heat shock protein (Hsp)-70 is a novel marker of the immunotolerance of pregnancy. It is decreased in the circulation of healthy pregnant women compared with non-pregnant adults[83] but asthmatic women exhibit higher levels of Hsp70 than their non-asthmatic counterparts.[84] The role of this marker in the chronic inflammation of asthma and impact on perinatal outcomes has not been fully elucidated yet.

IL-4 and gamma-interferon producing T-lymphocyte subsets were found to be significantly increased in pregnant women with asthma, compared with healthy pregnant women and non-pregnant asthmatic women, but was not related to whether women perceived their asthma to have improved or worsened during pregnancy.[85] Bronchial epithelial cells have demonstrated increased production of IL-8 and soluble intercellular adhesion molecule 1 in the presence of plasma from pregnant women with asthma, and results were suggestive of an increased chemotactic capacity[86] which may be a mechanism contributing to worsening asthma in some pregnant women.

Progression of maternal asthma symptoms in pregnancy were thought to be influenced by the sex of the fetus,[87–89] with female fetus having a higher incidence of hospitalization for asthma during pregnancy.[90] However, other reports do not support this association.[91,92] The largest study in this area of more than 10,000 asthmatic pregnancies in Quebec found no differences between women pregnant with male and female fetuses with regard to the occurrence of severe exacerbations, or the use of inhaled corticosteroids or short-acting beta agonist.[92]

## Effects of asthma on the parturient and fetus

A large meta-analysis of 40 publications between 1975 and March 2009 involving 1,637,180 subjects confirmed the link between maternal asthma and increased risk of adverse perinatal outcomes. Maternal asthma was associated with an increased risk of low birthweight (relative risk (RR) 1.46; 95% confidence interval (CI) 1.22–1.75), small for gestational age (SGA) (RR 1.22; 95% CI 1.14–1.31), preterm delivery (RR 1.41; 95% CI 1.22–1.61), and pre-eclampsia (RR 1.54; 95% CI 1.32–1.81). Encouragingly, the relative risk of preterm delivery and preterm labour were reduced to non-significant levels by active asthma management.[93] The increased perinatal risks in pregnant asthmatic women have been postulated to be due to (a) hypoxia and other physiological sequelae of poorly controlled asthma, (b) medications used to treat asthma, and (c) pathogenic or demographic factors (e.g. race, ethnicity, smoking, and obesity) associated with asthma but not actually caused by the disease or its treatment, such as abnormal placental function.[94] Other publications confirm that mothers with asthma during pregnancy are also more likely to have CDs, diabetes mellitus,[95] fertility treatments,[58] membrane-related disorders and antepartum hemorrhage,[95,96] pulmonary embolism and maternal ICU admissions,[95] and SGA, low birth weight, or preterm birth infants than non-asthmatic women.[97] A large Canadian cohort of 41,637 pregnancies found an increased risk of congenital malformations (especially the nervous system (excluding spina bifida), respiratory, and digestive systems) in patients with maternal asthma compared to non-asthmatics, postulated to be due to fetal oxygen impairment from the disease itself, although the authors stated that further research would be needed to disentangle the relative effect of asthma and medications used to treat this disease.[98] Lower maternal $FEV_1$ has also been shown to be associated with increased gestational hypertension and prematurity in asthmatic pregnancies.[99] Racial disparity also exists. Asthma during

pregnancy was found to be a risk factor for low birth weight outcomes in black non-Hispanics but not white non-Hispanic women. Higher BMI and increased alcohol, tobacco, and illicit drug use were found in the black non-Hispanics. [100] Pregnant asthmatics with disease of mild-to-moderate severity can have excellent maternal and fetal outcomes. Conversely, mothers with severe or suboptimally controlled asthma during pregnancy have an increased maternal and fetal risk[101,102] including increased perinatal mortality.[103]

New evidence suggests that circulating antioxidant profiles of pregnant women with asthma may impact fetal growth. Antioxidants are important during pregnancy due to their protective role against a state of high oxidative stress as gestation progresses. McLernon et al.[104] characterized the circulating profile of tocopherols and carotenoids in pregnant women with asthma to determine whether asthma severity and dietary intake were associated with an altered antioxidant profile, to account for the increased incidence of intrauterine growth restriction in pregnant asthmatics. They found that pregnant women with moderate/severe asthma had increased plasma concentrations of total carotenoids, lutein, and alpha-tocopherol late in gestation compared to those women with mild asthma and healthy pregnant controls. Moderate/severe asthmatics had higher erythrocyte alpha-tocopherol quinone levels early in gestation relative to the controls but this marker of oxidative stress decreased as gestation progressed. Tocopherols and carotenoids were positively associated with birth weight centile. These findings suggest that the maternal system adjusts antioxidant pathways in response to the presence of a high oxidative load induced by asthma during pregnancy in an attempt to ensure continued fetal growth in an adverse environment.[104]

## Medical management

The genetic predisposition to asthma and bronchial hyperactivity persists throughout life, and the adage that children outgrow their asthma is refuted.[105] The ultimate goal of asthma therapy during pregnancy is to maintain adequate fetal oxygenation by prevention of maternal hypoxic episodes. Other goals include minimization or eradication of asthmatic exacerbations, daytime or nocturnal maternal symptoms, limitations of activities, maintenance of normal or near normal pulmonary function, minimal use of short-acting bronchodilators, and minimal or no adverse effects from medications.

A team approach is advised for the management of the asthmatic parturient, involving the obstetrician, anaesthetist, and respiratory physician. Consultation with an asthma specialist is indicated for evaluation of the role of allergy and irritants, complete pulmonary function studies, or evaluation of the medication plan if there are difficulties in achieving the goals of therapy, especially if the asthma is severe.

The effective management of asthma during pregnancy relies on four integral components: objective measures for assessment and monitoring, patient education, avoidance or control of asthma triggers, and stepwise titration of asthma pharmacotherapy. Asthma medications should be continued during pregnancy and while breastfeeding.[106]

### Objective measures for assessment and monitoring

$FEV_1$ after a maximal inspiration is the single best measure of pulmonary function. A mean $FEV_1$ less than 80% predicted has been found to be significantly associated with increased preterm delivery between 32 and 37 weeks, and birth weight less than 2500 g.[99] However, measurement of $FEV_1$ requires a spirometer. The PEFR correlates well with the $FEV_1$, and can be reliably measured with inexpensive, disposable, portable peak flow meters by the parturient herself. This self-monitoring of PEFR can provide valuable insight to the course of asthma throughout the day, assess circadian variation in pulmonary function, and detect early signs of deterioration so that timely therapy can be instituted. Parturients with persistent asthma should be evaluated at least monthly and those with moderate-to-severe asthma should have daily home PEFR monitoring.[57] The typical PEFR in pregnancy should be 380–550 L/min. The pregnant woman should establish her 'personal best' PEFR, then calculate her individualized PEFR zones: green zone greater than 80% of personal best, yellow zone 50–80% of personal best, and red zone less than 50% of personal best PEFR as suggested by the American Lung Association.[106]

Management of asthma in pregnancy can also be guided by measurement of fraction of exhaled nitric oxide (FENO).[107] A recent double-blind, randomized controlled trial involving 220 parturients who had their treatment adjusted at monthly visits by an algorithm using clinical symptoms (control group) or FENO concentrations (active intervention group) to uptitrate (FENO > 29 ppb) or downtitrate (FENO <16 ppb) their inhaled corticosteroid dose, found that asthma exacerbations during pregnancy and neonatal hospitalizations could be significantly reduced with a validated FENO-based treatment algorithm.[107]

### Patient education and smoking cessation

Proper asthma management should ideally be started in the preconception period. Patients should be made aware that controlling asthma during pregnancy is especially important for the well-being of their fetus. Vital patient education should include a basic understanding of the medical management of asthma, adherence to controller medication, and early treatment of exacerbations. She should be instructed on the proper PEFR technique (performed standing, after maximal inspiration, and note the reading on the peak flow meter), monitoring of PEFRs, the correct use of inhalers, and strongly encouraged to quit smoking. Smoking is a well-recognized contributor to poor perinatal outcomes, and remains the most modifiable risk factor of asthma, so pregnant woman should avoid active and passive smoking. In pregnant women with asthma, current and former smokers had higher rates of severe exacerbation,[108] and greater number of symptomatic days and nights of sleep disturbance were found among active smokers than in non-smokers with asthma.[109] A recent meta-analysis found a 20% increase in wheeze and asthma in children exposed to passive smoking, therefore preventing parental smoking is crucial to the prevention of asthma.[110]

### Avoidance or control of asthma triggers

75-80% of patients with asthma have positive skin tests to common allergens like animal dander, house dust mites, cockroach antigens, pollens, and moulds. Avoiding or controlling triggers can reduce asthma symptoms, airway hyper-responsiveness, and need for medication.[57] Other non-immunological triggers include tobacco smoke, air pollutants, food additives such as sulphites, and certain drugs including aspirin and beta blockers. Exercise-induced asthma can be mitigated by inhalation of salbutamol 10–30 minutes before starting.

## Pharmacological therapy

Medications used for asthma control in the non-pregnant population are generally the same in pregnancy with a few exceptions. They are divided into two groups: the long-term controllers that prevent asthma manifestations (inhaled corticosteroids (ICS), long-acting beta-2-agonists (LABAs), leukotriene-receptor antagonists (LRTAs), cromoglicate, and theophylline) and rescue therapy such as salbutamol that provides quick relief of symptoms. Current pharmacological therapy emphasizes treatment of airway inflammation to decrease airway hyper-responsiveness and prevent asthma symptoms. The 'step-care' therapeutic approach uses the least amount of drug intervention necessary to control a patient's severity of asthma, and increases the number and frequency of medications with increasing asthma severity[106] (Table 42.1).

*Bronchodilators*: inhaled short-acting beta-2 agonists (SABAs) salbutamol, levalbuterol, and pirbuterol are currently recommended for all levels of asthma during pregnancy as quick relievers. Rapid onset of action by smooth muscle relaxation occurs within 5 minutes, peaking within 1 hour and lasts 4–6 hours. Side effects of tremor, tachycardia, and palpitations occur but are not common at standard doses. SABAs do not block the development of airway hyper-responsiveness. Increased frequency of SABA use would indicate the need for additional anti-inflammatory therapy. In 2004, the NAEPP released an updated expert panel report on the management of asthma in pregnant women.[57] Safety concerns of asthma medications in pregnancy were addressed, and a significant amount of reassuring data on the safety of SABAs were found, particularly salbutamol. A prospective cohort study found no significant differences in perinatal mortality, congenital malformations, preterm delivery, and low birth weight in asthmatic women who used SABAs compared with women who did not use treatment for asthma during pregnancy.[111,112] In non-pregnant patients, a possible association between LABAs and increased risk of severe and fatal asthmatic exacerbations was observed. Limited data exist on the use of LABAs like salmeterol and formoterol during pregnancy. An epidemiological study reported no adverse outcomes among 65 women who used salmeterol while pregnant, out of a cohort exceeding 15,000 patients in the United Kingdom.[113] Recent information suggest there is no such increased risk when LABAs are used in conjunction with inhaled corticosteroids[114], as in pregnancy. Current guidelines recommend salmeterol as the preferred LABA used in pregnancy, as it has been available for longer in the United States.[57] A recent study investigated the association between exposure to SABAs and LABAs in the first trimester of pregnancy and the risk of congenital malformations in 13,117 asthmatics[115]. It confirmed evidence of SABA safety during pregnancy, but found significant increased risks of major congenital malformations observed with LABA use. The authors cautioned that more research was required to assess whether the increased risk of malformations among LABA users was due to the medication, bias by asthma severity, or chance alone.[115]

**Table 42.1** Step therapy medical management of asthma during pregnancy

| Step asthma severity and medications |
|---|
| Mild intermittent |
| 1. No daily medications, salbutamol as needed |
| Mild persistent |
| 2. Low-dose inhaled corticosteroid (alternative: Cromoglicate, LTRA, or theophylline |
| Moderate persistent |
| 3. Medium-dose inhaled corticosteroid (alternative: low-dose inhaled corticosteroid and LABA, LTRA, or theophylline) |
| 4. Medium-dose inhaled corticosteroid and LABA (alternative: medium-dose inhaled corticosteroid plus LTRA, or theophylline |
| Severe persistent |
| 5. High-dose inhaled corticosteroid and LABA |
| 6. High-dose inhaled corticosteroid and LABA and oral prednisone |

LABA indicates long-acting β agonist; LTRA, leukotriene-receptor antagonist.

*Theophylline* is an alternative treatment for mild persistent asthma and an alternative add-on treatment for the step 3 or 4 management of moderate persistent asthma during pregnancy (see Table 42.1). Theophylline is only indicated for chronic therapy and is not effective for the treatment of acute maternal exacerbations. Theophylline's long duration of action (10–12 hours with sustained-release preparations) makes it especially useful for nocturnal asthma. Inhaled corticosteroids are preferred over theophylline because they lead to a greater improvement in $FEV_1$, have fewer side effects, and do not require serum monitoring. Serum theophylline concentrations should be maintained at 5–12 mcg/mL during pregnancy.[57] Theophylline can have significant interactions with other drugs, which can cause decreased clearance with resultant toxicity, for example, 70% increase in theophylline serum levels with cimetidine and 35% with erythromycin.

*LRTAs* (e.g. zafirlukast (Accolate®), montelukast (Singulair®), and modifier zileuton that inhibits the leukotriene pathway) are all pregnancy category B drugs. Their use originated from the observation that leukotrienes are released into the airways by immune cells, contributing to the inflammatory process. They are not useful for acute treatment of bronchospasm. Leukotriene modifiers are less effective as single agents than inhaled corticosteroids and less effective than LABA as add-on therapy.[57] Zileuton use has been associated with hepatic injury, and LRTA use with Churg–Strauss vasculitis, especially when steroid dosage is decreased. Human data are limited for their use in pregnancy. Investigators found that LRTA use in 96 pregnancies was not associated with a specific pattern of major structural anomalies but cautioned interpretation of the results due to the limited sample size.[116] A recent systematic review found that congenital malformations had been reported with LRTA exposure during pregnancy, but those women also had exposure to other medications, including oral corticosteroids.[117]

*Corticosteroids:* ICS (e.g. beclometasone, budesonide, fluticasone, and triamcinolone) are the preferred controller therapy for all levels of persistent asthma during pregnancy, of which budesonide is the safest. However, if a woman is well-controlled by a different ICS before pregnancy (e.g. beclometasone dipropionate and fluticasone), it would be reasonable to continue that medication during pregnancy. No clinically important adrenal suppression has been found with their administration in low to moderate

doses. LABAs are the preferred add-on therapy to medium to high-dose ICS.[64] Their beneficial effect on airway mechanics can take 4–6 hours in acute bronchospasm. Maternal glucose levels should be monitored during pregnancy. Adrenal suppression, infection, delayed healing, hyperglycaemia, and fluid retention are common complications of prolonged therapy.

*Cromoglicate sodium* and *nedocromil sodium* are mast cell stabilizers but of limited benefit, requiring several weeks for action, and have been replaced by ICS and leukotriene modifiers. Limited studies suggest cromolglicate's safety during pregnancy,[116] and greater clinical experience with its use for longer, hence its preferred use over nedocromil.

Anti-immunoglobulin E therapy, specifically *omalizumab*, is reserved for patients with moderate-to-severe persistent asthma who do not respond to standard treatment. It is costly and has no role in the acute management of bronchospasm.

### Overall safety of asthmatic medications

Women with asthma tend to significantly decrease their asthma medication use from 5 to13 weeks of pregnancy due to concerns about safety of medications for the fetus.[118] Prospective population or birth cohort studies have shown that acute asthma medications, SABAs, and controller medications (ICS, cromones, theophylline, leukotriene inhibitors) have no or minimal effects on fetal growth, and perinatal complications are reduced when maternal asthma is adequately controlled.[119] The NAEPP has found that the potential risks associated with asthma medications are lower than the risks associated with uncontrolled asthma, and it is imperative that women continue to use their asthma medications in pregnancy.[57]

A direct causal relationship is difficult to establish. When National Birth Defects Prevention Study data for 2853 infants with one or more selected birth defects (diaphragmatic hernia, oesophageal atresia, small intestinal atresia, anorectal atresia, neural tube defects, omphalocele, or limb deficiencies) were analysed, no statistically significant associations were observed for maternal periconceptional asthma medication use and most defects studied. However, positive associations were observed for anorectal atresia, oesophageal atresia, and omphalocele. These may be chance findings or may be a result of maternal asthma severity and related hypoxia rather than medication use.[120] Munsie et al. observed a statistically significant association between maternal bronchodilator use and the risk of orofacial clefts. They too concluded uncertainty on whether the increased odds ratios they found were due to the bronchodilators, the severity of asthma, or both, or to chance alone. Further studies to disentangle the role of asthma or asthma medications would help clarify these findings.[121] In a large retrospective insurance claims cohort study comprising approximately 12 million covered lives and more than 277,000 pregnancies linked to a live-birth outcome, Nelsen et al. did not find any cases similar to the six postmarketing surveillance events of limb-reduction defects among the 1535 infants born to mothers taking montelukast. Other anomalies, confirmed by medical chart review with blinded adjudication, were reported at rates that were similar in the montelukast, ICS, and general population cohorts. The conclusion from this study, together with findings from other pregnancy databases, was that there was no epidemiological evidence to support a causal relationship between montelukast and limb-reduction or other birth defects.[122]

## Obstetric management

Women with poorly controlled asthma are at increased risk of pregnancy complications, and would benefit from increased fetal surveillance: monthly ultrasounds for growth, and antepartum testing beginning at 32 weeks. Pregnant asthmatics should continue their medication regimen as prescribed throughout labour and delivery. If systemic corticosteroids have been used in the previous 4 weeks, the American College of Obstetricians and Gynaecologists (ACOG) guidelines recommend administering stress-dose corticosteroids (hydrocortisone 100 mg every 8–12 hours during labour and for 24 hours postpartum)[56] although there is little information about the benefit of corticosteroid replacement during labour. A recent study found maternal asthma was associated with less fetal movements per hour, but computerized cardiotocography did not demonstrate an association between the abnormal parameters of fetal heart rate and maternal asthma. The authors suggested further studies on the counting of fetal movements in pregnant women with asthma.[123]

The obstetric management of an asthmatic parturient may further differ from that of non-asthmatics at induction of labour, management of postpartum haemorrhage and treatment of hypertension. For labour induction, prostaglandin $E_2$ has a known risk of bronchospasm, and should be avoided. Misoprostol (a synthetic prostaglandin $E_1$ analogue) can be used in pregnant asthmatics for cervical ripening, and the management of spontaneous or induced abortions, but respiratory status should still be monitored for bronchospasm.[56] For management of postpartum haemorrhage, ergot alkaloids (ergometrine, ergonovine, and methylergonovine) and 15-methyl prostaglandin $F_{2\alpha}$ (carboprost, Hemabate®) should be used cautiously in asthmatics, as they have been associated with episodes of acute bronchospasm.[124,125] Oxytocin does not significantly affect airway tone and is the preferred uterotonic agent in asthmatics. Some hypertensive women are treated with beta-adrenergic receptor antagonists. In asthmatic women, these provoke bronchospasm, and should be avoided. There are no reports of bronchospasm associated with calcium channel blockers, hydralazine, and sodium nitroprusside, making them suitable alternatives. If tocolysis is needed, magnesium sulphate and terbutaline have bronchodilator effects and can be used safely; in contrast, indomethacin might induce bronchospasm in aspirin-sensitive patients.[56]

## Anaesthetic management

### Preoperative assessment and optimization

Ideally the severe asthmatic (a patient with prior admissions to the high dependency/intensive therapy unit (HDU/ITU) with asthma or is on oral steroids) should be seen at the high-risk anaesthetic clinic. However, not infrequently, the time frame for anaesthetic preoperative intervention is too short, with problematic cases presenting on the delivery suite. Additionally, the practitioner can be misled by the variable nature of the disease and symptoms may be completely absent before labour or delivery, with no less a potential for intraoperative bronchospasm. The anaesthetist should assess the severity of the disease, and whether an acute attack is occurring. A thorough history should elicit symptoms of wheezing, dyspnoea, and cough; the frequency and severity of acute asthma exacerbations, its course during pregnancy, past hospitalizations, history of intubation and mechanical ventilation; prior oral steroid

use; and known environmental asthma triggers. Physical examination is focused on the pulmonary system. Chest auscultation may reveal wheezing ± a prolonged expiratory phase. A 'silent' chest devoid of wheezing can occur if air movement is markedly reduced. Tachypnoea, use of accessory muscles of respiration, and pulsus paradoxus of 20 mmHg or greater point to an acute asthmatic exacerbation. A simple screening test for prolonged exhalation is the forced expiratory time (FET), which can be assessed by listening over the trachea while the patient exhales forcibly and fully. An FET longer than 6 seconds correlates with a substantially lowered $FEV_1$/FVC ratio and should initiate further investigation. Laboratory investigations in pregnant women with stable asthma have little yield in adding to management. A chest radiograph may reveal hyperinflation and flattening of the diaphragm, and helps diagnose exacerbating conditions like pneumonia, pneumothorax, and heart failure. Arterial blood gas analysis may show hypoxaemia and respiratory alkalosis during acute attacks, with hypercarbia secondary to fatigue. Blood eosinophil counts often parallel the degree of airway inflammation. If the patient is being evaluated in a pre-anaesthesia clinic with facilities for referral to respiratory physicians, then spirometry may be useful; however, PEFR measurements are perhaps a more useful bedside test. Chest physiotherapy, antibiotics, and bronchodilator therapy during the perioperative period can often improve reversible components of asthma. Ideally, the patients should be wheeze-free and have a PEF of more than 80% predicted or at the level of their personal best value before labour and CD.

### Issues affecting labour and vaginal delivery

The goal of adequate labour pain relief does not differ for pregnant asthmatics in labour. It is even more important to reduce maternal stress and hyperventilation in asthmatics describing exercise or stress-induced triggers. Maternal paralysis of respiratory muscles, maternal sedation, and neonatal depression should be minimized in seeking out the optimal labour analgesia technique. In contemporary obstetric anaesthetic practice, this is often achieved by a CSE or an epidural infusion employing dilute local anaesthetic solutions with a modest dose of opioids (delivered as a continuous infusion, patient-controlled epidural analgesia (PCEA), computer-integrated-PCEA, or programmed intermittent boluses).[126] The advantage of lumbar epidurals include continuous pain relief and reduction in the stimulus to hyperventilate in pregnant asthmatics. High thoracic motor blocks should be avoided to avoid respiratory insufficiency. The epidural catheter also allows extension of the sensory block for CD should the need arise, thereby avoiding the risk of general anaesthesia and endotracheal intubation in asthmatic parturients.

Other possible labour analgesic regimens include systemic opioids (e.g. fentanyl patient-controlled analgesia (PCA) and remifentanil PCA) but maternal respiratory depression, sedation, and neonatal depression remain real issues[127] that would disadvantage the pregnant asthmatic. Alternative neuraxial anaesthesia techniques of paracervical block and pudendal nerve block performed mostly by obstetricians, and the lumbar sympathetic block are rarely utilized these days in modern obstetric anaesthetic practice.

### Issues regarding caesarean delivery

Neuraxial anaesthesia techniques are preferred for CD in stable asthmatic parturients as it obviates airway instrumentation, and minimizes risk of bronchospasm. General anaesthesia for CD traditionally mandates a rapid sequence induction and endotracheal intubation which markedly increases airway resistance due to several pathophysiological mechanisms, for example, depression of the cough reflex, impairment of mucociliary function, reduction in palatopharyngeal musculature tone, depression of diaphragmatic function, and increased airway wall fluid.

A standard dose of spinal anaesthetic is appropriate in stable asthmatics, but high thoracic blocks that might impair accessory muscles of respiration required in a brittle asthmatic are undesirable. Thoracic adrenergic nerve blockade due to spinal anaesthesia might trigger asthmatic attacks by influencing the cholinergic ganglia of the lung and/or pulmonary blood flow, as was postulated to be the cause of bronchospasm triggered by a spinal anaesthetic in two women with T2 sensory levels.[128] Severe bronchospasm has also occurred during epidural anaesthesia for CD, postulated to be related to sympathetic nervous blockade allowing unopposed parasympathetically mediated bronchoconstriction.[129] Notwithstanding, many asthmatic patients have a subjective sensation of inability to breathe even with an appropriate level of neuraxial block as their intercostals are non-functioning and they need reassurance. Showing them their pulse oximetry often allays their fears.

When general anaesthesia cannot be avoided, rapid sequence induction and endotracheal intubation is indicated. Bronchospasm can be provoked by laryngoscopy, tracheal intubation, airway suctioning, cold inspired gases, and tracheal extubation. Airway tone is increased by vagal stimulation caused by endoscopy, peritoneal, or visceral stretch. Propofol or ketamine are the preferred IV induction agents in asthmatics.[130] Propofol is superior to thiopental and etomidate in constraining increases in airway resistance.[131] Propofol formulations containing metabisulphite induce higher airway resistance than that preserved with calcium edetate in heavy smokers undergoing anaesthesia,[132] and should be taken into consideration in asthmatics as well. Ketamine is a sympathomimetic agent which induces bronchodilation and inhibits neural reflexes, and should be administered with antisialogogue and benzodiazepine (post delivery of baby) due to its propensity to increase secretions and cause dysphoria. IV lidocaine can prevent bronchospasm by attenuating sensory responses to airway instrumentation or irritation.[133,134] Warm, humidified gases should be provided at all times. Anaesthetic maintenance with a volatile agent such as isoflurane or sevoflurane confers protective bronchodilation. However, there is evidence that desflurane provokes bronchoconstriction in smokers.[135] Histamine-releasing neuromuscular blocking drugs like atracurium should be avoided.[136] Rocuronium would be preferred in this setting. An adequately long expiratory time should be given during mechanical ventilation to avoid the build-up of intrinsic or auto-PEEP. This can be facilitated by using higher inspiratory flow rates or smaller tidal volumes than usual.[137] Patients should be kept adequately hydrated as usual, but fluid overload/pulmonary congestion should be avoided as it can precipitate 'cardiac asthma'. Intraoperative bronchospasm can be managed by administering beta-2 agonists by aerosol or increasing concentration of volatile agents, the latter risks increasing blood loss due to haemorrhage from increased uterine relaxation. IV adrenaline or ketamine may be required to break the spasm, and hydrocortisone should be administered. Intraoperative analgesia with fentanyl is associated with less

histamine release than morphine[138,139] and should be considered in brittle asthmatics, who would also benefit from PCA fentanyl over PCA morphine for postoperative analgesia, and a transversus abdominus plane block.[39] Upon tracheal extubation, bronchodilator therapy, incentive spirometry, deep breathing exercises, and early mobilization are beneficial. HDU care postoperatively could be considered. Severe asthmatics might benefit from a spell in ITU postoperatively if a general anaesthetic has been necessary.

Mask induction of general anaesthesia with sevoflurane in a parturient in status asthmaticus has been described.[140] The combination of non-invasive mechanical ventilation with neuraxial anaesthesia may be of value in selected parturients with acute or chronic respiratory insufficiency requiring surgery.[141] In cases of life-threatening status asthmaticus refractory to standard medical and ventilatory therapies in the third trimester, CD should be considered as a final effort to increase tidal volumes and improve maternal gas exchange. In one such case, significant maternal respiratory acidosis and difficulty with ventilation necessitated CD at 33 weeks of gestation in the medical ICU.[142] Cardiopulmonary resuscitative efforts are difficult in near-term parturients, and a promptly performed CD might have saved an infant and mother who suffered recurrent cardiopulmonary arrest due to status asthmaticus.[143]

# Pneumonias

## Epidemiology and prevalence

The reported incidence of antepartum pneumonia was 6/1000 deliveries (pre-1970s) that then declined in the 1970s and 1980s to 0.4/1000, with studies published in 1990–2003 reporting an increase to 2.72/1000 deliveries.[144] The latter reflects women with chronic illnesses now being able to conceive, prevalence of human immunodeficiency virus (HIV) infection, and rising illicit drug use in pregnant women. Rates tend to be higher in large urban hospitals than in community settings due to different risk populations, and also because the available data generally come from those hospitalized.

The odds of being admitted with pneumonia in the postpartum period are more than twice as high for patients who underwent CDs compared with vaginal deliveries,[145] purportedly due to more abdominal discomfort and splinting after CD. Pre-existing comorbidities in these women (asthma, obesity, diabetes, advanced maternal age) which may have necessitated the CD in the first place, may predispose them to infections.

## Pathophysiology

These alterations in pregnancy lead to an increased incidence and risk of complications from pneumonia:

- *Maternal physiological changes* predispose pregnant women to a more severe pneumonia course. The diaphragm is elevated up to 4 cm, a decrease in functional residual capacity, increase in oxygen consumption and increase in lung water makes a parturient less tolerant to even brief hypoxic episodes.[146] These alterations also decrease the ability of the pregnant woman to clear respiratory secretions and potentially aggravate airway obstruction associated with pulmonary infections.
- *Maternal immunological changes* in the second and third trimester are thought to occur generally to protect the fetus from rejection by the mother. Substances produced by the trophoblast block maternal recognition of major fetal histocompatibility antigens, resulting in a reduced lymphokine response to alloantigens. Other alterations in maternal cellular immunity include a reduced lymphocyte proliferative response, diminished cell-mediated cytotoxicity, decreased natural killer cell activity and reduced number of circulating helper T cells.[147,148] Hormonal changes during pregnancy (increased progesterone, human gonadotropin, alphafetoprotein, and cortisol) may also inhibit cell-mediated immune function.[147] These changes can predispose to infection with certain virus, fungi, and tuberculosis. Catanzaro showed the *in vitro* growth of *Coccidioides immitis* was enhanced by increased 17-oestradiols leading to increased pulmonary mycosis in pregnant women.[149]
- *Comorbidities:* maternal risk factors associated with increased incidence of pneumonia development during pregnancy include a history of underlying pulmonary disease (e.g. asthma, CF, and recent viral respiratory infection), smoking, anaemia (haemoglobin level < 10g/dL),[150] illicit drug use, HIV infection, other immunosuppressive illness, and therapy.
- *Labour and delivery* increases risk of aspiration pneumonia (although this is modifiable with antacids and $H_2$ antagonists).

## Aetiology

The bacterial, viral, and fungal pathogens causing pneumonia in pregnancy are similar to those in non-pregnant adults. The commonest is *Streptococcus pneumoniae*, which is identified in 15–20% of community-acquired pneumonia cases in pregnancy, followed by *Hemophilus influenzae*.[151] Atypical pathogens include *Legionella* species, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*; whereas influenza A and varicella are common viral agents in pregnancy. *Pseudomonas aeruginosa* is common in parturients with bronchiectasis and CF. In a patient suffering from acquired immunodeficiency syndrome (AIDS), *Pneumocystis jirovecii* is the most frequent pathogen.

## Clinical manifestations

A detailed history and high index of suspicion is needed in pregnant women presenting with cough and shortness of breath, as initial clinical symptoms of mild pneumonia may be subtle and mimic many other pathologies of pregnancy. Cough, fever, chills, rigors, pleuritic chest pain, sputum production, and dyspnoea usually present later in the clinical course. Non-respiratory symptoms include nausea, headache, myalgias, and fever. Chest auscultation may reveal decreased or bronchial breath sounds or occasional wheezing. Dullness to percussion may be elicited if consolidation is present. The new American Thoracic Society/Infectious Diseases Society of America (ATS/IDSA) guidelines have criteria for characterizing severe community-acquired pneumonia, but these are not specific to pregnant women: presence of at least one major criterion (e.g. mechanical ventilation requirement or septic shock requiring vasopressors) or the presence of three minor criteria (respiratory rate of at least 30 breaths per minute, $PaO_2/FiO_2$ ratio ≤250 mmHg, multilobar infiltrates, confusion or disorientation, blood urea nitrogen ≥ 20 mg/dL, white blood cell count < 400/mm$^3$, platelet count < 100,000/mm$^3$, hypotension requiring aggressive fluid resuscitation, and hypothermia). The guideline also suggested that criteria such as

hypoglycaemia, hyponatraemia, asplenia (as in sickle cell disease), and unexplained acidosis be considered in deciding the need for ICU admission.[152]

### Diagnosis

Pregnancy should not prevent the use of standard radiographic techniques[153] and *chest radiographs* should be obtained to confirm the diagnosis. The most common site of pneumonia was the left lower lobe (53.4%), followed by the right lower lobe (26.3%) and right middle lobe (8.3%); 9.8% were complicated with pleural effusion.[154] The differential diagnosis of pneumonia in pregnancy includes pulmonary embolism, infectious aetiologies with systemic inflammatory findings, pulmonary oedema consequent to tocolytic therapy, severe pre-eclampsia, and cardiomyopathy. With the increasing availability of portable ultrasound machines in perioperative anaesthesia settings to aid central venous catheter insertions, peripheral nerve blockade, and ultrasound-guided neuraxial blocks, the use of ultrasonography has become increasingly prevalent. *Lung ultrasonography* (LUS) has been described in the bedside detection of pneumonia.[155] It enables diagnosis and treatment of interstitial syndrome, lung consolidation, atelectasis, pleural effusion, and differentiation of the causes of acute breathlessness.[155] The use of LUS is ideal in parturients due to the lack of ionizing radiation and its non-invasiveness, allowing repeated scans to not only diagnose but guide and monitor therapy.[156] All admitted patients should have an assessment of gas exchange (arterial blood gas or oximetry), routine blood chemistry, and blood counts. Sputum culture, Gram stain, and blood cultures are recommended in severe pneumonia, as are *Legionella* and pneumococcal urinary antigen.

### Management

Patients should be admitted for evaluation, empirical initiation of antimicrobial therapy, fetal evaluation, and maintenance of normal maternal respiratory function. For patients with mild symptoms, the ATS recommends an advanced generation macrolide. For more severe disease, a macrolide and beta-lactam antibiotic should be initiated.[152] Doxycycline, recommended as a second-line antibiotic therapy, should be avoided in pregnancy as administration of tetracycline in the second and third trimesters of pregnancy has been associated with staining and banding of teeth and depression of bone growth, especially the fetal fibula, and fulminant maternal hepatitis. Patients at-risk of hospital-acquired pneumonia or aspiration pneumonia should receive an aminoglycoside for the coverage of *Pseudomonas* and enteric Gram-negative organisms.[152,157] IV aciclovir is indicated for varicella pneumonia. Trimethoprim/sulfamethoxazole is effective in prevention and treatment of pneumocystis pneumonia in immunocompromised individuals. Supplemental oxygen should be administered in patients with an increased alveolar–arterial gradient as reduction in maternal functional residual capacity predisposes them to overt respiratory distress, and oxygen delivery to the fetus will decrease when maternal oxygen saturation is less than 90%. The criteria for intubation in pregnancy are the same as in the non-pregnant state: inadequate oxygenation, inadequate ventilation, systemic sepsis, need for invasive haemodynamic monitoring, or persistent metabolic acidosis. The pneumococcal vaccine is recommended for pregnant women with underlying illnesses (e.g. immunocompromised states, asplenia, sickle cell disease, diabetes, or chronic cardiopulmonary diseases) to reduce the incidence of community-acquired pneumonia in these high-risk populations.

### Maternal and perinatal outcomes

In two nationwide population-based datasets,[158] 1462 women with pneumonia during pregnancy were found to have a significantly higher risk of low birth weight, preterm birth, SGA, low Apgar score infants, CD, and pre-eclampsia/eclampsia compared to 7310 unaffected women. Pneumonia was also significantly associated with placental abruption and intrauterine growth restriction but no significant differences were noted between the groups regarding labour induction, second stage non-progressive labour, and post-partum haemorrhage.[154]

## H1N1 influenza

The H1N1 virus is the subtype of influenza A virus that was the most common cause of 'swine flu' in 2009. It is an orthomyxovirus that contains the glycoproteins haemagglutinin and neuraminidase, and thus is described as H1N1, H1N2, etc. depending on the type of H or N antigens it expresses. Haemagglutinin causes red blood cells to clump together and binds the virus to the infected cell. Neuraminidase is a glycoside hydrolase enzyme which helps to move the virus particles through the infected cell and assist in budding from the host cells.

