- Ineffective uterine contractions
- Maternal muscular weakness and fatigue
- Muscular stiffness may make vaginal delivery (VD) difficult
- Often require assisted delivery

***Third stage:***

- Retained placenta
- Abnormal placentation, e.g. accreta
- Uterine atony and postpartum haemorrhage (PPH) risk

### Anaesthetic implications

***Antenatal***

- Cardiology:
  - Electrocardiography, 24-hour tape, echocardiography
- Respiratory:
  - Pulmonary function tests
- Endocrine:
  - Thyroid function
  - Diabetic screening
- Obstetric:
  - Assess for abnormal placentation (ultrasound/MRI)
  - Consider neonatal involvement and availability of care required
- Anaesthetic:
  - Consider and discuss implications of myotonia, agree anaesthetic plan for delivery—consider early labour epidural

***Peripartum***

- Temperature (prevent hypothermia, monitor for MH):
  - Monitor continually
  - Active warming
- Be prepared for PPH
- If requires GA:
  - Avoid suxamethonium—consider rapid sequence intubation with rocuronium
  - Monitor peripheral nerve stimulator
  - Avoid anticholinestereases—consider sugammadex for reversal of rocuronium

***Postpartum***

- Postoperative respiratory failure:
  - Postoperative analgesia:
    - Multimodal, opioids sparing
      - Consider continuing epidural postoperatively
      - Consider tranversus abdominis plane block
  - High dependency:
    - Consider invasive arterial monitoring
  - Respiratory physiotherapy

Data from various sources (see references).

  - Vascular (formerly type IV), 1/100,000—200,000
- Rare subtypes (<100 cases worldwide). Few reports, but available information suggests these are high risk and to manage as vascular subtype:[150]
  - Kyphoscoliotic
  - Arthrochalasia
  - Dermatosparaxis

Common subtypes are inherited in an AD manner and share similar obstetric and anaesthetic implications. The vascular subtype has additional risks.

### Obstetric implications

- PPH 20%
- Poor wound healing, abnormal scar formation (episiotomy or caesarean) 46%
- Uterine (15%) or rectal (11%) prolapse
- 50% neonatal disease.[151]

### Anaesthetic implications

- General considerations:
  - Bleeding or easy bruising, no specific associated coagulation defect:
    - Anticipate PPH
  - Friable skin, care with pressure points
  - Deep venous thrombosis risk (4.2%)[151]
  - Chronic joint pain—complex pain management
  - Resistance to local anaesthetic agents[149]
  - Arrhythmias (autonomic dysfunction, conduction defects)
  - Valvular heart disease
- Neuraxial anaesthesia—consider:
  - Reducing risk of epidural haematoma: spinal (smaller needle), epidural (flexible catheter)
  - Combined spinal–epidural (CSE)

**Box 46.5** Anaesthetic management for 27 parturients with myotonic dystrophy

- Two VDs:[124,133]
  - Uncomplicated with epidural[124]
  - Forceps delivery[133]
- 25 CD:
  - Five elective[126,130,136,137]
  - Nine emergency[123,125,129,131,132,134,135,138]
  - Rest undisclosed
- Anaesthetic technique:
  - Seven GA[123,132,135,137,138]
  - Three spinal[122,132] (one converted to GA for haemorrhage)[132]
  - Three epidural[129,131,136]
  - Three CSE[126,128,134]
- Complications (N = 25) (some > 1):
  - Four uncomplicated[128,129,131,134]
  - Six haemorrhage[122,123,130,132]
  - Six abnormal placentation[122,123,125,130,132]
  - Three hysterectomy[123,130,132]
  - Four uterine atony[122,123,129,132]
  - Four postoperative pneumonia[123,126,133,137]
  - Two postoperative ventilatory failure requiring reintubation[133,135]
  - One required supplementary oxygen postoperatively[138]
  - One masseter spasm, vigorous shivering following epidural top-up, intravenous fentanyl for inadequate block—no complications[136]
  - One paroxysmal atrial fibrillation, ventricular tachycardia, cardiogenic shock[127]

Data from various sources (see references).

**Table 46.6** Type 1 myotonic dystrophy, anaesthetic implications, and methods of mitigating risk

| Manifestations | Implications | Mitigate risk |
|---|---|---|
| **Myotonia precipitated by:** | | |
| *Cold* | Avoid hypothermia | Temperature monitoring<br>Warm fluids<br>Forced air warmer |
| *Depolarizing muscle relaxants* | Suxamethonium may cause masseter spasm or respiratory muscle myotonia<br>Difficult intubation and ventilation | Avoid GA if possible<br>Avoid suxamethonium<br>Risk prolonged blockade with NDMR |
| *Anticholinesterases*[140] | Avoid reversal | Use sugammadex for rocuronium[141] |
| *Shivering* | NA-induced[125] | Risk epidural>spinal |
| Respiratory muscle weakness and myotonia | Postoperative respiratory failure<br>Poor secretion clearance | Use sedatives with caution<br>Physiotherapy |
| Obstructive sleep apnoea<br>Abnormal central response to hypoxia, hypercarbia | Sensitivity to opioids, barbiturates[140] | Postoperative monitoring in high dependency<br>Monitor $PaCO_2$ |
| Dysphagia | Aspiration pneumonitis, postoperative respiratory failure | Adequate fasting<br>Antacid prophylaxis |
| Cardiac involvement | Arrhythmias[127]<br>Cardiac failure[127]<br>Sudden death[140] | Monitor ECG postoperatively |
| | Arrhythmia risk with sympathetic response to labour/delivery | Reduce stress response: early labour epidural, elective CD |
| Uterine involvement | Abnormal placentation[130]<br>APH[123]/PPH[122]<br>Increased risk hysterectomy[123,130,132] | Prepare for PPH |

APH, antepartum haemorrhage; CD, caesarean delivery; ECG, electrocardiogram; GA, general anaesthesia; NA, neuraxial anaesthesia; NDMR, non-depolarizing muscle relaxants; $PaCO_2$, arterial partial pressure carbon dioxide; PPH, postpartum haemorrhage.

Data from various sources (see references).

  - Possible prolonged surgery, difficult closure (tissue friability, bleeding)
  - Low-dose spinal component improves cardiovascular stability in presence of autonomic dysfunction
- Stringent testing of sensory block:
  - Possible reduced effectiveness of local anaesthetics[149]
- Monitor lower limb neurological recovery postpartum:
  - Proactively investigate abnormal or persisting neurology suggesting epidural haematoma, MRI
- General anaesthesia—consider:
  - Consent:
    - Risk dental and airway trauma (periodontal disease, friable tissue upper airway)
  - Careful cricoid pressure:
    - Potentially makes intubation more difficult[142]
  - Use airway adjuncts or awake fibreoptic intubation:
    - Reduce manipulation of hypermobile cervical spine, avoids cord trauma
  - Avoid high airway pressures:
    - Risk of pneumothorax
  - Attention to positioning and padding on operating table:
    - Skin friability

**Table 46.7** Other causes of myotonia

| Diagnosis | Inheritance | Features of note[142] |
|---|---|---|
| Myotonic dystrophy type 2 (proximal myotonic myopathy) | AD<br>ZNF9<br>Chr 3 | Proximal weakness. Milder than type 1<br>Similar multisystem involvement and anaesthetic implications |
| *Non-dystrophic myotonias* | | |
| Myotonia congenita<br>Thomson disease[143,144] | AD<br>CLCN1 mutation Chr 7<br>Defect chloride channel | Muscular hypertrophy<br>Not progressive or periodic |
| Myotonia congenita<br>Becker disease[145] | AR<br>CLCN1 mutation | Myotonia predominantly affects lower limbs; weakness upper limbs<br>Progressive, periodic |
| Paramyotonia congenita[146,147] | AD<br>Sodium channel defect SCN4A<br>Possible spectrum of disease with hyperkalaemic periodic paralysis[148] | Generalized myotonia, presents in childhood<br>Stiffness worsens with exercise |
| Hyperkalaemic periodic paralysis[148]<br>(adynamia episodica heredita) | AD<br>Sodium channel defect Chr 17<br>SCN4A | Flaccid paralysis with increased serum potassium, cold or emotional stress<br>Reduce extracellular potassium with diuretics, β-agonists |

AD, autosomal dominant; AR, autosomal recessive; Chr, chromosome.

Data from various sources (see references).

### Vascular (type IV) Ehlers–Danlos

Parturients with vascular subtype have a defect in type III collagen increasing the risk of vascular (aorta, vena cava) or visceral (bowel or uterine) rupture, with a peripartum mortality of up to 25%.[152] Identify this subgroup through genetic screening.

Preconception counselling is advised including discussing the option of medical termination in unplanned pregnancies. There is debate concerning optimum mode and timing of delivery. Both VD and CD have been described successfully.[152,153]

Reduce maternal risk by:

- Delivering in specialist centre
- Screening for existing major vessel disease (e.g. carotid dopplers, echocardiography, MRI)[154]
- Giving desmopressin (DDAVP)[153]
- Early labour epidural
- Extreme caution with labour induction or augmentation[155]
- Invasive blood pressure monitoring
- GA, obtund pressor response at intubation:
  - Use rapid-onset, short-acting opioids (e.g. remifentanil or alfentanil)
- Monitoring postpartum in high dependency area.

### Marfan syndrome

See Chapter 41.

## Autoimmune-associated musculoskeletal disease

Autoimmune function is affected by pregnancy:

- Maternal exposure to fetal antigens
- Proinflammatory effect of oestrogen, stimulating tumour necrosis factor alpha (TNF-α) production[119]
- Susceptibility to viral illnesses: possible trigger for autoimmune disease.

### Rheumatoid arthritis

Rheumatoid arthritis is a multisystem autoimmune disease, characterized by a distal, symmetrical deforming polyarthropathy. Disease-modifying antirheumatic drugs (DMARDs) reduce disease progression and side effects of long-term or high-dose corticosteroid therapy. Many DMARDs are teratogenic: conception should be planned when disease is stable on a low-risk drug. Biological agents (e.g. anti-TNF-α) are being used to treat severe disease; their effects on pregnancy and fetus are unknown.

Symptoms usually improve in 70–80% of rheumatoid patients by the second trimester.[156] Unfortunately nearly all experience a disease flare in the year following delivery.

#### Obstetric implications

- Teratogenic risk, especially unplanned pregnancies
- Balance risk from drug therapy and disease activity
- Hip involvement may require CD.

#### Anaesthetic implications

See Table 46.8 and Table 46.9.

##### *Antenatal*

- Assess:
  - Airway:
    - Predictors of difficult intubation—temporomandibular joint involvement
    - Presence of atlantoaxial subluxation
  - Respiratory:
    - Presence of fibrotic lung disease
    - Any functional deterioration with progression of pregnancy—consider lung function tests
  - Cardiovascular:
    - ECG—exclude conduction blocks
    - Echocardiogram—if functional limitation; exclude pericardial effusion
  - Haematology and biochemistry:
    - Anaemia:
      - Multiple causes—ensure haematinics optimised
    - Thrombocytopaenia—associated splenomegaly and platelet sequestration (Felty syndrome)

**Table 46.8** Complications of rheumatoid arthritis and anaesthetic implications

| System | Manifestation | Implications |
|---|---|---|
| Airway | Temporomandibular involvement | Avoid GA when possible<br>Difficult intubation, reduced mouth opening, mandibular protrusion |
| | Cricoarytenoid involvement | Difficulty passing endotracheal tube<br>Use smaller tube |
| | Atlantoaxial subluxation | Risk spinal cord injury<br>Consider intubation adjuncts |
| Respiratory | Interstitial lung disease (fibrosis) | Respiratory impairment<br>May decompensate with pregnancy or anaesthesia |
| | Pleural effusions | |
| Cardiac | Nodules in cardiac conduction system | Heart block<br>Ventricular dysfunction<br>May decompensate with pregnancy, delivery, or anaesthesia |
| | Pericarditis | |
| | Pericardial effusions | |
| Musculoskeletal | Hip/lumbar spine involvement | Difficult positioning for VD<br>Consider CD<br>NA difficult |
| | Skin at risk from long-term steroid therapy and joint deformity | Skin breakdown and neuropraxias at pressure points |
| Haematological | Anaemia | Reduced reserve if peripartum haemorrhage |
| | Associated Felty syndrome | Rheumatoid with splenomegaly, thrombocytopaenia<br>Risk: epidural haematoma |
| Other | Associated Sjögren syndrome (10%)[157] | Risk: corneal abrasion with GA<br>Consider eye lubrication |
| | Drug therapy | See Table 46.9 |

CD, caesarean delivery; GA, general anaesthesia; NA, neuraxial anaesthesia; VD, vaginal delivery.