### Epidemiology and prevalence

Influenza A H1N1 drew worldwide attention when identification of this new viral strain in humans was found to be a 'quadruple reassortant' virus containing gene segments from human, avian, and two swine lineages.[159] It spread rapidly after the first outbreak in Mexico and the United States, and was declared a global pandemic by the WHO in June 2009. The rate of admission for pandemic H1N1 influenza virus infection in pregnant women during the first month of the outbreak was higher than it was in the general population (0.32/100,000 pregnant women vs 0.076/100,000 population at risk).[73] When population-based data from the Emerging Infections Program in ten US states were examined, pregnant women represented 23.5% and 31.0% of all reproductive-aged women (15–44 years) hospitalized for seasonal (2005/2006 through 2008/2009) and 2009 H1N1 pandemic influenza A (pH1N1) virus infection respectively.[160] Worldwide, pregnancy was found to be a major risk factor for increased mortality and morbidity. The US Centers for Disease Control and Prevention (CDC) reported a 13% mortality in pregnant women in the first 2 months of the outbreak.[73] In a Brazilian series, the rate of maternal and perinatal mortality was 9.7%.[161]

### Pathophysiology

Little is known about the biological reasons for pregnant women being at high risk for influenza virus infection, but it is postulated to be due to the altered innate immunity and physiological changes of pregnancy. It was suggested that pregnant women had a greater likelihood of developing a Th2 response to H1N1 influenza which may be responsible for the systemic inflammatory response syndrome that causes pulmonary oedema and death.[162] When peripheral blood mononuclear cells (PBMCs) were isolated from 26 healthy non-pregnant women and 28 healthy pregnant women

and cultured with the 2009 pandemic influenza A (pH1N1) virus, PBMCs from pregnant women produced significantly less interferon alpha and interferon lambda.[69] Messenger RNA expression of protein kinase R (PKR) and toll-like receptors 3, 7, and 9 measured from cell lysates were also significantly reduced in PBMCs from pregnant women. This response improved with vaccination.[69] These novel findings help in understanding the increased susceptibility and disease severity to influenza virus infection during pregnancy and the importance of influenza vaccination.

## Clinical manifestations

Presenting features of the largest published cohort (N = 211) of H1N1-infected pregnant women presenting to a single tertiary referral centre over 4 months, were cough (90.5%), fever (62.6%), rhinorrhoea (62.1%), sore throat (58.8%), breathlessness (13.3%), headache (18.0%), and myalgia (32.2%).[163] Diarrhoea and vomiting were also a feature of the 2009 outbreak. Other parturients may have varying degrees of dyspnoea and tachypnoea, pneumonia, and increasing hypoxia requiring intubation and mechanical ventilation in the ICU. Severe H1N1 pneumonia, acute respiratory distress syndrome, multiorgan failure, and maternal deaths have all been reported.[73,164]

Maternal age and the time interval between onset of symptoms and hospital admission were not found to be risk factors for hospitalized pregnant women developing respiratory and multiple organ failure. The significant risk factor associated with critical illness was gestational age, with an odds ratio of 1.034 (95% CI 0.968–1.106) during the first trimester, 9.667 (95% CI 0.750–124.59) during the second trimester, and 87 (95% CI 6.750–1121.39) during the third trimester.[165] H1N1-infected pregnant women who went on to require mechanical ventilation tended to have more advanced gestational age, lower early oxygenation index, wider early-stage pneumonic lesions, and adverse pregnancy outcomes compared to those patients that did not require mechanical ventilation.[166]

## Diagnosis

Detection of influenza-specific RNA by real-time reverse-transcriptase *polymerase chain reaction* (rRT-PCR) is the recommended test for confirmation of novel influenza A H1N1 cases.[167] The H1N1 virus will test positive for influenza A and negative for H1 and H3. Samples can be obtained with a nasopharyngeal swab, nasal aspirate, or a combined nasopharyngeal and oropharyngeal swab. Duration of viral shedding is unknown but infected persons are assumed to be shedding virus and potentially infectious from the day prior to onset of symptoms up to resolution of fever. *Viral culture* does not yield timely results to guide clinical management, but serological tests on paired acute (within 1 week of illness onset) and convalescent (collected 2–3 weeks later) sera can help establish a retrospective diagnosis for epidemiological and research studies. Commercially available *rapid influenza diagnostic test kits* (RIDTs) can provide results within 30 minutes or less, but were initially varied in their sensitivities from 10% to 70% in detecting H1N1 compared to RT-PCR. Therefore a negative RIDT did not rule out H1N1 infection.[168,169] Newer assays have higher sensitivity and specificity for A(H1N1) virus of 76–95%.[170,171]

## Management

*Oseltamivir* (trade name Tamiflu®) and *zanamivir* (Relenza®) are two antivirals (neuraminidase inhibitors) currently recommended for H1N1 infection.[73] Early treatment (<2 days from diagnosis)[163,172,173] with oseltamivir prevents serious complications associated with H1N1 infection in pregnant women and does not affect perinatal outcome. The existing information on the safety of oseltamivir and zanamivir, the most used antivirals is limited but reassuring.[174] There is a significant association between late treatment with oseltamivir and increased hospitalization[173] and increased systemic complications in pregnancy.[161]

Anaesthetic technique for CD will depend on disease severity. Spinal or epidural anaesthesia for CD in mild H1N1 cases are acceptable. Most parturients in respiratory distress or failure would already be intubated and CD performed under general anaesthesia with postoperative ITU care.[175]

Pregnant women who come in close contact with a suspected or confirmed H1N1 infected person also need preventive antiviral therapy. Use of personal protective equipment (e.g. surgical masks) and *isolation precautions* to mitigate spread differ from country to country depending on whether the disease is in the containment or mitigation phase[176] and existing national resources.[177] Containment strategies include the triage of febrile patients at frontline healthcare settings, admission and isolation of confirmed cases, mandatory Quarantine Orders (QO) for close contacts, and temperature screening at border entry points. After sustained community transmission becomes established, containment shifts to mitigation. Hospitals only need to admit H1N1-2009 cases based on clinical indications, not for isolation. Mild cases are managed in the community. Contact tracing and QOs are tapered off, and border temperature screening ended.

## Maternal and perinatal outcomes

Pregnant women with mild clinical illness secondary to H1N1 virus are not at a greater risk of adverse pregnancy outcomes. However, severely infected women were more likely to deliver SGA babies and CD may be required.[178] There is a causal relationship between early exposure and fetal demise, as the H1N1 virus can be identified in maternal and fetal tissue confirming transplacental passage.[179] Not all patients require hospitalization, or result in preterm delivery when vigilance in assessment, early presentation, diagnosis and prompt treatment is initiated.[163,172,180] Indeed, complete recovery from H1N1 with no mortality was seen in all 235 infected parturients in one series.[172]

Myocarditis has also been reported, where two pregnant Caucasian women (aged 29 and 30 years) presented with respiratory manifestations of H1N1 influenza virus infection in their third trimester and developed evidence of myocarditis (one woman developed acute respiratory distress syndrome, nearly requiring extracorporeal membrane oxygenation, and subsequently developed persistent cardiomyopathy; the other recovered without any long-term consequence).[181] While it was not possible to ascertain retrospectively if myocarditis was caused by either infection with H1N1 virus or as a result of pregnancy (in the absence of endomyocardial biopsies), the significant association with myocardial involvement in both women demonstrates the increased risk of exposure to H1N1 influenza virus in pregnant women.

### Efficacy of H1N1 vaccination

With the emergence of the pH1N1 influenza, the US CDC recommended that pregnant women be one of five initial target groups to receive the 2009 monovalent H1N1 vaccine, regardless of prior infection with this influenza strain. Performance of haemagglutination inhibition assays (HAIs) for pH1N1 and maternal and

umbilical venous cord blood sampling at delivery revealed that pH1N1 vaccination conferred a similar HAI antibody response as compared to pH1N1 infection during pregnancy, both in quantity and quality. Illness or vaccination during pregnancy therefore confers passive immunity to the newborn.[182]

### Safety of H1N1 vaccination

Vaccination is imperative for parturients as unvaccinated women fare worse. A perinatal database of 55,570 mothers in Ontario, Canada reported that 23,340 (42.0%) mothers who had received H1N1 vaccination during the 2009–2010 H1N1 pandemic had improved fetal and neonatal outcomes (fewer SGA infants, preterm delivery, and fetal death) compared to unvaccinated women.[183] In the United States, for the 2009–2012 combined influenza seasons, a prospective cohort of 841 pregnant women who received the H1N1 monovalent or trivalent influenza (pH1N1) vaccine were not found to have increased relative risks for major birth defects, spontaneous abortion, or SGA infants when compared to 191 unexposed women.[184] These conclusions were also echoed by a Swiss medical birth registry[185] and a large French observational cohort study of 12,120 people in their French prescription database that compared 1645 women who were administered A/H1N1 vaccine during pregnancy to 3290 non-vaccinated women and found no increased risk of adverse pregnancy outcomes (all-cause pregnancy loss, preterm delivery, SGA, and neonatal pathology) in vaccinated pregnant women. The rate of SGA was also lower in the vaccinated group than in the non-vaccinated group.[186] Data from four regional centres in the United States collected as part of the Slone Epidemiology Center's Birth Defects Study found no meaningful evidence of increased risk for specific congenital malformations following pH1N1 influenza vaccinations in the 2009–2010 and 2010–2011 seasons.[187] Similarly, in a large Danish cohort, exposure to the adjuvanted influenza A(H1N1) pdm09 vaccine during pregnancy was not associated with a significantly increased risk of major birth defects, preterm birth, or fetal growth restriction.[188,189]

### Rare side effects of vaccination

A rare occurrence of Guillain–Barre syndrome was reported after immunization to influenza during the last trimester of pregnancy.[190]

## Conclusion

Respiratory illness in pregnant women is not uncommon. A multidisciplinary approach to care of these women is essential and anaesthetists play a vital role in diagnosis and management of these patients. Asthma is very common and usually does not cause a problem during pregnancy or delivery. CF on the other hand can pose a challenge and patients with CF may deteriorate such that severe maternal morbidity and mortality can ensue. The pneumonias and H1N1 disease can affect previously healthy women but appropriate therapy instituted in a timely fashion will usually result in effective treatment. Vaccination against H1N1 is recommended for pregnant women.

# CHAPTER 43

# Liver disorders

Chris Verslype, David Cassiman, and Johan Verhaeghe

## Introduction

Nearly 5% of pregnancies are complicated by liver disorders and this may result in considerable harm to mother and child. Early diagnosis and treatment of liver disease is challenging, given the wide spectrum of liver diseases that may be related or unrelated (either pre-existing or coincidental) to pregnancy. Before discussing liver disorders in detail, we focus on how to diagnose and assess liver disease in pregnant women. Special attention is also devoted to the management of clinically significant portal hypertension and to the guidelines regarding pregnancy in patients who have undergone liver transplantation.

## Diagnosis and assessment of liver disease in pregnant women

### Clinical assessment of patients with suspected liver disease during pregnancy

The assessment of pregnant patients with liver disorders is challenging due to the physiological changes of pregnancy that can be mistaken for liver dysfunction. Cardiovascular changes (fall in systemic vascular resistance and blood pressure, rise in cardiac output) seen in normal pregnancy are similar to the hyperdynamic circulatory state in the context of advanced liver disease. Increased splanchnic blood flow and compression of the inferior vena cava in the supine position by the uterus may induce transient portal hypertension.[1,2] The hyperoestrogenic state of pregnancy induces palmar erythema and spider naevi—considered as typical signs of chronic liver disease—that resolve by the seventh postpartum week in the majority of women.[3] During pregnancy, microscopic liver architecture appears normal and liver blood flow remains constant.[4]

Cholestasis, portal hypertension, and liver failure represent three major clinical entities that should be recognized early because of the prognostic implications for mother and child. *Cholestatic liver disease* should be suspected in a patient with pruritus and/or jaundice. The presence of ascites or enlarged portosystemic collateral veins (abdominal wall, gastrointestinal tract, and retroperitoneal space) or a history of gastrointestinal bleeding may point to *clinically significant portal hypertension*. Hepatic encephalopathy, which may range from mild confusion to deep coma, often preceded or accompanied by jaundice, and clotting failure is indicative of *liver failure*. In some patients, a combination of these clinical entities may exist.

Of note, significant liver disease may present without symptoms or signs. In these patients, a history of risk factors for liver disease (e.g. alcohol or drug intake, familial history of liver failure, tattoos, or blood transfusions prior to the introduction of tests for hepatitis C (1989)) may influence the choice of additional biochemical and/or imaging tests, which will be discussed below.

### Biochemical tests to detect liver disease and assess liver function during pregnancy

Biochemical tests are commonly used to screen and confirm the presence of liver disease, to estimate severity, prognosis, and to evaluate therapy. The 'liver function tests' (LFTs) include aminotransferases, alkaline phosphatase (AP), gamma-glutamyltransferase (GGT) and serum bilirubin. Strictly speaking, these tests do not assess liver function but a rise in their serum levels or activity may point to the presence of liver cell necrosis, impairment of bile flow (cholestasis), and hyperbilirubinaemia. The prothrombin time (after vitamin K administration) and, to a lesser extent, serum albumin are more indicative of hepatic synthetic capacity.

The aminotransferases (aspartate transaminase (AST) and alanine transaminase (ALT)) catalyse the reversible transformation of α-ketoacids into amino acids. Their serum level activity reflects the amount of liver cell injury and death on a day-by-day basis. The aminotransferases (predominantly AST) are not only found in hepatocytes but also in other tissues (muscles, kidney, brain, pancreas, lung, and red blood cells).

The liver contains 400 units of ALT/g protein (mainly cytoplasmic) and 500 units of AST/g protein (>80% contained in mitochondria and endoplasmic reticulum). Damage to 1 g of liver tissue results in a significant increase in the serum ALT and AST activity.[5,6] Serum aminotransferase levels can rise to over ten times the upper limit of normal (ULN) in hepatic hypoxia, acute viral hepatitis, toxin-induced necrosis, and acute bile duct obstruction. In chronic hepatitis, the levels are generally less than five times the ULN. The sensitivity and specificity of ALT for the detection of liver disease is around 83%.[5,6] The diagnostic sensitivity of AST is significantly lower (70%) and less specific. Serial assessment of transaminases can be used to monitor progress in an individual patient but correlation is poor between absolute values and the extent of necrosis. Serum ALT activity, but not AST, is slightly higher during the second trimester of pregnancy compared with non-pregnant women, but remains below the ULN.[7] Increased AST and ALT levels noted during labour may be secondary to uterine muscle contractions.[8,9] In conclusion, serum AST and ALT activities remain normal during pregnancy prior to labour, and increased values should lead to further investigation.

AP is found in the biliary pole of hepatocytes, bile duct epithelia, osteoblasts, kidney, lung, intestine, and placenta. Levels

of AP rise in cholestasis and to a lesser extent with hepatocyte injury. Serum AP levels increase significantly in late pregnancy due to placental and bone production. This limits the utility of AP as a test to diagnose cholestasis of pregnancy. Hepatic and non-hepatic causes of AP elevation can be differentiated by determination of AP isoenzymes or more easily by testing for GGT, which rises in liver but not in bone disease. GGT is found in hepatocytes, cholangiocytes, kidney, pancreas, epididymis, heart, lung, intestine, bone marrow, salivary glands, thymus, spleen, and brain, and therefore is not very specific for liver disease. Elevated values of GGT are caused by damage to cellular membranes, cellular regeneration, or by enhanced synthesis as a result of induction of the biotransformation enzyme system.[6] Known inducers are bile acids (cholestasis), prolonged regular abuse of alcohol, and especially antiepileptic drugs (phenytoin, carbamazepine). A decline in GGT can be observed during oestrogen administration or during the second and third trimester of pregnancy.[7] Fasting total bile acid concentrations are unaltered in normal pregnancy, and are therefore a specific test for the diagnosis of cholestasis. Conjugated bilirubin can be elevated in cholestatic and hepatocellular disease and is associated with a rise in the above-mentioned serum enzymes. An isolated rise in serum bilirubin (without enzyme elevation) may be familial (Gilbert's phenomenon) or due to haemolysis. Conjugated bilirubin concentrations are significantly lower during the second and third trimesters compared to non-pregnant women. This can be partially explained by haemodilution because albumin is the bilirubin transporting protein.[7]

The hepatocyte is the principal site of synthesis of coagulation proteins. The prothrombin time (after vitamin K administration) represents a good indicator of liver synthetic function, due to the short half-life of factor VII (100–300 minutes). Estimation of individual clotting factors is rarely necessary, although the level of factor V (not vitamin K dependent) is related to outcome in acute liver failure. Serum albumin levels[10] provide some indication of hepatic synthetic capacity. However, serum albumin levels may be normal with acute liver failure because the half-life of albumin is about 22 days. Low levels can be caused by increased loss through the kidneys or gastrointestinal tract, increased catabolism and altered vascular permeability. Because of haemodilution, serum albumin levels are significantly lower during all trimesters of pregnancy compared with non-pregnant women.[7] Alterations in the concentration of serum albumin must therefore be interpreted with caution.

## Liver function scoring systems

Several scoring systems have been developed to assess and classify liver function (Table 43.1). The Child–Pugh score reflects the severity of chronic liver disease according to the degree of ascites, the prothrombin time, the plasma concentrations of bilirubin and albumin, and the stage of encephalopathy. A total score of 5–6 signifies a well-compensated state (grade A), 7–9 is grade B, and 10–15 is grade C (decompensated disease). These grades correlate with 1- and 2-year patient survival.

More recently, the Model of End Stage Liver Disease (MELD) has been introduced in clinical practice to predict prognosis in patients with cirrhosis and to guide listing for liver transplantation. This score uses the prothrombin time, serum bilirubin, and creatinine as input values.[11] Patients having a MELD score <9 face a 2% 3-month mortality, whereas patients having a MELD score of 40 or higher have a mortality rate of 70% within 3 months.

**Table 43.1** Assessment of liver function

(A) Child–Pugh classification

| Factor | Units | 1 point | 2 points | 3 points |
|---|---|---|---|---|
| Serum bilirubin | µmol/L | <34 | 34–51 | >51 |
| | mg/dL | <2.0 | 2.0–3.0 | >3.0 |
| Serum albumin | g/L | >35 | 30–35 | <30 |
| | g/dL | >3.5 | 3.0–3.5 | <3.0 |
| Prothrombin time | Seconds prolonged | 0–4 | 4–6 | >6 |
| | INR | <1.7 | 1.7–2.3 | >2.3 |
| Ascites | | None | Moderate | Severe |
| Hepatic encephalopathy | | None | Mild | severe |

The score is calculated by adding the scores of the five factors:

Child–Pugh A: 5–6; B: 7–9; C: > 9.

(B) Model of End-stage Liver Disease (MELD)

$$\text{Formula} = \begin{bmatrix} (0.957 \times \log_e \text{Creat mg/dL}) + 0.378 \times \\ (\log_e \text{Br mg/dL}) + (1.120 \times \log_e \text{INR}) + 0.643 \end{bmatrix} \times 10$$

## Imaging of the liver during pregnancy

Real-time ultrasonography represents the most widely used imaging modality in clinical hepatology and is used to evaluate biliary tract obstruction, to identify splenomegaly and collateral vessels in portal hypertension, and to examine tumour vascularity. It is also valuable in diagnostic assessment of portal or hepatic vein thrombosis. More recently, liver elastography is used by many hepatologists to evaluate liver stiffness. This non-invasive technique uses both ultrasound (US) (5 MHz) and low-frequency (50 Hz) elastic waves, whose propagation velocity is directly related to elasticity.[12] There is no published experience in pregnancy and unfortunately, pregnancy has been a contraindication in clinical studies.

Magnetic resonance imaging (MRI) is a popular modality in pregnancy because of the lack of ionizing radiation. The classical T1- and T2-weighted images of MRI can be distinguished by considering the signal intensity of water: water has a low signal intensity ('black') on T1-weighted images while it has a high signal intensity ('white') on T2-weighted images. No contrast injection is needed for blood vessel or bile duct visualization. Image quality has improved to such a degree that MRI-cholangiography has replaced diagnostic ERCP.[13] Contrast agents (such as gadolinium) can be used to differentiate among focal liver lesions, but should be avoided during pregnancy because of transplacental transfer and unknown fetal effects.[14] More recently, diffusion-weighted imaging has been introduced allowing characterization of liver lesions, without contrast administration.[15]

# Liver disorders during pregnancy

In this section we will review the most frequent liver diseases that can be encountered during pregnancy. Liver disease in pregnancy is generally separated into disorders that are unique to pregnancy and those that coincide with pregnancy. We recommend a systematic approach that focuses on the major differential diagnostic characteristics of pregnancy-related liver diseases (Table 43.2) and a limited set of tests for pregnancy-unrelated liver diseases (Box 43.1).

## Pregnancy-related liver diseases

### Hyperemesis gravidarum

Hyperemesis gravidarum occurs in 0.3–2% of pregnancies and is characterized by intractable vomiting in the first half of pregnancy resulting in dehydration, electrolyte imbalance, weight loss, and ketosis.[16–18] Thiamine deficiency may lead to a superimposed Wernicke's encephalopathy. The aetiology is poorly understood and likely involves a combination of hormonal, genetic, and immunological factors. Serum ALT and AST are usually mildly elevated, but levels up to 20 times the ULN have been reported. Jaundice is uncommon and there is no risk of liver failure. Liver biopsy is not indicated but when performed shows focal necrosis, steatosis, or bile-plugs. Therapy involves frequent small low-fat meals, intravenous fluids, thiamine and folate supplementation, and antiemetic medication. Liver test abnormalities usually return to normal levels within a few days of volume expansion and the cessation of vomiting. Persistently elevated transaminases are indicative of an alternative diagnosis such as acute viral hepatitis. Other pregnancy-related conditions such as acute fatty liver of pregnancy (AFLP) and the haemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome typically present in the third trimester of pregnancy and are as such easily distinguished from hyperemesis gravidarum.

### Intrahepatic cholestasis of pregnancy

Intrahepatic cholestasis of pregnancy (ICP) is characterized by generalized pruritus (particularly affecting soles and palms and worse at night) and high fasting serum bile acid levels (>10 μmol/L) in the late second or third trimester.[17,18] Mild jaundice (serum bilirubin < 5 mg/dL) is present in 10–25% of women and appears 1–4 weeks after the start of pruritus.[16,17] Aminotransferase levels may be normal to mildly elevated with levels 10–20 times the ULN in rare cases. There is no evolution to liver failure. Diagnosis is made based on these clinical and biochemical findings. Liver ultrasound shows no dilated bile ducts. A liver biopsy may show signs of cholestasis and inflammatory changes, but is not required for the diagnosis. The incidence of ICP varies among different geographic areas and populations: from less than 0.5% in the United States and Australia, to 10-16% in Chile and Scandinavia. The condition is associated with a relatively high rate of fetal morbidity, due to premature birth and meconium-stained amniotic fluid and intrauterine fetal death (0.4–1.6%) from fetal anoxia.[16] The risk of adverse fetal outcome appears to increase with increasing bile acid levels, especially once a level of greater than 40 μmol/L is reached.[19]

Prognosis for the mother is good, despite the pruritus and an increased risk for postpartum haemorrhage (because of cholestasis-induced vitamin K malabsorption). The rapid and complete recovery following delivery (within 2 weeks) is a typical feature. Risk factors include multiparity, advancing maternal age, and multiple gestation and recurrence rates are high. Women with

**Table 43.2** Major differential diagnostic characteristics of pregnancy-related liver diseases in the second half of pregnancy

| | Intrahepatic cholestasis of pregnancy | Acute fatty liver of pregnancy | HELLP syndrome |
|---|---|---|---|
| Trimester | (2)–3 | 3 | (2)–3 |
| Symptoms | Pruritus | Malaise—fatigue—vomiting | Abdominal pain |
| Jaundice (bilirubin) | <5 mg/dL | Variable,<br>>5 mg/day severe cases | Rare, and if present <5 mg/dL |
| Liver failure<br>Hypoglycaemia<br>Mental status<br>Cause ↑ PT | No<br>No<br>Normal<br>Low vitamin K | Yes<br>Yes<br>HE ($NH_3$↑)<br>Liver dysfunction | No<br>No<br>Headache, seizures,<br>DIC |
| Thrombocytopenia | No | No | Per definition |
| ↑ Transaminases | Variable,<br>2–20 × ULN | Variable,<br>up to 10 × ULN | Per definition,<br>up to 10 × ULN |
| Haemolysis | No | No | Per definition |
| Arterial hypertension | No | 25–50% | 85% |
| Imaging | Normal | Fatty changes | Hepatic infarction, haematoma |
| Liver histology | Cholestasis, limited inflammation | Microvesicular steatosis (zone 3) | Patchy necrosis, sinusoidal thrombi and haemorrhage |

DIC, disseminated intravascular coagulation; HE, hepatic encephalopathy; HELLP, haemolysis-elevated liver enzymes-low platelets; PT, prothrombin time; ULN, upper limit of normal.

**Box 43.1** Non-invasive evaluation of patients with clinical or biochemical suspicion of liver disease

**1. Clinical history (medication!) and physical examination**

**2. Liver disease**

- Hepatobiliary imaging: liver ultrasound (or if in doubt MRI)
- Liver synthetic and excretory function: prothrombin time, albumin, bilirubin
- Specific tests:
  a. Viral hepatitis A*, B, C, D, E* and CMV*, HSV*, EBV*
  b. Autoimmune disease: antinuclear antibody, antimitochondrial antibody, smooth muscle cell antibody; liver-kidney microsomal antibodies; immunoglobulins
  c. α-1-antitrypsin deficiency: protein electrophoresis (genetic testing)
  d. Wilson's disease: serum ceruloplasmin, urinary copper excretion

**3. Excluding non-hepatic causes of elevated aminotransferases**

- Thyroid disorders: TSH
- Coeliac disease: tissue transglutaminase antibodies
- Muscle pathology: creatine kinase

*Only relevant to test in case of markedly elevated AST and ALT levels (>10 × ULN).

a history of ICP have more gallstone-related disease (pancreatitis, cholecystitis) and cholestasis due to oral contraceptive use.

The pathogenesis of the disease is only partially understood. Hormonal changes in oestrogen and progesterone metabolites, together with genetically determined mutations in bile transporter proteins, such as multidrug resistance glycoprotein 3 (MDR3) and bile salt export pump (BSEP) play a role.[20] The link between high bile salt concentrations and fetal morbidity is possibly related to induction of myometrial contractions and placental vasoconstriction.[17]

Intrahepatic cholestasis of pregnancy is associated with an approximately 1% risk of fetal death that occurs at a median gestational age of 38 weeks.[16] Delivery at 37–38 weeks is therefore commonly performed to minimize perinatal morbidity and mortality.[21] Fetal monitoring is recommended despite the inability to prevent cases of sudden fetal death. Ursodeoxycholic acid (UDCA) is considered the drug of choice for the treatment of ICP. In a double-blind, placebo-controlled study, 130 Swedish women with ICP were randomized to UDCA (1 g/day, 3 weeks) or dexamethasone (12 mg/day, 1 week). The patients that were treated with UDCA had significant improvement of pruritus and biochemical parameters of cholestasis.[22] There was no difference in fetal complications, but this may be due to the small group of patients (N = 34) with bile salt levels greater than 40 μmol/L. A management proposal for women with ICP, as followed in the University Hospitals Leuven (Belgium), is given in Figure 43.1.

### 'Haemolysis, elevated liver enzymes, low platelets' (HELLP syndrome)

HELLP syndrome occurs in 0.5–0.9% of pregnancies and in about 70% of the cases before delivery with a peak frequency between the 27th and 37th gestational weeks (see Chapter 36 and Chapter 48 for more detailed information).[23] It is considered the hepatic manifestation of preeclampsia. However, in 20% of cases there are no signs of (pre-)eclampsia, and HELLP is more often seen in older Caucasian multiparous women.[24] HELLP is thought to result from an acute rejection of the fetal allograft and the clinical picture is a reflection of a microangiopathic haemolytic anaemia with platelet consumption and fibrin degradation. The liver damage resembles a sinusoidal obstruction syndrome (previously called veno-occlusive disease) with reduction of liver blood flow,[25] and liver ischaemia.

By definition, the transaminases are variably elevated (up to ten times ULN), platelets drop in severe cases below 50,000/μL and there are signs of haemolysis (abnormalities in blood smear with contracted or fragmented red blood cells, anaemia, rise in serum lactate dehydrogenase (LDH), low haptoglobin, increased reticulocytes, and moderately elevated indirect bilirubin (<5 mg/dL)).[23] Two classifications for HELLP syndrome have been put forward. The Tennessee System classification is based on the following parameters: AST greater than 70 IU/L, LDH greater than 600 IU/L and platelets less than 100,000/μl. Accordingly, there are two forms: complete (all elements present) and partial HELLP syndrome (one or two elements present).[24] The Mississippi classification relies on the nadir of platelet counts: class I (<50,000/μL), class II (50,000–100,000/μL), and class III (100,000–150,000/μL).[26]

The combination of upper abdominal pain, 'malaise', nausea, and vomiting in the third trimester or postpartum (up to 8 days), should alert the physician. Approximately 80% of patients demonstrate signs of (pre-)eclampsia (hypertension and proteinuria). Liver imaging may show intrahepatic haemorrhage, subcapsular haematoma, or haemoperitoneum due to hepatic rupture (occurring in 1–2% of patients with HELLP).[27] Other serious maternal complications include placental abruption, disseminated intravascular coagulation (DIC), renal failure, and pulmonary oedema with variable maternal and especially fetal mortality ranging from 8% to 80%.[28,29] Interestingly, in women with postpartum HELLP syndrome, the risk of renal failure and pulmonary oedema is significantly increased compared to those with an antenatal onset.[30]

Most neonates born from a woman with HELLP have a normal long-term development. Prematurity at delivery is the main problem rather than HELLP in itself.[23]

The management of the patient with HELLP is similar to that applied for severe pre-eclampsia (control of hypertension, fetal monitoring, and seizure prophylaxis) and urgent delivery is needed. Severe maternal complications are more frequent when the induction of pregnancy is delayed. At a gestational age between 24–34 weeks and a stable maternal condition, corticosteroids are advocated to accelerate fetal pulmonary maturity. A randomized, double-blind, placebo-controlled study of high-dose dexamethasone included 132 women with the HELLP syndrome (60 patients with HELLP occurring in pregnancy and 72 after delivery).[31] Dexamethasone treatment did not reduce maternal complications (such as acute kidney injury, pulmonary oedema, and oliguria). There was no statistically significant difference between dexamethasone-treated and placebo-treated patients with respect to the time that was required to achieve a platelet count of greater than 100,000/mm$^3$. The rates of platelets and fresh frozen plasma transfusions were not significantly

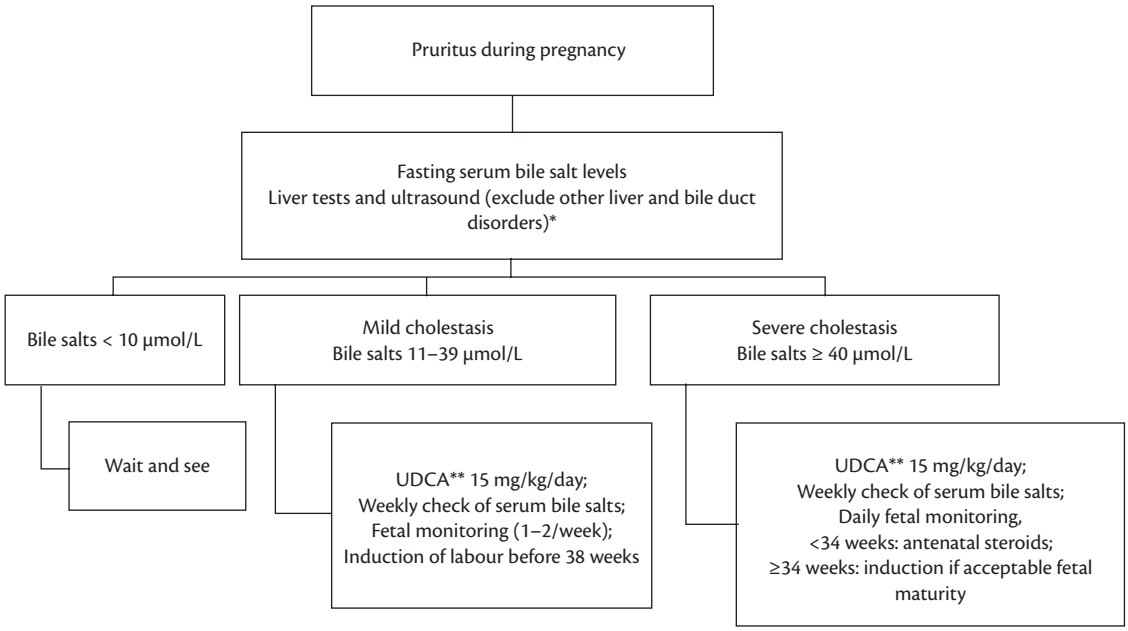

**Figure 43.1** Management algorithm for women with intrahepatic cholestasis of pregnancy, used at the University Hospital Leuven, Belgium.
*See Box 43.1; **UCDA: ursodeoxycholic acid.

reduced, nor was the time of recovery of laboratory test shortened, or the duration of hospital stay.[31]

The rupture of a subcapsular liver haematoma represents a surgical emergency (packing with gauze is preferable to lobectomy). Other options include arterial ligation, selective arterial embolization, or even liver transplantation.[23]

### Acute fatty liver of pregnancy

AFLP affects approximately 5/100,000 pregnancies and is associated with a 1–2% maternal and 10% perinatal mortality rate in the Western world.[32] Mothers with twin pregnancies are at greater risk. AFLP is caused by a defect in mitochondrial beta-oxidation and in up to 20% of cases a deficiency of the long-chain 3-hydroxyacyl-coenzyme A-dehydrogenase (L-CHAD syndrome) can be identified in the fetus which is usually male. The transfer of non-oxidated long-chain fatty acids from the fetus is most likely the cause of toxic liver damage of the mother. The characteristic microscopic alteration is microvesicular steatosis.[33] Patients usually present in the third trimester and may exhibit acute liver failure with hepatic encephalopathy, jaundice, marked elevation of transaminases, prolonged prothrombin time, and hypoglycaemia. The differential diagnosis includes acute viral hepatitis and HELLP syndrome (Table 43.2). The liver may have a bright appearance on ultrasound imaging, but this is not conclusive as nearly 20% of the general population has a fatty liver nowadays (see below). Management of AFLP involves intensive supportive care and prompt delivery. The clinical condition may deteriorate further within the first 48 hours following delivery and liver transplantation may be indicated in the absence of liver regeneration.[16] According to a retrospective evaluation of 54 admissions with pregnancy-related liver disease, the classical King's College criteria of acute liver failure were not effective in predicting outcome. Instead, a serum lactate of at least 2.8 mg/dL and the presence of encephalopathy had sensitivity of 90% and a specificity of 86% to predict liver transplantation or death.[34]

Following delivery, a rapid reversal of the clinical condition is expected, with no long-term sequelae. The risk of recurrence in future pregnancies is difficult to predict and genetic counselling of the newborn and parents should be offered.

## Liver diseases unrelated to pregnancy

Several viruses may induce hepatitis. The natural history of the disease is dependent upon the host's immune response to the virus. Most cases of acute hepatitis are characterized by malaise, nausea, anorexia, and vomiting. Jaundice and marked elevation of transaminases may develop. The occurrence of hepatic encephalopathy and prolongation of prothrombin time are indicative of acute liver failure. Several viruses (e.g. hepatitis A (HAV) and E (HEV), herpes simplex, cytomegalovirus, and Epstein–Barr viruses) that usually cause an acute self-limited hepatitis may occasionally result in acute liver failure.

Infections with hepatitis B, C, or D (HBV, HCV or HDV) may run a chronic course and the viral genome can be detected in the serum more than 6 months after infection. Most of these patients are asymptomatic, and are only diagnosed after detection of liver tests abnormalities. A longstanding infection can induce cirrhosis, which includes marked fibrosis, nodular regeneration, vascular shunt formation, and clinically significant portal hypertension. In addition to viruses, the pregnant women may develop autoimmune, drug-induced (including toxins) or metabolic liver disease.

### Hepatitis A

HAV is transmitted via the faecal–oral route and complicates 1/1000 pregnancies. Diagnosis is made by detection of anti-HAV immunoglobulin M. The clinical presentation and disease course are similar to non-pregnant patients. Acute hepatitis A in the third trimester of pregnancy is associated with preterm labour in approximately 60% of patients.[18,35] In case of acute liver failure, liver transplantation may be indicated. Perinatal HAV transmission is uncommon and most cases remain subclinical. A safe and

effective vaccine against HAV is available. After birth, children of mothers with hepatitis A in the last trimester should receive the vaccine and some experts also recommend administration of immunoglobulin.

### Hepatitis B and delta

HBV is highly infectious and transmitted parenterally by percutaneous or mucosal exposure, sexually, and from mother to infant. The clinical presentation and course of the disease are similar to non-pregnant infected individuals. Diagnosis of HBV infection is made by detection of hepatitis B surface antigen (HbsAg) in the serum. It is difficult to determine, in the absence of previous serology, if a patient acquired a new infection or has a flare of chronic hepatitis B. Although intrauterine infection has been reported, the intrapartum period is the time of greatest risk. Women with a high HBV viral load or those positive for the hepatitis B e antigen have an 80–90% chance of transmitting the virus to their infant.[17,18] Perinatal infection commonly progresses to chronic infection in the offspring, which is associated with an increased risk of cirrhosis and liver cancer. Because of the risk of vertical transmission, HbsAg status should be assessed early in pregnancy and unimmunized high-risk patients should be vaccinated, even during pregnancy. Administration of HBV human immune globulin and the HBV vaccine within 12 hours of birth to all neonates born to HbsAg positive women reduces the vertical transmission rate by 85–95%.[36] The use of antiviral drugs such as lamivudine or tenofovir during the third trimester in women with a high viral load appears to be safe during pregnancy and may further reduce the risk of vertical transmission.[16,36,37] There is no consensus concerning the cut-off of high viral load in this setting, but the risk of transmission seems very high if more than $10^8$ copies/mL are present. The vertical transmission rate does not appear to be affected by mode of delivery or breastfeeding.

Hepatitis delta is dependent upon the presence of HBV for replication. The diagnosis of HDV is established by serological testing. Vertical transmission is possible but preventable by using the measures to prevent HBV infection.

### Hepatitis C

HCV is transmitted through the parenteral route and is nowadays mainly a disease of intravenous drug users and men who have sex with men. Following a mostly asymptomatic acute infection, more than 80% of patients will develop chronic hepatitis and are at risk for developing cirrhosis or primary liver cancer over the following two to three decades. The incidence of chronic HCV infection in pregnant women is similar to that of the general population and ranges from less than 1% to 2.4%.[16,37] Screening for HCV exposure is performed by screening for HCV antibodies. Diagnosis of HCV infection is confirmed by the detection of HCV-RNA in the serum. The antibodies that are detectable are not protective and no effective vaccine is available. Transaminase activity levels may fall in the second half of pregnancy with a concurrent rise in serum HCV-RNA levels, but this is not clinically significant. Women with chronic HCV infection usually experience an uneventful pregnancy except when advanced fibrosis and portal hypertension are present.

Unlike HBV infection, vertical transmission of HCV is generally below 10%. Factors that increase this risk include co-infection with HIV, high viral load (>$10^6$ copies/mL) and membrane rupture greater than 6 hours.[16] Risk of transmission is unaffected by mode of delivery or breastfeeding. The presence of serum HCV-RNA at 6 months of age is indicative of congenital HCV infection. Vertically acquired neonatal HCV infection usually manifests as mild liver disease though spontaneous clearance later on is possible. Antiviral therapy is generally postponed until young adulthood. Current antiviral therapy for HCV includes interferon and ribavirin, which are contraindicated during pregnancy (Table 43.3). There are no new data yet on the newer direct acting antiviral agents.

### Hepatitis E

HEV is endemic to large areas of Africa, Asia, and Central America and shares the same faecal–oral transmission route as HAV. Sporadic cases are increasingly diagnosed in developed countries. Pregnant women are especially susceptible to this viral infection and HEV infection during the last two trimesters of pregnancy is associated with a 60% risk of fulminant hepatic failure, resulting in high maternal (41–54%) and fetal (69%) mortality rates.[18,38] Delivery does not affect maternal outcome and there is no therapy to prevent transmission. HEV vaccines are under development.

### Herpes simplex virus hepatitis

Pregnancy increases susceptibility to herpes simplex virus (HSV) hepatitis, which is otherwise rarely seen in adults. Maternal and neonatal mortality rates may be as high as 40%. Mucocutaneous lesions are not always present. High transaminase values and coagulopathy in the absence of jaundice ('anicteric' hepatitis) should raise suspicion of HSV hepatitis, for which intravenous therapy with aciclovir is effective.[39]

### Autoimmune hepatitis

Autoimmune hepatitis (AIH) has a prevalence of 0.1–1.2 cases/100,000 in the Caucasian population. The clinical manifestations of this condition vary widely and include asymptomatic patients, those with acute fulminant hepatitis and those with chronic hepatitis and cirrhosis. Although AIH is typically associated with infertility, a patient with well-controlled disease and even cirrhosis can become pregnant. AIH is classically treated with corticosteroids as induction therapy and azathioprine in maintenance. More recently, budesonide was shown to control the disease with less systemic side effects than dexamethasone. Autoimmune hepatitis tends to run a highly variable course in pregnancy. Postpartum flares are common (in at least 30% of patients), which is similar to other autoimmune conditions. The risk of fetal loss, preterm birth, and fetal growth restriction appears to be increased in women with AIH. However, successful pregnancy outcome is anticipated in women with well-controlled disease.[40–42] Treatment commonly consists of corticosteroids and/or azathioprine. Corticosteroids are considered safe during pregnancy. Azathioprine (US Food and Drug Administration (FDA) pregnancy category D) may be associated with fetal growth restriction and preterm birth, but teratogenic effects have not been documented.[43] In a recent series of 53 women with 81 pregnancies, flares in AIH were more likely in patients who were not on therapy or who had a disease flare in the year prior to conception.[44]

In patients with cholestatic autoimmune liver diseases, such as primary sclerosing cholangitis (PSC) or primary biliary cirrhosis, limited data are available concerning pregnancy outcome.[45] In patients with PSC, concomitant inflammatory bowel disease may pose specific problems that are out of the scope of this review. For

**Table 43.3** Indication and safety of drugs for liver disease during pregnancy

| Medication | FDA category | Indication | Remarks | Breastfeeding |
|---|---|---|---|---|
| Prednisone | C | Autoimmune hepatitis, post-liver transplantation | Safe | No, except low dose |
| Azathioprine | D | | Safe | No |
| Ciclosporin | C | | Safe | No |
| Tacrolimus | C | | Safe | No |
| Mycophenolate mofetil | D | | Not recommended, limited data | |
| Everolimus | | | | |
| Ursodeoxycholic acid | B | Intrahepatic cholestasis of pregnancy (ICP) | Indicated for ICP and safe | Yes |
| Lamivudine | C | HBV | Safe | No |
| Entecavir | C | HBV | Not recommended | No |
| Tenofovir | B | HBV | Safe | No |
| Interferon | C | HBV, HCV | Not recommended, high dose may induce abortion | No |
| Ribavirin | X | HCV | Contraindicated, fetal toxicity | Unknown |
| Penicillamine | D | Wilson's disease | Embryopathy, but need to continue therapy | No |
| Zinc | C | | Safe | Yes |
| Beta blockade | C/D Depending on agent | Oesophageal varices | Risk of fetal bradycardia and intrauterine growth retardation, but necessary to prevent variceal bleeding | Yes |
| Terlipressin | X | Variceal bleeding | Contraindicated, uterine ischaemia | No data |

both diseases, UDCA is a standard treatment and is safe during pregnancy.

### Non-alcoholic fatty liver disease

Non-alcoholic fatty liver disease (NAFLD) is becoming the most frequent liver disease in the Western world, with a prevalence of at least 20% in unselected populations.[46,47] NAFLD is a spectrum of liver disease, ranging from steatosis to steatohepatitis, with advanced fibrosis and eventually cirrhosis. NAFLD is the hepatic manifestation of the metabolic syndrome that includes obesity, arterial hypertension, hyperlipidaemia, and type 2 diabetes mellitus. The influx of free fatty acids together with insulin resistance on a susceptible genetic background is a possible mechanism, but the pathogenesis remains poorly understood.[48] Patients may remain asymptomatic for decades. The diagnosis is made by the combination of abnormal liver tests (typically with the ALT:AST ratio > 2:1), the suggestion of liver steatosis on imaging, and (rarely) a liver biopsy. The histological findings are similar to alcoholic liver disease, and therefore the differential diagnosis can only be made in patients who abstain from alcohol. Therapy includes control of the components of the metabolic syndrome and lifestyle changes. Despite the supposed high prevalence of NAFLD in the general population, there are virtually no data in the literature concerning NAFLD and pregnancy.[49] Despite the lack of data, an increased risk of pre-eclampsia is expected in women with NAFLD due to the associated comorbidities such as obesity and hypertension.

### Hepatic vein thrombosis (Budd–Chiari syndrome)

Pregnancy, along with other hypercoagulable states (i.e. myeloproliferative disorders and inherited thrombophilia), are risk factors for the rare condition of hepatic vein thrombosis.[50] The clinical picture is dependent upon the number of veins involved. Prognosis is poor in patients with painful hepatomegaly, jaundice, and marked ascites. Therapy consists of low molecular weight heparin and the timely placement of a transjugular portosystemic shunt to decompress the liver. Liver transplantation may be indicated in case of overt liver failure.

Treatment in pregnancy involves anticoagulation (low molecular weight heparins in the therapeutic dose as given outside pregnancy), though thrombosis may occur despite therapy. Maternal outcome is generally favourable but an increased rate of miscarriage and preterm delivery has been reported.[51]

### Wilson's disease

Wilson's disease is a rare autosomal recessive disorder of copper metabolism characterized by deposition of excess copper in the liver, brain, and kidney. Patients may present with jaundice, elevated transaminases, and haemolytic anaemia, which may be mistaken for HELLP syndrome.

Pregnant patients should continue anticopper therapy throughout pregnancy to prevent disease flare and acute liver failure. The dose of penicillamine, an FDA category D medication, should be decreased by 25–50% in pregnancy.[52] The authors demonstrated an excellent outcome of 12 pregnancies in patients with Wilson's disease who received D-penicillamine.[53] Zinc appears to be a safe and effective alternative.[54]

### Drug-induced liver disease, including alcohol

The liver is susceptible to damage by drugs and toxins as it has an important role in metabolizing xenobiotics. The degree of

drug-induced liver injury (DILI) can vary from mild transient elevation of liver tests to severe injury and acute failure. Hepatotoxicity is a result of multiple factors and is difficult to predict. Few drugs that cause DILI have a predictable, dose-dependent toxic mechanism of action, the most widely recognized being acetaminophen/paracetamol. When acetaminophen/paracetamol overdose is excluded, most cases of DILI are due to rare, unpredictable reactions to commonly used drugs.[55] The drug itself or its metabolite may be inherently hepatotoxic. The level of exposure, environmental factors, and genetic factors play a role in hepatotoxicity. During pregnancy, the liver remains vulnerable to these toxic drug reactions. Catastrophic cases of DILI have been reported in pregnancy, even with drugs that were presumed 'safe' in pregnancy.[56]

Ethanol ingestion in pregnancy may be associated with dangerous consequences for mother and child. In non-pregnant women, the intake of more than 2 units a day and especially binge drinking, is associated with many health risks, including but not limited to liver disease. The histologic liver changes caused by alcohol are similar to those seen with NAFLD. In contrast with NAFLD, patients with acute alcoholic hepatitis (without cirrhosis) may present with the clinical picture of acute liver failure (marked jaundice, prolonged prothrombin time, encephalopathy, portal hypertension, and moderately elevated serum transaminases), with a high risk of death (up to 50%). The pathogenesis of liver disease relates to ethanol metabolism with generation of acetaldehyde that is highly toxic because of the formation of protein and DNA adducts that promote glutathione depletion, lipid peroxidation, and mitochondrial damage.[57]

Alcohol ingestion may have several negative effects on pregnancy. The age-adjusted relative risk of second-trimester spontaneous abortions (15–27 weeks) was 1.03 (non-significant), 1.98 ($P < 0.01$), and 3.53 ($P < 0.01$) for women taking less than 1, 1–2, and more than 3 units daily, compared with non-drinkers.[58] Alcohol exposure in pregnancy may lead to fetal alcohol spectrum disorder that includes craniofacial, cardiac, growth, and behavioural abnormalities. Fetal injury may occur with alcohol exposure at any time in pregnancy, though the risk of birth defects is highest with first trimester consumption. Abstinence from alcohol is recommended during pregnancy because a safe level of consumption has not been determined.[59]

## Clinically significant portal hypertension during pregnancy

Portal hypertension may arise in the context of liver disease (most often cirrhosis due to various causes discussed earlier) or in non-cirrhotic cases (most often due to portal vein thrombosis). Fertility is unaffected in women with non-cirrhotic portal hypertension. Cirrhosis is associated with a high incidence of amenorrhea, making pregnancy less likely to occur.[60] The spontaneous abortion rate can be as high as 40% of pregnancies in women with cirrhosis.

Clinically significant portal hypertension is defined by the presence of oesophagogastric varices and/or ascites that correlate with an invasively measured hepatic venous pressure gradient of greater than 10 mmHg. The increased blood volume that occurs during pregnancy may worsen portal hypertension and increase the risk of variceal bleeding, which develops in 20–25% of patients.[16] Pregnancy outcome in women with cirrhosis and portal hypertension is variable. Fetal and maternal mortality rates up to 50% were reported in older studies. In a 2011 retrospective series of 62 pregnancies in 29 women with cirrhosis, maternal complications (ascites, encephalopathy, or variceal haemorrhage) occurred in 10% of patients and one mother died.[34] The reduction in complications in recent studies is likely due to the implementation of evidence-based treatments, such as the use of non-selective beta blockers propranolol and/or endoscopic band ligation of the varices. Mortality rates are higher in cirrhotic (10–50%) than non-cirrhotic patients (<10%).[61]

The existing prognostic models of cirrhosis severity are useful in determining outcomes in pregnant women with cirrhosis. Higher MELD and Child–Pugh scores (discussed in 'Liver Function Scoring Systems') are associated with poorer outcomes for mother and newborn. In the study of Westbrook,[34] a MELD score at the time of conception of 10 or higher predicted, with 83% sensitivity and 83% specificity, which patients were likely to have significant, liver-related complications. No patient who had a MELD score of 6 or below at the time of conception developed significant hepatological complications. Women with a MELD score of 10 or more should be advised against pregnancy.

Every patient with suspicion of cirrhotic or non-cirrhotic portal hypertension (history of liver disease and upper gastrointestinal bleeding, imaging suggestive of cirrhosis, and low platelets) who considers pregnancy should undergo upper endoscopy to identify varices. During pregnancy, the best timing of gastroscopy would be the second trimester. Primary prophylaxis with a non-selective beta blocker may be indicated. In case of intolerance to beta blockers or if gastrointestinal bleeding does occur during pregnancy, urgent endoscopic ligation of the varices is indicated.[62] The administration of vasoactive drugs like terlipressin is contraindicated because of uterine ischaemia and ischaemia of fetal digits (see Table 43.3).

In patients with known varices on a stable regimen of beta blockers before pregnancy, the role of repeated endoscopy during pregnancy is unknown. Interruption of beta blockers may be associated with rebound portal hypertension, so continuation of beta blockers during pregnancy (including labour) is mandatory.

Patients with portal hypertension may have significant varicose veins on the abdominal wall and in the epidural space.[63] Visualization of these collaterals by MRI may minimize the risk of neuraxial anaesthesia or caesarean delivery (Figure 43.2). An additional reason to perform an MRI in pregnant patients with portal hypertension is to look for splenic artery aneurysms. These vascular abnormalities are prone to rupture during the third trimester resulting in high fetal and maternal mortality rates.[64] Preconceptional screening and treatment (coiling) of splenic aneurysms in patients with known portal hypertension is recommended.[65]

Operative vaginal delivery following passive fetal descent is suggested to avoid Valsalva and minimize the risk of variceal bleeding.

## Special situations

### Pregnancy in women after liver transplantation

Nearly 90% of women of child-bearing age return to a fertile state by 7 months after liver transplantation. Women are generally

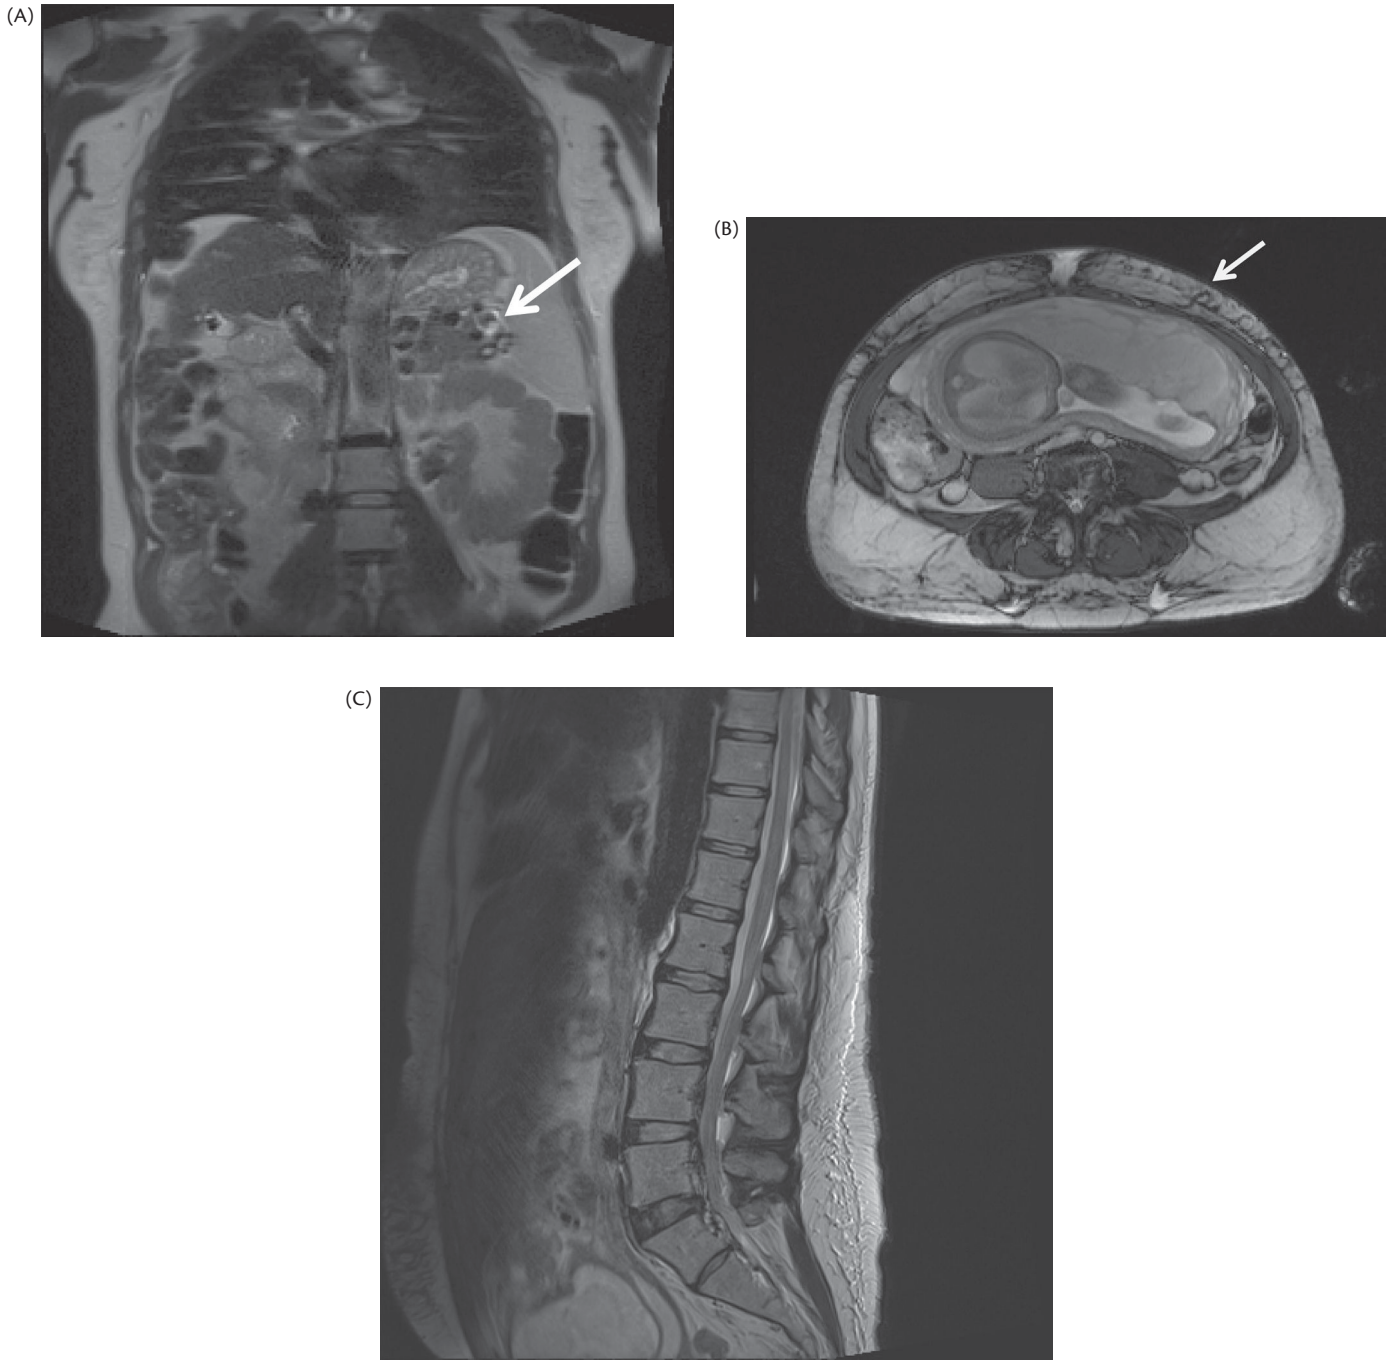

**Figure 43.2** MRI of a 37-year-old patient with cirrhosis (alfa-1-antitrypsin deficiency) at 32 weeks of gestation. Delivery 2 weeks later by uneventful caesarean section because of intrauterine growth retardation. (A) Coronal image showing small cirrhotic liver, ascites, and collateral veins (arrow) in the splenic hilum, perigastric, and pericolic area. (B) Pregnant uterus and venous collaterals in the anterior abdominal wall (arrow). (C) Normal epidural space, no venous collaterals.

advised to delay conception for at least 1 year to stabilize graft function and immunosuppressant dose and optimize control of comorbid conditions.[18] A 2012 meta-analysis that included 450 pregnancies in 306 liver transplant recipients revealed a live birth rate of nearly 77% and a miscarriage rate of 15.6%. The risk of pre-eclampsia (21.9%), preterm delivery (39.4%), and caesarean delivery (44.6%) were increased compared to the general US population.[66] The risk of gestational diabetes and low birth weight is also increased in the liver transplant recipient.[18] Variable rates of rejection during pregnancy (2–10%) and graft loss directly attributable to pregnancy (0–10%) have been reported.[66]

The safety of the immunosuppressive drugs is given in Table 43.3. Most data are available for corticosteroids, azathioprine, ciclosporin, and tacrolimus-based regimens. Mycophenolate mofetil

and everolimus should be avoided in pregnancy. Breastfeeding is contraindicated in women taking immunosuppressant drugs.

### Hepatocellular adenomas and bleeding risk

Hepatocellular adenomas (HCAs) are a rare but important problem. Some HCAs have a tendency for malignant transformation, but during pregnancy life-threatening bleeding is the major concern. The lesion typically develops in women and most often in long-term oral contraceptive users. The yearly incidence has been estimated in (older) case–control studies to be less than 5/100,000 long-term (>5 years) oral contraceptive users.

HCAs arise in a normal liver while a similar lesion in a cirrhotic liver is called a regenerative or dysplastic nodule.[67] Studies that correlate lesional genotype with phenotype form the basis of a new histological/molecular classification of hepatocellular adenomas. Based on molecular criteria (hepatocyte nuclear factor-1α and β-catenin mutations) and histological criteria (the presence/absence of inflammation, cytological and architectural atypia, steatosis, sinusoidal congestion, and mild ductular reaction), subgroups of hepatocellular adenoma can be defined with variable risks of bleeding and malignant transformation.

The occurrence of haemorrhage seems to cluster with the inflammatory HCA.[68] There are two types of haemorrhage: internal bleeding usually admixed with necrotic changes (this type is mostly observed in adenomas > 4 cm) and spontaneous rupture that causes subcapsular haematoma and possible haemoperitoneum. The diameter of bleeding adenomas in the literature varies between 6.5 and 19 cm. These tumours are prone to bleed in the third trimester, but one-third rupture in the postpartum period. Mortality rates of 44% and 38% respectively for mother and fetus have been described, when rupture occurred during pregnancy.[69] Other benign lesions, such as focal nodular hyperplasia or haemangiomas have no bleeding risk.

Preconceptional detection of an HCA by ultrasound, contrast-enhanced CT, and especially MRI allow for a specific diagnosis. Resection of an HCA before pregnancy is necessary with large (≥4–5 cm) tumours or when there are factors that suggest malignant transformation such as rapid growth, change in radiological characteristics or elevated serum alpha-fetoprotein. HCAs that are discovered during pregnancy should be followed by ultrasound at monthly intervals and should be treated according to the criteria above after multidisciplinary discussion.

## Conclusion

The management of liver disease during pregnancy requires a multidisciplinary collaboration between obstetrician, hepatologist, anaesthetist, and neonatologist in order to optimize outcome for mother and child. Interpretation of abnormal liver tests in pregnancy may be difficult, given the normal physiological changes that occur in this condition. The timely recognition of cholestasis, clinically significant portal hypertension, and liver failure is essential to minimize fetal and maternal morbidity and mortality. The differentiation of diseases related or unrelated to pregnancy is important and determines management.

# CHAPTER 44

# Kidney disease

Kate Wiles, Kate Bramham and Catherine Nelson-Piercy

## Renal physiology in pregnancy

Critical renal physiological adaptations occur early in pregnancy, including increased erythropoietin production and vitamin D hydroxylation[1] which appear to be fundamental to successful maternal and fetal outcomes.

### Glomerular filtration

Glomerular filtration rate (GFR) increases from the first day of menstruation and rises by approximately 10–20% until day 21 before returning to baseline levels.[2] Relaxin is a circulating peptide hormone released by the corpus luteum which increases in the luteal phase of the menstrual cycle, correlating with this transient rise in GFR.[3] Following conception, relaxin appears to be an important mediator of pregnancy-associated change in renal physiology. When the ovum is fertilized, the corpus luteum is maintained and relaxin production increases dramatically, stimulated by human chorionic gonadotropin (hCG).[4] At the same time, effective renal plasma flow increases by 80% over the next 16 weeks with a rise in glomerular filtration of 50%.

Relaxin has been shown to be essential for mediating increased renal blood flow in pregnant and non-pregnant rats.[5] Women with *in vitro* fertilization and embryo transfer, with undetectable relaxin levels, have a blunted gestational increase in GFR.[6] In addition, administration of intravenous recombinant human relaxin to non-pregnant volunteers leads to a 47% increase in renal blood flow. However, this increased blood flow does not lead to a parallel increase in glomerular filtration, suggesting that there are also additional unknown mechanisms mediating pregnancy-associated changes in GFR.

An increase in GFR is noted in both renal transplants and women with single kidneys.[7,8] Furthermore, healthy pregnant women given amino acid infusions have a further increase in GFR suggesting that the kidneys have a remarkable capacity for increased filtration on top of pregnancy-associated change.[9] Outside of pregnancy, hyperfiltration has been shown to be a precursor to progressive renal damage.[10] However, despite a sustained period of increased GFR in pregnancy there are no renal consequences. The preservation of renal function in normal pregnancy is proposed to be due to a lack of increase in transglomerular hydrostatic pressure demonstrated by single-nephron GFR studies in rat models.[11]

Increased renal blood flow results in up to a 70% rise in renal volume, and an approximately 1 cm increase in kidney length.[12] Hydronephrosis is a common finding in pregnancy due to progesterone mediated dilatation of the whole renal tract, and compression of the ureters by the enlarging uterus or iliac vessels. The right renal pelvicalyceal system dilates by a maximum of 0.5 mm each week from 6 to 32 weeks, reaching a maximal diameter of about 20 mm which is maintained until term. The left pelvicalyceal system reaches a maximal diameter of 8 mm at 20 weeks' gestation.[13]

### Proteinuria

Proteinuria increases in normal pregnancy and it is widely accepted that the upper limit of normal is 300 mg/24 h.[14] Women with pre-existing proteinuria usually have an approximate doubling of protein excretion in normal pregnancy. This increase in proteinuria is due to increased renal blood flow and alterations in the selectivity and charge of the glomerular basement membrane.[15] Albumin accounts for approximately 30% of urine protein excretion. Albuminuria increases two- to threefold during pregnancy and may not return to normal until 12 weeks postpartum.[16] There are also increases in urinary excretion of low-molecular-weight proteins, glucose, amino acids, calcium, and uric acid suggesting physiological compromise of proximal tubular reabsorption during pregnancy.

## Acute kidney injury in pregnancy

### Epidemiology

Acute kidney injury (AKI) is characterized by a rapid reduction in kidney function resulting in a failure to maintain fluid, electrolyte, and acid–base homoeostasis. AKI is a common clinical problem. Data from the United Kingdom estimate the incidence of AKI to be 486–630/million population/year[17] and between 5% and 20% of critically ill patients experience an episode of AKI during the course of their illness.[18]

The incidence of AKI in pregnancy varies depending upon the socioeconomic conditions of the population studied. The incidence of AKI in developed countries is estimated to be 1/15,000–20,000 pregnancies.[19] However, in developing nations, obstetric AKI remains a serious problem, complicating up to 1/2000 pregnancies[20] and resulting in as many as 25% of referrals to dialysis centres.[21] Improved prenatal care and the liberalization of abortion laws with consequent reduction in septic abortion are significant factors in explaining this variance.[6]

The presence of AKI is associated with an increased mortality regardless of the underlying aetiology.[22] The estimated maternal mortality from pregnancy-related AKI, although rare in the developed world, is up to 20% in developing countries.[23] Despite its decreasing incidence, AKI remains a serious complication in pregnancy.

**Table 44.1** RIFLE classification scheme for acute kidney injury

| RIFLE category | Creatinine (Cr), glomerular filtration rate (GFR) | Urine output |
|---|---|---|
| Risk | Cr ≥ 1.5 × baseline or decrease in GFR ≥ 25% | <0.5 mL/kg/h for ≥6 hours |
| Injury | Cr ≥ 2 × baseline or decrease in GFR ≥ 50% | <0.5 mL/kg/h for ≥12 hours |
| Failure | Cr ≥ 3 × baseline or Cr ≥ 354 μM with a rise of at least 44 μM or decrease in GFR ≥ 75% | <0.3 mL/kg/h for ≥24 hours or anuria ≥ 12 hours |
| Loss | Loss of kidney function for >4 weeks | |
| End-Stage | Loss of kidney function for >3 months | |

## Definitions of acute kidney injury: difficulties in pregnancy

In the past, studies of AKI were limited by the way AKI was defined and classified. Collaborative groups therefore worked to produce consensus definitions of AKI based on changes in serum creatinine and urine output (see Table 44.1 and Table 44.2).

However, the physiology of pregnancy includes an increase in renal blood flow and an associated 50% increase in GFR. In addition, there is an expansion in plasma volume causing haemodilution. Consequently, such consensus definitions of AKI are not valid in the pregnant woman.

In the United Kingdom, laboratories calculate an estimated GFR (eGFR) on all samples sent for creatinine measurement using the Modification of Diet in Renal Disease (MDRD) equation. When assessing for kidney injury it needs to be remembered that not only does this formula require plasma creatinine levels to be in steady state thereby precluding accurate assessment of acute changes in renal function, it also underestimates a gestational GFR calculated by inulin clearance by more than 40 mL/min.[26]

Clinicians are therefore limited to the interpretation of creatinine as a surrogate marker for renal function. Even then, the physiological changes of pregnancy mean that serum creatinine falls by an average of 35 μmol/L (0.4 mg/dL) in pregnancy.[27] Although a 'normal' laboratory value for creatinine can therefore still mask kidney injury in the pregnant patient, a creatinine of higher than 90 μmol/L is indicative of renal impairment in pregnancy.[28] In the context of the limitations of biochemical parameters to assess for AKI, the value of urine output criteria should be remembered, although oliguria is very common intra- and postpartum especially in the context of pre-eclampsia (see 'Pre-Eclampsia' section).

**Table 44.2** Acute Kidney Injury Network (AKIN) staging system for acute kidney injury

| AKIN stage | Serum creatinine (Cr) | Urine output |
|---|---|---|
| 1 | Cr ≥ 1.5–1.9 × baseline or Cr increase by ≥26.2 μM | <0.5 mL/kg/h for ≥6 hours |
| 2 | Cr ≥ 2–2.9 × baseline | <0.5 mL/kg/h for ≥12 hours |
| 3 | Cr ≥ 3 × baseline or Cr ≥ 354 μM with a rise of at least 44 μM or initiation of renal replacement therapy | <0.3 mL/kg/h for ≥24 hours or anuria ≥ 12 hours |

Acute Kidney Injury Network: report of an initiative to improve outcomes in acute kidney injury, *Critical Care*, volume 11, issue 2, R31. http://www.ccforum.com/content/11/2/R31. © 2007 Mehta *et al.*; This is an open access article distributed under the terms of the Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0), which permits unrestricted use, distribution, and reproduction in any medium, provided the original work is properly cited.

## Aetiology of acute kidney injury

AKI is a common medical problem affecting 5% of hospital in-patients and 30% of critically ill patients.[25] It is less common in the pregnant population ranging from 1/2000 to 1/20,000 pregnancies depending on the socioeconomic status of the population.[29] As in the non-pregnant patient, the aetiology of AKI can be considered as 'pre-renal' due to pathology of renal perfusion, 'renal' with intrinsic renal damage, or 'post-renal' caused by interruption to the normal outflow of the kidney. The pregnancy-related causes of AKI are listed in Table 44.3.

## Acute kidney injury in pregnancy: general principles

Supportive measures in the management of AKI apply to the pregnant population as in the non-pregnant population. Renal perfusion needs to be maintained. Fluid requirements need to be assessed in the context of a careful clinical examination of the pregnant patient remembering the physiological reduction in both blood pressure and oncotic pressure that occur in pregnancy. Doses of antibiotics, anticoagulants, insulin, and opiates may need to be adjusted when there is a decrease in GFR. Erythropoietin requirements can increase with AKI. Nephrotoxic drugs including aminoglycosides, postpartum non-steroidal anti-inflammatory drugs (NSAIDs), and radiocontrast agents should be avoided. Treatment of hyperkalaemia with ion-exchange resin, insulin, and glucose

**Table 44.3** Causes of acute kidney injury in pregnancy

| Pre renal | Renal | Post renal |
|---|---|---|
| Vomiting/hyperemesis | Pre-eclampsia | Gravid uterus |
| Postpartum haemorrhage | HELLP | Papillary necrosis |
| Placental abruption | AFLP | Urinary retention |
| Sepsis | TTP and HUS | Damaged ureters |
| Heart failure | Acute tubular necrosis | |
| | Interstitial nephritis | |
| | Glomerulonephritis | |

AFLP, acute fatty liver of pregnancy; HELLP, haemolysis, elevated liver enzymes, and low platelet count; HUS, haemolytic uraemic syndrome; TTP, thrombotic thrombocytopenic purpura.

can, and should, be given if required in pregnancy. Maternal and fetal indications for renal replacement therapy are considered below (see 'Dialysis' section).

## Acute kidney injury in pregnancy: specific conditions

### Pre-Eclampsia

Pre-eclampsia is a pregnancy-specific disorder characterized by new-onset hypertension and proteinuria after 20 weeks' gestation. Hypertension is defined as a blood pressure above 140/90 mmHg. Proteinuria is an excretion of greater than 300 mg/24 h. A 24-hour urine collection is considered the gold standard for quantification of proteinuria but a spot urinary protein:creatinine ratio greater than 50 mg/mmol may also be used for diagnosis.[27] Pre-eclampsia is a multisystem disorder which can affect any maternal organ including the kidney. Pre-eclampsia is the most common cause of AKI in pregnancy. In addition, as pre-eclampsia affects approximately 5% of pregnancies it is also the commonest glomerular disease in the world.[32]

The primary locus for kidney injury in pre-eclampsia is the glomerular endothelium. This substantiates the epidemiology of pre-eclampsia whereby diseases that are associated with endothelial dysfunction such as diabetes and antiphospholipid syndrome carry an increased risk for the development of pre-eclampsia. Endothelial cell swelling leads to capillary occlusion and endotheliosis (a swelling of the glomerulus, the degree of which correlates with disease severity).[33] Electron microscopy confirms the loss of renal fenestrae. Antiangiogenic factors are hypothesized to play a role in the interruption of normal endothelial health leading to a diffuse endotheliosis that is pathognomonic for pre-eclamptic renal injury. Impaired hydraulic permeability of glomerular capillary wall leads to a reduced plasma flow and a fall in GFR.[34] In pre-eclampsia, GFR and renal plasma flow decrease by 24–40% compared with normal pregnancy of the same gestation.[35,36] Of note, milder glomerular endotheliosis is seen in up to 50% of pregnancies complicated by hypertension without coexisting proteinuria suggesting that pregnancy-induced hypertension is part of the spectrum of pre-eclamptic renal disease.[33]

Although oedema is not a criterion for the diagnosis of pre-eclampsia it remains a common presenting symptom. The oedema in pre-eclampsia is not due to vascular underfilling driving the renin axis and causing renal sodium retention. It is better comparable to the 'overflow' state of acute nephritic syndromes in which GFR decreases disproportionately to renal plasma flow and glomerular–tubular imbalance is hypothesized to cause salt retention.[37] Decreased GFR, increased capillary permeability, and hypoalbuminaemia may all contribute to the oedematous clinical state.

The treatment of pre-eclampsia aims to maintain blood pressure at less than 140/90 mmHg to reduce the risk of hypertension in the mother whilst maintaining adequate uteroplacental perfusion. Treatment is mandatory for a blood pressure greater than 160/110 mmHg due to the risk of both maternal cerebral haemorrhage and placental abruption. Common agents used in the treatment of hypertension are outlined in Table 44.4.