Data from various sources (see references).

**Table 46.9** Drugs for autoimmune disease and fetal concerns

| Drug | Fetal and neonatal implications |
|---|---|
| Corticosteroids | Increased rates of:<br>◆ Gestational diabetes<br>◆ Pregnancy induced hypertension<br>◆ Infection<br>◆ Premature rupture of membranes<br>◆ IUGR<br>Risks increase with prednisolone dose > 20 mg |
| Non-steroidal anti-inflammatory drugs | Considered safe to 32 weeks' gestation[156]<br>Risk premature closure ductus arteriosus<br>Potential increased bleeding in neonates |
| COX-2 inhibitors | Avoid: affects neonatal cardiac and renal genesis |
| Hydroxychloroquine | Theoretical risk: oculo- and ototoxicity<br>Appears safe<br>Safe in breastfeeding (2% transferred)[156] |
| Sulfasalazine | Possible increased teratogenicity<br>Considered safe with folate supplementation[156] |
| Azathioprine<br><br>Ciclosporin | Appear safe in pregnancy, but not breastfeeding.[156] Possible IUGR<br>Both can cause leucopenia, thrombocytopaenia. |
| Methotrexate<br>Cyclophosphamide<br>Leflunomide | Not safe in pregnancy or breastfeeding<br>Teratogenic<br>Teratogenicity seen in animal studies, no human cases<br>Current recommendations to avoid for 2 years prior to conception (enterohepatic recirculation)[156] |
| Immunoglobulins (pooled donor IgG) | Safely used to manage various autoimmune conditions in pregnancy<br>Increased thromboembolic risk |
| Biological agents:<br>anti-TNF-α e.g. infliximab, etanercept or B-cell depletion, e.g. rituximab | Limited clinical experience in pregnancy or breastfeeding<br>Current recommendation to avoid[156] |

COX 2, cyclooxygenase 2; IUGR, intrauterine growth restriction; TNF, tumour necrosis factor.

Data from various sources (see references).

  - Disease-modifying medication—ensure no associated neutropaenia or abnormal liver function
  - Thyroid function—common associated autoimmune disease
- Discuss labour and delivery analgesia and anaesthesia:
  - Discuss anaesthetic options, risks and benefits
  - Explore patient concerns and wishes.

### *Peripartum*

- Assess for any deterioration in cardiorespiratory function with advancing pregnancy
- Careful positioning and pressure point care:
  - Reduced joint mobility
    - Assess range of movement prior to NA, do not exceed
  - Increased risk of pressure sores
- If hip involvement, increased likelihood of CD
- May need steroid supplementation
- NA:
  - Technically challenging
- GA:
  - Potential difficult intubation
  - Reduce manipulation and movement of cervical spine
    - Use intubation aids
    - Consider fibreoptic intubation
  - Consider protective eye lubrication (Sjögren syndrome).

### *Postpartum*

- Impaired cardiovascular reserve:
  - Recovery in high dependency area
- Relatively immunosuppressed:
  - Monitor for postoperative infection:
    - Wound
    - Epidural abscess
- Increased thromboembolic risk
- May suffer flare of rheumatoid disease postpartum:
  - Involve rheumatologist in management of immunosuppressive therapy.

## Ankylosing spondylitis

Ankylosing spondylitis is a human leucocyte antigen-B27 associated seronegative spondyloarthropathy, characterized by sacroiliac joint arthritis progressing to spinal fusion, 'bamboo spine'. It is typically a slowly progressing disease, therefore few suffer severe symptoms at child-bearing age.[158] The effect of pregnancy on symptoms is variable: 38% improve, 62% worsen.[158]

### Obstetric implications

Pelvic or hip (30%)[159] involvement may affect VD. Biological agents (i.e. anti-TNF-α) may increase susceptibility to infection.[160]

### Anaesthetic implications

Both GA and NA may be challenging (Table 46.10). There are a few case reports describing different methods of anaesthesia in parturients, all were successful.

- Spinal for emergency CD[161]
- Labour epidural analgesia, fifth attempt[162]
- Labour epidural, easy insertion, topped-up for emergency CD[158]
- Planned CSE (failed to feed epidural catheter)[163]
- Two awake fibreoptic intubations for elective CD[164,165]
- CSA for labour (two failed epidurals, abnormal spread of local anaesthetic).[166]

Although epidurals are possible,[158] one should anticipate difficulty as evidenced by larger studies of anaesthesia for non-obstetric patients.[159] The risk of epidural haematoma[167] and total spinal[168] appears to be greater.

Spinals are probably more reliable than epidurals in patients with ankylosing spondylitis. One retrospective study reported a 77% (10/13) success rate with spinals for lower limb surgery, compared to 0% (0/3) for epidurals.[159]

### *Considerations*

- Labour:
  - Progress may be affected by pelvic or hip disease
  - Epidural analgesia may be difficult or impossible to establish and relatively high risk
  - In emergency, NA and GA may be challenging, placing fetus at risk

**Table 46.10** Ankylosing spondylitis and anaesthetic implications

| System | Manifestation | Implications |
|---|---|---|
| Airway | Temporomandibular dysfunction (10–30%)[160] | Potential difficult intubation. Consider awake fibreoptic |
| | Reduced cervical spine mobility | Difficult airway equipment immediately available |
| | Cricoarytenoid involvement | |
| | Atlantoaxial subluxation (up to 21%)[160] | Potential cervical cord injury with intubation |
| Respiratory | Restrictive defect | May decompensate with pregnancy or anaesthesia |
| | Fibrosis (especially apical) | Consider screening pulmonary function tests |
| Cardiac | Aortic regurgitation (up to 43%)[158] | May decompensate with pregnancy, labour, or anaesthesia. Consider screening ECG, echocardiogram |
| | Conduction defects | |
| Neuraxial | Vertebral fractures: 47% have associated sensory or motor neurological disease, e.g. cauda equina syndrome, nerve root compression[160] | Relative contraindication to NA<br>Document existing neurological findings |
| | Restricted spinal flexion | Difficult NA |
| | Calcification of ligaments | Paramedian approach may be more successful[169]<br>Increased risk epidural haematoma[160]<br>Careful neurological follow-up postpartum |
| Other | Peripheral disease | Care with positioning patient, reduced range of movement |

ECG, electrocardiogram; NA, neuraxial anaesthesia.

Data from various sources (see references).

- Elective CD:
  - Spinal anaesthesia: approximately 75% success; risk of requiring emergency GA if complication
  - Elective awake fibreoptic intubation allows controlled, safe induction, with minimal cervical manipulation; requires compliant parturient.
- For all cases:
  - Difficult intubation equipment should be immediately available.

## Achondroplasia

Achondroplasia is the commonest of over 100 causes of dwarfism with an incidence of approximately 1.5/10,000 live births with an AD inheritance, although 80% are *de novo* mutations.[170] The typical short tubular bones and other features (Table 46.11) are the

**Table 46.11** Features of achondroplasia, anaesthetic implications, and methods to mitigate

| Features | | Implications | Suggestions to mitigate |
|---|---|---|---|
| Cranial abnormalities:<br>Macrocephaly<br>Frontal bossing<br>Mid-face hypoplasia<br>Flattened nose<br>Large mandible<br>Large tongue<br>Short neck[172] | | Difficult ventilation<br>(poor seal with mask)<br>Difficult intubation<br>Risk of obstructive sleep apnoea[172]<br>Reduced neck extension | Prepare for difficult airway<br>Choose endotracheal tube on weight rather than age[173]<br>Consider awake fibreoptic[174]<br>ENT surgeon available for urgent tracheostomy<br>Attention to extubation and recovery |
| Foramen magnum stenosis | | Extreme cases, hydrocephalus | Avoid increased ICP<br>Avoid spinal anaesthesia |
| Atlantoaxial subluxation | | Risk cervical cord injury with hyperextension[173] | Care at intubation |
| Short stature | | Dose of NA unpredictable,<br>risk high block | Use titratable NA, e.g. epidural, CSE, or CSA |
| Pelvis broad and flat with wide iliac wings.<br>Pelvic inlet narrow.[175] | Uterus displaced from pelvis | Head will not engage in pelvis | Cephalopelvic disproportion, likely CD (especially if fetus achondroplastic with macrocephaly)[172] |
| | | Greater encroachment on diaphragm decreasing FRC (exacerbated by short stature) | Elective CD: anaesthetic provided by experienced obstetric anaesthetist<br>Maximal preoxygenation |
| Marked lumbar lordosis and osteophytes | Displaces uterus further into abdominal cavity | Greater aortocaval compression, supine hypotension | Attention to positioning<br>Alpha agonist for hypotension<br>Ensure antacid prophylaxis, adequate fasting |
| | | Increased abdominal pressure, risk of regurgitation and aspiration | |
| | | Increased epidural vein engorgement, risk of IV cannulation with epidural | Use flexible epidural catheter |
| | | Bony landmarks indistinct<br>Reduced lumbar intervertebral spaces<br>NA difficult | Use prepuncture ultrasound<br>Insert low thoracic, rather than lumbar epidural[176] |
| Thoracic scoliosis | | See 'Scoliosis' in main text | |
| Pectus carinatum and rib hypoplasia[170] | | Risk of respiratory compromise | Use titratable NA<br>May require early delivery |
| Short pedicles<br>Thickened laminae<br>Spinal stenosis | | Difficulty threading epidural catheter[177] | Consider paramedian approach[178] |
| | | Increased risk of dural puncture[179] | |
| | | Appropriate dose NA unknown<br>Risk of high block[173] | Use titratable NA, e.g. epidural,[176] CSE, CSA.<br>Possible lower limb neurological deterioration post NA[26] |
| | | Possible lumbar laminectomy for spinal stenosis[180] | Difficult NA, may be inadequate |
| Normal size spinal cord in small vertebral canal[181] | | CSF may not flow freely | Failure to identify intrathecal space, despite being in it<br>Affects local anaesthetic spread, inadequate block[179] |

CD, caesarean delivery; CSA, continuous spinal anaesthetic; CSE, combined spinal–epidural; CSF, cerebrospinal fluid; ENT, ear nose throat; FRC, functional residual capacity; ICP, intracranial pressure; IV, intravenous; NA, neuraxial anaesthesia.

Data from various sources (see references).

result of a mutation in fibroblast growth factor receptor 3, causing failure in endochondral ossification at growth plates.[171]

## General versus neuraxial anaesthetic

Some suggest achondroplastic patients should have a GA for CD, due to concerns over the safety of spinal anaesthesia.[175] There are, however, reports of safe administration of intrathecal anaesthesia, although there is debate about appropriate dosing: in three reported cases, 5 mg bupivacaine produced adequate anaesthesia.[171,182,183] Using a titratable technique (epidural, CSE, or CSA) is an alternative.[182]

The spinal cord appears to terminate at a similar level to the normal population, therefore spinal injection below L3 should not result in cord or conus injury.[184]

There are nine reports describing GA for CD in achondroplastic parturients:[41,174,179,185–189] two after failed NA,[174,185] one awake fibreoptic for predicted difficult intubation,[174] one where intubation was not attempted (spontaneous ventilation with face mask),[185] and one intubation was described as difficult.[188] A retrospective study reported 35 cases without complication.[175]

### Antenatal

- Confirm diagnosis of achondroplasia; ensure not an alternative cause of dwarfism, for example, syndrome or metabolic disorder
- Consider investigating those with history of associated complications:
  - Obstructive sleep apnoea—polysomnography
  - Spinal stenosis—MRI spine
  - Raised intracranial pressure—MRI head
- Airway:
  - Examine for predictors of difficult airway
  - Cervical spine mobility—symptoms of cervical cord compression
- Spinal anatomy:
  - Examine lumbar spine
  - Ultrasound assessment
- Perform neurological examination of lower limbs:
  - Abnormal, consider MRI spine
- Discuss labour and delivery analgesia and anaesthesia:
  - Discuss anaesthetic options, risks and benefits:
    - Potential technical difficulties with insertion: increased risk of high block
    - Increased risk of dural puncture
  - Potential advantages of controlled setting and elective CD
  - Agree on technique if presents as an emergency:
    - If not enough time to establish epidural, are the risks of single shot spinal acceptable?
  - Explore patient concerns and wishes.