Fluid management is important in pre-eclampsia. Aggressive hydration in women with pre-eclampsia is associated with increased maternal mortality and it is advised that women are 'kept dry' to avoid these risks.[39] Oliguria is common in pre-eclampsia and does not imply volume depletion.[40] There is no evidence of benefit of fluid expansion in pre-eclampsia[41] and a fluid challenge with either crystalloid or colloid does not ensure improved uteroplacental perfusion.[42] Equally, from an anaesthetic perspective it should be remembered that women with pre-eclampsia firstly, are vasoconstricted and not at increased risk of hypotension either during or after regional anaesthesia and secondly, that there is no evidence that a bolus of crystalloid as a preload prevents hypotension.[39,43]

There is a natural diuresis at 36–48 hours postpartum. Judicious fluid management is needed until this occurs. A fluid restriction of 80 mL/h is suggested.[39,44] Before the postpartum diuresis, oliguria is common and does not require further management. It is suggested that a urine output greater than 40 mL in 4 hours is sufficient in the immediate postpartum period[39] but there is no evidence that maintenance of a specific urine output prevents the rare development of overt renal failure. Urine output is, however, used to guide magnesium treatment in severe pre-eclampsia and eclampsia. The kidney is the key player in magnesium homeostasis and a fall in GFR increases the potential for developing hypermagnesaemia. When urine output falls to less than 20 mL/h, dose adjustment of magnesium sulphate is required. However in the event of eclampsia, the usual loading bolus dose of 4 g should be given.

The reversible glomerular endothelial pathology in pre-eclampsia that temporarily compromises renal function may be complicated both by hypovolaemia and overzealous fluid restriction. Permanent renal damage in pre-eclampsia is unusual suggesting that restriction of fluid in pre-eclampsia is either not clinically significant or that permanent clinical sequelae are rare.[44] Renal function is, however, vulnerable in patients with pre-eclampsia and a nephrotoxic hit from NSAIDs should be avoided with alternative postpartum analgesia prescribed.

The glomerular swelling and renal endothelial changes in pre-eclampsia usually resolve by 8 weeks postpartum coinciding with the clinical regression of hypertension and proteinuria.[37] However, research has demonstrated a longer regression trajectory in those with higher blood pressures and greater quantities of gestational proteinuria. It has been found that 14% of women have persistent proteinuria at 3 months, falling to 2% at 2 years postpartum with an estimate of 16% longer to remission for every 1 g/day increase in proteinuria during pregnancy.[45] However, it is advised that patients who continue to demonstrate proteinuria at 6–8 week postpartum are reviewed again at 3 months postpartum and a referral to a nephrologist is considered to exclude underlying renal disease.

Pre-eclampsia is known to increase the risk of vascular disease in later life including chronic hypertension, ischaemic heart disease, cerebrovascular disease, and venous thromboembolism.[46] For this reason, women who have developed pre-eclampsia are advised to undergo annual assessment of their vascular risk, appropriate modification of lifestyle factors, and treatment when risk thresholds are reached. In addition, pre-eclampsia is an independent risk factor for both renal biopsy and subsequent end-stage renal disease (ESRD). Women with pre-eclampsia whose babies weigh less than 1.5 kg have a 17-fold increase risk of proceeding to renal biopsy.[47] In addition, although the absolute risk of ESRD is low, pre-eclampsia increases that risk by 3–15 times depending on the number of pregnancies in which pre-eclampsia develops.

**Table 44.4** Common pharmacological agent used to treat hypertension in pregnancy and the postpartum period

| Agent | Dose | Side effects | Comments |
|---|---|---|---|
| *Antenatal* | | | |
| Methyldopa | 250 mg bd–1 g tds | Lethargy<br>Depression | Documented safety profile<br>7-year follow-up of offspring |
| Labetalol | 200 mg bd–500 mg tds<br>or intravenous infusion | | Avoid in asthma |

Data from *Hypertension in pregnancy: The management of hypertensive disorders in pregnancy,* National Institute for Health and Clinical Excellence, 2011.

These data include correction for pre-existing renal disease, rheumatic disease, essential hypertension, and diabetes mellitus.[48]

## Haemolysis, elevated liver enzymes, and low platelets (HELLP syndrome)

Severe pre-eclampsia is complicated by a consumptive coagulopathy and microangiopathy in 10–20% of cases.[33] HELLP syndrome is the constellation of haemolysis, elevated liver enzymes, and low platelets and is an important variant of severe pre-eclampsia. AKI may complicate any pre-eclampsia but the incidence of renal failure is much higher in HELLP syndrome. HELLP affects 10–20% of patients with severe pre-eclampsia and the largest study estimates that AKI complicates 3% of HELLP.[49] Abruption, disseminated intravascular coagulation, sepsis, haemorrhage, and intrauterine death all increase the risk of AKI in HELLP. A rise in serum creatinine in association with HELLP worsens prognosis.[50]

Although AKI in HELLP can be severe enough to require renal replacement therapy, it is observed that most patients will recover renal function. In addition, successful cadaveric renal transplantation from patients with HELLP and renal involvement are described.[51] This potential for renal recovery means that there are limited biopsy data on the nature of the renal insult in HELLP. Limited case reports describe the glomerulosis of pre-eclampsia with additional thrombotic microangiopathy. It is therefore hypothesized that the endothelial pathology which triggers kidney injury in pre-eclampsia, can extend to produce a thrombotic microangiopathy in HELLP. The resulting renal tissue ischaemia is more severe, producing both tubular and cortical necrosis.[52,53]

The management of HELLP is supportive and mirrors that of pre-eclampsia. A double-blind randomized controlled trial showed that the use of steroids did not alter hospital stay, recovery of laboratory parameters, or complication rates.[54] Although the renal pathology is that of a thrombotic microangiopathy, there are no prospective trial data to either support or refute the use of plasmapheresis.

## Thrombotic microangiopathy

### *Thrombotic thrombocytopenic purpura*

Thrombotic thrombocytopenic purpura (TTP) is characterized by thrombocytopenia, microangiopathic haemolytic anaemia, and organ dysfunction which can include AKI. Pregnancy-associated TTP usually occurs in the second or third trimesters or in the postpartum period.[55] The average gestational age at diagnosis is 26 weeks. Pregnancy is both a trigger factor for new disease and for disease flare in those with a history of TTP. (See Chapter 48 for more haematological details of TTP.)

The pathogenesis of TTP is characterized by the deposition of platelet-rich thrombi in the microcirculation of multiple organs, including the kidneys. Von Willebrand factor (vWF) plays a

haemostatic role by inducing the formation of platelet plugs. In TTP, von Willebrand proteins do not undergo their normal rapid breakdown due to either a quantitative or functional deficiency of the vWF cleaving protein, ADAMTS13. This leads to platelet aggregation, red cell fragmentation, and the clinical picture of TTP. Pregnancy is a procoagulant state with increased levels of factor VIIa, factor VIII, vWF, and fibrinogen as well as increased amounts of fibrin degradation products. This suggests that mild intravascular coagulation is a phenomenon of normal pregnancy.[53] In addition, levels of ADAMTS13 decrease in normal pregnancy during the second and third trimesters. A severe deficiency of ADAMTS13 has been recorded in pregnancy-associated TTP with 20% of patients having levels of less than 5%.[56]

TTP can be difficult to diagnose in pregnancy as thrombocytopenia, haemolysis, renal dysfunction, and neurological symptoms exist in both TTP and HELLP. Twenty per cent of woman with pregnancy-associated TTP are diagnosed with coexisting pre-eclampsia/HELLP.[53] Clotting abnormalities are, however, more common (20%) in HELLP and so elevated antithrombin and fibrinogen levels may increase the clinical suspicion of TTP.[53] ADAMTS13 levels may not be diagnostically helpful as a reduced level has been described in HELLP without evidence of concurrent TTP.[57] Levels below 5% are diagnostic of TTP. The presence of antibodies against ADAMTS13 suggest the more common acquired form as opposed to congenital TTP.

Renal disease in TTP is due to thrombotic microangiopathy within the kidney and is common in pregnancy-associated TTP; 30–80% of pregnant women with TTP will demonstrate renal dysfunction which is a higher rate than in TTP outside of pregnancy.[53] Treatment is with fresh frozen plasma infusion and/or plasma exchange which will replace the deficiency of normal anticoagulant factors and/or neutralize circulating antibodies against them. Plasma exchange has improved maternal mortality from over 50% to less than 10%.[55] Fetal outcome, however, remains poor with a perinatal mortality rate of 30–80% attributed to microangiopathy of the placental arterioles.[58] Reports of long-term renal outcome are variable. The literature describes renal recovery as 'typical' in some cohorts.[53] In patients with a known history of TTP who subsequently become pregnant, serial monitoring of ADAMTS13 levels is advised where a quantitative deficiency is measurable, with prophylactic plasma exchange instituted to prevent disease flare.

#### *Haemolytic uraemic syndrome*

Haemolytic uraemic syndrome (HUS) and TTP are clinically similar disorders, traditionally segregated on the basis of clinical presentation. Those with microangiopathic haemolytic anaemia causing neurological deficit were traditionally classified as TTP, whereas microangiopathy without neurological symptoms but predominant renal impairment was labelled HUS. The same patient might have been labelled as HUS by a nephrologist and TTP by a haematologist.[59] The term TTP/HUS was therefore coined to avoided uncertainty of diagnosis.

However, a more detailed understanding of the molecular basis of both TTP and HUS has facilitated clinical distinction once more. An acquired or constitutional deficiency of ADAMTS13 is associated with the clinical picture of TTP, whereas mutations to proteins involved in the complement pathway are described in HUS. Patients with microangiopathy in association with complement dysregulation have significant renal disease and 76% progress to ESRD.[60]

In the same way that pregnancy can trigger the onset and/or relapse of ADAMTS13-deficient TTP, it can also initiate complement dysregulation-associated HUS. Interestingly, complement dysfunction is also described in HELLP[61] which, as discussed, can be difficult to distinguish from isolated microangiopathy (see 'Thrombotic thrombocytopenic purpura' section).

Pregnancy-associated HUS accounts for up 21% of non-diarrhoea-associated HUS in women of whom 86% have a detectable complement gene mutation.[60] In contrast to TTP, most cases (>75%) of pregnancy-associated HUS occur in the postpartum period. It is theorized that placental expression of complement regulatory proteins is protective in pregnancy and when this control is lost at delivery HUS can present.[60]

As for TTP, treatment of HUS includes plasma infusion and exchange. In addition, eculizumab is now licensed for the treatment of non-diarrhoea-associated HUS. Eculizumab inhibits activation of the alternative complement pathway in HUS via anti-C5 blocking antibody. Small prospective studies show an improvement in GFR including dialysis-requiring patients becoming independent of renal replacement for the duration of treatment.[62] Data on eculizumab are limited in pregnancy but use at a lower dose for paroxysmal nocturnal haemoglobinuria is reported.[63,64]

Pre-pregnancy counselling of women with known complement dysregulation is difficult as there is incomplete penetrance at a molecular level and pregnancy may, or may not, be a sufficient trigger for clinical disease. A 20% risk of pregnancy-associated disease is quoted.[60]

### Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare obstetric emergency, which has the potential to progress to fulminant liver failure. This disorder has been linked to genetic mutations in maternal and fetal mitochondrial fatty acid oxidation genes leading to an excessive hepatotoxic fatty acid load and impaired liver function.

AKI is a common complication occurring in 20–100% of patients.[53] The underlying renal pathology is variable and includes acute tubular necrosis and the endotheliosis of coexisting pre-eclampsia. Tubular free fatty acid deposition has also been seen which links directly with current theories of liver pathogenesis.[65]

Treatment requires early diagnosis, supportive care, and prompt delivery. Maternal and perinatal mortality is between 10–20% but in most women there is complete liver and renal recovery after delivery.[66]

### Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is primarily a disease of young women. It therefore has the potential to present for the first time in pregnancy with AKI. The diagnostic difficulty and management of lupus in pregnancy plus the indications for renal biopsy in pregnancy are considered below in the sections on lupus nephritis and renal biopsy in pregnancy.

### Urinary tract infection

Physiological changes to the urinary tract increase the risk of bacterial colonization. These include increased bladder volume, decreased detrusor muscle tone, progesterone-driven ureteric dilatation, and glycosuria. The incidence of urinary tract infection (UTI) in pregnancy is approximately 2%[67] with a 0.07% incidence of pyelonephritis.[68] However, pyelonephritis carries a high (23%) risk of recurrence in the same pregnancy.[69]

Any infection of the urinary tract is associated with increased risk of adverse outcomes for both mother and child. Pyelonephritis represents the most serious type of infection which if untreated leads to pyonephrosis, abscess formation, septicaemia, and organ failure. Antepartum pyelonephritis is associated with adverse perinatal outcomes and is an independent risk factor for preterm delivery.[68]

Screening and effective treatment of asymptomatic bacteriuria and cystitis will reduce the risk of pyelonephritis. Treatment of asymptomatic bacteriuria should be directed by urine culture and continued for a minimum of 7 days.[70] Cystitis and pyelonephritis should be treated empirically with broad-spectrum agents until culture and sensitivity results are available. A 10-day course of antimicrobial therapy is advocated for symptomatic infection with up to 21 days recommended for pyelonephritis.[71] It is important to exclude renal tract anomaly with persistent, recurrent, or clinically significant infection. Recurrent infection carries the same risks as primary infection and low-dose antibiotic prophylaxis may be required for the remainder of the pregnancy.[72]

Women with vesicoureteric reflux have a higher incidence of UTI in pregnancy but this is not associated with excess maternal or fetal morbidity provided there is no renal scarring. It is the existence of renal scarring, rather than the presence or absence of reflux, which increases the risk of hypertension and pre-eclampsia in pregnancy [73] (see 'Reflux Nephropathy' section).

### Obstructive nephropathy

AKI secondary to an obstructive nephropathy is rare although patients with a single kidney, multiple pregnancy, or polyhydramnios have an increased risk.[74] Bladder neuropathy in those with transplant-treated diabetic renal disease or neurological disorders (e.g. spina bifida) needs to be remembered.

Evaluation of renal tract obstruction is made difficult in pregnancy as the pelvicalyceal system and ureter dilate from as early as 6–10 weeks' gestation, particularly on the right. Certain radiological features are, however, useful in the distinction between physiological and pathological renal obstruction in pregnancy. Firstly, a dilated ureter distal to the pelvic brim suggests a cause other than pregnancy for the dilatation. Secondly, resistance indices (Doppler sonography of arcuate or interlobar renal arteries) are normal in physiological hydronephrosis and an increased index, particularly where there is an inter-renal difference, is suggestive of an alternative pathology. Finally, an absence of ureteric jets can suggest obstruction, but the pregnant patient should be examined both supine and in the contralateral decubitus position in order to negate the effect of the gravid uterus before conclusions can be made.[75]

## Chronic kidney disease

### Prevalence

Chronic kidney disease (CKD) is estimated to affect 3% of women of childbearing age.[76] A 2012 population cohort study in the United States demonstrated a significant increase in chronic hypertension due to renal disease from 1995 to 2008.[77] Both increasing age and body mass index are associated with CKD.[78] Therefore, the trend of women delaying pregnancy and increasing obesity in women of childbearing age are likely to result in a greater number of pregnancies complicated by CKD. Table 44.5 and Table 44.6 offer practical guidance in the prepregnancy and antenatal management of women with CKD.

In 1975, a review of renal disease in pregnancy reported that 'Children of women with renal disease used to be born dangerously or not at all—not at all if their doctors had their way'.[79] Dramatic improvements in pregnancy outcomes have occurred over recent decades, such that the majority of women with CKD have successful pregnancies. However, a meta-analysis of studies, including 2682 women with CKD, confirmed a high incidence of both maternal and neonatal adverse outcomes.[80]

### Influence of pregnancy on renal disease

Despite the increasing demands of pregnancy on renal function, pregnancy has no detrimental effect on renal function for the majority of women with CKD. However, in some individuals pregnancy may precipitate a rapid decline in renal function, which may result in ESRD. The complexities of life as a new mother combined with the practical and psychological issues of commencing dialysis needs to be considered and explained carefully to women at risk.

There are few studies exploring the incidence of pregnancy-associated decline in renal function. Renal outcomes from 908 pregnancies which reached 24 weeks' gestation reported in the literature between 1985 and 2007, are shown in Table 44.7.

An earlier study of 89 pregnancies in 62 women with initial serum creatinine greater than 125 μmol/L reported 20% of women experiencing a decline in renal function during pregnancy and 23% having a decline in renal function postpartum.[81] A prepregnancy GFR of less than 40 mL/min/1.73 $m^2$ and proteinuria greater than 1 g/24 hours were risk factors for a 50% decline in renal function and requirement for renal replacement therapy.[82]

Temporary deterioration in renal function in women with CKD is common and frequently this can be difficult to distinguish from the normal physiological rise in creatinine towards the end of pregnancy. A study of 105 pregnancies in renal transplant recipients reported that 38% of women had a greater than 20% rise in creatinine during their pregnancy.[83] Causes for AKI should be explored, before pregnancy-associated decline in renal function is assumed.

### Influence of renal disease on pregnancy

#### Hypertension in pregnancy

Women with CKD and associated prepregnancy hypertension may have an initial fall in blood pressure due to the physiological changes during pregnancy, and may be able to discontinue antihypertensive treatment. However, many women have an increase in blood pressure towards term. Normotensive women with CKD are also more likely to develop gestational hypertension than healthy controls.[80]

Pre-eclampsia is more common in women with CKD, and the likelihood of occurrence is related to both severity of underlying renal disease,[1] and the aetiology of renal disease. Women with lupus nephritis, reflux nephropathy, and renal transplants are more susceptible to pre-eclampsia than women with other causes of renal impairment with the same level of renal function.[84] Presence and severity of pre-existing hypertension and proteinuria have also been identified as risk factors for the development of pre-eclampsia in women with CKD.[85]

**Table 44.5** Prepregnancy counselling strategy for women with renal disease

| | |
|---|---|
| Gynaecological and obstetric history | Review current menstrual cycle, previous pregnancies, current contraceptive use |
| | Discuss effects of age, weight, and renal function on fertility |
| | Consider investigations for infertility if necessary |
| Pregnancy and renal outcomes | Discuss effects of renal disease on pregnancy, e.g. pre-eclampsia |
| | Discuss effects of pregnancy on renal disease |
| | Discuss implications of loss of renal function if relevant, e.g. symptoms of chronic kidney disease, lifestyle of renal replacement therapy |
| | Inform of necessity of hospital-based antenatal care |
| | Advise that vaginal delivery is achievable and desired, but that caesarean delivery may be required |
| Medication | Start folic acid 5 mg daily |
| | Advise to start aspirin 75 mg daily at conception |
| | Review medication and switch to non-teratogenic alternatives |
| | Discuss drug safety in pregnancy and breastfeeding |
| | Optimize haemoglobin and iron stores |
| | Treat vitamin D deficiency |
| Disease activity and/or stability | Advise not to conceive if disease flare or episode of transplant rejection within 6 months |
| | Consider delaying conception if renal function rapidly deteriorating |
| | Consider renal biopsy if underlying disease unknown |
| Disease-specific issues | Discuss inheritance and screening for adult polycystic kidney disease and reflux nephropathy |
| | Inform of risk of neonatal lupus if anti-Ro/La positive |
| | Discuss importance of glycaemic control in type 1 and type 2 diabetes prior to conception and during pregnancy |
| Other medical history | Assess for other concurrent medical disorders which may impact on pregnancy outcome, e.g. pulmonary hypertension, cardiac disease, respiratory disease |
| Advice for when conceives | Do not stop all medications other than those discussed |
| | If problems taking medication due to nausea or vomiting to seek medical advice |
| | Give contact details in order to inform relevant health professionals when conceives to allow early pregnancy assessment and viability scan |

The diagnosis of pre-eclampsia that is superimposed on pre-existing hypertension may be difficult. Research definitions of superimposed pre-eclampsia specify that additional features are required in order to confirm the diagnosis including clinical symptoms or changes in other parameters such as liver function tests or platelet count.[86] In practice, additional features may be absent but women with CKD may have a rapid rise in blood pressure or dramatic increase in proteinuria, coupled with non-specific clinical features such as oedema or headache. Frequently women with suspected superimposed pre-eclampsia may require inpatient admission for maternal and fetal assessment. A decision to deliver is made by a multidisciplinary team evaluating the risk of deterioration of renal disease in the mother versus the complications of preterm delivery.

There is limited evidence for the role of novel markers for the diagnosis of pre-eclampsia in women with CKD. However, soluble FMS-like tyrosine kinase-1 and placental growth factor ratios have been found to be significantly higher in women with pre-eclampsia compared to women with CKD[87] suggesting they may be useful discriminators.

Uterine artery Doppler has not been formally evaluated in women with CKD although one study of women with CKD due to lupus nephritis has calculated a mid-trimester negative predictive value of only 47%.[88] Despite this, most clinicians would measure uterine artery Doppler indices in women with CKD and plan ongoing fetal assessment according to estimated risk. There is some evidence that normal flow velocity waveforms distinguish women with CKD from those with pre-eclampsia, but the role of Doppler for diagnosing superimposed pre-eclampsia is unclear.[89]

Aspirin has been shown to be of benefit in reducing the risk of pre-eclampsia by 17%.[90] The absolute risk reduction is greater in higher-risk populations including women with CKD.

### Fetal loss

The majority of women with CKD have successful pregnancies. Data on rates of early fetal loss and termination of pregnancy for medical reasons are limited due to under-reporting, but both early and late miscarriage are more common in women with CKD, particularly in those with severe renal impairment.[1]

### Preterm delivery and fetal growth restriction

Preterm delivery is more common in women with CKD than the general population.[80] The majority of preterm deliveries are iatrogenic, predominantly for maternal reasons including progression of hypertension, proteinuria, or renal dysfunction.[91] Women should be counselled carefully about the short- and long-term consequence of a preterm delivery prior to conception, particularly those with severe renal impairment, as the challenges of managing deteriorating maternal health, and the emotional

**Table 44.6** Antenatal and postnatal care of women with chronic kidney disease

| | |
|---|---|
| Antenatal care | Target blood pressure < 140/90 mmHg |
| | Monitor serum creatinine and proteinuria |
| | Thromboprophylaxis if albumin < 20 g/dL or proteinuria > 2 g/24 h or protein:creatinine ratio > 200 mg/mmol |
| | Low-molecular-weight heparin if serum creatinine < 200 µmol/L |
| | Unfractionated heparin if serum creatinine > 200 µmol/L |
| | Regular urine culture, and start antibiotic prophylaxis after one infection |
| | Aim to keep haemoglobin 10–11 g/dL—use oral or intravenous iron and erythropoietin as necessary |
| | Monitor tacrolimus or ciclosporin levels every 4 weeks—aim for non-pregnant therapeutic range |
| | Treat vitamin D deficiency—cholecalciferol and/or 1-alpha-calcidol depending on level of renal impairment |
| | Consider haemodialysis if urea > 20 mmol/L, or problems with hyperkalaemia or acidosis |
| | Uterine artery Dopplers at 20–22 weeks' gestation, and repeat if notching at 24 weeks |
| | Serial growth scans in women with CKD stage 3–5 or CKD 1–5 with hypertension |
| Postnatal care | Review blood pressure and fluid balance—target blood pressure <140/90 mmHg |
| | Reduce tacrolimus or ciclosporin to prepregnancy dose and monitor levels |
| | Continue thromboprophylaxis for 6 weeks postpartum |
| | Stop aspirin if not required for long-term cardiovascular disease prophylaxis |
| | Assess for proteinuria at 6 weeks and revise target blood pressure accordingly: |
| | <130/80 mg/mmol if protein creatinine ratio > 150 mg/mmol |
| | <140/90 mg/mmol if protein creatinine ratio < 150 mg/mmol |
| | Discuss future contraception |

demands of having a very preterm infant in intensive care may be underestimated.[92] The rate of preterm delivery is higher in women with more severe renal impairment and reaches more than 90% in women with serum creatinine greater than 180 µmol/L.[1]

Fetal growth restriction is estimated to be up to five times more common in women with CKD,[93] with risks increasing with severity of renal disease.[1,80] Serial growth scans are recommended from 24 weeks' gestation in women with a reduced GFR, hypertension, or significant proteinuria.

## Chronic kidney disease: specific conditions

### Transplantation

Women with renal transplants frequently have successful pregnancies;[83] however, their pregnancies are associated with more complications than women with matched levels of kidney function.[84] This is likely to reflect irreversible endothelial damage from previous ESRD. Pre-eclampsia is increased sixfold and low-dose aspirin should be offered to all these women after conception to try and reduce this. A prospective study of 105 pregnancies in renal transplant recipients in the United Kingdom demonstrated a higher risk of pregnancy complications compared to healthy controls with 20% of women requiring high dependency care at some point during their pregnancy.[83] An additional finding of this study was that 45% of women with a second or subsequent graft had poor pregnancy outcomes possibly reflecting the vascular damage of reaching ESRD on two or more occasions.

Transplant recipients are seen frequently by medical professionals and are a population who should be able to plan pregnancies and receive appropriate prepregnancy counselling. A 2013 study in the United Kingdom of pregnancies in renal transplant recipients found that only 64% were taking folic acid at conception, suggesting that a third of women had unplanned pregnancies.[83]

The timing of conception following renal transplantation is controversial. The first year post transplantation is associated with most episodes of acute rejection, and therefore it is felt that pregnancy should be avoided during this time. A transplant-to-pregnancy interval of 12–24 months is suggested by the European Best Practice Guidelines for renal transplantation.[94] The American Society of Transplantation Guidelines recommended that pregnancy may be considered after 1 year in women who are at low risk of complications[95] on the basis of favourable outcomes.[96,97] However, a meta-analysis of 50 studies of pregnancy following renal transplantation did not identify an association between time from transplant and pregnancy outcome.[98]

Remarkably, physiological changes seen in native kidneys are also reported in renal transplants.[8] An increase in GFR is expected in women with a preserved GFR prepregnancy. Hydronephrosis may be identified and positional scanning is recommended to

**Table 44.7** Pregnancy and renal outcomes

| | Effects on pregnancy outcome | | | | Loss of >25% renal function | | |
|---|---|---|---|---|---|---|---|
| **Mean prepregnancy creatinine (µmol/L)** | **Fetal growth restriction** | **Preterm delivery** | **Pre-eclampsia** | **Perinatal deaths** | **During pregnancy** | **Persists postpartum** | **ESRF after 1 year** |
| <125 | 25% | 30% | 22% | 1% | 2% | 0% | 0% |
| 125–180 | 40% | 60% | 40% | 5% | 40% | 20% | 2% |
| >180 | 65% | >90% | 60% | 10% | 70% | 50% | 35% |
| On dialysis | >90% | >90% | 75% | 50% | N/A | N/A | N/A |

ESRF, end stage renal failure; N/A, not applicable.

assess whether or not this is pregnancy associated. Causes for a decline in transplant renal function are listed in Table 44.8.

Most studies report no significant effects of pregnancy on graft function,[96,99–102] although a single study of 48 pregnancies reported a 20% decline in function at 6 months postpartum.[103] Women at risk of pregnancy-associated accelerated decline in function are those with impaired GFR, hypertension, and one or more previous transplants.[104] There is no evidence of increased rates of acute rejection in the postpartum period with the restoration of cellular immunity.

### Kidney–pancreas transplantation

There are now several successful pregnancies reported in women with simultaneous kidney–pancreas transplants (SPK). Unfortunately these pregnancies appear to be more complicated than those of women with single-organ transplants. The intraperitoneal position of the graft makes obstructive nephropathy more common.[105] The United States National Transplant Pregnancy Register records high rate of fetal loss (29%), hypertension (66%), infection (48%), pre-eclampsia (34%), preterm delivery (77%), and low birthweight (62%).[106] Graft loss of one or both organs postpartum is reported to be up to 19% in one series of 43 women.[106] Prepregnancy creatinine does not appear to be a predictor of graft loss.[107] There is no evidence for an adjustment in immunosuppressive regimens other than switching to non-teratogenic medication prior to pregnancy and maintaining calcineurin inhibitor levels in the desired non-pregnant range for that individual.

**Table 44.8** Causes of rise in serum creatinine in pregnant transplant recipients

| Cause | Features |
|---|---|
| Normal physiological return to prepregnancy levels in third trimester | No concerning features identified |
| Urinary tract infection | Positive MSU, clinical features may be absent due to denervated kidney |
| Pre-eclampsia | Worsening pre-existing or new onset hypertension, worsening pre-existing or new onset proteinuria, possibly abnormal liver function tests, low platelets |
| Obstruction | Improved renal function after bed rest with patient lying on opposite side to transplanted kidney. Hydronephrosis on ultrasound with no other cause found. Exclude urinary retention. |
| Calcineurin inhibitor (tacrolimus/ciclosporin) toxicity | High trough drug levels |
| Hypovolaemia | Hyperemesis, antepartum haemorrhage, sepsis |
| Viral infections | Polyoma virus (decoy cells in urine), cytomegalovirus (CMV PCR) |
| Acute rejection | Diagnosis confirmed on renal biopsy.<br>Consider pulsed steroids, or intravenous immunoglobulin<br>Avoid monoclonal antibodies or antithymocyte globulin[95] |

MSU, midstream specimen of urine; PCR, polymerase chain reaction.

Pre-existing complications of diabetes need to be considered, including the risk of deterioration in diabetic retinopathy associated with pregnancy and chronic urinary retention due to bladder neuropathy.[105]

### Dialysis

Women on dialysis (stage 5 CKD) are frequently amenorrhoeic due to suppression of the hypothalamic–pituitary–gonadal axis associated with severe renal impairment.[108] This coupled with a reduced libido makes conception on dialysis uncommon. Rates of pregnancy in women of child-bearing age on dialysis are as low as 1–1.5%.[109] Fetal loss is probably under-reported but up to 25% miscarry in the first trimester.[109]

With the advent of improved dialysis regimens and treatment of erythropoietin deficient anaemia, pregnancy on dialysis is becoming more frequent,[110] and contraception should be discussed with women of child-bearing age. The majority of women with stage 5 CKD are hypertensive and oestrogen-containing contraception should be avoided, but progesterone preparations can be considered. Pregnancy may be difficult to identify early in women with oligo- or amenorrhoea and increased erythropoietin requirements may be the only clinical feature.

Live birth rates have dramatically increased over recent decades for women on dialysis. Recent series have reported 100% successful pregnancy outcomes[111,112] compared with 23% in 1980.[113] These improvements are likely to be a consequence of advances in neonatal care, and the introduction of intensive dialysis regimens as soon as conception is confirmed, with some women receiving up to 48 hours/week of nocturnal haemodialysis. A small study has suggested that women receiving greater than 20 hours of dialysis per week have better pregnancy outcomes when established on dialysis with a viable pregnancy in the second trimester.[114]

A systematic review of 222 pregnancy outcomes of women on renal replacement therapy found a mean delivery gestation of 32 ± 6.7 weeks, mean birth weight of 1810 ± 1193 g, and high rates of neonatal (11.9%) and perinatal deaths (17.9%).[115] Women who conceive on dialysis compared with women who start dialysis during pregnancy tend to have worse pregnancy outcomes. Years of dialysis prior to conception is also a negative confounder.[115]

Urea is fetotoxic and it is recommended that dialysis should be commenced when maternal urea levels are 15–20 mmol/L.[110] Polyhydramnios is a consequence of placental transfer of raised maternal urea, but has been shown to be associated with better pregnancy outcomes, possibly reflecting adequacy of function of the fetoplacental unit.[116] Ideally fluid shifts during dialysis should be minimized in order to maintain placental perfusion, and this should be achieved by restricting ultrafiltration during dialysis to 1–1.5 L per session.[110] This needs to be titrated to the woman's fluid intake and hours of dialysis. Volume status should be assessed regularly during pregnancy to allow for dry weight increases due to fetal and placental growth. Increased dialysis frequency allows a relaxation of potassium and phosphate restriction, and dialysate may need to be supplemented with potassium and phosphate in order to maintain serum levels.[110] Water-soluble vitamins should be prescribed including folic acid 5 mg daily.

Anaemia in women with CKD should be treated promptly and aggressively. Those already requiring intravenous iron and/or subcutaneous erythropoietin usually need up to a 50% increase in dose.[117] Women on haemodialysis with higher third-trimester

haematocrits have been shown to have better pregnancy outcomes.[116] There have been no reports of teratogenicity in women taking recombinant human erythropoietin and there does not appear to be significant placental transfer.[118,119] Whilst there have been no reports of thrombosis associated with recombinant erythropoietin use, this is a possibility due to the hypercoagulable state during pregnancy and it is advisable to reduce or temporarily withhold treatment in women with haemoglobin levels higher than 11 g/dL. Anticoagulation doses should be increased in pregnant women on dialysis due to hypercoagulability.[120]

### Lupus nephritis

Women with lupus nephritis have more complex pregnancies than those matched for renal function,[84] and even those with treated renal disease and preserved renal function have worse pregnancy outcomes than women with SLE without renal involvement.[88] Risk factors for pregnancy complications include black ethnicity, low complement at conception, pre-existing hypertension, positive antiphospholipid antibodies, and severity of renal impairment.[121] Fetal loss is higher particularly in those with hypertension, proteinuria and antiphospholipid antibodies. It is recommended that women conceive after their disease is quiescent for 6 months as active disease at conception is also associated with worse pregnancy outcomes.[122] Class of lupus nephritis does not appear to be a risk factor for complications.[121]

Disease flare during pregnancy has been variably reported including both renal and extrarenal disease. A meta-analysis of 37 studies published between 1984 and 2009, including 1842 women with lupus nephritis with varying baseline renal function and 2751 pregnancies, showed lupus flare rates of 26% with 16% renal disease.[121] Diagnosis of new or a flare of pre-existing lupus nephritis during pregnancy can be challenging as many features are present in normal pregnancy or with the onset of pre-eclampsia. Table 44.9 shows common and distinguishing features between the conditions.

A renal biopsy may be required to confirm the diagnosis of lupus nephritis flare. Indications and risks of biopsy in pregnancy are discussed later (see 'Renal Biopsy in Pregnancy' section). Treatment for active lupus nephritis during pregnancy includes methylprednisolone. Cyclophosphamide and mycophenolate mofetil are contraindicated in the first trimester due to teratogenicity, but can be considered in the second or third trimesters, although pregnancy outcomes reported are variable[123] and fetal bone marrow toxicity is possible. Rituximab may be given but if used later in pregnancy has been shown to be associated with absent B cells in infants for up to 6 months, and the long-term effects are unknown.[124]

All women with SLE should be assessed for the presence of anti-Ro or anti-La antibodies. Offspring of women with anti-Ro/anti-La antibodies are at risk of congenital heart block due to the placental transfer of the antibody resulting in fibrosis of the fetal cardiac conducting system. Fetal cardiac scans should be performed at 18–25 weeks' gestation and assessment of the fetal heart rate during obstetric examination is mandatory. The risk of congenital heart block is 2%, but if a previous child has been affected the risk increases to 15–20%, and if two children have been affected the risk may be as high as 50%.[125] Treatment options are limited although hydroxychloroquine may confer some benefit.[126] High-dose steroids, plasma exchange, and intravenous immunoglobulin have not shown any significant beneficial effect.[125,127] Fetal mortality is up to 30% and a neonatologist should be present at the delivery of an affected infant.

Approximately 5% of infants of women with anti-Ro/anti-La antibodies may develop neonatal cutaneous lupus.[128] This is a benign condition which resolves spontaneously after 6 months, when maternal antibody levels fall. It does not usually require any specific treatment.

**Table 44.9** Features of systemic lupus erythematosus (SLE) compared to problems in normal pregnancy and pre-eclampsia

| Features | SLE | Pregnancy |
|---|---|---|
| General | Fatigue and malaise | Fatigue |
| Hair | Loss | Loss or gain |
| Skin | Malar rash | Melasma/chloasma<br>Facial flushing |
| Joint pain and swelling | Inflammatory synovitis | Mechanical arthralgia<br>Bland knee effusion |
| Anaemia | Haemolytic anaemia<br>Anaemia of chronic disease | Haemodilution |

### Immunoglobulin A nephropathy

Women with immunoglobulin A (IgA) nephropathy tend to have successful pregnancies and there is no evidence that disease progression is affected by pregnancy, other than in women with more severe disease. Women with prepregnancy creatinine higher than 120 μmol/L, eGFR less than 50 mL/min/1.73m$^2$, heavy proteinuria, or severe histological lesions on renal biopsy are most likely to have pregnancies complicated by pre-eclampsia, fetal growth restriction, preterm labour, and a pregnancy-associated decline in renal function.[129,130] A multicentre case–control study has shown that pregnancy does not affect long-term renal function in women

with IgA nephropathy with prepregnancy creatinine less than 110 µmol/L over a median follow-up period of 10 years.[131]

### Polycystic kidney disease

Adult polycystic kidney disease (APKD) in women of childbearing age is usually associated with normal or mild renal impairment. Hypertension and renal impairment are associated with worse pregnancy outcomes.[132] Cyst growth has not been found to progress with pregnancy and uterine expansion is not compromised by the presence of enlarged kidneys. Urinary tract and cyst infection are more common in pregnancy, and should be treated promptly and aggressively.[132]

Genetic defects for APKD have been identified and whilst prenatal screening is possible many women choose not to have genetic testing. Cysts are not usually present until an individual is in their teens or early twenties and therefore the absence of cysts in the fetus or baby does not provide any reassurance about inheritance.

### Reflux nephropathy

Reflux nephropathy is a common cause of renal impairment in women of childbearing age and may be associated with worse renal and pregnancy outcomes. High rates of superimposed pre-eclampsia (up to 75%), recurrent UTIs (28–65%), decline in renal function (13%), and ureteral obstruction requiring drainage (5%) are reported.[133] Reflux nephropathy is diagnosed after the identification of cortical scarring, usually in an individual with a history of childhood urinary tract infections. Antenatal care should include vigilance for UTIs and prophylaxis after infection. Offspring should be screened for the presence of reflux, as inheritance can be autosomal dominant.

### Diabetic nephropathy

Women with diabetic nephropathy have complicated pregnancies. Women with prepregnancy microalbuminuria may develop macroalbuminuria when pregnant, although one study has suggested that urinary albumin excretion in women with type 1 diabetes is unchanged in early pregnancy.[134] Proteinuria, including microalbuminuria, at conception has been shown to be associated with worse pregnancy outcomes in women with type I diabetes.[134] In a review of nine studies of pregnancies in women with diabetic nephropathy, proteinuria increased from 1–3 g/24 h at baseline to 4–8 g/24 h in the third trimester[135] but proteinuria usually returns to baseline levels after delivery, even in women with nephrotic range excretion.[136] Associated problems with nephrotic range proteinuria include severe oedema that may require judicious use of diuretics, and increased thrombotic risk that should be managed with thromboprophylaxis. Although women with diabetes are at risk for macrosomia, the presence of renal impairment appears to outweigh the effects of hyperglycaemia and nearly 50% of infants of mothers with diabetic nephropathy are small for gestational age.[134]

Glycaemic control and blood pressure treatment have been shown to be associated with better pregnancy outcomes.[137] A small study of intensive angiotensin-converting enzyme inhibition for 6 months preconception together with improved glycaemic management in women with diabetic nephropathy, showed a reduction in proteinuria that was maintained during and after pregnancy, compared to women with no treatment.[138] Angiotensin-converting enzyme inhibitors and/or angiotensin II receptor blockers should probably be continued until conception if possible in women with significant proteinuria prepregnancy.

### Chronic kidney disease: drugs in pregnancy

Preconception counselling should include a review of a woman's medication. All women with CKD who are considering conception within 3 months should start folic acid 5 mg daily. Aspirin should be continued or commenced with confirmation of pregnancy. Statins and bisphosphonates should be discontinued. Specific considerations of commonly used drugs in women with CKD are outlined in Table 44.10.

## Renal biopsy in pregnancy

The indications to perform a renal biopsy in pregnancy include rapidly deteriorating renal function and severe nephrotic syndrome. A biopsy should only be performed if the findings are likely to change management and renal biopsy should not be used to diagnose pre-eclampsia. After 28 weeks, delivery should be considered with biopsy performed postpartum. Complexities of performing a renal biopsy in a pregnant woman include difficulties in positioning due to the gravid uterus. In addition, vasopressin to reduce biopsy-associated bleeding is not usually given due to the increased thrombotic risk of pregnancy. A recent systematic review including 243 renal biopsies performed during pregnancy suggested that the risks of major or minor bleeding, haematoma, or loin pain were 7% when performed antenatally compared with 1% postpartum.[139]

## Mode of delivery and anaesthesia

The mode of delivery depends on many factors including the progression of renal disease, the development of pregnancy-related complications (e.g. pre-eclampsia), and the well-being of the fetus.

Unless renal function is severely impaired and hypertension is present, non-invasive monitoring should suffice for both labour and caesarean delivery. If arteriovenous fistulae are present, care should be taken to avoid that arm for blood pressure cuffs or arterial lines.

There is hyperacidity in renal patients and these patients will require a histamine $H_2$-receptor antagonist, for example, ranitidine, during labour. Women with renal disease attempting vaginal birth can be offered an early epidural providing there are no contraindications to neuraxial anaesthesia. Patients with CKD may be anticoagulated due to their thrombotic risk in the context of antenatal proteinuria or for vascular indications, but labour and delivery can usually be timed to allow neuraxial anaesthesia, for example, 4 hours since the last dose of unfractionated heparin or 12 hours post prophylactic low-molecular-weight heparin. The patient must also be euvolaemic following dialysis or else hypotension may follow neuraxial blockade. An early epidural would not only provide analgesia but eliminate the catecholamine surges with pain which increase the risk of hypertension, particularly if pre-eclampsia is also present. Further, there will be a lower threshold for operative delivery in a patient with CKD, and an epidural can be topped-up to facilitate this. Ropivacaine is the local anaesthetic of choice for epidural top-up as its pharmacokinetics are not affected by renal failure.[140]

**Table 44.10** Commonly used drugs in chronic kidney disease

| Drug | Trans-placental passage | Teratogenicity | Fetal/neonatal effects | Safe in pregnancy | Safe in breastfeeding | FDA classification |
|---|---|---|---|---|---|---|
| Angiotensin-converting enzyme inhibitor (ACEI), angiotensin receptor blocker (ARB) | ✓ | ✓ | Cardiovascular, central nervous system defects in 1st trimester and oligohydramnios, intrauterine growth restriction, and neonatal anuria in 2nd and 3rd trimesters | × Stop at conception | ✓ Enalapril is recommended treatment of hypertension during breastfeeding by NICE<br>× Other ACEI/ARB breastfeeding safety unknown | D |
| Prednisolone | Limited | Possible increase in oral clefts | Rare—except at large doses. (cataract, adrenal insufficiency and infection) | ✓ | ✓ (Breastfeeding is not encouraged if > 60 mg prednisolone daily) | C |
| Hydroxychloroquine | ✓ | × | × | ✓ | ✓ | C |
| Azathioprine | ✓ | × | Sporadic congenital abnormalities, transient immune alterations in neonates | ✓ | ✓ | D |
| Mycophenolate mofetil | ✓ | ✓ | | × Stop 3/12 preconception | × | D |
| Tacrolimus | ✓ | × | Hyperkalaemia and renal impairment | ✓ Usually increased doses required to achieve prepregnancy target levels | ✓ | C |
| Cyclophosphamide | ✓ Animal data | ✓ | Chromosomal abnormalities and cytopenia | ✓ (Only after the 1st trimester in life-threatening maternal disease.) | × | D |
| Ciclosporin | ✓ | × | Transient immune alterations | ✓ Usually increased doses required to achieve prepregnancy target levels | Probably possible | D |
| Intravenous immunoglobulin | ✓ | × | None reported | ✓ | ✓ | C |
| Recombinant erythropoietin | × | × | | ✓ Increased doses usually required<br>Possible risk of hypertension | No reports, but neonates frequently treated with erythropoietin safely<br>Protein likely to be broken down in infants' gastrointestinal tract | C |

The rate of caesarean delivery is high in women with CKD even in those with a preserved GFR.[91] Neuraxial anaesthesia is the technique of choice and either topped-up epidurals, single-shot spinals, or combined spinal–epidurals can be used. Provided the patient has a normal volume status before surgery, hypotension associated with neuraxial block is best treated with phenylephrine rather than fluid to avoid overloading and possible pulmonary oedema.

General anaesthesia should be avoided if at all possible. But if this is the only possible option, measures should be taken to obtund the hypertensive response to laryngoscopy, using a short-acting opiate like remifentanil or alfentanil. The conventional rapid sequence induction with suxamethonium may result in a rise of potassium and should not be given if the starting potassium is over 5.5 mEq/L. Atracurium is the non-depolarizing relaxant of choice due to its Hoffman degradation which is independent of renal function. Renal blood flow is maintained with desflurane and isoflurane but reduced with sevoflurane.[141] Morphine can accumulate in renal patients as can fentanyl.[142]

Patients with significant renal dysfunction should have their postpartum care in the high dependency unit. Thromboprophylaxis post caesarean delivery is important in women with heavy proteinuria and should be continued for 6 weeks postpartum.[143]

A reduced dose of low-molecular-weight heparin should be considered in women with impaired renal function (serum creatinine > 200 umol/l), or alternatively, a switch to twice-daily unfractionated heparin. Women with CKD should not be prescribed non-steroidal analgesia due to the risk of deterioration in renal function and exacerbation of hypertension.

## Conclusion

AKI can develop during pregnancy but may be masked by a normal serum creatinine due to a physiological increase in glomerular filtration. The prevalence of pre-eclampsia makes it the most common cause of AKI in pregnancy and the most common glomerular disease worldwide. Other pregnancy-related diseases can also result in AKI and non-pregnant aetiologies should not be missed. The management of AKI in pregnancy is supportive and aims to maintain renal perfusion and avoid nephrotoxicity whilst treating the underlying cause.

Women with pre-existing CKD are likely to have successful pregnancies, but require heightened antenatal surveillance. Monitoring of haemoglobin, renal function, vitamin D, albumin, proteinuria, and bacteriuria throughout pregnancy is recommended. Prepregnancy counselling is important to optimize maternal health and medication, inform women of possible pregnancy outcomes, and in a minority, to explain the potential risk of accelerated progression of renal impairment.

# CHAPTER 45

# Neurological disease

James Griffiths and Kate Drummond

## Introduction

Neurological disease is an important cause of maternal morbidity and mortality,[1] and presents a significant challenge to the obstetric anaesthetist. The eighth Confidential Enquiries into Maternal Deaths (CEMD) reported 36 women who died from neurological causes. These women died from such conditions as subarachnoid haemorrhage, intracerebral haemorrhage, thrombosis, and epilepsy. Overall, the rate of maternal mortality related to neurological disease (1.57/100,000 maternities) has remained little changed over the past several decades, despite significant improvements in overall maternal morbidity and mortality. Eleven of the 36 deaths in the reported triennium had major elements of substandard care 'where different treatment might have altered the outcome'.[2] It is critical that any anaesthetist involved in the care of pregnant women is aware of the implications of neurological disease for the safe provision of both neuroanaesthesia and obstetric anaesthesia, sometimes in combination.[3,4]

This chapter will predominantly focus on the provision of obstetric anaesthesia and analgesia for the parturient with neurological disease. However, there are some important principles and considerations when undertaking neurosurgical procedures in pregnant women and these will also be outlined briefly.[3,5,6]

Anaesthetists may be asked to care for the parturient with neurological disease in several clinical settings. Firstly, women may present at any stage of pregnancy requiring urgent surgical intervention for neurosurgical disease, such as space-occupying lesions or subarachnoid haemorrhage. Secondly, women with pre-existing neurological disease may present requesting analgesia for labour and delivery or anaesthesia for caesarean delivery. Also, anaesthetists are often requested to assist in the evaluation and management of women who present whilst pregnant or immediately postpartum with a new onset of neurological symptoms, such as headache or peripheral numbness.[7] It is important that the anaesthetist is aware that pregnant women may present with neurological symptoms associated with obstetric disease, such as pre-eclampsia, those indirectly related to or exacerbated by pregnancy, such as cerebral venous thrombosis or subarachnoid haemorrhage, and also those conditions related to anaesthesia, such as postdural puncture headache and neuropraxia following obstetric neuraxial blockade.[8,9]

Although a pregnant woman is, in general, no more likely to suffer from a serious neurological or neurosurgical condition than a non-pregnant woman, the physiological and anatomical changes associated with pregnancy and the concern for both maternal and fetal welfare, which may be conflicting, add to the complexity of management. This is hampered by the lack of class I or II evidence for these complex decisions in the majority of instances. Case reports and case series provide some important guidance but the majority of management is based on general principles. Care of the pregnant woman with a neurological condition thus requires a coordinated approach involving a multidisciplinary team, including neurosurgeon, neurologist, obstetrician, anaesthetist, midwife, neonatologist, and potentially, interventional radiologist. Surgery is generally avoided in pregnancy, occurring in less than 2% of parturient women,[10] with neurosurgical procedures being rare. However, recent studies suggest the safety of planned neurosurgical procedures during pregnancy when warranted, and undue delay may result in neurological deterioration with poor outcomes for mother and child.[5,6,11,12] Care is likely to be optimal in a tertiary setting, particularly if neurosurgical, obstetric, and neonatal management can occur on the same site.

Care for the fetus involves consideration of the timing of delivery (which may be before, after, or coincidental with a neurosurgical procedure), fetal monitoring, and maternal positioning during procedures to minimize the impact on placental perfusion. Fetal welfare may be compromised by any derangement of maternal physiology, including hypotension, hypoxaemia, and hypocarbia, and by many drugs commonly used in neurological disorders and neuroanaesthesia. Intraoperative fetal monitoring is only of benefit if sufficiently experienced staff are available to interpret the data, and clinical facilities are available to expedite delivery should this be indicated. Careful planning with specialist radiologists should be undertaken to optimize the diagnostic utility of neuroimaging, with due consideration to the use of contrast and radiation shielding to optimize fetal outcomes.[13]

## General considerations

Many of the principles of anaesthesia for neurosurgery in the pregnant women are identical to those when undertaking any non-obstetric procedure.[14] These include planning for a potentially difficult airway, appropriate aspiration prophylaxis and airway protection, maternal positioning to avoid aortocaval compression and optimize placental perfusion, fetal monitoring, suppression of preterm labour, and the risk of postpartum haemorrhage if caesarean delivery is combined with a non-obstetric procedure.

The great majority of procedures will be undertaken under general anaesthesia, although spinal surgery under epidural anaesthesia has been reported.[15] There is no evidence that any specific anaesthetic technique is contraindicated in pregnancy. Early studies suggested prolonged occupational exposure to nitrous oxide may be associated with increased risk of fetal loss; however, more recent studies have refuted this.[16–20] When propofol is used for maintenance of anaesthesia during caesarean delivery, it has been

shown to result in reduced neurobehavioural performance in the neonate.[21] It is unlikely this would be clinically significant in a neurosurgical setting. Potent opioids (such as remifentanil and alfentanil) are useful to ablate the haemodynamic responses to laryngoscopy and intubation, but, however, may result in neonatal chest wall rigidity and respiratory depression.[22,23] Intra-arterial monitoring of blood pressure should be used for all but the most minor procedure in a pregnant patient with neurosurgical disease.

### Positioning

Depending on the nature of the procedure, neurosurgery may be undertaken in a variety of positions including supine, lateral, prone, and sitting. Great care must be undertaken when positioning pregnant patients for surgery. The prone position may add to difficulties with fetal heart rate monitoring, emergency caesarean delivery, and potentially increases epidural venous bleeding.[3] It has been proposed that surgery in the prone position should be avoided altogether in pregnancy.[24]

### Raised intracranial pressure

Strategies for maintaining stable intracranial pressure are critical in any intracranial surgical procedure. A number of common approaches need to be modified in the pregnant patient. The physiological increase in ventilation in later pregnancy results in a respiratory alkalosis, with arterial carbon dioxide tension ($P_ACO_2$) falling to around 4–4.2 kPa. Excessive hyperventilation has been associated with worsening of neurosurgical outcomes due to cerebral ischaemia from intense vasoconstriction, but also may result in uterine artery vasoconstriction and decreased placental blood flow.[3] Animal studies have demonstrated that the administration of mannitol may result in a number of adverse fetal effects including hyperosmolarity, hypernatraemia, and reduced lung fluid production.[25,26] However, published cases report the use of small doses of mannitol (0.25–0.5 mg/kg) and it appears to be safe.[3,14]

### Oxytocics

There is limited data available regarding the use of oxytocics in the setting of neurological and neurosurgical disease. Syntocinon® causes a brief but significant decrease in systemic blood pressure with a corresponding increase in heart rate and cardiac output.[27] Ergometrine causes significant systemic hypertension which may be associated with a corresponding increase in intracranial pressure, and should be used with caution in patients with raised intracranial pressure. There is limited data to support the use of prostaglandins such as $E_1$ and $F_{2\alpha}$ in a neurosurgical/obstetric setting, although it has been proposed.[28]

### Steroids

Glucocorticoids are frequently used in neurosurgical disease (such as to reduce oedema surrounding brain tumours) but also in neurological disease (e.g. to treat acute exacerbations of multiple sclerosis (MS)). Single doses or short courses of dexamethasone or methylprednisolone have not been shown to be harmful to the fetus, and will actually contribute to fetal lung maturity.[29]

## Epilepsy

### Aetiology

Epilepsy is a common neurological disorder in pregnancy, with an incidence in the order of 0.3–0.7%.[30] The condition is characterized by repeated paroxysmal seizures in the absence of another cause (such as drug withdrawal or hypoglycaemia). A variety of types of seizures and patterns of epilepsy have been classified, based on the clinical description of the seizure event.[31] Clinically observed seizures are triggered as a result of excessive neuronal firing, which can either be localized or generalized. Seizures from a localized source reflect the abnormal activity related neuroanatomically to that site. Seizures are considered simple or complex, depending on whether consciousness is affected, and focal (partial) or generalized depending on whether a localized area or the entire cerebral cortex is involved.

### Obstetric considerations

Epilepsy remains a major cause of morbidity and mortality in pregnancy, with 14 deaths reported in the 2006–2008 CEMD report published in 2011.[2] The hypoxia and respiratory acidosis associated with maternal seizures may also increase the risk of fetal loss. In a case series of 154 pregnancies in women with epilepsy, only 31% were seizure free throughout pregnancy. Seizure frequency increased in 32%, decreased in 14%, and remained unchanged in 23% of cases.[32]

Women with epilepsy require carefully coordinated care between their neurologist and obstetrician, preferably commencing prior to conception. In most patients, effective seizure prophylaxis must continue through pregnancy, as the adverse effects of seizures during pregnancy outweigh the risk to the fetus of antiepileptic medication. However, choice of agent remains controversial.[33] There is evidence that the risk of fetal abnormalities increases with the use of multiple agents, so in general, the aim should be monotherapy, at the lowest possible effective dose.[33] Many antiepileptic drugs (AEDs) are known to increase the risk of fetal abnormalities.[34] Older AEDs, including phenytoin, valproate, carbamazepine, and barbiturates, are all known to cause abnormalities in humans, whereas data is lacking for newer agents (such as lamotrigine, gabapentin, and levetiracetam).[35] It appears that valproate is the least acceptable agent for use in pregnancy. Common abnormalities for all AEDs include neural tube defects, orofacial abnormalities, alimentary tract atresia, diaphragmatic hernia, and congenital heart disease.[35]

Low maternal plasma levels of folate have been shown to be associated with major fetal malformations particularly neural tube defects.[36] Folate supplementation appears to decrease this risk and all pregnant women should take low-dose (0.4 mg/day) supplemental folate. Animal studies have shown that carbamazepine and valproate both act to decrease maternal folate plasma concentrations and high-dose supplementation (4 mg/day) may be of benefit.[37]

In addition to folate supplementation, consideration should be given to prescribing vitamin K supplementation to women taking AEDs in late pregnancy. AEDs (particularly phenytoin and carbamazepine) cross the placenta and induce hepatic microenzymes, resulting in degradation of neonatal vitamin K. There are published data to both support and refute the possibility that this increases the risk of neonatal haemorrhage.[38,39] Whilst neonatal vitamin K should be administered routinely, many practitioners recommend the additional administration of maternal vitamin K as a cheap and low-risk intervention.[40]

There are many reasons why seizure frequency may increase during pregnancy, including non-compliance with medication, altered metabolism of drugs, fluid and electrolyte retention,

hyperventilation leading to respiratory alkalosis, stress, sleep deprivation, and hormonal changes. If available, drug levels should be monitored during pregnancy and dosage adjusted accordingly especially phenytoin, carbamazepine, and lamotrigine. Consideration should be given to parenteral administration of AED if gastric absorption in labour is uncertain. Many antiepileptic drugs are unavailable parenterally, so an alternative agent may be needed in labour (such as phenytoin or levetiracetam).

While most pregnancies proceed uneventfully, it is possible that pregnant women with epilepsy taking AEDs may be at increased risk of a number of obstetric complications, including pre-eclampsia, preterm labour, and peripartum bleeding.

In addition to the risk of major malformations, associated with AEDs, women with epilepsy appear to be at higher risk of low birth weight babies (<2500g). Infants of epileptic mothers also may be at higher risk of developmental delay.

### Anaesthetic implications

A patient presenting with a seizure during pregnancy is a medical emergency. Whilst standard resuscitation measures are instituted, a broad differential diagnosis must be considered (Box 45.1), even in a known epileptic.[32] If eclampsia is likely, then seizures should be treated with magnesium sulphate and delivery should be expedited once the patient is stabilized. Magnesium sulphate is, however, not appropriate treatment for epileptic seizures, which should be treated with a benzodiazepine. In the setting of emergency caesarean delivery, general anaesthesia is indicated if the airway is compromised by the postictal conscious state.

Many AEDs have the potential to cause important but complex pharmacokinetic interactions with a wide variety of other classes of medication.[41] Some (including carbamazepine, phenytoin, and phenobarbitone) can induce hepatic microenzymes of the cytochrome P450 subtype, leading to the accelerated metabolism—and hence lower plasma levels—of many other medications. Medications which may be affected include antibacterials, immunosuppressants, and cardiovascular medications such as amiodarone and beta blockers.[42] Conversely, other AEDs, such as valproate, can inhibit enzyme activity leading to delayed metabolism and hence higher plasma levels of other drugs. Benzodiazepines, valproate, and phenytoin are highly protein bound and may compete for protein binding sites, increasing the free concentrations of other drugs.

**Box 45.1** Differential diagnosis of seizures in pregnancy

- (Pre-) Eclampsia
- Epilepsy
- Local anaesthetic toxicity
- Amniotic fluid embolism
- Cerebral venous thrombosis
- Space-occupying lesion (e.g. tumour, haemorrhage)
- Drug withdrawal (e.g. alcohol)
- Electrolyte abnormality (e.g. hyponatraemia, hypoglycaemia)
- Pseudo-seizure

Many anaesthetic agents have the potential to either increase or decrease the seizure threshold.[41] Benzodiazepines and barbiturates are all anticonvulsant. Opioids, particularly pethidine (meperidine), may cause seizures, as may etomidate. Somewhat confusingly, propofol has been associated with excitatory activity including seizures and seizure-like phenomena; however, it also has a role in status epilepticus.[43] Neuraxial analgesia and anaesthesia is safe, although high doses of local anaesthetic may also reduce the seizure threshold and thus, these agents should be titrated judiciously.

## Cerebrovascular disease

### Introduction

Cerebrovascular disorders are the neurological diseases most commonly seen during pregnancy and include cerebral aneurysm, arteriovenous malformation (AVM), cavernous haemangioma, intracerebral haematoma, ischaemic stroke, and cerebral venous sinus thrombosis (CVT), as well as a number of newly defined cerebral vasoconstriction entities, including reversible cerebral vasoconstriction syndrome (RCVS), and posterior reversible encephalopathy syndrome (PRES).[7] Overall, these lesions are uncommon in pregnancy, but the risk is increased compared to the general population[44] and there is some evidence that the rate is increasing.[45] The reported rates for ischaemic stroke are 4–11/100,000 live births, for intracerebral haematoma 3.7–9/100,000 live births, and for subarachnoid haemorrhage 2.4–11/100,000 live births.[44–51] The risk may be increased in Asian patients.[52] Despite their rarity, cerebrovascular disorders account for more than 10% of all non-obstetric maternal deaths.[47,53–55] Anaesthetic considerations are twofold; firstly there is the patient presenting with an acute event, such as a subarachnoid haemorrhage or intracerebral haemorrhage from an aneurysm or AVM, who needs treatment during pregnancy and the second is management of delivery in the patient with a known lesion at risk for rupture. The natural history of many of these lesions in pregnancy is unknown due to their rarity. Guidelines that exist for management of the non-pregnant patient[56,57] may not apply due to the physiological changes associated with pregnancy, which may change the risk profile of the lesion, and the paucity of pregnant patients included in most large trials. Most studies are case series or case reports.[11,58–60] However, from these limited reports it would appear that neurosurgical treatment of these lesions, as dictated by standard neurosurgical care, may result in good maternal and fetal outcomes, with minimal additional morbidity and mortality associated with the surgical procedure.

It should be remembered that the differential diagnosis between these uncommon lesions and the much more common pre-eclampsia and eclampsia (which occur in up to 8% of pregnancies)[61] can be difficult. Acute neurological symptoms in pregnancy are more likely to be due to these latter conditions, but there is a significant overlap, and symptoms such as hypertension and proteinuria can also be present in neurological disorders such as aneurysmal subarachnoid haemorrhage.[62] Pre-eclampsia can result in ischaemic stroke, intracerebral hypertensive haematoma, subarachnoid haemorrhage, and CVT.[7] Severe vasoconstriction can also occur in pre-eclampsia, resulting in cerebral infarction or haemorrhage, and is associated with RCVS and PRES.[63]

Pre-eclampsia and eclampsia are the cause of up to 50% of strokes in pregnancy.[47,48,64]

The clinical presentation of these lesions is with the sudden onset of a severe headache (thunderclap headache), often described as 'the worst headache of my life', which is the result of haemorrhage into the subarachnoid space from a ruptured aneurysm or AVM, CVT, or severe hypertension in pre-eclampsia. Cerebral vasospasm, arterial dissection or pituitary apoplexy can result in a similar headache.[65] Intracerebral bleeding may present with a more gradual onset headache with evolving neurological deficit and decreased level of consciousness and ischaemic stroke with the sudden onset of a neurological deficit. Each of these presentations requires immediate expert review[66] and thorough investigation, initially with computed tomography (CT) scan, but if negative, with lumbar puncture and, if necessary, advanced imaging such as magnetic resonance imaging (MRI) or angiography. The risk of a missed serious diagnosis far outweighs the negligible risk of a brain CT scan with lead shielding of the fetus.[67–69]

The association of pregnancy with intracranial haemorrhage, particularly from an aneurysm or AVM, has been suggested to be due to hormonal and physiological effects on the cerebral blood vessels, but often with scanty evidence. These effects include vascular wall weakening due to hyperplasia of arterial smooth muscle and loss of normal elastic fibre alignment.[70] Pregnancy-induced hypertension, increased plasma volume, and increased cardiac output are also thought to play a role.[47,62,71] However, the literature is inconclusive as to whether the incidence of bleeding is actually higher in pregnancy and depends on the methodology and population used to determine incidence.[46,53,54,58,62,64,72,73]

Many of the cerebrovascular disorders discussed above are important causes of neurological presentations in pregnancy, but are unlikely to require neuroanaesthesia for surgical intervention or to have serious implications for mode of delivery. These include arterial dissection,[74–76] CVT,[77,78] RCVS,[63,79] and PRES.[80–82] Thus, they will not be considered further and the reader is directed to the relevant reviews cited. Those most relevant to obstetric anaesthesia are cerebral aneurysm, AVM, cavernous haemangioma, and ischaemic stroke and these are discussed in further detail.

## Cerebral aneurysms and arteriovenous malformation

### Ruptured aneurysms and AVM

Spontaneous subarachnoid haemorrhage occurs in 0.01–0.05% of pregnancies and is due to ruptured aneurysm in 77% of cases and ruptured AVM in 23%, with a reported maternal mortality varying widely between 10% and 83%, but probably closest to 10–20% with aggressive modern multimodality management. The fetal mortality is 17–26%.[47,53,55] The incidence of rupture rises with advancing trimester, being 6% in the first trimester and 55% in the third for cerebral aneurysms.[6,83] Once ruptured, the risk of recurrent haemorrhage from an untreated aneurysm or AVM is 25–50%, with an associated maternal mortality of 50–70%. For AVM, the calculated 26% rebleeding rate in the same pregnancy is higher than the 6–7.3% re-bleed rate in the first year in the general population.[73,84,85] Due to this risk of devastating recurrent haemorrhage, aggressive management is particularly warranted. Thus, standard neurosurgical management of ruptured lesions is advocated, with immediate securing of the ruptured aneurysm or resection or other treatment of the AVM. Standard medical management of symptomatic vasospasm, which complicates approximately one-third of aneurysmal subarachnoid haemorrhages, should also be as for non-pregnant patients. The mainstay of this treatment, 'triple H therapy', that is, intravenous fluid with or without pressors to achieve 'hypertension, hypervolaemia, and haemodilution' may not need to be as aggressively pursued due to the hypervolaemia of pregnancy. Nimodipine, a calcium channel antagonist, is widely used for vasospasm prophylaxis and treatment in both aneurysmal subarachnoid haemorrhage and pre-eclampsia and eclampsia, but is of unproven safety for the fetus and may cause maternal and fetal hypotension.[6,62,86]

Management of ruptured lesions along reported neurosurgical principles, results in the most favourable maternal and fetal outcomes and is almost universally recommended.[11,53,58–60,71,73,85,87] In pregnant patients with a pre-viable fetus, neurosurgical or endovascular treatment of the lesion should occur during pregnancy with later delivery. For a viable fetus, delivery by caesarean delivery under general anaesthesia followed immediately by definitive treatment is recommended.

Aneurysm rupture usually results in subarachnoid haemorrhage (Figure 45.1A), with thunderclap headache, vomiting, photophobia, focal neurological signs, and decreased level of consciousness. However, AVM may present with either haemorrhage or seizures. Rupture is more commonly into the cerebral parenchyma, rather than the subarachnoid space, with more gradual headache and focal neurological deficit. Initial imaging is with CT scan, as described above, but definitive imaging of the lesion requires either CT angiography or digital subtraction angiography (Figure 45.1B).[13] In general, imaging involving ionizing radiation is avoided in pregnancy, however, the gravity of an aneurysm or AVM diagnosis warrants their judicious use. Most reports would suggest minimal or no risk to the fetus with properly planned imaging[68,69,88] and consideration of the risks of hypothyroidism in the neonate after administration of iodinated contrast agents.[89–92] MRI is also useful to determine the position and characteristics of an AVM. MRI is safe in pregnancy and is further discussed in the section on intracranial tumours.[90,93–96]

The choice of treatment modality, either surgical or endovascular (Figure 45.1C), of ruptured aneurysms in the pregnant patient is controversial. In the non-pregnant population, the International Subarachnoid Aneurysm Trial (ISAT) study[56] reported improved outcomes with coiling over clipping and has resulted in an exponential increase in endovascular coiling of aneurysms if technically feasible. However, in the pregnant patient, concerns for ionizing radiation with a prolonged neuro-interventional procedure, iodinated contrast load, the risk of only partial obliteration of the aneurysm, and the possible need for short- and long-term anticoagulation are pertinent.[6] The literature would suggest that clipping, with definitive occlusion of the aneurysm, continues to be favoured by neurosurgeons for pregnant patients.[54] However, safe and successful endovascular coil embolization has been described in pregnancy with phantom calculations of radiation dose to the fetus being within acceptable limits.[88,97] For AVM, treatment options include surgery, endovascular obliteration, and stereotactic radiosurgery, or combinations thereof. Treatment decisions are complex, particularly in pregnancy, and largely based on incomplete and retrospective data, with no level 1 evidence.[98] Thus, decisions should be made in the context of a multidisciplinary discussion including the cerebrovascular team,

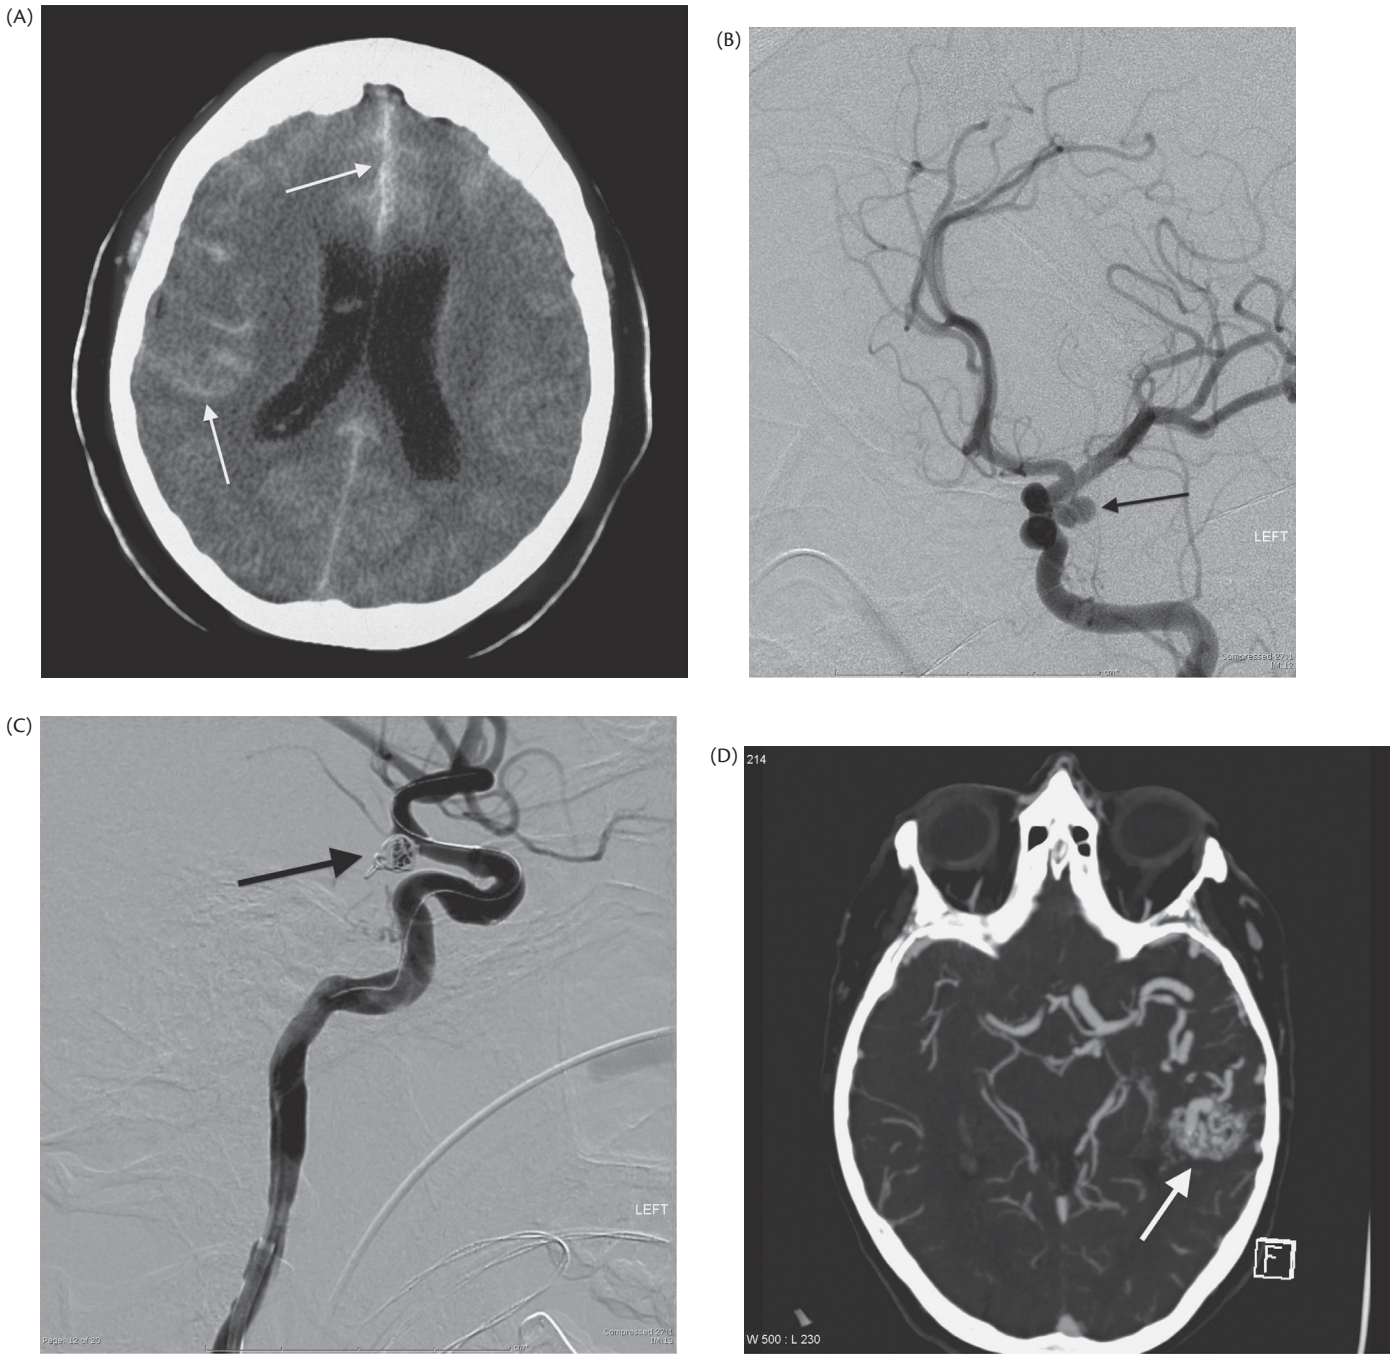

**Figure 45.1** (A) Axial CT scan brain showing subarachnoid haemorrhage with hyperdense blood in the interhemispheric region and cortical sulci (arrows). (B) Oblique projection of a left internal carotid angiogram showing a posterior communicating artery aneurysm (arrow). (D) Axial CT angiogram showing a left temporal arteriovenous malformation.

obstetrician, neonatologist, and anaesthetist. Facilities offering both neurosurgical and obstetric care are optimal.[99]

During routine surgery for clipping of a cerebral aneurysm, induced hypotension is commonly used to facilitate clipping of the aneurysm; however, this should be avoided in pregnancy due to the risk of uterine hypoperfusion, as uterine blood flow is not autoregulated. Similarly, vigorous osmotic diuresis should be avoided to avoid hypotension and fetal hyperosmolarity, although small doses of mannitol (0.5–1 g/kg) can probably be used safely.[62]

As for all neurosurgical procedures, hypertension during induction of anaesthesia, endotracheal intubation, or application of skull clamp pins should be avoided.