### Peripartum

- Increased likelihood of CD
- Non-invasive blood pressure may be difficult because of limb proportions:
  - Consider invasive arterial monitoring
- Care with supine positioning: cardiorespiratory compromise:
  - Relative increased uterine size:
    - Pronounced aortocaval compression
    - Increased respiratory compromise
- If no evidence of lower limb neurology or spinal stenosis, titratable NA technique ideal:
  - Increased risk of difficult or failed insertion
  - Low-thoracic or paramedian approaches may be easier
- Reduce dose of single-shot spinal:
  - Risk of high block
- Anticipate difficult airway:
  - Fibreoptic equipment
  - Ear nose and throat (ENT) surgeon available.

### Postpartum

- If obstructive sleep apnoea:
  - Consider high dependency care
  - Multimodal analgesia to reduce opioids requirements—consider epidural for post CD analgesia.

## Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is the result of a defect in type I collagen, the main provider of tensile strength in bone, ligaments, sclera, and dentine. OI results in a disease spectrum, characterised by multiple fractures, often from trivial injury. It occurs in approximately 1/25,000 pregnancies[190] and is classified into four subtypes on the basis of clinical presentation and inheritance (Table 46.12).[172,190,191]

### Obstetric implications

Pelvic fractures and deformity lead to cephalopelvic disproportion or malpresentation, increasing risk of CD.[172]

### Anaesthetic implications

Most anaesthetic techniques have been successfully reported without complication: general,[193–198] epidural,[191,192,199–201] spinal,[190,191] CSE,[202] and local infiltration (Table 46.13).[192]

**Table 46.12** Subtypes of osteogenesis imperfect

| | |
|---|---|
| **Type I** | Most prevalent |
| Mild | AD inheritance, with incomplete penetrance |
| | Normal stature |
| | Blue sclera (choroid pigment seen through sclera)[192] |
| | Several fractures a year, starting in childhood, decreasing after puberty[193] |
| **Type II** | AR |
| Severe | Multiple *in utero* fractures, deformity |
| | Early fetal or neonatal demise |
| **Type III** | AD and AR |
| Severe | Some suffer fractures *in utero* |
| | Dentinogenesis imperfecta |
| **Type IV** | AD |
| Mild to moderate | Multiple fractures |
| | Short stature |
| | Normal sclera |
| | Multiple fractures, resulting in deformity |
| | Dentinogenesis imperfecta |

AD, autosomal dominant; AR, autosomal recessive.

The classification system for subtypes of OI was originally proposed by DO Sillence:

**Table 46.13** Osteogenesis imperfect: anaesthetic implications and methods of mitigating risks

| Manifestation | Consequences | Method of reducing risk |
|---|---|---|
| Bone fractures with minimal force | Fractures with normal VD (e.g. pubic rami)[192] or assisted VD[172] | Consider elective CD in severe disease<br>Extra padding for positioning[200] |
| | Brittle teeth, may dislodge (dentinogenesis imperfecta)<br>Mandible fractures with minimal force[197] | Avoid GA where possible<br>Consider intubation aids, awake fibreoptic intubation |
| | Potential for fracture with high inflation pressures with non-invasive BP cuff[203] | Consider invasive arterial monitoring[199] |
| | Possible fracture from suxamethonium fasciculations[197] | Avoid GA<br>Use rocuronium for intubation |
| | Vertebral collapse, scoliosis[191] | See 'Scoliosis' in main text |
| Joint hypermobility<br>Odontoid peg hypoplasia[191] | Cervical cord damage with neck hyperextension | Care with intubation<br>Consider intubation aids |
| Blood vessel involvement[191] | Risk: haemorrhage | Prepare for blood loss |
| Uterine muscle involvement | Risk: rupture, tearing, uterine atony[190,192] | |
| Platelet function abnormalities (adhesion and aggregation)[191] | Risk: haemorrhage | History/examination looking for platelet function<br>Avoid NSAIDs |
| | Risk: epidural haematoma | Risk/benefit of NA:<br>Spinal < epidural[204]<br>Use flexible epidural catheter[204] |
| Endocrine and metabolic abnormalities<br>Thyroid activity increased by 50%[197] | Hyperthermia (non-MH)[196]<br>Increased oxygen utilization | Monitor temperature, $EtCO_2$ with GA (exclude MH)<br>Active cooling[199]<br>Supplemental oxygen<br>Check thyroid function |
| Hereditary | Risk *in utero* fractures<br>May influence delivery method | Some evidence delivery mode does not affect fetal outcome[172,202] |
| Otosclerosis and hearing impairment (25–50%)[193] | Challenge with communication | Counsel preoperatively<br>Ensure has hearing aid, as appropriate<br>Alternate communication, e.g. written |

BP, blood pressure; CD, caesarean delivery; $EtCO_2$, end-tidal carbon dioxide; GA, general anaesthesia; MH, malignant hyperthermia; NA, neuraxial anaesthesia; NSAIDs, non-steroidal anti-inflammatory drugs; VD, vaginal delivery.

Data from various sources (see references).

## Antenatal

- History:
  - Previous fractures:
    - Site, mechanism, and frequency—indication of severity of disease
  - Platelet function:
    - Easy bleeding/bruising
- Physical examination:
  - Presence of blue sclera; suggestive of type I and milder disease
  - Petechiae around pressure points, for example, non-invasive blood pressure
- Investigation:
  - Thyroid function
- Discussion:
  - Discuss benefits of the controlled setting of an elective CD in severe disease
  - Risks/benefits of GA versus NA
  - Explore patient concerns and wishes.

## Peripartum

- GA:
  - Prepare for difficult intubation
  - Avoid suxamethonium
- NA:
  - Caution if history of platelet dysfunction
  - Spinal less risk than epidural
- Anticipate and prepare for PPH
- History of platelet dysfunction:
  - Caution with NSAIDs
- Consider:
  - Extra padding for operating table
  - Invasive arterial monitoring
  - Temperature monitoring.

### Postpartum

- NA:
  - Postoperative neurological monitoring of lower limbs
    - Exclude epidural haematoma formation.

## Conclusion

Women with musculoskeletal disease may have their first presentation around delivery, but as most know their diagnosis antenally they generally have the opportunity to be reviewed in an obstetric anaesthetic high-risk clinic. A multidisciplinary approach is essential, along with detailed examination and appropriate investigations. Formal obstetric delivery and anaesthetic plans should be made, discussed, and documented in this challenging group of patients.

# CHAPTER 47

# Endocrine and autoimmune disorders

Mirjana Kendrisic and Borislava Pujic

## Diabetes mellitus

### Definition

Diabetes mellitus (DM) is defined as a clinical and metabolic disorder of the pancreas and characterized by hyperglycaemia.

### Epidemiology

DM is one of the most common chronic diseases worldwide and continues to increase both in numbers and severity. Changing lifestyles of the world population lead to reduced physical activity and increased obesity. According to World Health Organization (WHO) published estimates, the number of people with diabetes in the world is expected to approximately double between 2000 and 2030, based solely upon demographic changes.[1] Prevalence of diabetes in Europe will continue to rise from 8.6% to 10% between 2010 and 2030. Although the highest incidence is registered in developed countries, the largest increase in number of people with diabetes is expected to occur in developing countries.

The main types of DM are type 1 (T1D, insulin-dependent), type 2 (T2D, insulin-independent) and gestational diabetes. All of them may be present during pregnancy. Approximately 87.5% of pregnancies complicated by diabetes are due to gestational diabetes. Prevalence of gestational diabetes in European countries varies from 2.0% to 6.0%. Data from Northern Europe showed less than 4% of gestational diabetes in that region comparing to Southern Europe where more than 6% was estimated. Another 7.5% of pregnant women with diabetes have T1D and the remaining 5% are due to T2D. The prevalence of T1D and T2D continues to rise in pregnant women worldwide.[2]

### Type 1 diabetes

T1D (previously known as insulin-dependent diabetes) is a chronic inflammatory disease in which destruction of the beta-cells in the islets of Langerhans results in insulin deficiency and hyperglycaemia. This type of diabetes, also known as juvenile-onset diabetes, accounts for 10–15% of all people with the disease. It can appear at any age, although commonly under the age of 40, so women of childbearing age may be affected. It is important to know that it is now possible to identify people at risk of future disease accurately, by using islet cell autoantibody assays.

Disease can be triggered by environmental factors such as viruses, diet, or chemicals in people who are genetically predisposed. This type of diabetes is divided into three groups, according to aetiology—autoimmune, idiopathic, and mixed (double):

1. Autoimmune DM is associated with appearance of islet autoantibodies.
2. Idiopathic DM has the clinical features of T1D, but the autoimmune component is not detected.
3. Mixed or double DM is a combination of autoimmunity and characteristics of T2D such as obesity, insulin resistance, and dyslipidaemia.

#### *Pathophysiology of T1D*

**Genetic predisposition for T1D**

T1D is considered to be a heterogeneous disease. To date, several loci at different chromosomes have been linked to T1D susceptibility in humans.[3,4] Population studies confirmed that children with a first-degree relative withT1D have higher risk for the development of T1D and this risk increases further if both parents are affected.[5,6] The risk for offspring of a mother with T1D is 1.3–4%, while the risk for offspring of a father with T1D is 6–9%. It has been suggested that pregnancy may protect the infant from T1D. A possible explanation is that autoantibodies transmitted from the mother with T1D may protect the child from the development of autoantibodies and T1D later in life.[7,8] Such protection could be due to fetal and neonatal exposure to antibody-mediated presentation of autoantigen. The exposure provides a state of immune ignorance against autoantigen or a more efficient elimination of autoreactive T-cell clones, especially in offspring without a high-risk human leucocyte antigen (HLA) genotype.[9] The concordance of T1D between monozygotic twins is high (up to 50%), while between dizygotic twins it is only 10%.[10] However, the lack of 100% concordance shows that some environmental factors increase the risk of developing T1D.

**Islet autoimmunity**

The selective destruction of beta cells of pancreatic islets in T1D is the result of the interaction among beta cells, the immune system, and environmental factors in genetically susceptible individuals. However, the mechanisms which start the changes in this interaction and lead to the development of T1D have not been fully clarified yet. In the beginning of the autoimmune process against beta cells, patients produce several different antigens.[11] After presentation of the antigen by the macrophages to T lymphocytes, cellular

and humoral immune responses are induced. The most important mechanism of cellular response is a decrease in number and function of regulatory T cells. Regulatory T cells are essential for many aspects of immune tolerance, including the suppression of autoimmune responses.