### Unruptured aneurysms and AVM

The risk of rupture of an unruptured aneurysm during pregnancy and delivery is unknown and it has been suggested that pregnancy and labour confers increased risk,[46,53,58] although not all authors agree.[72] A recent, large, 20-year population-based study suggested

the risk of rupture during pregnancy to be 1.4% and during delivery to be 0.05%, which is similar to that of the general population. Interestingly, the caesarean delivery rate amongst patients with a known unruptured aneurysm was over 70%, almost triple that of the general population, and the authors suggested that this may be unwarranted based on their estimates.[54] Neurosurgical or endovascular management of an unruptured aneurysm diagnosed in or before pregnancy should be along standard neurosurgical practice, with no evidence to suggest benefit of treatment during or before pregnancy of an aneurysm that would otherwise be observed based on guidelines from large international trials.[57] Enlarging, symptomatic, or high-risk aneurysms can be considered for treatment, with decisions regarding the timing and mode of therapy being made by a multidisciplinary team considering the characteristics of the aneurysm and the risk to maternal and fetal welfare.[54]

For AVM (Figure 45.1D), the risk of rupture is probably higher in the pregnant patient compared to that in the non-pregnant female population, although, as for aneurysms, the data is conflicting. The risk of a primary haemorrhage from an unruptured AVM in a pregnant patient is reported to be between 3.5% and 9.3%.[58,59,73,85,100–102] An increased haemorrhage rate is attributed to, as for cerebral aneurysms, pregnancy-related hormonal and physiological effects on the vessel wall, plasma volume, blood pressure, and cardiac output, and is highest in the second trimester.[53,85,100] Thus, treatment of the unruptured AVM, if feasible, is often recommended prior to conception. If discovered during pregnancy, a caesarean delivery under general anaesthesia is usually recommended, although, as for cerebral aneurysms, there is scant evidence on which to base this recommendation.[73,84,103]

Overall, the most appropriate mode of delivery for women with treated, untreated or partially treated aneurysms and AVM is unknown, although commonly caesarean delivery under general anaesthetic is recommended unless the aneurysm or AVM has been definitively treated with clipping or complete excision. Only 2% of aneurysms actually rupture during labour, with 90% of ruptures occurring during pregnancy and 8% postpartum[53,54] but if the rupture rate is corrected for the time spent in each of the stages of pregnancy, labour and the postpartum period carry the highest risk.[44,47,50,62,71] However, the literature is inconclusive, and there is no evidence to suggest improved outcomes or a reduced rupture rate with caesarean delivery over closely supervised vaginal delivery, particularly under epidural anaesthesia.[53,58,60,85] Broadly, the mode of delivery of ruptured aneurysms and AVM should be based on neurosurgical considerations and the management of unruptured or definitively treated lesions should be based on obstetric considerations. Generally, the use of epidural anaesthesia and an assisted second stage of labour to avoid hypertension and the Valsalva manoeuver are advised, unless the lesion is confidently obliterated.[6,105] Less certain methods of treatment with respect to completeness of exclusion from the circulation, such as partial endovascular coiling or embolization should be considered with caution. It has been suggested that spinal anaesthesia, and also inadvertent dural puncture during epidural anaesthesia, should be avoided in unruptured or incompletely obliterated aneurysms and AVM, due to the risk of rupture with cerebrospinal fluid (CSF) drainage and reduction in the lesion transmural pressure.[106]

### Cavernous haemangioma

Cavernous haemangiomas ('cavernomas') are common vascular malformations consisting of sinusoidal venous channels within the cerebral parenchyma. They are present in 0.4% of the population and are frequently asymptomatic.[107] Symptomatic presentation is with seizure or bleeding with intracerebral haematoma, although catastrophic haemorrhage is uncommon unless located in the brainstem or other eloquent area. Similar to other vascular malformations, an increased propensity to bleed during pregnancy is reported or assumed.[50,53,108] However, two large recent studies would suggest no increased risk from pregnancy and found no contraindication to normal vaginal delivery.[109,110]

### Ischaemic stroke

Ischaemic stroke is uncommon in pregnant and postpartum women but the incidence is three times higher than in the age-matched non-pregnant female population.[44,46,47] This increased incidence is likely to be related to the hypercoagulability of pregnancy and the risk is increased by hypertension (including pre-eclampsia), dehydration, anaemia, electrolyte and acid–base disturbance, haemorrhage, transfusion, infection, and caesarean delivery.[111] There is some evidence that women with pre-eclampsia undergoing caesarean delivery under general anaesthesia may have more than double the incidence of stroke compared to women receiving neuraxial anaesthesia[112].

Most strokes occur in the days before or after delivery and the mortality can approach 13%.[44,46] Management is as for ischaemic stroke in the non-pregnant population, including the use of intravenous or intra-arterial tissue plasminogen activator, although the safety profile in pregnancy is not yet clear.[113,114] Increasingly, ischaemic strokes are managed using chemical thrombolysis or mechanical thrombectomy or embolectomy in the interventional neuroradiology suite, with similar concerns to those outlined for endovascular coil embolization of cerebral aneurysms. These interventions are generally performed under general anaesthesia. Considerations are of raised intracranial pressure due to the mass effect of the stroke, similar to that for an intracranial tumour, and meticulous blood pressure control to avoid hypertensive bleeding into the ischaemic brain or hypotension with uterine hypoperfusion.

## Multiple sclerosis

### Introduction

MS is a chronic immune-mediated disease resulting in demyelinated plaques within the central nervous system. The disease is more common in women than men, and commonly presents in women of reproductive age.[115] Estimates of the prevalence vary widely but typically range between 66 and 168/100,000.[116] There is evidence that the incidence of the disease may be increasing in some parts of the world, particularly in females.[102,117]

### Pathology

MS is thought to be fundamentally an organ-specific autoimmune disease. The initial pathology is thought to be inflammation, demyelination, and axonal degeneration secondary to autoreactive lymphocytes. This is followed, in more chronic stages, by microglial activation and chronic neurodegeneration.[118]

## Aetiology

Whilst the disease is primarily autoimmune in nature, a wide variety of genetic, environmental, and immunological factors have been implicated in the aetiology. Current theories suggest that susceptible individuals are more likely to develop the disease if they are exposed to certain environmental triggers, such as smoking. Susceptible individuals include those with a family history, certain ethnic groups, and particular human leucocyte antigen subtypes. Epidemiological studies in Australia and Canada suggest an association with exposure to ultraviolet light (and/or vitamin D levels). Previous infection with a viral illness such as Epstein–Barr virus may also be implicated,[119,120] and this raises the controversy as to whether previous viral immunization may be associated with MS.[119]

## Clinical course

MS is characterized by episodic relapses and remissions of discrete neurological deficits. There may be complete recovery between episodes ('relapsing remitting MS') or a gradual progression of underlying disability ('chronic progressive MS'). Many patients over time with relapsing remitting MS will gradually develop chronic progressive symptoms. Relapses tend to evolve over several days. Common presentations include optic neuritis (with decreased vision and pain in one eye), limb ataxia, limb weakness and paraesthesia, bladder dysfunction, and progressive symptoms of respiratory weakness and fatigue.

Diagnosis is based on a characteristic clinical course and the presence of diagnostic lesions on T2-weighted and fluid-attenuated inversion recovery (FLAIR) MRI images of the brain, optic nerve, or spinal cord.[121] There may also be characteristic abnormalities in CSF or changes in visual or somatosensory evoked potentials.

Treatment of MS aims to accelerate resolution of symptomatic episodes, prevent recurrent episodes, and slow the progression of the disease. Treatment of acute episodes may include high-dose methylprednisolone or plasma exchange transfusion. Interferon and glatiramer are both used to prevent recurrence of attacks.[122] Interferon slows progression of the disease by immune modulation, reducing T cell proliferation and tumour necrosis factor alpha production. Side effects include flu-like symptoms, liver enzyme elevation, and leucopenia. Glatiramer is structurally similar to myelin and hence may act as an alternative target for T-helper cells in the inflammatory pathway. Glatiramer may reduce relapse by as much as 29%.[123] Other features of progressive disease such as spasticity and depression may be treated with baclofen and standard antidepressants. Patients may develop bladder spasticity requiring anticholinergics or intermittent catheterization. Depression and epilepsy are both more common in patients with MS,[119] and may be treated with routine medications.

## Obstetric considerations

A meta-analysis of several large studies demonstrated a reduction in the likelihood of relapse during pregnancy (particularly during the third trimester), but then an increase in the 3 months postpartum.[124–126] This postpartum increase may be due to fatigue, intercurrent infection, or the removal of antepartum immunosuppression. Consideration between patient and neurologist should be given to the choice of disease modifying therapy during pregnancy. There is limited data to support the safety of either interferon or glatiramer in pregnant women.[127] Some patients with severe progressive disease may be treated with immunosuppressant medication, such as cyclophosphamide or methotrexate. These medications are associated with congenital malformations and should be avoided in pregnancy.[128]

There is no evidence that mode of delivery, breastfeeding, or the use of epidural labour analgesia influence the rate of relapse. There is no evidence that pregnancy has any impact on the long-term progression of the disease.[129,130] However, it is important for these women to have careful specialist follow-up as minor postpartum symptoms such as bladder dysfunction and paraesthesia may be misinterpreted as MS relapse.

There is inconclusive evidence to suggest that women with MS may be at some increased risk of a variety of obstetric complications. Several large studies have suggested women with MS had an increased risk of giving birth to babies of low birth weight, and a higher rate of requiring induction of labour and operative interventions for delivery.[131,163]

## Anaesthetic issues

### Neuraxial anaesthesia

It has previously been proposed that areas of demyelinated neurons within the spinal cord may be damaged by the direct application of concentrated local anaesthetic, such as during spinal anaesthesia. There was concern that this may either result in direct toxicity, or increase the risk of MS relapse. This concern led initially to a reluctance to perform neuraxial anaesthesia at all, and later, a preference to perform epidural rather than spinal anaesthesia, in order to reduce the concentration of local anaesthetic directly reaching the spinal cord.[132] In fact, there is little evidence to support these contentions, and neuraxial anaesthesia (both spinal and epidural) appears safe.[133] Recent surveys suggest that most anaesthetists are now happy to proceed with neuraxial anaesthesia in the setting of MS.[134] Patients with autonomic dysfunction may be at increased risk of hypotension following neuraxial anaesthesia.

### General anaesthesia

Many of the potential issues associated with administering general anaesthesia in the setting of MS are more likely to be relevant in severe advanced disease, which is unlikely to be seen in an obstetric setting. A brief overview is provided, and more detail is available elsewhere.[120]

A thorough preoperative assessment is critical for planning intraoperative and postoperative management. A careful documentation of the current neurological state is valuable if there are concerns later about postoperative relapse. An assessment of bulbar symptoms and respiratory weakness is important as this can increase the risk of aspiration and atelectasis postoperatively. Demyelinating lesions in the thoracic cord can lead to autonomic dysfunction, leading to intraoperative haemodynamic instability, particularly hypotension that can be resistant to treatment. This may also be relevant in the setting of neuraxial anaesthesia. Consideration should be given to the patient's current medications, and their potential relevance to anaesthesia. Recent high-dose steroid use may require perioperative supplementation to avoid adrenal insufficiency. Use of baclofen may increase sensitivity to non-depolarizing neuromuscular blocking drugs.

Patients with advanced MS and an element of limb spasticity are potentially at risk of exaggerated hyperkalaemia in response

to suxamethonium. It is possible that high-dose rocuronium may be more appropriate in this setting; however, there are several reasons why patients with MS may have unpredictable responses to non-depolarizing muscle relaxants. Denervation may result in upregulation of postsynaptic acetylcholine receptors and increased resistance to non-depolarizing neuromuscular blocking drugs. Conversely, pre-existing weakness and reduced muscle mass may result in increased sensitivity. As previously stated, baclofen treatment for limb spasticity may also contribute to sensitivity to non-depolarizing neuromuscular blocking drugs.

Hyperthermia has been implicated in recurrence of MS. Temperature should be monitored and excessive warming should be avoided.

## Brain tumours

### Incidence and presentation

Central nervous tumours are uncommon neoplasms, with an annual incidence of 5.1–7 cases/100,000 population, but only 1.8–3.2 cases/100,000 women between the ages of 20 and 39.[135] The incidence is not increased in pregnant women compared to the non-pregnant female population,[136,137] but an increased growth rate during pregnancy may occur in some tumour types. Studies in various Western countries estimate that this translates to peripartum diagnosis of malignant brain tumour of 3.6–32/100,000 live births.[136,138] These studies excluded common benign tumours such as meningiomas and pituitary adenomas. The relative frequencies of common brain tumour types in the normal population are shown in Table 45.1; however, these vary between reports and populations. In particular, meningiomas are three times more common in women than men. Brain metastases are often not included when tumour incidence is considered, but with the increasingly aggressive treatment of common cancers such as breast, lung, renal, and bowel cancer and melanoma, these are most commonly seen and treated. In practice, the tumours most likely to present as a clinical dilemma in pregnancy are low- and high-grade gliomas (Figure 45.2A), meningiomas (Figure 45.2B, C), acoustic neuromas, pituitary tumours, and the multiple lesions associated with the phacomatoses (neurofibromatosis (NF)-1, NF-2, and von Hippel–Lindau disease) (Figure 45.2D). One large population-based study of pregnant women with brain tumours found an increased risk of maternal mortality, preterm labour, and intrauterine growth retardation associated with malignant brain tumours and of preterm labour associated with benign brain tumours. Both were associated with an increase in caesarean delivery rates,[139] and similar outcomes have been reported in smaller studies.[140,141] Although uncommon, brain tumours can precipitate catastrophic neurological deterioration with devastating fetal and maternal outcomes.[138]

**Table 45.1** Relative frequencies of common brain tumours in the general population

| Histological type | | Percentage |
|---|---|---|
| Glioma | High-grade (malignant) glioma | 25 |
| | Low-grade glioma | 20 |
| Meningioma | | 25 |
| Acoustic neuroma | | 8 |
| Pituitary tumour | | 8 |

Brain tumours generally present in one of three ways: symptoms of raised intracranial pressure, seizures, or focal neurological deficit related to the location of the tumour. Other presentations, such as with catastrophic haemorrhage, are uncommon. Dramatic presentation with a seizure, which occurs in 30–50% of patients,[142] presents no diagnostic challenge unless eclampsia is suspected—seizures occurring in late pregnancy are more likely to be due to eclampsia.[143] The clinical features of raised intracranial pressure, including headache, nausea, vomiting, and lethargy are frequent in normal pregnancy, making diagnosis more difficult. New, constant, progressive, or morning headache, nausea or vomiting occurring in, or persisting into, the second or third trimester, drowsiness, confusion, or new neurological deficit should always be investigated. Headaches that are worse with bending, lying down, coughing, and other manoeuvers that increase intracranial pressure are particularly suspicious.

A small percentage of brain tumours grow significantly during pregnancy, although the exact incidence of this is difficult to assess, and some reports show no relationship of tumour growth to pregnancy.[144] Tumour growth usually presents in the second and third trimesters.[145] For malignant tumours growth would be expected over the time period of a normal pregnancy, but there have also been reports of unusual growth of benign tumours during pregnancy. This has classically been attributed to hormonal effects on cell proliferation, which is probably true for pituitary tumours. The normal pituitary gland increases in size during pregnancy[146] and pituitary adenomas may undergo significant enlargement due to hormonal stimulatory effects. This is particularly the case for prolactin-secreting macroadenomas (>1 cm in diameter), 24% of which may appreciably enlarge during pregnancy.[147] More than 80% of meningiomas also express receptors for progesterone or oestrogen;[67] however, their significance is unclear as many meningiomas do not grow during pregnancy, the receptors are equally present in meningiomas in children and men, and treatment directed against these receptors has been fruitless. Additionally, the increased mass effect with neurological deficit occurring in pregnancy may improve after delivery, which should not occur if the effect is due to enhanced cell proliferation. Therefore, it has also been suggested that the hypervolaemic state of pregnancy may exacerbate the mass effect of the tumour. One study of meningiomas requiring resection for mass effect during pregnancy showed no particular change in proliferation rate but features of hypervascularity, intracellular and stromal oedema, and haemorrhage when compared to meningiomas in non-pregnant women.[145] This may also occur in other benign tumours, such as acoustic neuromas,[148] and low-grade gliomas, and the risk of deterioration due to mass effect continues into the immediate postpartum period.[149] Immunological tolerance has also been suggested as an aetiological factor in brain tumour growth in pregnancy.

### Diagnosis and investigation

In a patient suspected to harbour a brain tumour, imaging should not be delayed due to pregnancy. If possible, a CT scan should be avoided to limit exposure to ionizing radiation; however, if MRI

is not readily available and clinical presentation warrants urgent imaging, then CT scan should be performed with lead shielding of the fetus, which results in a negligible radiation exposure.[68,69] MRI does not involve ionizing radiation, is not known to have harmful effects on humans[90,94] and is frequently used safely for imaging of the fetus.[96] Thus, it is the preferred maternal brain imaging modality in pregnancy, and indeed in the non-pregnant patient suspected to suffer from a brain tumour as it provides more detailed and sensitive brain tumour imaging than CT scan. Intravenous contrast agents improve the diagnostic yield of cranial imaging and have not been specifically shown to have mutagenic or teratogenic effects[89] but are generally avoided in pregnancy based on the general principle of drug avoidance. Iodinated contrast used for CT scan may cause anaphylaxis and is nephrotoxic and has been reported to cause hypothyroidism in the fetus.[90–92] Gadolinium-based contrast used for MRI is less likely to cause allergic reactions and is not nephrotoxic and has no known adverse effects for the fetus.[92] Nonetheless, a non-contrast MRI scan is usually sufficient for diagnosis of the majority of lesions and can be performed in the first instance. Consultation with the radiologist to ensure maximal benefit from limited imaging is essential.[13]

## Anaesthetic and obstetric considerations

The management of a brain tumour is complex in the non-pregnant patient, requiring the expertise of a multidisciplinary team including neurosurgeons, radiation oncologists, medical oncologists, and epilepsy specialists. The complexity of management in the pregnant patient is amplified and the team expands to include obstetricians, neonatologists, and anaesthetists. Decisions relating to both maternal and fetal welfare need to be balanced, with many routine therapies such as radiotherapy or chemotherapy used with caution, or contraindicated. A detailed outline of brain tumour management in pregnancy is not warranted here, but is found elsewhere.[149,150] Anaesthetic considerations are twofold; the first is the pregnant patient with a non-viable fetus who requires urgent surgery to remove a brain tumour, usually for mass effect or suspected malignancy. The second is delivery of the child in a patient with a brain tumour, which may be followed by immediate surgical resection.

In the patient with raised intracranial pressure, steroids can be used to reduce cerebral oedema, which is usually a component of the mass effect, and may delay surgery. These are generally considered safe in pregnancy and have the additional advantage of promoting fetal lung maturity but the benefit needs to be weighed against the possibility of growth retardation and adrenal insufficiency in the fetus. Increased maternal cortisol secretion in the second trimester may be somewhat protective against brain tumour associated oedema.[151] Management of seizures is considered in the epilepsy section. Many AEDs are teratogens or of unknown risk,[68] therefore choice of agent is limited. However, the risk of uncontrolled seizures outweighs the potential side effects of many medications. Prophylactic AEDs would commonly be used for the patient with a brain tumour but no seizures, at least perioperatively, but should be avoided in pregnancy. Surgery can be avoided for pituitary tumours in some cases using medications with an acceptable safety profile including bromocriptine and other dopamine analogues for prolactin-secreting tumours.[152]

In pregnant patients who are known to have a brain tumour, frequent clinical review is necessary to monitor signs of raised intracranial pressure and neurological deficit as appropriate to the location of the lesion. Thus, catastrophic deterioration can be avoided and semi-elective, rather than emergency, surgery can be undertaken. This would include a careful history, examination of the fundi for papilloedema, neurological examination, and imaging as indicated. For pituitary tumours, regular visual field examination is necessary.

Surgery during pregnancy is usually required when the mass effect of the tumour threatens life or function. Up to 48% of hospital admissions of pregnant patients with malignant brain tumours will result in a neurosurgical procedure, and 19% of those for benign tumours.[139] The histological type of tumours detected during pregnancy, such as after a seizure, can be accurately predicted with advanced imaging, therefore tissue diagnosis and treatment of many tumours can be safely delayed until after delivery.[11,143] However, a large tumour, or that in a critical location, can be safely removed during pregnancy if necessary, without an increase in adverse outcomes.[5,11,139] Thus, delay of an indicated procedure is not warranted and most studies suggest that delayed surgery after neurological deterioration results in worse outcomes.[5,12] Small tumours, such as pituitary microadenomas or meningiomas that have not grown during pregnancy (Figure 45.2B), are unlikely to result in significantly raised intracranial pressure and normal vaginal delivery can be planned.

There are a number of considerations for the pregnant patient who is to undergo surgery for removal of a brain tumour. The prone or supine position may not be possible, therefore the sitting, semi-lateral, or lateral position is often preferred to avoid aortocaval or fetal compression.[153] Fluid shifts and haemodynamic changes that are tolerated by the normal pregnant patient may exacerbate cerebral oedema, hypotension may result in inadequate cerebral perfusion pressure, and hypertension may result in intracranial haemorrhage and worsening of cerebral oedema, thus hypotension, hypertension, hypotonic fluids, and fluid overload should be avoided. Intubation should occur without hypertension or raised intracranial pressure. Emergence and extubation should avoid haemodynamic instability, coughing, and the Valsalva manoeuver.

If delivery prior to surgery or other therapy for a brain tumour with significant mass effect is planned, the mode of delivery will need to be considered. The decision should involve the neurosurgical, obstetric, and anaesthetic teams. Intracranial pressure may rise to over 70 $cmH_2O$ with the Valsalva manoeuvre in labour,[154] normal being less than 20 $cmH_2O$. Thus, in the patient with even mildly elevated intracranial pressure due to an intracranial mass, the risk of cerebral herniation is high and vaginal delivery may be contraindicated. Inhaled nitrous oxide and systemic narcotics may result in drowsiness and hypoventilation and are contraindicated. Epidural anaesthesia is potentially contraindicated due to the risk of inadvertent dural puncture, increasing the risk of herniation,[155] and of raised intracranial pressure with bolus injection into the epidural space.[156] Therefore, caesarean delivery under general anaesthesia is most commonly recommended,[11,27] particularly if surgery is to immediately follow delivery. However, others have advocated careful epidural anaesthesia with caesarean delivery or instrumental vaginal delivery to avoid pushing with a pain-free second-stage labour.[157] Neuraxial anaesthesia has the advantage of allowing neurological assessment during delivery.

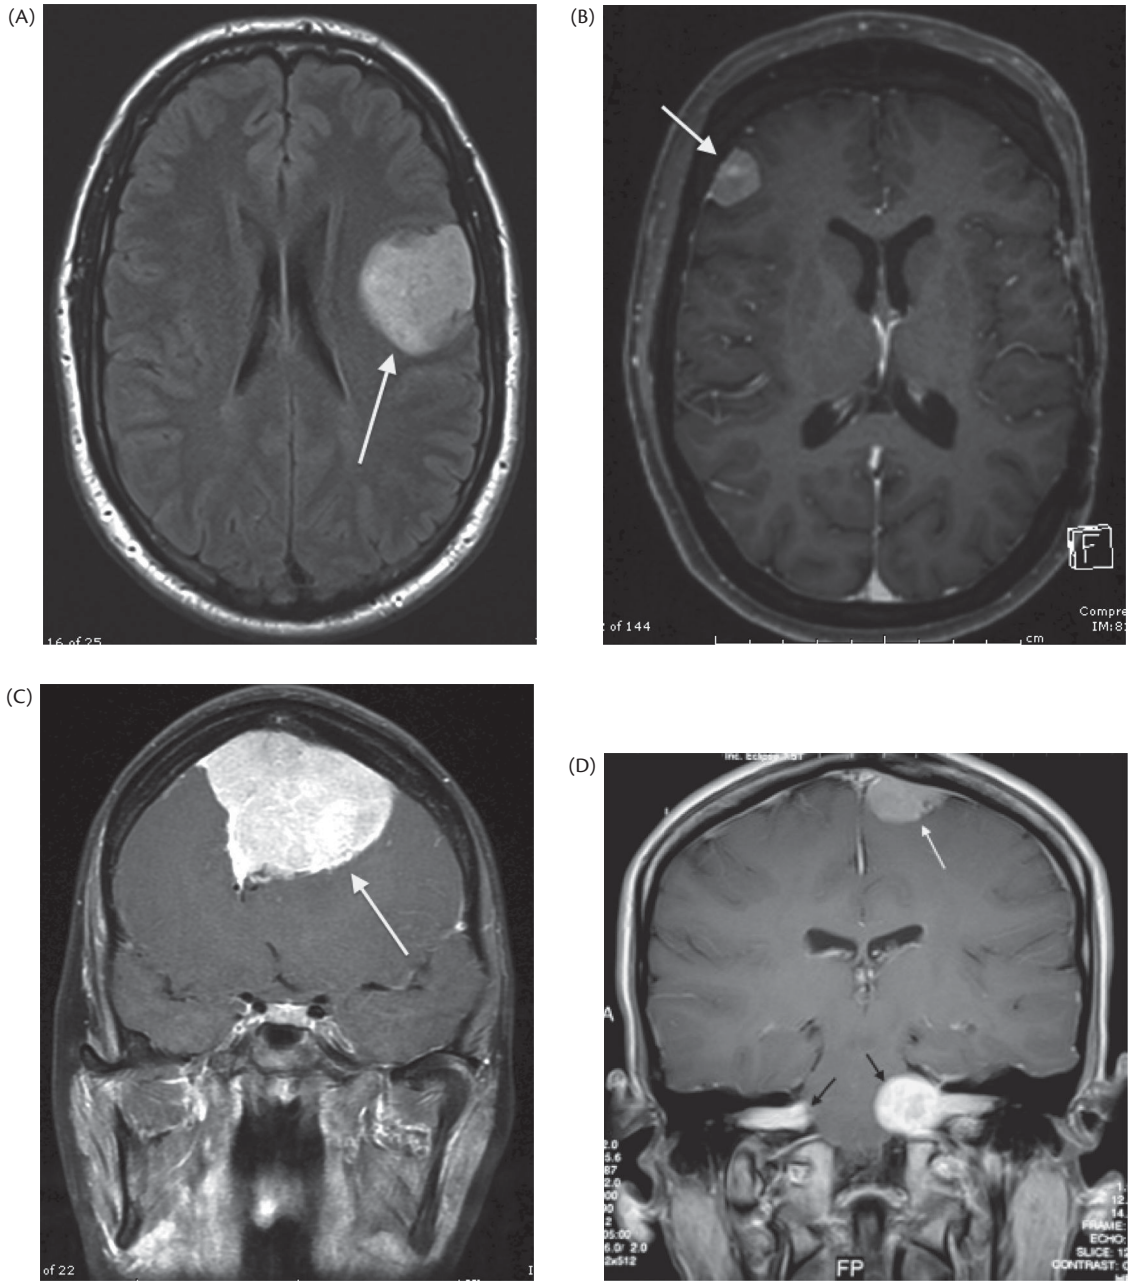

**Figure 45.2** (A) Axial fluid-attenuated inversion recovery (FLAIR) brain MRI showing a left parietal low grade glioma. This tumour was diagnosed during pregnancy when the patient suffered sensory seizures. In retrospect she had suffered similar episode during a previous pregnancy that she had ignored. (B) Axial T1-weighted contrast-enhanced brain MRI showing a small right frontal meningioma (arrow). Small benign tumours can be observed during pregnancy with a low risk of significant enlargement. This tumour did not grow during pregnancy and the patient had a normal vaginal delivery. (C) Coronal T1-weighted contrast-enhanced brain MRI showing a large frontal falcine meningioma with significant mass effect. This tumour was not diagnosed during pregnancy and the patient had a normal vaginal delivery before suffering seizures in the postpartum period. (D) Coronal T1-weighted contrast-enhanced brain MRI showing typical lesions of neurofibromatosis-2 including bilateral acoustic neuromas (black arrows) with brainstem compression on the left, and a small convexity meningioma (white arrows). Decisions regarding pregnancy and delivery in the patients with an autosomal dominant inherited disorder and multiple intracranial and spinal lesions of varying size and severity are complex and should be made in a multidisciplinary setting.

## Hydrocephalus, idiopathic intracranial hypertension, and cerebrospinal fluid shunts

### Hydrocephalus

Hydrocephalus is a condition in which there is an abnormal accumulation of CSF in the cerebral ventricles. It may be obstructive (non-communicating) hydrocephalus, where there is a mechanical obstruction to CSF flow within the ventricular system, or communicating hydrocephalus, where there is an abnormality of CSF absorption from the ventricles into the venous system. In obstructive hydrocephalus, the enlarged ventricles act as an intracranial mass, with the resulting risk of tonsillar herniation.

In communicating hydrocephalus, the raised pressure is distributed evenly throughout the neuraxis, with no risk of herniation. There are many causes of hydrocephalus, both congenital and acquired, particularly after intracranial infection, haemorrhage, or tumour.

The mainstay of treatment of hydrocephalus is insertion of a CSF shunt. This is a CSF diversion system that comprises three parts. The first is a catheter in the CSF space, usually the lateral ventricles, but less commonly in the lumbar theca. The second is a valve system to regulate the pressure or flow of CSF, of which there are many types, and the third is a drainage catheter that diverts CSF into a body cavity, most commonly the peritoneal cavity, but the pleural cavity or right atrium are also utilized. Thus, the most common types of CSF shunt are ventriculoperitoneal and lumboperitoneal; however, ventriculopleural and ventriculoatrial shunts are also used for various indications, including an unsuitable peritoneal cavity due to adhesions, infection, or peritoneal dialysis. Increasingly, endoscopic third ventriculostomy is used to treat hydrocephalus in suitable patients. An opening is made in the floor of the third ventricle to allow ventricular outflow into the basal cisterns, but is dependent on normal CSF absorption capacity.[158]

Women with a shunt report increased headache and abdominal pain, and have an increased incidence of shunt complications, during pregnancy. In one study, 76% of patients had a shunt complication during pregnancy, including 59% with worsening symptoms of raised intracranial pressure. Symptoms generally resolve after delivery. The risk of shunt obstruction is probably increased, with a reported 23% of patients requiring surgical shunt revision during pregnancy.[159,160] Patients with hydrocephalus who have not required a shunt prior to pregnancy may decompensate during pregnancy and require shunt insertion.[160] Differential diagnosis from the headache of pre-eclampsia, CVT, and other causes of headache due to raised intracranial pressure in pregnancy may be difficult.

The reasons for worsening of hydrocephalus and shunt malfunction in pregnancy include physiological changes such as increased plasma volume and increased intra-abdominal pressure. Anatomical changes associated with the enlarging uterus may also be relevant.[161,162] Premature uterine contractions have been attributed to irritation from a shunt peritoneal catheter.[5]

### Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH), previously known as pseudotumour cerebri or benign intracranial hypertension, is raised intracranial pressure with normal CSF composition and in the absence of hydrocephalus, a mass lesion, or impaired consciousness. It is likely a disorder of CSF absorption, being associated with cerebral venous sinus outflow obstruction.[164] It is common in obese women of child-bearing age and the chief symptoms are severe headache and visual loss due to chronic papilloedema. If medical treatment of the headache or visual failure is inadequate, a lumboperitoneal, or less commonly, ventriculoperitoneal shunt may be inserted.[162]

The symptoms of IIH worsen with pregnancy and exogenous oestrogens. The onset of the disease may also occur during pregnancy, particularly the first and second trimesters, although the incidence is probably not increased in pregnancy.[165,166] Generally, maternal and fetal outcomes are good and visual outcomes are similar to non-pregnant patients.[165–168] If there is severe papilloedema, caesarean delivery to minimize raise intracranial pressure during delivery can be considered to avoid irreversible visual loss, but generally vaginal delivery is appropriate. Neuraxial anaesthesia is not contraindicated if the patient does not have a lumboperitoneal shunt. Lumbar puncture is often used therapeutically and does not result in herniation due to the even distribution of pressure throughout the neuraxis.[167,177]

### Anaesthetic concerns

Parturients with raised intracranial pressure present a major challenge to the obstetric anaesthetist. Dural puncture in the setting of obstructive hydrocephalus may allow a rapid decrease in CSF pressure, potentially leading to tonsillar herniation or intracranial haemorrhage. Intracranial subdural haematoma and subarachnoid haemorrhage have been described following epidural and spinal anaesthesia.[170,171] As mentioned previously, intracranial pressure increases significantly during labour contractions, particularly during the second stage.[172] A planned assisted instrumented delivery will reduce the increase in intracranial pressure associated with pushing and the Valsalva manoeuver. This is advisable even for those patients with IIH or communicating hydrocephalus, who are not at risk of herniation, or those with obstructive hydrocephalus and a functioning ventriculoperitoneal shunt or ventriculostomy.[174]

Patients with a functioning ventriculoperitoneal shunt or communicating hydrocephalus can safely receive neuraxial analgesia or anaesthesia and a vaginal delivery is not contraindicated.[174,176] It would seem reasonable to administer prophylactic antibiotics to shunt patients, although this is not universally recommended.[176] Patients with a lumboperitoneal shunt for IIH should not receive neuraxial blockade. Firstly, there is the potential for unpredictable spread of local anaesthetic, and secondly, the risk of damaging the catheter itself with the spinal or epidural needle.[177] There have, however, been reports of successful epidural anaesthesia in patients with lumboperitoneal shunts.[41]

Overall, treatment of hydrocephalus, IIH and shunt malfunction in pregnancy using standard neurosurgical guidelines and in consultation with the obstetric and anaesthetic team is associated with good maternal and fetal outcomes. [5,11,165,166,174,176]

## Spina bifida

### Introduction

Spina bifida is one of a spectrum of congenital disorders relating to failure of closure of the neural tube. Subtypes of spina bifida describe the anatomical extent of the abnormality. The mildest form of the disease is known as spina bifida occulta, implying that there is no external defect visible, although there is frequently a patch of hair or dimpling of the skin overlying the abnormality. In the more severe forms, collectively known as spina bifida cystica, the neuraxis is exposed along the dorsal aspect of the body to a variable degree by defects in the formation of covering structures.[178] The incidence is falling due to maternal folate supplementation and a rise in prenatal diagnosis with termination of significantly affected pregnancies.[179] The current incidence is in the order of 0.1–0.3% of the population, although it is much higher in the offspring of sufferers, and may be as high as 3–4%.[180,181]

### Obstetric considerations

Survivors of spina bifida who reach reproductive age frequently suffer kyphoscoliosis, abnormal pelvic shape, and neuropathic

bladder, and may have undergone multiple corrective procedures for musculoskeletal, neurological, or urological abnormalities.[182] Recurrent urinary tract infections and latex allergy are common.[181] Whilst normal vaginal delivery of women with spina bifida has been reported, the combination of abnormal pelvic shape and lower body muscular weakness means instrumental and operative delivery is frequently required. Great care needs to be taken at caesarean delivery to avoid ureteric trauma in the setting of previous urological procedures.[181]

### Anaesthetic considerations

Neuraxial anaesthesia may be challenging (or impossible) in the parturient with spina bifida for several reasons, and many anaesthetists would consider spina bifida to be a contraindication for neuraxial techniques. Firstly, the procedure may be technically difficult to perform due to abnormal anatomy such as kyphoscoliosis or scarring from previous corrective surgery. Secondly, local anaesthetic spread is unpredictable due to abnormalities in CSF flow and the abnormal structure and integrity of the epidural space. This may lead to a variety of problems, including inadequate caudal spread of local anaesthetic beyond the level of the defect, excessive cephalad spread of anaesthetic, possibly related to decreased epidural space volume and increased dural permeability, or unilateral block.[178] Thirdly and most significantly, abnormal anatomy may increase the risk of trauma to the spinal cord, spinal nerves, or dura. A significant proportion of patients with spina bifida have a 'tethered' spinal cord, where the spinal cord ends below the normal level due to a shortened filum terminale, or other spinal dysraphism (a congenital abnormality of the spine). The incidence of tethered spinal cord may be as high as 60%.[1,183] Hydrocephalus and CSF shunts are also common in these patients. Thus, close liaison with the treating neurosurgeon to define the anatomical abnormalities and the potential for complications is essential. It is wise to have imaging available before embarking on the route of a neuraxial anaesthetic technique.

## Arnold–Chiari malformation and syringomyelia

The Arnold–Chiari malformations are a spectrum of disorders of varying severity resulting from the descent of hindbrain structures through the foramen magnum.[184] They may be associated with obstruction to CSF flow and hydrocephalus, syringomyelia, and spina bifida.[185] Syringomyelia is the formation of a longitudinal cystic cavity within the spinal cord.[186] Arnold–Chiari malformations are divided into four subtypes, associated with greater degrees of hindbrain displacement and worsening clinical severity. In type 1, the mildest form, only the cerebellar tonsils extend beyond the foramen magnum (Figure 45.3). This malformation is often asymptomatic and diagnosed incidentally, but may become symptomatic in adolescence and young adulthood.[185] Type 2 is more severe, with displacement of the cerebellar vermis, brainstem, and fourth ventricle, and is more likely to be associated with hydrocephalus and a lumbar myelomeningocoele and diagnosed in the pre-natal period or at birth. Types 3 and 4 are rare, and describe more severe descent of hindbrain structures. The most common clinical manifestations include headache (particularly 'cough' headache), neck and upper limb pain, ataxia, and nystagmus, which may worsen with the Valsalva manoeuver. Surgical correction most commonly involves suboccipital craniectomy and upper cervical laminectomy, which provides bony and dural decompression of the structures crowded within the foramen magnum and upper cervical canal. Treatment is only required in symptomatic patients or those developing syringomyelia. Insertion of a CSF shunt is commonly necessary to treat hydrocephalus.[185]

The uneventful use of both neuraxial analgesia and anaesthesia has been described in parturients with Arnold–Chiari type 1 malformation[184,186–189] and syringomyelia.[190,191] However, there are also reports of exacerbation of neurological symptoms postpartum (specifically headache and nystagmus) following the use of neuraxial anaesthesia.[192,193] Some authors propose that dural puncture should be avoided, due to abnormalities in CSF circulation and the potential for a differential pressure gradient to develop between the brain and spinal cord, particularly during straining.[194–196] Chantigian and colleagues reported on 50 years' experience at the Mayo Clinic, during which only 12 women with known Arnold–Chiari malformations delivered a total of 30 babies. A variety of techniques were used including general, epidural, and spinal anaesthesia. None of the patients undergoing neuraxial anaesthesia experienced exacerbation of their neurological symptoms (although one required an epidural blood patch for a postdural puncture headache).[189] In patients with asymptomatic or adequately treated Arnold–Chiari malformations, delivery based on obstetric considerations would seem reasonable, with additional caution for symptomatic, untreated patients.

## Spinal trauma, paraplegia, and quadriplegia

### Incidence

It is estimated that in the United States approximately 52,000 women are affected by spinal injury and approximately 2400 new spinal injuries are reported each year.[197] Causes include motor vehicle accidents, gunshot wounds, horse-riding accidents, and diving accidents.[198] Lesions below T1 result in paraplegia whereas lesions above T1 result in quadriplegia. There may be complete loss of neurological control (motor, sensory, and autonomic) below the lesion or varying degrees of incomplete loss. There may be associated bony deformity.

### Obstetric considerations

Fertility is not generally affected in women with spinal cord injury (SCI).[198] Complications of SCI relevant to obstetrics include iron deficiency anaemia, folate deficiency, urinary tract infection, and decubitus ulcers. Asymptomatic bacteriuria and urinary tract infection are extremely common in women with SCI, and routine urinary culture at each antenatal visit is recommended.[199] Antibiotic prophylaxis should be considered. Thromboprophylaxis may be warranted, but is not universally recommended.[198]

Ability to detect labour pain depends on the level of the injury. Women with injuries above T10 may experience painless labour and delivery. Preterm labour appears to be no more common than in the general population; however, consideration should be given to how these women will diagnose the onset of labour, in order to avoid unattended delivery from undetected contractions. Possible options include home uterine activity monitoring, teaching women to palpate their own uterine contractions, and recognition of sympathetic nervous system activity such as leg or abdominal wall spasms or increased lower limb spasticity. Some

authors recommend frequent assessment of cervical dilatation after 28 weeks and inpatient management of women with cervical dilatation.[200,201]

Published case series suggest that whilst vaginal delivery is possible in women with SCI, the likelihood of instrumental or operative delivery is increased, especially in women with higher cord lesions.

### Anaesthetic considerations

Women with high thoracic or cervical SCI should have an assessment of respiratory function either prior to conception or early in pregnancy.[202] Baseline spirometry should be performed with subsequent serial assessment of vital capacity, due to the increased respiratory requirements in late pregnancy. Careful attention to pulmonary care is important, and non-invasive ventilatory support may be required in labour.[202] Hypo- or hyperthermia may occur as a result of impaired thermoregulation.

Autonomic dysreflexia is very common in labour, and may be seen in 75% of women with higher SCI (above T6).[199] Precipitants may include cervical dilatation, bladder or bowel distention, vaginal examination, urinary catheterization, and temperature change in the lower limbs (e.g. placing the legs into cold or hot water).[202] The syndrome results from sympathetic hyperactivity below the level of the lesion. Symptoms include severe hypertension (may be confused with pre-eclampsia), bradycardia, tachycardia, or other arrhythmias. Uterine vasoconstriction may result in fetal distress. Reported complications of autonomic dysreflexia include intracerebral haemorrhage and myocardial infarction. Invasive monitoring of blood pressure should be considered.[198]

Epidural analgesia should be used early in labour to prevent these complications, even if the patient is insensate to labour pain.[198] If epidural analgesia has not yet been administered, or is contraindicated, other agents such as labetalol and nifedipine can be used. Sodium nitroprusside may be required. The use of magnesium sulphate has also been described.[203] Epidural anaesthesia has also been successfully used for caesarean delivery in a quadriplegic patient.[204]

### Acute spinal cord injury during pregnancy

Acute SCI has been reported during pregnancy via mechanisms such as motor vehicle accident, gunshot wounds, or traumatic falls.[198] Management is complex, and requires input from a specialized multidisciplinary team with experience in both high-risk obstetrics and spinal trauma. Care must be taken with immobilization of the entire spine to prevent worsening of injury. Pelvic tilt must be achieved in pregnant women beyond 24 weeks' gestation, where aortocaval compression may contribute to hypotension.

Acute SCI may also be associated with haemodynamic instability. Neurogenic shock is a syndrome of hypotension, bradycardia, and hypothermia resulting from loss of sympathetic tone below the level of the lesion (and resulting unopposed parasympathetic tone). Adequate volume resuscitation and pressor support should be instituted. Bradycardia resulting from neurogenic shock may complicate assessment of volume status. In addition to this, the gravid uterus may make examination of the abdomen more difficult. There should be a high index of suspicion for internal bleeding. Deep venous thrombosis is very common following acute SCI, and routine thromboprophylaxis should be considered.[198]

## Peripheral neuropathy

This section will briefly consider several conditions associated with peripheral neuropathy in the obstetric population, including Guillain–Barré syndrome (GBS) and poliomyelitis. In clinical practice, obstetric anaesthetists will far more commonly be asked to assess patients presenting with new peripheral neurological symptoms, especially postpartum. A thorough knowledge of the aetiology, pathology, and relevant anatomy of the peripheral nervous system are important for developing a framework for adequately assessing these patients.

### Guillain–Barré syndrome

GBS is an acute post-infectious inflammatory polyneuropathy. It typically develops within a few weeks of an infectious illness such as an upper respiratory tract infection or gastroenteritis, and presents with a syndrome of ascending motor weakness and numbness, with loss of deep tendon reflexes.[118] *Campylobacter jejuni* has been implicated as a common causative pathogen.[205] Symptoms may develop over 1–2 weeks, reaching peak severity after 4 weeks, but in severe cases may deteriorate over a few hours. Patients with severe disease may develop respiratory weakness requiring mechanical ventilation (up to 30% of patients) and autonomic dysfunction (up to 70% of patients). Symptoms of autonomic dysfunction may include tachycardia, urinary retention, and hypo- or hypertension. Other supportive care includes physiotherapy, thromboprophylaxis, and antibiotics, which may be required as nosocomial infection such as pneumonia and urinary tract infection are common. Disease-modifying treatment may include plasma exchange transfusion or intravenous gammaglobulin.[206]

GBS does not appear to occur with increased frequency in pregnancy.[205] The successful use of plasma exchange transfusion and intravenous gammaglobulin are both well established.[205] Uncomplicated GBS does not appear to influence the rates of assisted or operative delivery, which should be undertaken on obstetric grounds.[207] The occurrence of GBS in the neonate of a parturient with GBS has been described in a single case report.[165]

Whilst it has been proposed that the use of neuraxial analgesia and anaesthesia may have the potential to exacerbate the severity of GBS,[161] this has largely been discredited.[205] Parturients may, however, be sensitive to the effects of local anaesthetic medications, requiring reduced doses to achieve adequate anaesthesia. Also, patients may be at risk of exaggerated haemodynamic instability during establishment of neuraxial anaesthesia. Careful titration of epidural anaesthesia has been recommended in favour of single-shot spinal anaesthesia.[207]

Suxamethonium should be used with caution due to the potential for exaggerated release of potassium due to postsynaptic receptor proliferation. Succinylcholine-induced cardiac arrest has been reported in a patient recovering from GBS.[167] However, patients can also be highly sensitive to non-depolarizing muscle relaxants,[207] which should be titrated in small doses, with appropriate monitoring. Facilities for postoperative ventilation should be available.

Autonomic instability may also be prominent during general anaesthesia and should be treated aggressively.

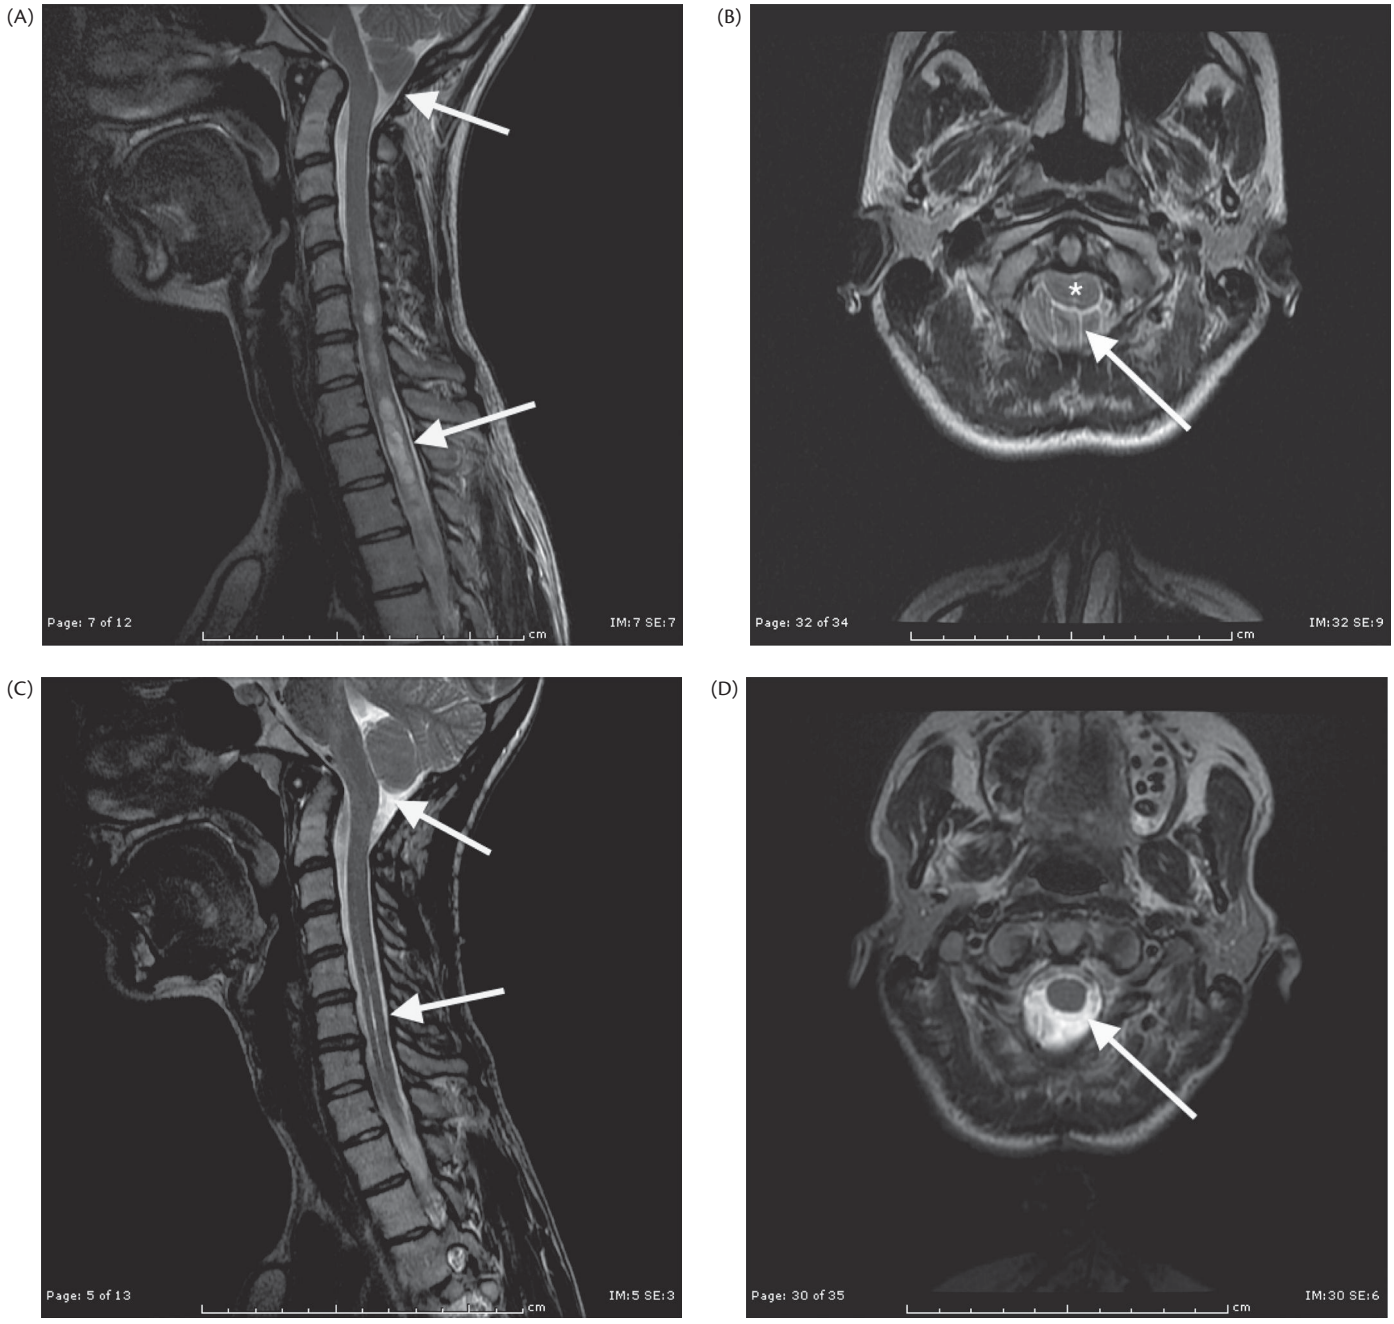

**Figure 45.3** (A) Sagittal T2-weighted MRI of the craniocervical junction showing a Chiari 1 malformation with displacement of the cerebellar tonsils into the foramen magnum (upper arrow) and an extensive cervical syrinx (lower arrow). (B) Axial T2-weighted MRI at the level of C1/2 showing the medulla/spinal cord (asterisk) compressed by the cerebellar tonsils (same patient as Figure 45.3A). (C) Sagittal T2-weighted MRI of the patient in Figure 45.3A,B after surgical posterior fossa decompression with a capacious foramen magnum region (upper arrow) and resolution of the cervical syrinx (lower arrow). (D) Axial T2-weighted MRI of the patient in Figure 45.3 A,B showing the decompressed medulla/spinal cord.

## Charcot–Marie–Tooth disease (hereditary motor sensory neuropathy)

Charcot–Marie–Tooth disease is a rare inherited defect in myelin structure and function, also known as hereditary motor sensory neuropathy. It has an incidence of approximately 36/100,000. It results in a progressive distal limb weakness and muscle atrophy, leading to gait disturbance and deformity.[118] Parturients with Charcot–Marie–Tooth disease appear to have higher rates of malpresentation, higher rates of operative delivery, and an increased incidence of postpartum haemorrhage.[166] Symptoms of the disease may be temporarily or permanently worsened by pregnancy.[169] Neuraxial analgesia and anaesthesia are not contraindicated in these patients, although it may be challenging if there is kyphoscoliosis.[208]

## Polio (and post-polio syndrome)

Infective poliomyelitis ('polio') is a highly infectious viral illness predominantly affecting children under the age of 5. The enterovirus replicates in the gut and is spread rapidly by faecal–oral contamination. Most sufferers only experience a mild influenza-like illness. However, one in 200 sufferers develops an acute flaccid paralysis as a result of spread to the motor neurones in the anterior horn of the spinal cord. Five to ten per cent of these patients die from respiratory failure. It is not known why such a small proportion of sufferers develop paralysis, although risk factors are known to include pregnancy, previous tonsillectomy, strenuous physical activity, and minor trauma such as intramuscular injections.[158] Survivors of spinal paralysis may have lifelong sequelae, including deformity and physical disability such as limb contractures, kyphoscoliosis, and chest wall deformity, which may contribute to respiratory insufficiency.

Around 40% of patients who survive paralytic polio will go on to develop additional worsening symptoms 15–40 years following the illness. This worsening of symptoms is known as post-polio syndrome (PPS). These symptoms include muscle weakness, chronic pain, fatigue, and impaired activities of daily living.[209] The number of worldwide cases of polio has dropped by 99% due to highly successful vaccination programmes, from an estimated 350,000 cases in 1998 to 650 reported cases in 2011.[173] Polio is now endemic in only three countries—Pakistan, Afghanistan, and Nigeria.

There is a paucity of data in the recent literature examining obstetric outcomes in female survivors of polio. One study searched the Medical Birth Register of Norway and reported on 2495 births between 1967 and 1998. The authors found that women with a past history of polio were significantly more likely to develop pre-eclampsia (3.4% vs 2.8%), urinary tract infection (3.5% vs 2.4%), and antepartum haemorrhage (3.8% vs 2.4%).[175] Labours were more likely to become obstructed (6.1% vs 2.0%) and caesarean delivery was more common (13.2% vs 8.3%). Infants of mothers with polio were significantly smaller (3383 vs 3483 g) and had a higher risk of perinatal death (2.1% vs 1.1%).

The patient with post-polio sequelae may present a number of significant challenges to the anaesthetist, in the performance of either neuraxial anaesthesia or general anaesthesia. Issues of general anaesthesia include concern over using both depolarizing and non-depolarizing muscle relaxants, sensitivity to analgesic and sedative medication, and the risk of postoperative respiratory depression and aspiration.[133]

Issues requiring preoperative assessment include the degree of respiratory compromise, which may be due to anatomical deformity, particularly kyphoscoliosis, but also due to obstructive or central sleep apnoea. Patients may also have bulbar dysfunction, increasing the risk of aspiration.[210] Other issues include management of chronic pain, which is a common feature of PPS, and cold intolerance. As with many other conditions associated with denervation of peripheral muscle, the use of suxamethonium carries the risk of exaggerated release of potassium and cardiac arrest. However, the safe use of suxamethonium has been described for caesarean delivery in the post-polio patient.[211] Patients may also be sensitive to normal doses of non-depolarizing muscle relaxants.[212]

Whilst neuraxial anaesthesia represents an attractive option, there are still several areas of concern. These include the potential for neuraxial anaesthesia to temporarily affect accessory muscles required for respiration, potential to exacerbate the underlying disease process, and also the difficulty in adequately assessing for complications of neuraxial anaesthesia in the setting of pre-existing neurological pathology. Achieving successful neuraxial anaesthesia may also be technically challenging in the patient with abnormal neuraxial anatomy.[133] The use of ultrasound-guidance has been proposed as a technique for improving success rate in patients with complex kyphoscoliosis.[172]

There is no convincing evidence in the literature that neuraxial anaesthesia worsens neurological disability in patients with post-polio sequelae or PPS [133]. However, it has been proposed that spinal neurons in these patients may be both damaged and reduced in number, and therefore these patients may be at risk of direct local anaesthetic neurotoxicity.

## Bell's palsy

Bell's palsy is the paralysis of the facial nerve resulting in asymmetrical facial expression and unilateral weakness of eye closure. Bell's palsy is idiopathic and a wide variety of immunological and viral mechanisms have been considered.[213] The condition is two- to fourfold more common during pregnancy.[118] Treatment options are identical during pregnancy and in the non-pregnant population, and consist of supportive care, particularly to avoid trauma to the non-closing eye, and early treatment with oral glucocorticoids, for which there is limited evidence of benefit. Oral glucocorticoids are not recommended in the first trimester in pregnancy due to a risk of increased cleft palate.[214] The prognosis of Bell's palsy depends on the severity of the paralysis. Incomplete lesions are more likely to resolve than complete lesions. Whilst overall, 85% of patients will regain normal or near normal function, this may be significantly less in pregnancy.[4,215] Possible explanations for this are that pregnant patients may be less likely to receive treatment, or may be more likely to develop complete lesions.

## Carpal tunnel syndrome

Carpal tunnel syndrome is an extremely common condition resulting from compression of the median nerve as it passes under the flexor retinaculum at the wrist. This results in pain, paraesthesia and/or numbness of the thumb, index and middle fingers, as well as the radial half of the ring finger, which may wake the patient from sleep. The condition is thought to be more common in pregnancy as a result of fluid retention and peripheral oedema.[118] Symptoms commonly occur in the third trimester and may last for several weeks or months postpartum. The condition has a good prognosis for resolution after delivery and should rarely be treated surgically during pregnancy, unless there is the threat of permanent neurological disability.

## Postpartum peripheral neuropathy

The process of labour and delivery, either vaginally or at caesarean delivery, can potentially damage peripheral nerves by excessive compression or traction. Several case series have been published suggesting that the incidence of postpartum compression neuropathy is in the order of 0.5% of pregnancies.[216–218] Risk factors include nulliparity and a prolonged second stage of labour. Neuraxial anaesthesia may contribute either directly or indirectly to peripheral neuropathy. Indirectly, it may allow women

to push for longer periods without changing position, unaware of impending nerve injury.[216] The incidence of neuropraxia directly related to obstetric analgesia (spinal or epidural) is probably in the order of 1–2/10,000 parturients.[217,220,221] Although rare, the consequences of neuraxial abscess or haematoma can be devastating. Careful consideration should be given to this possibility and urgent radiological imaging (preferably MRI) and neurosurgical opinion should be sought in a patient with motor or sensory dysfunction after delivery.[8,222] Further details of the presentation, investigation, and treatment of neuraxial abscesses and haematomas are to be found in Chapter 28.

The most commonly affected peripheral nerve is the lateral femoral cutaneous nerve of the thigh, which can be stretched by retraction during caesarean delivery, or compressed beneath the inguinal ligament, especially with prolonged hip flexion. This results in the condition known as 'meralgia paraesthetica'. Associated risk factors include obesity, exaggerated lumbar lordosis, and an anatomical variant where the lateral femoral cutaneous nerve bisects the inguinal ligament. Other commonly injured peripheral nerves include the femoral nerve, the lumbar component of the sacral nerve (compressed as the fetal head enters the pelvis, especially during mid-cavity forceps deliveries), and the common peroneal nerve (compressed against the head of the fibula in the lithotomy position).

Assessment of new neurological symptoms in the postpartum period requires a careful history and thorough examination, including detailed documentation of the findings. In patients who have received neuraxial anaesthesia, consideration should always be given to the potential diagnosis of a neuraxial space-occupying collection (such as abscess or haematoma). If this possibility exists, then urgent imaging (preferably MRI) and early neurosurgical intervention is required to optimize neurological recovery. Otherwise, assessment should focus on the likely causative peripheral nerves. The lateral femoral cutaneous nerve is sensory only, and causes pain and noxious paraesthesia and numbness over the anterolateral part of the thigh, without motor deficit. Femoral nerve injury results in quadriceps weakness and numbness or paraesthesia over the lower anterior thigh. Peroneal nerve compression at the fibular head may result in foot drop and numbness over the lateral lower leg and dorsum of the foot. Compression of the obturator nerve is less common, but results in numbness and paraesthesia of the medial thigh and weakness of hip adduction.

The natural history of postpartum neuropraxia is one of gradual improvement to normal (or near-normal) function. In most patients, complete recovery occurs over 2–3 months, although in some this may take up to 2 years.[218]

# Myasthenia gravis

## Aetiology and presentation

Myasthenia gravis (MG) is an autoimmune disease resulting in fatigable weakness of skeletal muscle. The disorder is caused by T-cell dysfunction which results in the production of antibodies against the nicotinic acetylcholine receptor on the neuromuscular end-plate of skeletal muscle.[223] The disease commonly affects young women (male:female ratio 1:3), frequently in the third or fourth decade of life. The incidence is approximately 1/10,000[224] and may present for the first time in pregnancy.[225] Patients present with symptoms of skeletal muscle weakness, which worsens after a period of activity. MG may be isolated to ocular muscles (presenting with diplopia or ptosis), or more generalized, affecting a variable combination of ocular, bulbar, peripheral, and respiratory muscles. Weakness may fluctuate throughout the day, but tends to be worse in the evening. Approximately 10–15% of patients with MG have an underlying thymoma.

## Treatment

Treatment priorities are similar to non-pregnant patients and should include exclusion of coexisting autoimmune disease (such as thyroid disease), evaluation of respiratory muscle dysfunction, and aggressive treatment of infections (such as endometritis and mastitis), which may precipitate MG exacerbation. Acute worsening of MG, particularly of respiratory function, is known as *myasthenic crisis*, and may require intubation and mechanical ventilation. Increased dosage of cholinesterase inhibitors is indicated and immunoglobulin or plasmapheresis may be required in this setting. Excessive treatment with cholinesterase inhibitors may also lead to a clinical syndrome of weakness, known as *cholinergic crisis*. The two crises may be difficult to distinguish, although cholinergic crisis may be accompanied by excessive sweating, salivation, and bradycardia. A single dose of edrophonium can also be given—symptoms will improve in the setting of myasthenic crisis and worsen or remain unchanged in cholinergic crisis.[226]

## Obstetric considerations

The disease has a variable progression in pregnancy.[227,228] In a published case series, symptoms improved during pregnancy in 39% of patients, worsened in 19%, and remained unchanged in 42%.[229] If exacerbation occurs it is likely to be in the first trimester or in the immediate postpartum period.

Acetylcholinesterase inhibitors (such as pyridostigmine) are the first-line treatment for MG, and may require dose adjustment in pregnancy. They should be given parenterally during labour, due to variable gastric absorption. Other treatments may include glucocorticoids, and immunosuppressive therapy such as ciclosporin and azathioprine. Ciclosporin and azathioprine have been associated with spontaneous abortion, preterm labour, and low birth weight infants.[223] They should also be avoided in breastfeeding.

Magnesium sulphate must be avoided as it may precipitate myasthenic crisis. Hypertension should be treated with methyldopa or hydralazine. Beta blockers and calcium channel blockers should also be avoided if possible. If seizure prophylaxis is required in the setting of pre-eclampisa, levetiracetam or valproate should be used. Phenytoin may also exacerbate skeletal muscle weakness.

Uterine smooth muscle is not affected by MG and therefore the first stage of labour usually progresses uneventfully. However, the second stage of labour may be slowed by the weakening of skeletal muscle, and an assisted instrumental or operative delivery may be required. Stress and excessive exertion may also precipitate respiratory weakness and myasthenic crisis and should be avoided. Epidural analgesia should be strongly considered in this setting.

All infants born to mothers with MG should be observed in a special care nursery. Up to 10–20% of infants may develop neonatal MG as a result of passive transfer of maternal antibodies.[227]

### Anaesthetic considerations

MG presents a number of challenges for the anaesthetist mainly due to the risk of respiratory weakness, and the difficulty of managing neuromuscular blockade if required.[226] Patients are also at risk of perioperative myasthenic (or cholinergic) crisis. Because patients with MG have a reduced number of normally functioning acetylcholine receptors, they may display abnormal responses to both depolarizing and non-depolarizing neuromuscular blocking agents. If the patient is treated with cholinesterase inhibitors, these medications also inhibit plasma cholinesterase, and therefore may result in a prolonged effect of suxamethonium. However, if untreated, due to the reduced number of normally functioning receptors, they may be relatively resistant to suxamethonium, but for the same reason, highly sensitive to non-depolarizing neuromuscular blockers. Neostigmine may be ineffective at reversing neuromuscular blockade as the cholinesterase may be already maximally inhibited. If rapid sequence induction is required, muscle relaxation with rocuronium followed by reversal with sugammadex may provide an attractive alternative to reversal with cholinesterase inhibitors.[225,230]

Neuraxial anaesthesia is both safe and recommended both for labour analgesia and caesarean delivery.[225,226] The potential for respiratory weakness resulting from a high block should be considered, and a carefully titrated epidural may be more prudent than single-shot spinal anaesthesia. Alternatively a combined spinal–epidural may be suitable with a small dose of spinal and then a titrated epidural dose to bring the block up. Acute respiratory muscle weakness requiring intubation and mechanical ventilation has been described following single-shot spinal anaesthesia for caesarean delivery.[225]

## Conclusion

Although most neurological conditions are relatively rare, many can occur in women of child-bearing age. A number of important issues may need to be considered during the pregnancy, particularly with regard to planning for labour and delivery. Some patients may need to modify ongoing treatments (e.g. antiepileptic medications) due to potential adverse effects for the fetus. Patients with peripheral muscle weakness (such as MG and MS) may be at risk of respiratory failure in the later stages of pregnancy. Many neurological conditions also have important implications for the safe conduct of neuraxial anaesthesia and analgesia, such as spina bifida, hydrocephalus, and raised intracranial pressure. Parturients with neurological disease will benefit from coordinated care by a multidisciplinary team including an obstetrician, neurologist, neurosurgeon, and anaesthetist.

# CHAPTER 46

# Musculoskeletal disorders

James P. R. Brown and M. Joanne Douglas

## Introduction

Musculoskeletal diseases present challenges for obstetricians and anaesthetists. The physiological changes of pregnancy and labour may exacerbate existing symptoms and stress cardiorespiratory reserve; this may also result in the first presentation of previously undiagnosed musculoskeletal disorders.

Many musculoskeletal conditions are rare. Anaesthetic management is based mainly on case reports that are subject to reporting and publication bias and may represent worst-case scenarios. Musculoskeletal diseases have a spectrum of phenotypic expression, associations, and functional consequences. Anaesthetic management needs to be tailored to the individual parturient and should, where possible, be planned in advance by the multidisciplinary team with the mother.

## Malignant hyperthermia

Malignant hyperthermia (MH) is a pharmacogenetic disease of muscle with an autosomal dominant (AD) inheritance.[1] Mutations for MH have been found in genes encoding the ryanodine (RYR1) and dihydropyridine (DHPR) receptors, but not all mutations have been identified.[2,3]

The volatile anaesthetic agents may trigger a MH episode, either alone or in combination with suxamethonium. There is debate as to whether suxamethonium alone can trigger MH.[4] In MH susceptible (MHS) individuals, volatile agents can lead to prolonged excitation–contraction coupling (ECC) due to excessive release of calcium from the sarcoplasmic reticulum.[5,6] This ECC results in muscle rigidity and a hypermetabolic syndrome that presents as an increase in carbon dioxide, lactate, and eventually temperature with a decrease in bicarbonate, pH, and oxygen. If untreated, rhabdomyolysis will occur with myoglobinaemia, myoglobinuria, hyperkalaemia and an increase in creatine kinase (CK).[1] MH may not be triggered with every anaesthetic exposure;[1] rarely it occurs in the absence of triggering agents.[7]

Following suxamethonium, masseter muscle rigidity can be the first sign[1] and may prevent endotracheal intubation. When suxamethonium is not used, an increase in end-tidal carbon dioxide, unrelated to ventilation, may be the initial presentation. Spontaneously breathing patients will become tachypnoeic. Sympathetic stimulation leads to tachycardia, arrhythmias, and hypotension. Generalized muscle rigidity, rhabdomyolysis, and hyperthermia may occur if the episode is not treated early.

Treatment of MH consists of calling for help, stopping volatile agents, administering 100% oxygen (provides additional oxygen, purges anaesthetic machine), administration of dantrolene, and supportive treatment of acidosis, hyperthermia, and hyperkalaemia.[8]

Dantrolene sodium is the specific treatment for MH[9] and has been used successfully in parturients. Dantrolene crosses the placenta[10] and may be found in breast milk after its use.[11] A report of uterine atony following use[12] may have been related to mannitol in the formulation, rather than dantrolene itself.[13]

Confirmatory evidence of a MH episode is by a positive *in vitro* contracture test,[8] unless the individual has one of the known genetic mutations. If the genetic mutation is known it may be possible to diagnose MHS in a newborn using umbilical cord blood.[14]

Case reports of MH occurring in parturients during anaesthesia for obstetric surgery are rare, possibly because neuraxial anaesthesia (NA) is commonly used. There are multiple reports of anaesthesia for MHS parturients.[15] Ideally, NA will be used for obstetric surgery in MHS parturients, but when contraindicated, general anaesthesia (GA) can be safe, providing trigger agents are avoided and the parturient fully monitored.[16] Some recommend avoidance of triggers in non-MHS parturients who may be carrying a MHS fetus (father MHS). Most medications used in obstetrics are safe in MHS parturients, although the prostaglandins may cause maternal fever; as may prolonged epidural analgesia and sepsis. Fever may lead to erroneous diagnosis of MH in a MHS parturient. Prior to use the anaesthetic machine should be purged of volatile agents.[17] Many anaesthetic agents may be safely used in patients with MH (Box 46.1).

## Backache

### Pregnancy-related backache

Backache has a background population prevalence of approximately 25%.[18] At term, pregnancy-related backache (PRB) is present in up to 50% of parturients. Proposed aetiologies include weight gain, altered posture and mechanical loading of the spine (especially posterior elements e.g. facet joints), increased lumbar lordosis, and forward tilting of the pelvis with a gravid uterus (Figure 46.1), ligament laxity secondary to oestrogen, and relaxin. PRB is a significant cause of sick leave and can impair activities of daily living.[19]

PRB can be divided into lumbar pain or pelvic girdle pain, which commonly involves the symphysis pubis or the sacroiliac joints and radiates into the thighs. There is no radicular or neurological component to PRB. Pelvic pain is linked to greater levels of dysfunction and increased sick leave compared with lumbar backache.[18]

In one survey, 50% of parturients had backache 12–15 months post delivery. For many, backache at this stage is not a direct

**Box 46.1** Anaesthetic drugs that may be used safely in parturients susceptible to malignant hyperthermia

**Induction agents**
- Propofol
- Thiopentone
- Ketamine
- Benzodiazepines
- Etomidate

**Analgesics**
- Remifentanil
- Alfentanil
- Fentanyl
- Sufentanil
- Morphine
- Oxycodone
- Pethidine

**Muscle relaxants**
- Atracurium
- Rocuronium
- Vecuronium

**Anaesthetic gases**
- Nitrous oxide

**Local anaesthetics**
- Lidocaine
- Prilocaine
- Bupivacaine
- Ropivacaine
- 2-Chloroprocaine

result of labour and delivery; 21% of those with postpartum backache did not have backache during pregnancy.[20] The most significant predictor of postpartum backache is an antenatal history of backache.[21] Prospective studies suggest labour epidurals may be associated with an increase in acute backache in the first 24 hours postpartum, but do not increase chronic backache.[22–24] Physical fitness is protective against PRB and physiotherapy aimed at strengthening core muscles, providing increased stability to the pelvis and lumbar region, is first-line treatment.