Humoral immune response is represented by islet autoantibodies. Islet cell autoantibodies are strongly associated with the development of T1D. The autoimmune process may persist subclinically in the majority of patients. Pancreatic autoantibodies are commonly present years before the diagnosis of T1D. Childhood onset of T1D is associated with the first signs of islet autoimmunity by the age of 2 years.[12] Risk of progressing to T1D is increased by the number of antibody types, so it rises from 60% to 100% in individuals with three to four antibody types. Clinical symptoms do not appear until up to 80% of cells have been destroyed. Therefore, detection of autoantibodies in the pre-diabetes phase has been most useful.[13–15]

**Environmental factors**

Environmental factors play an important role in the pathogenesis of T1D. The most important factors are infectious, dietary, perinatal, and psychosocial ones. Viral infections, breastfeeding, the early presence or lack of certain foods, birth weight, childhood over-nutrition, and negative stressful events are related to the prevalence of T1D.[16]

Viruses may trigger islet autoimmunity by molecular mimicry with islet antigens. Some viral infections including enteroviruses (especially Coxsackie B virus), rubella, mumps, rotavirus, parvovirus, and cytomegalovirus have long been suggested as potential environmental triggers for the disease.[17]

Cows' milk-based infant formulas and consumption of cows' milk within the first 3 months of life are associated with increased risk of T1D. The gut-associated immune system plays a major role in disease development, probably because of disturbed oral tolerance mechanisms and normal maturation of the gut.[18]

The concept of dietary regulation of autoimmunity cannot be applied only to cows' milk protein, but also to other dietary proteins. Early introduction of gluten-containing foods has been found to be a risk factor for the development of T1D-associated autoimmunity in children with certain genotype of parents with T1D.[19]

## Type 2 diabetes

T2D (previously known as non-insulin dependent diabetes) is the most common form of diabetes, affecting 85–90% of all diabetic cases. This type of diabetes, also known as late-onset diabetes, is characterized by insulin resistance and relative insulin deficiency. T2D is increasingly common throughout the world in younger people and children. Lifestyle factors, such as excess weight, inactivity, high blood pressure, and poor diet, are major risk factors.[20]

### *Genetic Predisposition for T2D*

T2D is a heterogeneous disorder caused by a combination of genetic and acquired abnormalities that affect insulin sensitivity and insulin secretion. At least 36 genes are identified to be associated with a risk of T2D. However, only about 10% of the heritability of T2D can be explained. The concordance of T2D between monozygotic twins is high (34–58%), while the rate of impaired glucose tolerance is up to 100%.[21,22] Despite the statistical significance of genetic data, it is not clinically possible to predict the risk of T2D. To date, most of the discovered gene variants have been linked to beta-cell dysfunction. There is no evidence that genetic variations may cause insulin resistance.

### *Pathogenesis of T2D*

The metabolic changes underlying T2D are insulin resistance, beta-cell dysfunction, and impaired hepatic glucose production. Insulin resistance is defined as the inability of exogenous or endogenous insulin to increase glucose uptake and utilization in an individual compared to the normal population. Possible causes underlying the development of insulin resistance include genetic abnormalities of proteins of the insulin action cascade, fetal malnutrition, and increase in visceral adiposity.[23] T2D is characterized by impaired insulin secretion. Some evidence suggests that a decrease in beta-cell mass contributes to this. Progression of the disease is associated with decline in beta-cell function.[24]

## Gestational diabetes mellitus

Gestational diabetes mellitus (GDM) is defined as glucose intolerance with an onset or first recognition during pregnancy. Pregnant women with GDM are a heterogeneous group. Some of the patients have unrecognized pre-existing T2D and a minority of them has T1D with first onset during pregnancy. This condition may persist after pregnancy leading to a significant risk of developing permanent diabetes.[25] The risk factors for GDM are found in Box 47.1.

About 40–60% of women with GDM do not have any of these risk factors. According to the recent guidelines from areas with significant prevalence, screening of all pregnant women should be done to diagnose patients at risk for GDM.[26]

### *Genetic predisposition and pathophysiology of GDM*

Genetic susceptibility for GDM has not been proven despite the higher risk of hyperglycaemia during pregnancy in patients from families with either T1D or T2D.[27,28] During normal pregnancy, particularly in the third trimester, there is a physiological increase in insulin resistance. Normally, the mother's beta cells can produce additional insulin to overcome the insulin resistance. Patients with GDM are more insulin resistant than pregnant non-diabetic women because their insulin resistance precedes pregnancy and continues to increase in pregnancy.

**Box 47.1** Risk factors for gestational diabetes mellitus

- Family history of T2D
- Maternal age (>35 years)
- Maternal obesity (BMI > 30)
- Ethnicity (African, black Caribbean, South Asian, Hispanic, Middle Eastern origin)
- Polycystic ovarian syndrome
- Past history of GDM or glucose intolerance
- Previous poor obstetric history
- Fetal macrosomia (body weight > 4000 g at term) in previous pregnancy

Data from Working group on gestational diabetes. National guidelines for gestational diabetes. *Duodecim* 2008; 124:1556–1569.

Placental products, such as human placental growth hormone (GH) and tumour necrosis factor alpha (TNF-α), have been suggested to be the mediators of insulin resistance. This effect of placental hormones usually begins 20–24 weeks into the pregnancy. The growing placenta in the third trimester has a greater effect on insulin resistance in patients with GDM. Excessive secretion of proinsulin, is often observed in women with GDM. Persistent insulin resistance leads to beta-cell dysfunction. The precise mechanism still remains unknown because the deficit in beta-cell function is multifactorial and polygenetic.[29]

### Preconceptual care of patients with diabetes

T1D and T2D are associated with a greater risk of congenital malformations and poor pregnancy outcome. Women with diabetes who are planning pregnancy should be informed about the importance of strict glycaemic control, diet, and exercise in the preconception period and the level of haemoglobin (HbA1C) should be maintained below 6.1%. If possible, HbA1C values should be targeted towards normal (3.5–5.5%), although this runs the risk of hypoglycaemia. Pregnancy is not recommended for diabetic patients with HbA1C above 8.6%. Women with diabetes who are hyperglycaemic should be tested for ketones in blood and urine.[30] Guidelines advocate blood glucose self-monitoring and prescription of insulin for better glycaemic control. Metformin has been a safe alternative in patients resistant to insulin or in cases of insulin refusal.[31]

Retinal and renal assessment should be performed preconceptually in diabetic patients. Pregnancy is not recommended for women undergoing islet transplantation. There are insufficient data showing potential adverse effects of immunosuppressive drugs (daclizumab and rapamycin) on pregnancy.

## Clinical presentation of diabetes in pregnancy

Gestational diabetes is usually asymptomatic or the symptoms are mild and not life-threatening to the pregnant woman. Many of the signs of T1D and T2D are similar (Box 47.2).

### Type 1 diabetes and pregnancy

Pregnancy is considered to be a diabetogenic state due to increases in cytokines (TNF-α) and hormones such as cortisol, progesterone, oestrogen, prolactin, and human placental lactogen. Activities of these factors and hormones result in elevation of postprandial glucose levels and decreased insulin sensitivity. Pregnancy in women with T1D is associated with an increased risk of poor maternal and fetal outcome. Complications during pregnancy related to a mother with T1D are hypoglycaemia, diabetic ketoacidosis (DKA), retinopathy, and nephropathy.

#### *Hypoglycaemia*

Avoidance of hyperglycaemia and tight glycaemic control increase the likelihood of insulin overdose and hypoglycaemia. It is recommended that blood glucose levels are maintained higher than 3.9 mmol/L. Nocturnal hypoglycaemia is a relatively common complication of T1D during the first and third trimester. The most severe complication of hypoglycaemia is hypoglycaemic coma, where urgent management is needed.[32]

#### *Diabetic ketoacidosis (DKA)*

DKA is a potentially life-threatening complication in patients with DM. In pregnancy, DKA is usually precipitated by stressful events, such as vomiting, infections of urinary and respiratory tracts, insulin delivery system failure, and poor management of DM. It usually occurs in the later stages of pregnancy.

Relative or absolute lack of circulating insulin and an excess of counter-regulatory hormones (e.g. glucagon) result in DKA. Hyperglycaemia and ketosis develop, leading to polyuria, polydipsia, and dehydration. Although DKA is less frequent in diabetic patients compared to hypoglycaemia, it can result in fatal complications—death (rarely) and fetal demise (reported in up to 35% of cases).

Patients with DKA need aggressive intravenous (IV) isotonic fluid replacement with 15–20 mL/kg/h of normal saline in the first 2 hours.

The average fluid deficit in these patients is around 100 mL/kg and it should be replaced within 24 hours. If possible, 50% of the fluid deficit should be given in the first 12 hours. A fixed rate IV insulin infusion (0.1 unit/kg/h based on estimate of weight) of 50 units human soluble insulin (Actrapid® or Humulin S®) made up to 50 mL with 0.9% sodium chloride solution should be commenced.[33] Total body potassium is decreased, but serum potassium levels are unreliable in DKA. Replacement is commenced if serum potassium is lower than 5 mmol/L. Use of bicarbonate is recommended in DKA at admission only if pH is lower than 6.9. Administration of bicarbonate can increase blood lactate and ketone bodies.[34]

#### *Retinopathy*

The progression of diabetic retinopathy in pregnancy is often associated with poor glycaemic control, hypertension, and duration of diabetes for longer than 15 years. Laser photocoagulation is a proven effective treatment and may protect patients against rapid progressive diabetic retinopathy (PDR). Vaginal delivery is debatable in cases of severe PDR. A multidisciplinary approach is needed for a decision with respect to mode of delivery.[35]

**Box 47.2** Signs and symptoms of diabetes in pregnancy

**Common symptoms**

- Excessive thirst
- Increased hunger
- Frequent urination
- Unusual fatigue

**Less common signs and symptoms**

- Blurred vision
- Dry itchy skin and skin infections
- Impaired healing of cuts or sores
- Tingling or numbness in hands or feet
- Urinary tract infections
- Vaginal infection (usually fungal)
- Psychological symptoms (irritability, lethargy, agitation)

Data from The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus: Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. *Diabetes Care* 1997; 20:1183–1197.

#### *Nephropathy*

Diabetes nephropathy is not a common complication of pregnancy and renal function remains preserved in patients with a normal serum creatinine level and normoalbuminuria. Hypertension is likely to be an aggravating factor in patients with microalbuminuria (albumin excretion is between 30 and 300 mg/day (20–200 mcg/min)). Therefore, intensive antihypertensive therapy is strongly recommended in combination with low-dose aspirin. In patients with macroalbuminuria (albumin excretion above 300 mg/day (200 mcg/min)), risk of pre-eclampsia and preterm delivery is significantly higher.[36]

#### *Pre-eclampsia*

Pregnancies affected by T1D are at increased risk of pre-eclampsia, which might lead to serious complications for both mother and baby. Appropriate metabolic control and antihypertensive therapy are essential for preventing eclampsia.[37]

#### *Impact of T1D on fetal and neonatal outcome*

Strict glycaemic control is needed in early pregnancy during organogenesis, because of a higher risk of miscarriage and fetal abnormalities. Diabetic nephropathy is associated with fetal growth restriction. In late pregnancy, poor glycaemic control increases the risk of macrosomia and birth trauma.[38]

### Type 2 diabetes and pregnancy

Patients with T2D are older compared with other groups of diabetic patients and usually multiparous. There is a higher incidence of T2D in certain ethnic groups such as people of African, black Caribbean, South Asian, Middle Eastern, or Chinese family origin. Language and cultural barriers may result in poor preconception care. Cessation of oral hypoglycaemic therapy is important before conception due to its possible teratogenic effects.

Risk of perinatal mortality is similar to that of patients with T1D, but significantly higher compared to healthy patients (2.5–6.7% cf 0.7%). The incidence of caesarean and preterm delivery is significantly higher. Risk of congenital malformations, macrosomia, and neonatal hypoglycaemia, hypocalcaemia, and hyperbilirubinaemia is also significant.[39]

## Gestational diabetes mellitus and pregnancy

Pregnant women with GDM are mostly overweight and have an increased risk of developing T2D after pregnancy. Children of mothers with GDM are also at higher risk of obesity and T2D later in life.[40]

Blood glucose levels are mostly in the normal range in GDM patients during the first trimester. Therefore, the risk of congenital birth defects is lower compared to patients with T1D. GDM is associated with perinatal complications—macrosomia, stillbirth, shoulder dystocia, and birth injuries. Rates of hypoglycaemia and hyperbilirubinaemia in the babies are higher immediately after delivery.[41]

### Diagnosis of GDM

Diabetes screening for gestational diabetes is divided into three phases:

#### *Phase 1: Risk assessment*

Risk of developing GDM should be assessed in all pregnant women. If any of the risk factors are present, testing for GDM is strongly recommended. However, if only these women are tested, approximately 40% of GDM patients will remain undiagnosed. It is still debatable whether universal screening is beneficial and cost-effective.

#### *Phase 2: Early detection of GDM in high-risk group*

Selective screening for GDM is recommended for women diagnosed with GDM in a previous pregnancy. Recommended screening tests are early self-monitoring of blood glucose and oral glucose tolerance test (OGTT) at 16–18 weeks. The 2-hour 75 g OGTT should be used to test for GDM. If results are within the reference range, a further OGTT should be repeated at the 28th week.