## Prolapsed intervertebral disc

Acute disc herniation causing radiculopathy is rare in pregnancy, 1/10,000,[25] although there are case reports of cauda equina syndrome requiring urgent back surgery.[26] Symptoms in parturients with pre-existing disc disease commonly deteriorate during pregnancy. A study investigating parturients who have had previous

**Figure 46.1** Sagittal MRI of lumbar spine, demonstrating increased lumbar lordosis and forward tilting of pelvis at 25 weeks of gestation.

microdiscectomy, demonstrated worsening radiculopathy in 24% of patients; 6% developing a motor deficit.[25]

Stable pre-existing neurology from a prolapsed intervertebral disc is not necessarily an absolute contraindication to NA (epidurals are commonly used in treatment). A pragmatic approach can be taken, clinically evaluating existing neurological deficit, discussing the risks and benefits of epidural versus alternative labour analgesia, or NA versus GA for operative delivery. These patients need to be actively followed up; including doing a postpartum neurological exam. If the level of disc herniation is known, risk may be reduced by avoiding this level when inserting NA.[26]

## Spondylolisthesis

This is a misalignment of the lumbar vertebrae, most commonly an anterior displacement of L5 relative to L4 as a result of degenerative change. Pregnancy does not appear to worsen symptoms associated with pre-existing spondylolisthesis.[27]

## Anaesthetic considerations

### Antenatal

- Confirm diagnosis/cause of backache:
  - PRB
  - Other cause (e.g. prolapsed disc, spondylolisthesis)
- Prolapsed intervertebral disc:
  - Full neurological assessment of lower limbs
  - Evidence of cauda equina:
    - Magnetic resonance imaging (MRI)
    - Neurosurgical consultation

- Consider physiotherapy referral
- Anaesthetic review:
  - Any previous spinal imaging
  - Review, discuss, and agree anaesthetic plan
  - PRB:
    - No evidence epidurals increase chronic backache
  - Prolapsed disc:
    - Discuss rare possibility of worsening neurological symptoms (exact risk unknown)
    - Risk/benefit of alternative labour analgesia or GA for operative delivery.

### Peripartum

- Confirm no acute deterioration or development of new neurological signs or symptoms
- Assess pain-free range of movement of legs prior to NA
- Ensure passive positioning does not exceed pain-free active range of movement:
  - Lithotomy may not be possible
- Ensure symmetrical movement of legs when positioning
- Consider passive second stage if prolapsed disc.

### Postpartum

- Neurological exam to rule out deterioration.

## Scoliosis

Scoliosis is defined as a lateral curvature of the spine of greater than 10°. It is commonly accompanied by vertebral rotation and rib deformity. There is a female to male preponderance of 3.5:1;[28] the majority of cases are idiopathic. Table 46.1 lists other causes with their specific anaesthetic considerations. Changing aetiology (e.g. lower rates of polio and tuberculous osteomyelitis) and modern management with evolving surgical techniques have improved outcomes. Management is guided by severity of scoliosis Figure 46.2. Traditional scoliosis surgery involves fusing the spine posteriorly.[29]

### Obstetric considerations

- Generally tolerate pregnancy, labour, and delivery well; complications similar to normal population[35]
- Abnormal pelvic weight-bearing alters anatomy, possible labour dystocia, fetal malpresentation
- Increased labour induction (odds ratio (OR) 1.6)[28]
- Increased caesarean delivery (CD) (OR 1.8):[28]
  - Uterine forward displacement increases fetal malpresentation
- Possible classical uterine incision for surgical access:[36]
  - Risk of uterine rupture/dehiscence with subsequent pregnancies.

### Anaesthetic considerations

#### General anaesthesia

There are 34 cases in the literature describing GA for CD in parturients with idiopathic scoliosis,[36–40] including 13 cases with severe restrictive respiratory disease.[36,37] Most were uncomplicated, but one required prolonged ventilation following CD.[40]

Reduced neck flexion and spinal hump may make positioning for intubation challenging. Difficult intubation[41] and respiratory dysfunction[30] are more likely in patients with scoliosis secondary to another disorder.

Respiratory problems are rare if respiratory volumes are greater than 50% of predicted: mortality and morbidity increase with vital capacities less than 1 L.[42] Several respiratory defects may occur (Box 46.2).

#### Neuraxial anaesthesia

An early labour epidural reduces the stress response and ensures time to achieve adequate function if operative delivery required. However, NA can be difficult due to:

- Failure to locate epidural or intrathecal space:
  - Rotation of vertebrae makes identification of midline difficult
  - If surgically corrected, anatomy is distorted causing risk of subdural or intrathecal placement[43,44] (> 5% epidurals following surgical correction)
- Unpredictable anaesthetic block:
  - Short stature and decreased volume of cerebrospinal fluid:[45]
    - Risk high block
  - Abnormal intrathecal spread of hyperbaric local anaesthetic:
    - Although the intrathecal space is usually not affected by surgery,[46] abnormal curvature and rotation affect gravitational spread
    - Positioning or mixing iso- and hyperbaric anaesthetic may overcome[47 48]
  - If surgically corrected:
    - Possible adhesions in epidural space or indentation by instrumentation (20% inadequate subarachnoid block despite locating space).[38,49,50]

In 89 labour epidurals reported in parturients with scoliosis, 96% were successful in non-operated compared to 60% in operated.

Methods to improve success:

- Angle of approach (Figure 46.3)[42,58]
- Level of approach:
  - L5/S1 interspace:
    - 20% of fixations extend to L3/4—potentially more problematic[51]
    - Fusion unlikely to involve L5/S1[46]
  - Caudal epidural[52]
- Guided approach—prepuncture ultrasound[53] (see Chapter 54):
  - Assess vertebral rotation (asymmetry of transverse processes), guiding needle direction[54]
  - If surgically corrected:
    - Identify lower extent of fixation; may not correspond to scar[55]
    - Spinal instrumentation: lateral marker of midline[56]

**Table 46.1** Aetiology of scoliosis with summary of anaesthetic considerations

| | Aetiology | Considerations | |
|---|---|---|---|
| Vertebral anomalies | Congenital defects, e.g. hemivertebrae | Ensure isolated defect rather than part of syndrome | |
| | Velocardiofacial[30] | Facial dysmorphism, difficult airway<br>Cardiac defects 75%<br>Thymic dysplasia, immune defects | |
| | VACTERL syndrome[31] | Difficult airway<br>Cardiac defects | |
| | Spina bifida[32] | Pelvic abnormalities, CD likely<br>Risk inadvertent dural puncture with epidural<br>Tethered cord, risk trauma with spinal<br>Previous spinal surgery common<br>Possible shunt for hydrocephalus | |
| Osteochondrodystrophies | Achondroplasia | See 'Achondroplasia' and 'Osteogenesis Imperfecta' in main text | |
| | Osteogenesis imperfecta | | |
| Neurological | UMN | Cerebral palsy | Scoliosis |
| | LMN | Postpolio syndrome[32] | Respiratory impairment, sensitivity to opioids and anaesthetic agents<br>Bulbar dysfunction, aspiration risk |
| | | Spinal muscular atrophy[32] | Respiratory muscle weakness, sensitivity to NDMR<br>Hyperkalaemia with suxamethonium |
| | Other | Syringomyelia[33] | Hyperkalaemia with suxamethonium<br>Prolonged neuromuscular block with NDMR<br>Aspiration risk if syringobulbia<br>Deterioration with increased ICP, e.g. pressor response to intubation |
| | | Neurofibromatosis[34] | Spinal cord neuromas; relative contraindication to NA<br>Raised ICP<br>Respiratory impairment<br>Associated phaeochromocytoma |
| | | Friedreich (spinocerebellar) ataxia[34] | Hyperkalaemia with suxamethonium<br>Unpredictable response to NDMR<br>Respiratory muscle weakness<br>Associated cardiomyopathy, arrhythmias, diabetes mellitus<br>Aspiration risk |
| Muscular | Muscular dystrophy | See 'Muscular Dystrophy' in main text | |
| Infection | Tuberculosis (Pott disease) | Respiratory impairment | |
| Connective tissue disease | Marfan syndrome | See Chapter 41 | |
| | Ehlers–Danlos syndrome | See 'Ehler-Danlos syndrome' in main text | |

CD, caesarean delivery; ICP, intracranial pressure; LMN, lower motor neuron; NA, neuraxial anaesthesia; NDMR, non-depolarizing muscle relaxants; UMN, upper motor neuron; VACTERL, Vertebral, Anal, Cardiac, Tracheo-oEsophageal fistula, Renal, Limb.

Data from various sources (see references).

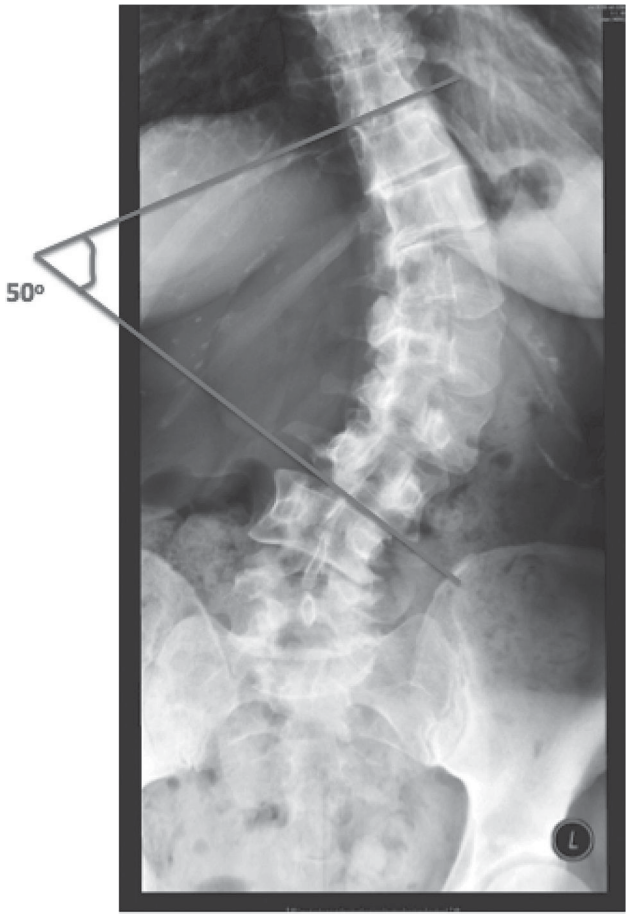

**Figure 46.2** Severity of scoliosis can be described by Cobb angle. This X-ray demonstrates a severe thoracolumbar scoliosis (Cobb angle of 50°) with an apex at L2, with marked rotation and convexity to the left.

- Continuous spinal anaesthesia (CSA):[49]
  - Ability to titrate:
  - Reduces cardiovascular and respiratory compromise
  - Control block height
- Dural puncture epidurals:[57]
  - Puncture dura (25 G needle through epidural needle), without injecting intrathecal anaesthetic. Improves quality and adequacy of epidural block in parturients without scoliosis, probably by direct spread of local anaesthetic to subarachnoid space.

**Box 46.2** Respiratory defects associated with scoliosis

- Reduced lung volumes
- Reduced compliance
- Restrictive defect
- Hypoxaemia
- Increased pulmonary vascular resistance
- Pulmonary hypertension
- Cor pulmonale

## Summary of anaesthetic considerations

### *Antenatal*

- Assess specific co-morbidities (secondary scoliosis (Table 46.1))
- Cardiology:
  - Electrocardiogram (ECG):
    - Right atrial dilatation or ventricular hypertrophy
  - Echocardiography:
    - Right ventricular hypertrophy or pulmonary hypertension
- Respiratory:
  - Pulmonary function tests
- Anaesthetics:
  - Spinal anatomy:
    - Previous radiological imaging
      - Operative report from spinal surgery
    - Ultrasound assessment: lower extent of scoliosis or operative correction
  - Discuss labour and delivery analgesia and anaesthesia:

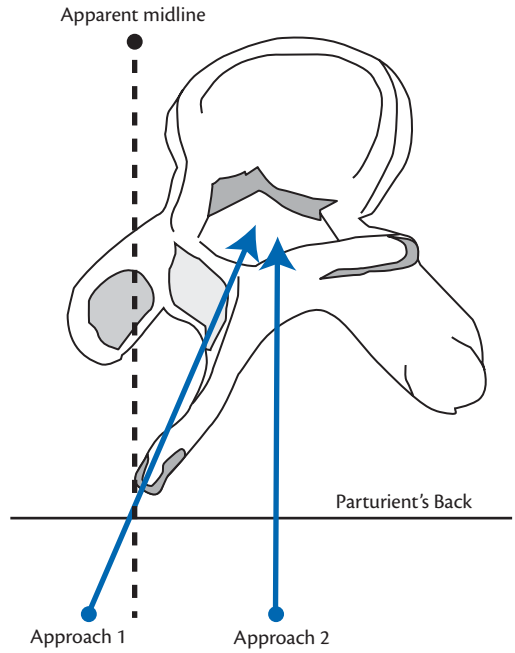

**Figure 46.3** Suggested approach to epidural space in parturients with scoliosis. Lumbar vertebra in a parturient with scoliosis, convexity is to the right of apparent midline. The vertebra is rotated, with a wider angle between the transverse and distorted spinous process on the convex (right) side.

*Approach 1:* aim towards the convexity of the scoliosis, in-line with spinous processes. Advantage: starting in the apparent midline and approaching through familiar tissue planes.

*Approach 2:* approach via the paramedian route, away from the midline on the side of convexity; advance needle onto lamina, prior to '*walking off*'. Advantages: a familiar perpendicular approach and aiming for larger interlaminar space.

- Potential technical difficulties with insertion, increased risk of failure and complications with NA (especially following operative repair)
- Explore patient concerns and wishes.

***Peripartum***

- Establish early labour epidural:
  - Assess effectiveness
  - Actively manage
  - Titrate anaesthetic, use low-dose local anaesthetic with opioid—high blocks may precipitate cardiovascular/respiratory deterioration if no functional reserve
- If GA:
  - Exclude associated MH risks with secondary scoliosis
  - Anticipate difficult intubation and ventilation.

***Postpartum***

- Severe cardiorespiratory compromise:
  - Invasive arterial monitoring
  - Manage in high dependency unit.

If secondary scoliosis, please see Table 46.1 for additional specific anaesthetic considerations.

## Myopathies

A myopathy is a primary disease of muscle. Causes of myopathy are:

- Inherited:
  - Muscular dystrophies
  - Myotonia
  - Congenital:
    - Central core
    - Nemaline
    - Centronuclear
  - Familial periodic paralysis
  - Metabolic:
    - Glycogen storage
    - Lipid metabolism
    - Mitochondrial
    - Myoadenylate deaminase (MADA) deficiency
- Acquired:
  - Inflammatory:
    - Dermatomyositis, polymyositis, inclusion body myositis
  - Endocrine:
    - Thyroid, adrenal
  - Metabolic:
    - Hypokalaemia, hypocalcaemia, hypercalcaemia
  - Drug induced:
    - Glucocorticoid, alcohol
  - Infectious:
    - Human immunodeficiency virus (HIV)
  - Paraneoplastic
  - Critical illness.

### Anaesthetic implications

#### Antenatal

- Multidisciplinary input:
  - Cardiology
    - Electrocardiography, 24-hour tape, echocardiography
    - Implantable pacemaker or defibrillator
    - Reduced exercise tolerance:
      - Skeletal muscle weakness
      - Respiratory insufficiency
      - Cardiomyopathy
  - Respiratory:
    - Restrictive respiratory defect:
      - Pulmonary function tests
    - Associated sleep apnoea:
      - Screening questionnaire (e.g. STOP BANG[59])
      - Sleep studies
    - Presence of pulmonary hypertension:
      - Echocardiography
  - Anaesthetic:
    - Consider and discuss implications of myopathy
    - Agree anaesthetic plan for delivery.

#### Peripartum

- Assess progression of symptoms with pregnancy
- Increased incidence of assisted delivery or CD:
  - Early senior anaesthetic review
  - Consider early labour epidural
- CD:
  - Titratable NA where possible:
    - Avoid high block; may precipitate respiratory compromise
  - Reduce risk of rhabdomyolysis with GA:
    - Avoid suxamethonium, caution with volatile agents
    - Consider non-depolarizing muscle relaxants (NDMRs) and total intravenous anaesthesia
    - Purge anaesthetic machine
    - Measure serum potassium and CK perioperatively, continue cardiac monitoring into recovery period
    - Dantrolene immediately available
  - Prepare for difficult intubation.

### Postpartum

- Anticipate respiratory compromise:
  - Multimodal analgesia for operative delivery:
    - Opioid sparing
    - Consider postoperative epidural analgesia
    - Consider tranversus abdominis plane block
  - High dependency
  - Invasive arterial line, monitoring adequacy of ventilation
  - Respiratory physiotherapy.

Despite different underlying causes, all myopathies have similar anaesthetic considerations (Table 46.2). Specific considerations for different causes of myopathy are discussed in their respective sections below.

## Risk of malignant hyperthermia with myopathies

The pathophysiology of rhabdomyolysis in myopathies differs to MH;[60] the two do not appear to be linked. In myopathies, the muscle membrane integrity is unstable and even in the resting state can lead to increased serum potassium and CK release. Depolarizing muscle relaxants and halogenated agents can further stress the membrane causing rhabdomyolysis and hyperkalaemia. The exceptions are myopathies involving the RYR1 receptor, which are associated with MH: central core disease (CCD) and King–Denborough syndrome.[61,62]

Consensus is that suxamethonium should be avoided in all myopathies.[63,64] There is limited evidence to quantify risk of volatile agents; use an alternative technique where possible to avoid MH risk, that is, NA or total intravenous anaesthesia.

## Muscular dystrophies

This is a collection of inherited degenerative muscle disorders which, depending on the specific genetic defect, lead to progressive weakness of variable distribution and severity. The progressive nature and age of onset mean that they may first present peripartum. Molecular genetics are refining the traditional clinical classification (Box 46.3)[65] and each has different anaesthetic considerations (Table 46.3).

**Table 46.2** Anaesthetic implications of myopathy, in general

| System | Manifestation | Implication |
|---|---|---|
| Airway | Dysmorphia | Difficult intubation |
| | Bulbar involvement | Aspiration risk |
| Respiratory | Muscle weakness | Respiratory failure |
| | Associated scoliosis | See 'Scoliosis' in main text |
| Cardiovascular | Cardiomyopathy or conduction defects | Arrhythmias<br>Cardiac failure |
| Musculoskeletal | Unpredictable rhabdomyolysis with suxamethonium or volatile agents | Hyperkalaemia<br>Myoglobulinuria |

**Box 46.3** Classification of muscular dystrophies

- X-Linked:*
  - Duchenne
  - Becker
  - Emery–Dreifuss (also AD form, chromosome (Chr) 1)[66]
- Limb-girdle:[66]
  - 6 AD subtypes
  - 9 AR subtypes
- Distal:
  - Late onset (AD), e.g. Welander, Markesbery
  - Early onset (mostly AR), e.g. Miyoshi, Nonaka, Laing (AD)
- Congenital (mostly AR), e.g. Fukuyama, muscle–eye–brain disease, Walker–Warburg, merosin-deficient, merosin positive, integrin deficient
- Other:
  - Fascioscapulohumeral (AD), Chr 4
  - Oculopharyngeal (AD), Chr 14
  - Myotonic dystrophy:
    - Type 1, Chr 19
    - Type 2, Chr 3

*Parturients who are carriers may suffer mild disease.[64]

Data from various sources (see references).

## Other myopathies

### Congenital myopathies

This heterogeneous group[63,71,80–82] of over 40 different disorders (autosomal recessive (AR), AD, or X-linked[80]) present with neonatal hypotonia and muscle weakness.[64] Cardiac involvement is rare but reported.[63] Nemaline myopathies are associated with dysmorphic features that may cause difficult intubation (e.g. high-arched palate, mandibular abnormalities).[82,83] Central core disease is a result of AD or AR abnormality of RYR1 and is associated with MH.[61,84]

### Metabolic myopathies

Metabolic myopathies are inborn errors of metabolism that affect myocyte adenosine triphosphate (ATP) production (Figure 46.4). Metabolic myopathies are caused by inherited enzyme abnormalities: either defects in the conversion of glycogen to pyruvate, fatty acids to acetyl CoA, or in the respiratory chain.

### Glycogen storage disorders

There are 11 enzyme disorders of glucose (glucose-6-phosphate) metabolism (type I—XI),[85] leading to abnormal deposition of glycogen. Collectively known as glycogen storage disorders (Table 46.4) they present with exercise intolerance; resting energy production is usually sufficient.

### Lipid metabolism disorders

Lipid metabolism disorders (Table 46.5) are a result of failure in processing fatty acids. They present during periods of starvation or physiological stress, as a result of defects in the following:[96]

**Table 46.3** Muscular dystrophies and anaesthetic implications

| Dystrophy | Characteristics | Implications |
|---|---|---|
| Duchenne or Becker[67] | X-linked, 12% carriers have skeletal muscle weakness; 18% cardiac abnormalities, e.g. dilated cardiomyopathy (7%), arrhythmias<br>Phenotypically similar to limb-girdle[66] | Consider screening ECG, Holter monitoring, echocardiography |
| Limb-girdle[68–70]<br>prevalence 8/million[66] | Pelvis and shoulder, wasting and weakness<br>Restrictive respiratory impairment<br>Cardiomyopathy (some subtypes only)[66]<br>Conduction defects | Risk of deterioration peripartum (>50%)[71]<br>Likely require assisted VD or CD because of pelvic involvement (>50%)[71] |
| Fascioscapulo-humeral[72,73]<br>prevalence 8/million[66] | Usually presents in childhood >90% affected by age 20<br>Asymmetrical facial weakness, especially orbicularis oris and oculi. Shoulder girdle weakness<br>Legs affected later (10% wheelchair bound) | Relatively less cardiomyopathy and conduction defects,[74] although described[66,73]<br>Bulbar and respiratory muscles relatively spared[73] |
| Emery–Dreifuss[75–77] | Childhood onset<br>Tendon contractures of:<br>Achilles, elbow, posterior cervical; predates weakness[66]<br>Humeral and peroneal weakness and wasting<br>Cardiomyopathy (age < 30)[76]<br>Arrhythmias (97%) including conduction blocks, VT, VF, sudden death | Contractures limit neck movement: difficult intubation<br>Risk of intracardiac thromboembolic disease, may require anticoagulation[77]<br>Often need implantable cardiac defibrillator<br>Consider echocardiography |
| Oculopharyngeal[66,78] | Extraocular muscles<br>Ptosis<br>Weakness neck, proximal arms<br>Dysphagia | No case reports<br>Typical onset after child-bearing age[78]<br>Aspiration risk |
| Congenital[79]<br>prevalence 25/million[66] | Heterogeneous group<br>Hypotonia, weakness at birth<br>Weakness non-progressive<br>Cardiac involvement unusual<br>May affect intelligence | Respiratory muscle weakness<br>Aspiration risk |

CD, caesarean delivery; ECG, electrocardiogram; VD, vaginal delivery; VF, ventricular fibrillation; VT, ventricular tachycardia.

Data from various sources (see references).

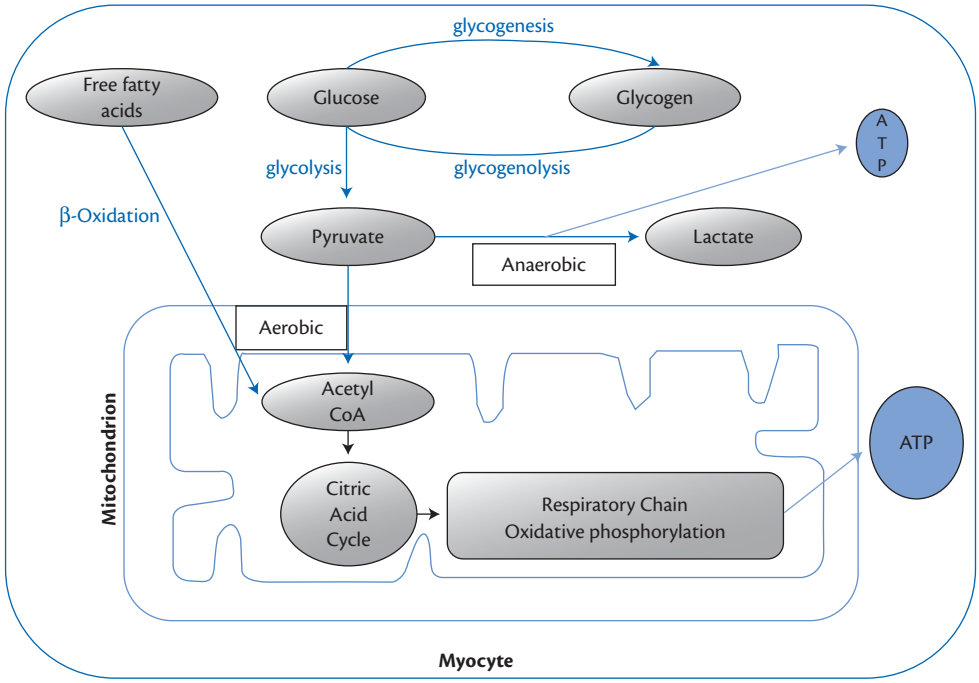

**Figure 46.4** Normal myocyte adenosine triphosphate (ATP) production.

**Table 46.4** Adult presentations of glycogen storage disorders and anaesthetic implications, all AR

| Glycogen storage disease | Features | Implications | Case reports |
|---|---|---|---|
| II Pompe[86]<br>(acid maltase deficiency) | Incidence 1/40,000[86]<br>Glycogen abnormally deposited in all cells<br>Dysphagia<br>Macroglossia<br>Obstructive sleep apnoea<br>Cardiac impairment<br>Progressive muscular weakness<br>Scoliosis | Aspiration<br>Difficult intubation<br>Opioid sensitivity<br>Arrhythmias<br>Cardiac failure<br>Slowly progressive respiratory failure<br>See section 'Scoliosis' in main text | 1 parturient<br>2 pregnancies<br>1st pre-eclampsia and IUGR,<br>CD at 27 weeks: neonatal death<br>2nd uncomplicated CD with CSE[86] |
| III Cori–Forbes[85,87–90]<br>(debranching enzyme deficiency) | Incidence 1/100,000[87]<br>Onset 3rd–4th decade<br>Hepatic, myocardial, erythrocyte, leucocyte, skeletal muscle involvement<br>Risk of hypoglycaemia with starvation<br>Ketosis and lactic acidosis with physiological stress, including pregnancy<br>Risk intrauterine death<br>Associated with hepatic adenomas | **Screen**: echocardiography,<br>liver function tests<br>**Prevent hypoglycaemia**: cornstarch,<br>IV dextrose,<br>nocturnal NG feed<br>**Labour or CD**:<br>Consider invasive arterial pressure monitoring<br>Monitor serum lactate | 6 parturients with 9 deliveries<br>4 CD[85,87,89,90]<br>1 stillbirth 28 weeks[90]<br>1 emergency CD for fetal distress at 34 weeks, following maternal hypoglycaemia associated with coma and seizures[89] |
| IV Anderson<br>(branching enzyme deficiency) | Most commonly an isolated myopathy | | No reports |
| V McArdle<br>(phosphorylase deficiency[91–94]) | Exercise intolerance<br>Muscle cramps<br>Myoglobinuria with exercise (50%)[95]<br>Rhabdomyolysis, associated renal impairment (27%)[95]<br>'Second-wind' effect as muscle switches to alternate substrate[94] | Pregnancy and delivery usually well tolerated | 16 parturients with 24 pregnancies[91–94]<br>2 assisted deliveries<br>5 CD<br>2 worsening muscle cramps<br>1 mild myoglobinuria post delivery |
| VII Tarui<br>(phospho-fructokinase deficiency)<br>(Also X, XI) | Presentation similar to McArdles[96]<br>Tarui is associated with haemolysis | | No reports |

I and VI have no associated myopathy.

VIII and IX are X-linked.

AR, autosomal recessive; CD, caesarean delivery; CSE, combined spinal–epidural; IUGR, intrauterine growth restriction; IV, intravenous; ng, nasogastric.

Data from various sources (see references).

- Transport of long chain fatty acids across mitochondrial membrane (e.g. carnitine-palmitoyl-transferase deficiency—types 1 and 2)
- Transport of carnitine into the cell (e.g. carnitine transporter deficiency)
- Enzymes responsible for β-oxidation (e.g. acetyl-CoA dehydrogenase).

## Mitochondrial myopathies

This is a heterogeneous group[96,110–115] of over 100 different defects in the respiratory chain.[113] Parturients may not be able to meet the increased energy demands of pregnancy (20% increased oxygen consumption) or labour (63% increase) leading to lactic acidosis.[112]

Depending on severity of the defect it may cause multiorgan dysfunction, especially in organs with higher energy requirements; brain, muscle, and heart, for example, MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes).[112]

### *Anaesthetic Considerations*

- Antenatal:
  - Baseline: renal, liver function, clotting studies, glucose, lactate
- Peripartum:
  - Monitor serum lactate
  - Supplementary oxygen
  - Early labour epidural (25% reduction oxygen consumption)
  - Elective CD avoids increased labour oxygen consumption
  - Prevent hypothermia:
    - Shivering increases oxygen consumption
  - Avoid lactate-containing crystalloid solutions

**Table 46.5** Lipid metabolism disorders and anaesthetic implications

| | Presentation | Cases | Implications |
|---|---|---|---|
| **Carnitine-palmitoyl-transferase (CPT) deficiency**<br>Two enzyme complexes CPT 1 on outer and CPT 2 on inner mitochondrial membrane | Commonly presents in childhood with hypoketotic hypoglycaemia, hepatomegaly, seizures and cardiomyopathy<br>Adult presentation: most commonly myopathy after prolonged exercise<br>May be associated with rhabdomyolysis, myoglobinuria[96] | 8 parturients, 10 pregnancies:<br>2 with CPT 1[97,98], 4 with CPT 2[99–101,102]<br>2 unknown[103,104]<br>2 first presented in pregnancy[97,98]<br>6 term VD[97,99,100,102–104], 1 induction 34 weeks<br>**Labour analgesia and VD:**<br>1 spinal[104]<br>1 CSE,[102] 2 epidurals,[99,100]<br>All: IV glucose during labour<br>4: increased CK,<br>1: hypoglycaemia,<br>1: myoglobinuria<br>**3 CD:**[98,101,103]<br>1 spinal, 2 anaesthetic not described<br>1 abruption, preterm labour 26 weeks,[101]<br>1 massive haemorrhage, hysterectomy, renal replacement therapy to treat metabolic acidosis[98] | Prevent hypoglycaemia, hypothermia<br>Early labour epidural or elective CD<br>Hydration reduces risk of renal impairment if myoglobinuria<br>Monitor CK<br>Check liver function and clotting<br>(HELLP syndrome from associated fatty liver)[98] |
| **Carnitine transporter deficiency**<br>Systemic (hepatic, cardiac) or isolated skeletal disease[105]<br>AR inherited carnitine transporter defect<br>OCTN 1 and 2 genes[106] | 50% present as infants with hypoketotic hypoglycaemia, hepatomegaly, hepatic encephalopathy<br>50% present ages 1–7 with cardiomyopathy ± progressive muscle weakness<br>Can present as sudden death or remain asymptomatic[107] | Serum carnitine decreases with pregnancy, symptoms may progress intrapartum with significant deterioration[105,107–109]<br>1 uncomplicated CD: OCTN 2 deficiency, anaesthetic technique not described[106] | Treat: carnitine supplementation<br>Screen: liver, cardiac involvement<br>Prevent: hypoglycaemia, hypothermia<br>Early labour epidural or elective CD |

AR, autosomal recessive; CD, caesarean delivery; CK, creatine kinase; CSE, combined spinal–epidural; HELLP, Haemolysis, Elevated Liver enzymes, Low Platelets; IV, intravenous; VD, vaginal delivery.

Data from various sources (see references).

- Postpartum:
  - Ensure good postoperative analgesia.

Both local and general anaesthetic agents have been used successfully in mitochondrial myopathies,[113] but theoretically some could adversely affect the respiratory chain (e.g. propofol infusion syndrome).[112]

### Myoadenylate deaminase deficiency

Myoadenylate deaminase (MADA)[96,116] is unique to skeletal muscle and catalyses conversion of adenosine monophosphate to inosine monophosphate. A defect in this enzyme is present in up to 2% of the population[96] and affects muscle ATP availability. Although often asymptomatic, MADA may present with exercise intolerance, cramps, progressive weakness, exertional myoglobinuria, and rhabdomyolysis.[116] There is a report of two uncomplicated vaginal deliveries (VDs) in one parturient.[116]

### Idiopathic inflammatory myopathies

Polymyositis and dermatomyositis are autoimmune-mediated diseases, characterized by inflammatory muscular infiltrates, proximal muscle weakness, abnormal electromyography, and increased serum CK. They can occur in isolation or in combination with other autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, or systemic sclerosis.[117] Myositis has a bimodal age distribution peaking at 10–25 and 30–60 years, with a prevalence of 2.5–10/100,000.[118] A heliotrope (purple) perioribital, butterfly rash is typical of dermatomyositis, 20% are associated with malignancy.

#### *Obstetric implications*

Fetal outcome is related to maternal disease activity and is worst in parturients presenting with myositis for the first time in early pregnancy.[117]

- Outcome is better when in remission (72% healthy)[117]
- Active disease:[117]
  - Fetal loss, 43%[117]
  - Intrauterine growth restriction (IUGR), 33%[117]
  - Premature delivery.

Theoretically proximal muscle weakness may increase assisted or CD rates, but this is not reported in the limited case literature. Uterine muscle is not involved.[64]

Management of acute disease is challenging as many drugs used for treatment are contraindicated in pregnancy. Corticosteroids appear relatively safe and immunoglobulin therapy has been used successfully.[119]

### *Anaesthetic implications*

There is only one report discussing the anaesthetic management of a parturient with myositis.[120] There is no evidence that one anaesthetic technique is superior.

## Myotonic dystrophy

Myotonic dystrophy (type 1) is the commonest cause of myotonia (delayed muscular relaxation). The incidence in Europe is 3–5/100,000.[121] Also known as myotonia dystrophica, myotonia atrophica, or Steinert disease, there is an inherited defect of the myosin kinase gene in skeletal, smooth, and cardiac muscle. The condition is caused by an unstable trinucleotide code (CTG) on chromosome 19,[121] the defect is amplified by meiosis; offspring have a greater number of repeated CTG sequences. Because of this, myotonic dystrophy demonstrates anticipation: subsequent generations are affected at an earlier age by more severe disease.

Subtypes of myotonic dystrophy are classified by age of onset: congenital, childhood, adult, or late.[121] Adult onset (classical disease) is most relevant to obstetrics (Box 46.4).

There are 27 reports of anaesthesia for myotonic parturients (Box 46.5).[122–138] Maternal diagnosis is frequently made only after the congenital form is found in offspring.[129,130,133,137] These are high-risk patients. There was a 24% incidence of postpartum haemorrhage (PPH), abnormal placentation, and postoperative respiratory complications, as well as a parturient suffering arrhythmia with cardiogenic shock.[127] Table 46.6 presents methods of mitigating risks.

The disease process is distal to the neuromuscular junction therefore NA and NDMR will not improve myotonia. Treatment of a crisis (generalized myotonia, masseter spasm, chest rigidity, arching of spine) is with quinine, procainamide, or phenytoin.[139] Localized myotonia may be treated with local anaesthetic infiltration, for example, abdominal muscles stimulated with diathermy or uterine myotonia.[122,132]

Anaesthetic considerations are similar for parturients with non-dystrophic myotonias (Table 46.7), although cardiac risks and uterine myotonia are not seen.

## Connective tissue disease

### Ehlers–Danlos syndrome

Ehlers–Danlos is a group of genetically inherited collagen diseases. Collagen is a product of 19 proteins, coded for on 15 different chromosomes: disease severity, organ involvement, and clinical manifestations depend on the specific genetic defect.[149] Shared characteristics include joint hypermobility, tissue fragility with poor wound healing, and easy bruising and bleeding. There are two classifications based on clinical and genetic findings.

- Berlin classification:
  - Types I—XI
- Villefranche classification:[150]
  - Common subtypes, prevalence:[149]
    - Classical (formerly type I and II), 1/20,000–40,000
    - Hypermobility (formerly type III), 1/10,000–15,000 (*some authorities suggest this is a spectrum of joint hypermobility syndrome)*

**Box 46.4** Features of myotonic dystrophy (adult onset)

**First diagnosis 20–50 years**

- Skeletal muscle:
  - Progressive weakness and wasting:
    - Facial:
      - Ptosis
      - Masseter and temporalis
    - Accessory respiratory muscles, e.g. sternocleidomastoid
    - Distal limbs
  - Myotonia, e.g. inability to relax grip
  - Stiffness improving with repetitive movement:
    - 'Warm-up phenomenon'
  - Raised serum creatine kinase
- Smooth muscle:
  - Dysphagia
  - Uterine myotonia
- Cardiac:
  - Arrhythmias, can be exercise induced
  - Cardiomyopathy
  - Sudden death
- Respiratory:
  - Progressive restrictive defect
  - Aspiration risk
- Cataracts
- Frontal balding
- Endocrine:
  - Gonadal hypotrophy
  - Hypothyroidism
  - Diabetes mellitus
- Low intelligence quotient
- Premature death, aged 48—60

**Obstetric implications**

***Increased risk***

- Spontaneous abortion (uterine myotonia)
- Genetic inheritance with anticipation:
  - Neonatal myotonic dystrophy
  - Consider:
    - Preconception counselling
    - Genetic screening of fetus
    - Medical termination
- Weakness and myotonia:[122]
  - Possible first presentation[123]
  - Progressive disease, possible previous uncomplicated delivery[122]

- Polyhydramnios
- Preterm labour

***Peripartum***

- Labour exacerbates weakness and myotonia
- Risk fetal malpresentation

***First stage:***

- Slow progress; abnormal uterine contractions, slow cervical dilatation:
  - Likely require oxytocin augmentation
- May be rapid: uterine functional incompetence

***Second stage:***