#### *Phase 3: Late detection of GDM*

Screening for GDM is recommended for all pregnant women without diagnosed diabetes before pregnancy (except for those at very low risk) at 24–28 gestational weeks using the OGTT test after overnight fasting.[42]

#### *Threshold values for diagnosis of GDM*

The significant threshold values for the OGTT which have an impact on pregnancy outcome have not been clarified yet. According to WHO criteria, the threshold for fasting plasma glucose (FPG) should remain at 6.1 mmol/L.

The threshold values on the 2-hour 75 g OGTT for the diagnosis of GDM have been derived from Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study data (Table 47.1). For the diagnosis of GDM, one or more of these values have to equal or exceed the threshold. Using these criteria, the total incidence of GDM in the HAPO study was 17.8%. According to the study, a rise in glucose levels was associated with the greater frequency of adverse pregnancy outcomes.[43]

## Diagnosis of overt diabetes

Overt DM during pregnancy is associated with significantly increased risks of adverse perinatal outcomes compared to GDM. Identification of women with overt diabetes should be at the earliest possible opportunity. Targets for blood glucose control should be determined in the same way as for women with pre-existing diabetes. Early testing is recommended at the first prenatal visit, especially in the high-risk population.

Overt diabetes can be confirmed by measurement of FPG, HbA1C, or random plasma glucose. In the absence of a reliable gold standard test for detecting overt diabetes early in pregnancy, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) suggested using standard laboratory

**Table 47.1** Threshold values of the oral glucose tolerance test for diagnosis of gestational diabetes mellitus

| Glucose concentration threshold | | |
|---|---|---|
| **Glucose measure** | **mmol/L** | **mg/dL** |
| FPG | 5.1 | 92 |
| 1 h plasma glucose | 10.0 | 180 |
| 2 h plasma glucose | 8.5 | 153 |

Data from The HAPO study cooperative research group. Metzger BE, Lowe LP, Dyer AR, Trimble ER *et al*. Hyperglycemia and Adverse Pregnancy Outcomes. *N Engl J Med* 2008; 358:1991–2002.

**Table 47.2** Standard laboratory methods for diagnosis of overt diabetes

| Measure of glycaemia | Threshold for diagnosis of overt diabetes |
|---|---|
| FPG | ≥7.0 mmol/L (126 mg/dL) |
| HbA1C | ≥6.5% (DCCT/UKPDS standardized essay) |
| Random plasma glucose | ≥11.1 mmol/L (200 mg/dL)[a] |

DCCT, Diabetes Control and Complications Trial; UKPDS, United Kingdom Prospective Diabetes Study.

[a]If random plasma glucose is used for screening of DM, diagnosis of overt diabetes in pregnancy should be confirmed by FPG or HbA1C.

Data from Metzger BE, Gabbe SG, Persson B, Buchanan TA, Catalano PA, Damm P, *et al.* International association of diabetes and pregnancy study groups recommendations on the diagnosis and classification of hyperglycemia in pregnancy. *Diabetes Care* 2010; 33(3):676–82.

methods for measuring glucose (FPG, random plasma glucose, or HbA1C)[44] (Table 47.2).

## Management of diabetes in pregnancy

The aim of diabetes therapy in pregnancy is normoglycaemia. The key to achieving this goal is management of women with diabetes by a specialized multidisciplinary team.

### Diet and physical activity

A dietary plan should be individualized for every patient and recommended by a nutritionist. The recommended calorie intake for pregnant woman is 30–35 kcal/kg/day. Obese women with a pregestational body mass index (BMI) greater than 27 have to reduce their caloric intake to 24 kcal/kg/day. Plasma glucose concentration and morning insulin requirements suddenly increase between 5:00 and 9:00 a.m. (dawn phenomenon), even in healthy people. Women with GDM have deficiency in the first phase of insulin secretion. It is necessary to adjust the morning meal and insulin therapy in order to avoid hyperglycaemia and its consequences. During the night, insulin requirements increase and nocturnal hypoglycaemia may be a significant problem in diabetic patients. An evening snack is recommended for pregnant women receiving insulin therapy due to the inability of insulin preparations to maintain normoglycaemia overnight.[45]

Moderate exercise is associated with better glycaemic control and improved maternal and fetal outcome. If there is no medical or obstetric contraindication, physical activity should be maintained until the last weeks of pregnancy.

### Insulin therapy

Before the introduction of insulin in everyday practice, women were counselled to avoid pregnancy due to an extremely high risk of fetal mortality (up to 100%) and maternal mortality (30%). Since 1980, insulin therapy and better glycaemic control have led to improved maternal and fetal outcomes.[46]

Insulin is the first-line pharmacotherapy in women with GDM if medical nutritional therapy results in inadequate glucose control. Patients with T1D require lifelong insulin therapy to substitute endogenous secretion, but the insulin regimen needs to be adapted in pregnancy.

Insulin is considered safe for the treatment of diabetes in pregnancy and a large body of research evidence supports its safety and efficacy. It was not initially thought that insulin can be transferred from the maternal to fetal circulation, but it is now confirmed that small amounts of insulin (1–5%) do cross the human placenta. Maternal hyperglycaemia, rather than maternal hyperinsulinaemia, results in fetal hyperinsulinaemia. Fetal hyperglycaemia and consequent hyperinsulinaemia cause macrosomia, the most prevalent complication in offspring of diabetic mothers.[47]

**Box 47.3** Basic types of insulin and duration of action

- Rapid-acting insulins: lispro, aspart, and glulisine (2–4 hours)
- Short-acting insulin: regular insulin (4–6 hours)
- Intermediate-acting insulins: neutral protamine Hagedorn (NPH) insulin (14–20 hours)
- Long-acting insulins: glargine and detemir (20–24 hours)

To date, only human neutral protamine Hagedorn (NPH) insulin, regular human insulin, and the rapid-acting insulin analogues lispro and aspart are approved for use in pregnancy. Older types of insulin are considered safe for use during pregnancy. It is less clear if the newer insulin medications are also safe. Box 47.3 contains basic types of insulin and their duration of action.

Combination insulins are:

- Intermediate-acting plus short-acting: NPH insulin/regular insulin.
- Intermediate-acting plus rapid-acting: insulin lispro protamine/insulin lispro.

Human insulin is available in two forms, a short-acting (regular) form and an intermediate-acting (NPH) form (Table 47.3).

Insulin analogues are developed in order to achieve pharmacokinetic properties of endogenous insulin by changing the primary amino acid sequence (Box 47.4 and Tables 47.4 and 47.5).[48–51]

**Table 47.3** Characteristics of short-acting and intermediate-acting insulin forms

| | Short-acting (regular) form | Intermediate-acting (NPH) form |
|---|---|---|
| Multiple-dose regimen insulin (well-controlled patients) | Pre meal (three times daily) | Basal requirements pre breakfast + bedtime (twice daily) |
| Patients with poor glycaemic control | Continuous subcutaneous insulin infusion | |
| Advantages | Extensively used during pregnancy | Well studied during pregnancy |
| Disadvantages | Increases risk of macrosomia<br>Postprandial hyperglycaemia | Nocturnal hypoglycaemia |
| Onset/peak/duration of action | 30–60 min/1–2 h/4–6 h | 1–2 h/5–7 h/14–20 h |

Data from International Society for Pediatric and Adolescent Diabetes DKA Guidelines. *Pediatric Diabetes* 2009: 10 (Suppl. 12): 118–133. http://www.bsped.org.uk/professional/guidelines/docs/DKAGuideline.pdf

**Box 47.4** Short-acting and long-acting insulin analogues

- Short acting:
  - Insulin lispro
  - Insulin aspart
- Long acting:
  - Insulin glargine
  - Insulin detemir

Data from Angelina L. Trujillo. Insulin Analogs and Pregnancy. *Diabetes Spectrum* 2007; 20(2):94–101.

## Oral hypoglycaemic agents

Oral hypoglycaemic agents, such as glibenclamide and metformin, have been approved for use in pregnancy, especially for treatment of GDM. Some of the patients diagnosed with T2D can also be treated with oral therapy. These agents are possible alternatives in patients who refuse insulin therapy.

### *Metformin*

Metformin has become increasingly popular in pregnancy, since published data suggested its safety and efficacy in patients with polycystic ovary syndrome (PCOS). Although it crosses the placenta, teratogenic effects are not found. Metformin has been shown to improve fertility in patients with PCOS and may prevent early pregnancy loss. However, evidence of its effects on maternal outcome is still controversial.[52]

### *Glibenclamide (Glyburide)*

Glibenclamide is an oral sulfonylurea long-acting hypoglycaemic agent. Most women with GDM who are treated with glibenclamide can achieve adequate glycaemic control. Risk of neonatal hypoglycaemia is significantly lower in comparison with patients on insulin therapy. There are no published data about teratogenic effects of glibenclamide.[53]

**Table 47.4** Characteristics of short-acting insulin analogues when compared to regular human insulin

| | Insulin lispro | Insulin aspart |
|---|---|---|
| Chemical structure | Inversion of prolin-lysin into lysin–prolin (positions 28–29) | Aspart instead of prolin at the 28th position |
| Pharmacokinetic properties | Fast rise and higher pick of insulin concentration | Similar to insulin lispro |
| | Better glycaemic control<br>Lower risk of postprandial hypoglycaemia | Similar to insulin lispro |
| Neonatal outcome | No difference in perinatal outcome | In patients with T1D, reduces fetal mortality |
| Duration of action | 2–4 h, onset of action 15–30 min | 2–4 h, onset of action 10–20 min |

Data from García-Domínguez M, Herranz L, Hillman N, Martín-Vaquero P. *et al.* Use of insulin lispro during pregnancy in women with pregestational diabetes mellitus. *Medicina Clínica*, 2011, volume 137, issue 13, pp. 581–586; and Mathiesen ER. Insulin aspart in diabetic pregnancy: state of the art. *Women's Health*, 2008, volume 4, issue 2, pp. 119–24.

**Table 47.5** Characteristics of long-acting insulin analogues when compared to regular human insulin

| | Insulin glargine | Insulin detemir |
|---|---|---|
| Chemical structure | 2 molecules of arginine have been added (B chain)<br>Aspartic acid replaced by glycine (A chain at position 21) | Threonine is removed at B30<br>Myristic acid is added to lysine at position 29 |
| Pharmacokinetic properties | High affinity for insulin-like growth factor I receptor | Weak affinity for insulin-like growth factor I receptor |
| Advantages | Glycaemic stability<br>Reduced incidence of nocturnal hypoglycaemia | Reduce fasting glucose levels<br>Reduced HbA1C levels |
| Neonatal outcome | Risk for macrosomia was not confirmed | Lower incidence of macrosomia |
| Duration of action | >24 h, onset of action 4–5 h | 20 h, onset of action 4–6 h |

Data from Pollex EK, Feig DS, Lubetsky A, Yip PM, Koren G. Insulin glargine safety in pregnancy: a transplacental transfer study. *Diabetes Care*, 2010, volume 33, issue 1, pp. 29–33; and McElduff A. Insulin Detemir in Pregnancy: A Small but Significant Step Forward? *Diabetes Care*, 2012, volume 35, issue 10, pp. 1968–69.

### *Chlorpropamide and tolbutamide*

Chlorpropamide and tolbutamide are oral sulfonylurea long-acting hypoglycaemic agents. They are shown to cross the placenta in higher proportion than glibenclamide. Due to their potential teratogenic effects, their use in patients who are planning pregnancy or who are pregnant is not recommended.

## Obstetric management of women with diabetes

All women diagnosed with diabetes during pregnancy carry a higher risk for obstetric complications and careful obstetric follow-up is needed from the first antenatal visit. The purpose of this follow-up is to provide good perinatal outcome by:

- antenatal fetal surveillance techniques.
- meticulous selection of the most appropriate timing and route of delivery.

Obstetricians should be aware that severity of the disease and poor metabolic control may worsen fetal well-being. Therefore, multidisciplinary strategies for metabolic optimization should be performed together with diabetologists to reduce consequences of maternal hyperglycaemia on fetal growth.[54]

### Fetal surveillance

- Serial monitoring by ultrasound is recommended. In the first trimester, an ultrasound scan should be performed at 7–10 weeks to confirm viability. During the second trimester, an ultrasound between 18 and 20 weeks is recommended to exclude fetal anomalies. During the third trimester, a minimum of two ultrasound scans should be performed for evaluation of fetal growth.
- Monitoring of fetal movements. Self-monitoring of fetal movements should start from the 32nd week of gestation. Reduction in fetal movements over a period of 2 hours should be reported immediately to the obstetrician.

- Non-stress testing (NST) has been suggested from the 32nd week of gestation in high-risk patients and 'near term' in patients with low risk for complications.[55]
- Biophysical profiles and amniotic fluid index are suggested only if they are clinically indicated.

### Timing and route of delivery

- In diabetic patients with good metabolic control and fetal surveillance, medically indicated delivery should be performed between 37 and $38^{+6}$ weeks of pregnancy.[31] Delivery before 37 weeks' gestation is not recommended in the absence of evidence of fetal compromise due to increased risk of fetal lung immaturity.
- Diabetes itself in pregnancy is not an indication for caesarean delivery. However, neonatal complications, such as macrosomia, shoulder dystocia, clavicular fracture, brachial palsy, and unexplained intrauterine fetal death, are significantly higher in diabetic patients. Therefore, patients with an ultrasound confirmation of a macrosomic fetus should be informed of the risks and benefits of vaginal birth.
- Women affected by pre-existing DM need tertiary-level obstetric care due to an extremely high risk of adverse perinatal outcomes.[56]

## Anaesthetic management of women with diabetes

### Low-risk diabetic patients

#### *Labour and delivery*

Most pregnant women with diabetes and good metabolic control may have an induction of labour. Labour epidural analgesia can have a positive effect in these patients, due to its superior pain relief. Epidural analgesia also removes the stress response to the pain of labour and helps to facilitate blood glucose control. Attenuation of the stress response and reduction in maternal hyperventilation may have a beneficial effect on fetal metabolic acidosis.[57] Avoidance of fetal metabolic acidosis is one of the possible factors which can reduce the risk of stillbirth in diabetic mothers.

Pregnant women, who were offered information based on the current available evidence during antenatal care, were more likely to receive labour epidural analgesia than women with no pregnancy risk factors.[58] Furthermore, according to some evidence, epidural analgesia was not found to be an independent risk factor for caesarean delivery, but rather a protective factor.[59] However, there is insufficient evidence from well-designed studies on the influence of epidural analgesia on labour in women with diabetes. Despite being at a high risk for infection, there are no published data on the higher incidence of epidural abscesses in diabetic patients.

Fasting during induction of labour is still a controversial issue independently of DM. During established labour, blood glucose levels should be maintained between 4 and 7 mmol/L. Measurement of capillary blood glucose should be performed hourly. IV fluids and insulin should be administered during labour and adjusted according to the blood sugar—the 'sliding scale', especially in patients with T1D.[31]

#### *Elective caesarean delivery*

Diabetic patients with obstetric complications and/or poor metabolic control are candidates for elective caesarean delivery.

Women with complications of diabetes and/or obesity should have an anaesthetic assessment in the antenatal period, or immediately after admission to the delivery suite. During the anaesthetic evaluation, the presence of diabetic complications (nephropathy, diabetic heart disease) and medical comorbidities should be assessed.

If the patient is scheduled for planned caesarean delivery, the operation should be performed early in the morning, to enable better glucose control. Monitoring of blood glucose levels is essential perioperatively. Diabetic patients require a minimum of hourly glucose monitoring and titration of short-acting insulin for successful glycaemic target achievement.

Neuraxial anaesthesia (NA) is the preferred choice. Both spinal and combined spinal–epidural (CSE) anaesthesia are well known for its safety and reliability. Diabetic women are likely to have pre-eclampsia and autonomic neuropathy. Therefore, there has been concern regarding severe hypotension following subarachnoid block.[60] Preloading with crystalloid or colloid has not always been found to be effective. Once the placenta is delivered, insulin requirements decrease dramatically and any insulin infusion is usually stopped. Blood sugars are monitored thereafter and many patients can resume their prepregnancy insulin doses soon after delivery. Caesarean delivery results in moderate to severe postoperative pain. Management of postoperative pain relief in diabetic mothers leads to better glycaemic control and enables breastfeeding.[61]

### High-risk diabetic patients

#### *Urgent caesarean delivery*

Urgent caesarean delivery is needed in patients with maternal or fetal compromise, which is not immediately life-threatening. The preferred anaesthetic technique is NA (see chapters in Part 6).

#### *Emergency caesarean delivery*

Emergency caesarean delivery is needed if an immediate life-threatening condition exists for mother and/or fetus. General anaesthesia (GA) with rapid sequence induction is the usual technique. Obesity and pregnancy each increase the risk of difficult airway. Obesity in diabetic mothers, especially with T2D, is associated with a higher likelihood of unanticipated difficult airway. There may also be difficult airway challenges with T1D due to the 'stiff joint syndrome'—problems with the atlanto-occipital joint resulting in reduced neck extension.

Fetal compromise is more frequent in diabetic mothers due to an increased risk of fetal hypoxia. Fetal hyperglycaemia and hyperinsulinaemia increase oxygen consumption by up to 30%. Patients with pre-existing diabetes are more likely to have placental insufficiency. The placenta has a limited ability to increase oxygen delivery, but insufficiency remains largely subclinical during pregnancy. Pain during labour may decrease the oxygen supply to the fetus. Intermittent hypoxia that occurs with uterine contractions of normal labour leads to fetal asphyxia in the compromised fetus of diabetic mother.

Unstable diabetics will require care in the high dependency unit as close monitoring of their blood sugars and insulin regimen is required.[62]

## Acute neonatal complications in offspring of diabetic mothers

Acute neonatal complications are hypoglycaemia, hypocalcaemia, hypomagnesaemia, hyperbilirubinaemia, and respiratory distress.

Neonatal hypoglycaemia is the most common complication in the newborn of diabetic mothers. During pregnancy, prolonged maternal hyperglycaemia leads to fetal hyperglycaemia and consequent fetal hyperinsulinaemia. After delivery, there is a sudden drop in blood glucose levels in the presence of hyperinsulinaemia. This condition usually occurs within 2 hours after delivery and persists up to 72 hours. Hourly blood glucose testing is needed in high-risk infants.

Hypocalcaemia and hypomagnesaemia are caused by low parathyroid levels and the immaturity of neonatal parathyroid gland. Calcium can be easily transferred through the placenta. Hypocalcaemia occurs within 72 hours of birth, if parathyroid hormone response is delayed. Hyperbilirubinaemia is precipitated by expansion of fetal red cell mass. The immature neonatal liver is unable to conjugate and excrete larger amounts of bilirubin, caused by polycythaemia. Common causes of respiratory distress are lack of surfactant before 38 weeks of gestation and meconium aspiration in macrosomic babies. Babies of mothers who have DM are more likely to develop the disease in later life. This is even more likely if the father has T1D.[63]

### Breastfeeding

Breastfeeding is recommended in patients with T1D.[64] However, it may be delayed due to neonatal morbidity and poor maternal metabolic control. In women with GDM and T2D, breastfeeding has been found to have numerous advantages for both mother and newborn. Women who breastfeed their babies have a lower risk of breast and ovarian cancer. Breastfed offspring may have lower risks of obesity, cardiovascular disease, hypertension, and T2D later in life.[65,66]

## Pituitary gland

The pituitary gland ('master gland') is a small endocrine organ that controls a multitude of important functions in the body. It is located in a sella turcica and is functionally connected to the hypothalamus. It is composed of three lobes—anterior, intermediate, and posterior—which secrete nine hormones (Box 47.5).

### Pregnancy and the pituitary

Pituitary volumes during pregnancy are increased from 45% to 120%. The highest volumes were observed during the first 3 days postpartum.[67] It returns to normal size within 6 months postpartum. Anterior pituitary cells (lactotrophs) produce prolactin (PRL). PRL secretion is also stimulated by progesterone. Increased PRL secretion during pregnancy is important for the preparation of breast tissue for lactation.

Normal gestation is associated with increased maternal hypothalamic–pituitary–adrenal axis (HPA) activity. The placenta is the source of elevated corticotropin-releasing hormone (CRH) and appears to be the major stimulus for the HPA axis, especially during the third trimester.[68] Placental GH is detectable by the fifth week of pregnancy and levels increase exponentially and peak at 35–37 weeks.[69]

### Hyperpituitarism

Hyperpituitarism is a condition in which the pituitary gland is overactive. The most common causes are pituitary tumours (Box 47.6).

**Box 47.5** Products of the anterior and the posterior pituitary

**Products of the anterior pituitary**

- Growth hormone (GH)
- Thyroid-stimulating hormone (TSH)
- Adrenocorticotropic hormone (ACTH)
- Prolactin (PRL) or 'luteotropic' hormone (LTH)
- Luteinizing hormone (LH) or 'lutropin'
- Follicle-stimulating hormone (FSH)
- Melanocyte-stimulating hormones (MSHs)

**Products of the posterior pituitary**

- Oxytocin
- Antidiuretic hormone (ADH, vasopressin)

Data from Karaca ZF, Unluhizarci K, Kelestimur F. Pregnancy and pituitary disorders. *Eur J Endocrinol* 2010; 162(6):453–475.

Prolactinomas are the most common cause of persistent hyperprolactinemia.[70] The risk of tumour growth in pregnant patients with macroprolactinomas is higher than that in those with microprolactinomas. Medical treatment with bromocriptine has been recommended, but it should be stopped if pregnancy is confirmed.[71] Prolonged treatment with dopamine agonists is associated with the higher probability of conception.[72]

In healthy individuals, hormonal activity of the pituitary returns to normal 11 months after delivery. The abnormal enlargement of the pituitary gland during pregnancy might shrink spontaneously after delivery and these patients might have a higher risk of postpartum hypopituitarism.[73]

### Hypopituitarism

Hypopituitarism is a rare disorder, characterized by deficient or diminished production of pituitary hormones and can be caused by disease in the pituitary or in the hypothalamus. The lack of hormone results in a loss of function of the gland or organ that it controls. Damage to the pituitary gland can be caused by tumour, radiation, surgery, infections, postpartum haemorrhage (Sheehan's syndrome), or other conditions. The symptoms

**Box 47.6** Types of pituitary tumours

- By function:
  - Tumours which produce hormones (~35%)
  - Tumours which do not produce hormones (65%)
- By size:
  - Microadenomas (<1 cm)
  - Macroadenomas (>1 cm)

Data from Arafah BM, Nasrallah MP. Pituitary tumors: pathophysiology, clinical manifestations and management. *Endocrine-Related Cancer* 2001; 8:287–305.

depend on which hormone is involved.[74] The pituitary gland can also revert spontaneously to normal after delivery and the patient remains asymptomatic in a subsequent pregnancy. If the disorder has been diagnosed before or during the pregnancy and hormone replacement therapy has also been started, it should be continued. Surgical treatment should be avoided during pregnancy, except if symptoms worsen. After neurosurgery, hormone replacement is needed throughout life.

### Diagnosis

This depends on the specific lack of hormones. Magnetic resonance imaging (MRI) without contrast is mandatory. The enlarged pituitary gland can cause visual problems and together with hypertension can mimic pre-eclampsia.

### Anaesthetic management

Delivery can be undertaken under epidural, spinal, or CSE. GA has been described in a patient who had her pituitary tumour removed after delivery under NA.[75]

### Complications

Ischaemia and necrosis may also occur in the pituitary gland at the end of pregnancy or in the postpartum period. Modest hypertension of 140/70 mmHg in younger patients (during pre-eclampsia/eclampsia) can cause cerebral oedema and haemorrhage and further increases the risk of pituitary necrosis.[76] Haemorrhage in the gland, ischaemia, and necrosis may cause death. Emergency treatment is needed for pituitary necrosis: surgical or medical (bromocriptine, hydrocortisone, thyroid hormone replacement).[77] The severe consequences of missing the diagnosis underline the importance of this potentially lethal endocrine emergency.[78]

## Thyroid gland

The thyroid gland is responsible for the synthesis of thyroxine ($T_4$) and triiodothyronine ($T_3$). Thyroid-stimulating hormone (TSH) released from the pituitary gland binds the TSH receptor on the thyroid cells and stimulates them. Thyroxine is produced as the precursor of thyroglobulin which is cleaved by enzymes to produce active $T_4$. The lysosomal enzymes cleave the $T_4$ from the iodinated thyroglobulin. Activity of thyroid hormone depends on free $T_4$ and $T_3$. Thyroid hormones have negative feedback on thyroid-releasing hormone and TSH production. Therefore, TSH is a very sensitive and specific marker of thyroid function.

TSH secretion has a daily circadian rhythm. The highest TSH level is reached during the second part of the night. TSH level is the best screening test for both hyperthyroidism (decreased TSH level) and hypothyroidism (increased TSH level) diagnosis.

Thyroid cells release $T_4$ and $T_3$ into the bloodstream. There is 0.03% free $T_4$ and 0.03% free $T_3$, which is three- to five-fold more active than $T_4$. The levels are regulated by iodothyronine transporters.[79] All cells in the body are targets for thyroid hormones and their metabolic effects are summarized in Box 47.7.

Plasma concentration of cholesterol and triglycerides is inversely correlated with thyroid hormone levels. One of the diagnostic signs of hypothyroidism is increased blood cholesterol concentration. Thyroid hormones stimulate gluconeogenesis and glycogenolysis to generate free glucose.

Normal levels of thyroid hormones are essential for the development of the fetal and neonatal brain. In the first trimester and at the end of pregnancy, serum TSH level is sometimes below the normal range outside of pregnancy.[80,81] Serum TSH is a more accurate indication of thyroid status in pregnancy than any of the other markers. In the first trimester, the fetus is totally dependent on maternal hormones. In the second trimester the fetal thyroid gland starts the production of its own hormones, but it is still dependent on the mother.[82] Fetal $T_3$ remains low until 30 weeks of gestation and increases at term. The increased demand for thyroid hormones (and iodine) is reached by about 20 weeks of gestation and persists until term. Additionally, the placenta contains deiodinases that can convert $T_4$ to $T_3$. The WHO recommends increasing iodine intake from the standard 100–150 mcg/day to 200 mcg/day during pregnancy, because lack of iodine results in maternal goitres.[83]

**Box 47.7** Metabolic effects of thyroid hormones

- Basal metabolism regulation
- Thermoregulation
- Control of energy production in brain, heart, and muscles
- Protein, fat, vitamin, and carbohydrate metabolism

Data from *Thyroid Disease and Pregnancy 2012*. The American Thyroid Association. http://www.thyroid.org.

### Thyroid disease

Thyroid disease is not uncommon in pregnancy. Thyroid dysfunction may be detected for the first time during pregnancy. The most common cause (80–85%) of maternal hyperthyroidism is Graves' disease (1/1500 pregnancies). If untreated, thyroid disorders can have profound effects on both mother and fetus.

Limited amounts of $T_3$ and $T_4$ cross the placenta and influence fetal thyroid function. In mild thyroid disorders, there is no implication for the fetus.[84]

### Hyperthyroidism

Hyperthyroidism affects 0.1–0.4% of pregnancies. Approximately 0.2% of cases of hyperthyroidism are diagnosed before pregnancy and only 0.05% are diagnosed during pregnancy. Symptoms of hyperthyroidism may be difficult to recognize in pregnancy, because normal pregnancy may mimic them (Box 47.8). The effects of hyperthyroidism on the pregnancy and fetus are shown in Box 47.9.

**Box 47.8** Symptoms of hyperthyroidism

- Fatigue
- Tachycardia
- Heat intolerance
- Appetite changes
- Emesis and hyperemesis

- Preterm delivery

**Effects of maternal hyperthyroidism on fetus**

- Low weight
- Prematurity
- Neonatal hyperthyroidism
- Stillbirth

Data from *Thyroid Disease and Pregnancy 2012*. The American Thyroid Association. http://www.thyroid.org.

### Medical and surgical management

Thyroid hormones should be assessed monthly during the treatment in pregnancy. Hyperthyroidism is diagnosed by high free $T_4$ and reduced TSH levels. Thyroidectomy is relatively contraindicated in pregnancy. If it is necessary, the optimum time to perform thyroidectomy is in the late second trimester. All antithyroid drugs (Box 47.10) cross the placenta. Propylthiouracil (PTU) may cause hepatotoxicity.[85–87] Beta blockers are recommended only for thyroid crisis. Radioactive iodine is contraindicated in pregnancy. Pregnancy should be postponed until 6 months after radioactive iodine treatment.

### Anaesthetic management

Ideally, parturients presenting for labour should be euthyroid. Early epidural analgesia is the method of choice for vaginal delivery in order to avoid pain and potential thyroid crisis. Epidural, spinal, or GA can be used for caesarean delivery. IV administration of hydrocortisone 100 mg may be considered preoperatively to prevent adrenal insufficiency. Prehydration prior to NA is useful to minimize haemodynamic changes. Phenylephrine is recommended for the treatment of hypotension. It should be administered as a 20–40 mcg an IV bolus or by infusion. NA should be performed with caution to minimize maternal anxiety and to avoid maternal and fetal respiratory depression. If GA is needed, careful airway assessment has to be performed preoperatively. An enlarged thyroid gland can affect the airway, making endotracheal intubation difficult. Thiopentone, the induction agent of choice for caesarean delivery under GA, can have an antithyroid effect. Light anaesthesia, atropine, and ketamine are not recommended because they can stimulate the sympathoadrenal axis. Volatile anaesthetic agents of choice for maintenance of anaesthesia are isoflurane and sevoflurane. Muscular weakness may occur and neuromuscular monitoring can be useful.

**Box 47.10** Medical management of hyperthyroidism

- Propylthiouracil (PTU): 100–150 mg/8 h increasing up to 250–300 mg/8 h—*first choice*
- Carbimazole: second trimester, nursing period, more potent

Data from Stagnaro-Green A, Abalovich M, Alexander E, *et al.* Guidelines of the American Thyroid Association for the diagnosis and management of thyroid disease during pregnancy and postpartum. *Thyroid* 2011; 21(10):1081; and Rosenfeld H, Ornoy A, Shechtman S, Diav-Citrin O. Pregnancy outcome, thyroid dysfunction and fetal goitre after in utero exposure to propylthiouracil: a controlled cohort study. *Br J Clin Pharmacol* 2009; 68:609.

### Complications

Thyroid storm or thyrotoxic crisis can occur during vaginal delivery or induction of GA. Thyrotoxicosis is defined as 'the clinical syndrome of hypermetabolism and hyperactivity that results when the serum concentrations of free $T_4$ and/or free $T_3$ are high'. Symptoms are found in Box 47.11. It is associated with high serum hCG levels.[88,89] The most common cause is Graves' disease.

The differential diagnosis of thyroid storm includes malignant hyperpyrexia. Patient should be admitted to the intensive care unit and managed by a multidisciplinary team (anaesthetist, intensivist, endocrinologist, obstetrician, and neonatologist). The treatment of thyroid storm is summarized in Box 47.12.

Postpartum thyroiditis is the most common complication within the first 3 months after delivery, especially in Graves' disease. Therefore close monitoring of thyroid function tests is important during this period.

## Hypothyroidism

Hypothyroidism has been defined as the presence of an elevated TSH concentration and is found in 2–3% of apparently healthy, non-pregnant women of childbearing age. It is estimated that 0.3–0.5% of these women have overt hypothyroidism with raised TSH and reduced free $T_4$, while 2–2.5% have subclinical hypothyroidism where TSH is elevated but free $T_4$ levels are normal.[90]

Deficiency in thyroid hormones is not compatible with normal health. Hashimoto thyroiditis is the most common cause of hypothyroidism in pregnant women. According to data

**Box 47.11** Symptoms of thyroid storm

- Acetaminophen
- Cold fluids, cooling blankets

Data from Braverman LE. Utiger RD. Introduction to thyrotoxicosis. In: Braverman LE, editor; Utiger RD, editor. Werner and Ingbar's *The Thyroid: A Fundamental and Clinical Text*. 9th. Lippincott, Williams and Wilkins; Philadelphia 2005; 453–455; and Patil-Sisodia K. Mestman JH. Grave's hyperthyroidism and pregnancy: a clinical update. *Endocr Pract* 2010; 16:118–129.

from the United States, hypothyroidism affects up to 2.2% of pregnant women. Prevalence is higher in countries with iodine insufficiency.[91] Causes of hypothyroidism are found in Box 47.13.

Almost all patients with Hashimoto disease are positive for antithyroid peroxidase antibody. Of these patients, 50–70% also have positive results for antithyroglobulin antibodies. Over-treatment with antithyroid drugs can cause hypothyroidism, especially in the postpartum period. Overt maternal hypothyroidism is usually associated with infertility. Signs and symptoms of severe hypothyroidism are found in Box 47.14.

Hypothyroidism may also manifest itself with other conditions (Box 47.15).

Subclinical hypothyroidism has been associated with spontaneous abortion, preterm labour, increased risk for severe pre-eclampsia, developmental disease, and can influence children's intellect. Fetal self-sufficiency of thyroid hormones protects the fetus against brain development abnormalities caused by maternal hypothyroidism.[92]

If the mother suffers from autoimmune hypothyroidism, her antibodies could cross the placenta and destroy the fetal thyroid gland. Most children with isolated fetal hypothyroidism are without symptoms at birth, due to the presence of their mother's hormones. It is therefore important to recognize the disease and start with treatment as soon as possible after the birth. If the treatment has not been started on time the result may be permanent damage.[93]

Iodine deficiency is the most common cause of combined maternal and fetal hypothyroidism and endemic iodine deficiency remains a substantial public health problem in many parts of Europe, Asia, Africa, and South America.

**Box 47.13** Common causes of hypothyroidism

- Autoimmune disease (Hashimoto thyroiditis)
- Surgical removal of the thyroid gland
- Post irradiation
- Congenital
- Lack of iodine in mother's diet
- Medication
- Inflammation

Guidelines of the American Thyroid Association for the diagnosis and management of thyroid disease during pregnancy and postpartum. *Thyroid* 2011; 21(10):1081.

## Obstetric management

The Endocrine Society recommends screening of all pregnant women for serum TSH abnormalities by 9 weeks of gestation or at the first prenatal visit.[94] Women at risk of developing hypothyroidism are those with a goitre, or prior treatment for hyperthyroidism or a positive family history of thyroid disease.

**Box 47.15** Clinical manifestations of hypothyroidism

Guidelines of the American Thyroid Association for the diagnosis and management of thyroid disease during pregnancy and postpartum. *Thyroid* 2011; 21(10):1081.

Fetal thyroid dysfunction should be screened during pregnancy by ultrasound between the 18th to 22nd week of gestation and repeated every 4–6 weeks.

If hypothyroidism develops during pregnancy, treatment should be started immediately with levothyroxine. If iodine supplementation has been started in the third trimester, it will harm the developing fetus. Ideally, women with hypothyroidism should have their levothyroxine dose optimized prior to becoming pregnant. Women should increase their dose by 25–50% during pregnancy and check thyroid function every 6–8 weeks. After delivery, a woman may return to her usual prepregnancy dose.

### Anaesthetic management

Epidural analgesia has been recommended for labour. If caesarean delivery has been indicated, NA with prehydration is the preferred choice. Coagulation should be assessed before initiation of neuraxial analgesia/anaesthesia. Administration of sedatives may cause respiratory depression. Ketamine might be a preferred induction agent for GA.[95] Volatile agents should be avoided because of potential myocardial depression. Opioids have not been recommended for postoperative pain relief in these patients.

## Adrenal glands

The adrenal glands are endocrine glands located above the kidneys. The adrenal cortex and the adrenal medulla secrete different hormones. They are responsible for releasing hormones in response to stress (cortisol and catecholamines—epinephrine and norepinephrine), androgens, and aldosterone. These hormones exert their effect on every tissue in the body and under stressful conditions help them to maintain homeostasis.

The adrenal cortex produces glucocorticoids and mineralocorticoids. The release of glucocorticoids is triggered by the hypothalamus and pituitary gland. The hypothalamus produces CRH and it stimulates the pituitary gland to release adrenocorticotropic hormone (ACTH). ACTH than stimulates the adrenal cortex to produce hormones and release them in the bloodstream via a positive feedback system. Corticosteroids are involved into the metabolism of fat, carbohydrates, and proteins and also have an effect on the immune system by suppression of inflammatory reactions. Aldosterone regulates the level of sodium excreted into the urine and blood pressure. Androgen hormones are converted in the body to female hormones (oestrogens) and male hormones (androgens).[96]

The adrenal medulla secretes epinephrine (adrenaline) and norepinephrine (noradrenaline). Epinephrine is responsible for increasing heart rate, facilitates blood flow to the muscles and brain, causes relaxation of smooth muscles, and helps with conversion of glycogen to glucose in the liver. Epinephrine is critical in life-threatening situations as it rapidly prepares the body to spring into action. Norepinephrine has a strong vasoconstrictive effect, and thus increases blood pressure.

### Pregnancy and adrenal glands

Pregnancy dramatically affects the HPA axis leading to increased circulating cortisol and ACTH levels during gestation.[97] The hormones reach levels similar to that in Cushing's syndrome (CS).The cause of increased secretion of ACTH may also be placental synthesis and release of CRH and ACTH, pituitary desensitization to cortisol feedback, or enhanced pituitary responses to corticotropin-releasing factors.[98]

Normal pregnancy is characterized by adaptation of the renin–angiotensin system (RAS) to increased demands upon the maternal circulation. Normal pregnant women retain 200–300 mEq of sodium, which results in an increase in extracellular fluid by 4–6 L.[99] Elevations in mineralocorticoid levels are necessary for maintenance of normal sodium balance and volume homeostasis.[100] In normal pregnancy, levels of plasma and urinary aldosterone rise and result in a 10- to 20-fold increase until the 38th week of gestation.

Ability to handle stress in pregnancy is preserved. Cortisol and ACTH levels are subsequently increased during the stress of labour. ACTH secretion is elevated 10-fold during labour and delivery. CRH concentrations fall rapidly after delivery.[101] Vaginal delivery is associated with a higher level of plasma cortisol when compared with caesarean delivery.[102] In the immediate postpartum period (within 2 hours), plasma CRH and ACTH tend to decrease to normal levels, whereas normalization of plasma cortisol levels is more protracted.

### Cushing's syndrome

CS occurs in the presence of hypercortisolism. The most common cause is prolonged treatment with corticosteroids. This type of CS is called iatrogenic CS and can be a side effect of corticosteroid treatment of allergies, asthma, autoimmune diseases, and transplanted patients. Less common non-iatrogenic causes include excessive ACTH secretion or adrenal hypersecretion of cortisol independent of ACTH. Hypersecretion of ACTH can be induced by pituitary adenomas. A common cause of adrenal hypersecretion of cortisol is an adrenal cortex tumour.[103] The clinical manifestations of CS are found in Box 47.16.

### Diagnosis

If CS is suspected, midnight plasma or salivary cortisol may be a better diagnostic alternative than morning levels. The dexamethasone 1 mg suppression test has limited utility in pregnancy. Ultrasound appears to be less sensitive for detecting small tumours, so MRI is recommended. Pituitary MRI should

**Box 47.16** Clinical features of Cushing's syndrome

- Hyperglycaemia

Data from Lindsay JR, Nieman LK. The Hypothalamic-Pituitary-Adrenal Axis in Pregnancy: Challenges in Disease Detection and Treatment. *Endocr Rev* 2005; 26(6):775–799.

be obtained in all non-pregnant patients with ACTH-dependent CS.[104] MRI has been considered safe for pregnant women after 32 weeks of gestation. Surgical treatment of CS in pregnancy is recommended, except in the late third trimester, while medical treatment is preferable choice. Most patients undergo adrenalectomy, trans-sphenoidal surgery (for pituitary tumours), or receive medical therapy with metyrapone.[105,106]

### Obstetric management

This disturbance is seen extremely rarely during pregnancy because it prevents normal follicular development and ovulation. The first case was reported by Hunt and McConahey in 1953 and some sporadic cases were reported later.[107] It is often not detected until 12–26 weeks' gestation. The most common complications of CS in pregnancy are hypertension and diabetes. Maternal death is rare. In a series of 136 pregnancies complicated by CS there were 107 (79%) live births, almost half of which were premature.[97]

### Anaesthetic management

These patients are often hypertensive and hypervolaemic. Many of them are receiving long-term antihypertensive drugs. All antihypertensive agents have to be continued until the morning of surgery.[108]

Hyperglycaemia is problematic in these patients. The aim of the treatment is to maintain blood glucose levels within 7–10 mmol/L, using regular subcutaneous insulin.[109] Patients with CS are usually overweight. Obesity is often associated with hypertension, hyperglycaemia, and hypercoagulability. Therefore, prevention of perioperative venous thromboembolism and pulmonary embolism using low-molecular-weight heparin (LMWH) and compression of lower extremities must be provided. Care must be taken during positioning of the patient to prevent bone fractures and skin damage. The airway must be assessed properly because of the risk of difficult intubation caused by the buffalo hump. Arterial blood gases and pulmonary functional tests are useful to predict postoperative respiratory failure.

GA is usually required for laparoscopic adrenalectomy. Due to the risk of possible gastric aspiration, ranitidine 50 mg IV and sodium citrate should be administered orally prior to surgery. Standard and invasive monitoring of the patient is mandatory. Large-bore peripheral vein cannulae must be placed. Central vein cannulation should be considered. Antibiotic prophylaxis is necessary to prevent infection. Patients undergoing adrenalectomy may require intraoperative glucocorticoid replacement, for example, hydrocortisone 100 mg.

In the postoperative period, pulmonary atelectasis can be prevented by effective pain relief (patient-controlled analgesia or epidural) and physiotherapy. Early mobilization is recommended in order to avoid pulmonary embolism. Postoperative glucose, cortisol, and electrolyte levels must be routinely checked. Replacement therapy should be continued postoperatively.

## Addison's disease (adrenal insufficiency)

Addison's disease in pregnancy is uncommon. It affects mostly the Caucasian population and its range varies from 39 to 117 per million.[110] Adrenal insufficiency (AI) can be primary, caused by damage of adrenal cortex. Atrophy or insult of the adrenal cortex results in impairment of aldosterone and/or cortisol secretion. Autoimmune adrenalitis and tuberculosis are the most common causes of primary AI. Secondary adrenal insufficiency is most commonly caused by discontinuation of glucocorticoids. Current asthma guidelines support the use of inhaled corticosteroids as opposed to oral steroids for treatment in pregnancy due to less systemic absorption and therefore reduced likelihood of suppression of the adrenals.[111] Less frequently, ACTH deficiency may be caused by pituitary insufficiency or tumours. Pregnancies in women with panhypopituitarism should be considered high risk.[112] The signs and symptoms of Addison's disease are found in Box 47.17.

### Diagnosis

Urinary and plasma cortisol and aldosterone levels are low or undetectable in these patients. Severe hyponatraemia and hyperkalaemia are present, as well as unexplained orthostatic hypotension. Adrenal antibodies can be present in some cases. There is no reliable diagnostic test for use in pregnancy. If a diagnosis has been made during pregnancy, it is necessary to confirm it after the first week postpartum. Patients with positive adrenal antibodies have an autoimmune aetiology and do not require imaging.[113] Ultrasound imaging has limited resolution, especially during pregnancy. Therefore, MRI without gadolinium administration is recommended.

### Obstetric management

Treatment includes mineralocorticoid and/or corticosteroid replacement therapy in the antenatal period, during labour, and in the postpartum period. An endocrinologist, obstetrician, and experienced surgeon should provide multidisciplinary management. Surgery, if necessary, may be postponed to the postpartum period in selected cases. The second trimester is the optimal time to perform surgery. During the first and the second trimesters, careful monitoring and titration of therapy is required to avoid corticosteroid over-replacement, and in women with coexisting T1D, to prevent recurrent hypoglycaemia. Hydrocortisone is the recommended choice due to its inactivation by the placenta. Replacement dose of hydrocortisone varies between 20 and 25 mg.[114] The total daily dose is usually divided into two doses: two-thirds in the morning and

one-third in the afternoon. Mineralocorticoids are required only in primary Addison's disease at the time of diagnosis. Mineralocorticoid dosages are usually stable throughout pregnancy, but sometimes doses are reduced during the third trimester to avoid the side effects of oedema or exacerbation of hypertension.

### Anaesthetic management

Vaginal delivery should be offered to women with Addison's disease. The oral dose of hydrocortisone should be doubled during labour in these patients. Patients undergoing caesarean delivery should be given stress doses of hydrocortisone: 100 mg IV or intramuscularly, before induction of anaesthesia followed by 100 mg IV at 6- to 8-hour intervals after delivery for the first 48 hours.

## Adrenal crisis

Adrenal crisis is often associated with hypotension, hypoglycaemia, or coma. Hydrocortisone bolus 100–200 mg IV is required, followed by 50–100 mg IV every 6–8 hours. Infusion of 5% dextrose or saline is also recommended.

## Phaeochromocytoma

Most phaeochromocytomas (90%) are adrenal medullary tumours, characterized by excessive production of catecholamines. A phaeochromocytoma can develop at any age and may be life-threatening if unrecognized or untreated. The prevalence of phaeochromocytomas in patients with hypertension is only 0.1–0.6%.[115] Most phaeochromocytomas are benign and unilateral. The signs and symptoms of phaeochromocytoma are found in Box 47.18.

### Obstetric management

The reported incidence is less than 0.2/10,000 pregnancies.[116] Untreated phaeochromocytomas carry a risk of mortality for both mother and fetus, as high as 58%.[117] Conversely, early detection and proper treatment during pregnancy decrease the maternal and fetal mortality to less than 5% and 15% respectively.[118] Pregnancy limits diagnostic imaging methods. Tumour activity may be triggered by the enlarging uterus. If hypertension develops in a pregnant woman in the first 20 weeks' gestation, it could be misdiagnosed as gestational hypertension or pre-eclampsia. On the other hand, the presence of unexplained orthostatic hypotension in a pregnant hypertensive patient should arouse immediate suspicion of a phaeochromocytoma.[119,120]

**Box 47.18** Symptoms of phaeochromocytoma

- Flushing
- Anxiety
- Weight loss

Data from Lenders JW, Eisenhofer G, Mannelli M, Pacak K. Phaeochromocytoma. *Lancet* 2005; 36:665–675.

### Diagnosis

Blood and urine metanephrines testing are diagnostic methods of choice.[121] Sensitivity of plasma-free metanephrines varies between 95% and 100%. Some authors prefer ultrasound imaging. MRI is increasingly being used in diagnosis of phaeochromocytoma with a sensitivity of greater than 90%. Genetic tests could be useful, especially in cases with a positive family history of phaeochromocytoma.[122]

### Surgery

The best treatment for most phaeochromocytomas is surgery. Before surgery alpha- and beta blockers have been used to treat high blood pressure.

Alpha blockers (phenoxybenzamine, prazosin, and terazosin) exert their activity by preventing the vasoconstriction caused by norepinephrine and thus reduce blood pressure. Phenoxybenzamine is a non-competitive alpha-1- and alpha-2-adrenoceptor antagonist. The recommended starting dose is 10 mg twice a day. The dose should be increased at 2–3-day intervals by 20 mg up to a final dose of 1 mg/kg per day. Its prolonged action after tumour removal may be predisposing factor of postoperative hypotension.[123] Phenoxybenzamine crosses the placenta and neonates must be monitored for the first few postnatal days, because of possible hypotension and respiratory depression.[124] Doxazosin is an effective alternative to phenoxybenzamine. The recommended initial dose of doxazosin should be gradually increased from 2 mg to 16 mg, up to 32 mg per day.[125]

Beta blockers (atenolol, metoprolol, and propranolol) exert their effects by blocking norepinephrine, preventing arrhythmias and inhibiting the release of renin from kidneys. Beta-adrenergic blockade should be started a few days after appropriate alpha-adrenergic blockade in order to prevent a hypertensive crisis.[126] Both propranolol (40mg three times daily) and atenolol (25–50 mg once daily) are considered suitable for this purpose.

**Box 47.19** Drug therapy for management of hypertension during phaeochromocytoma surgery

  - Labetalol 0.25 mg/kg up to 20 mg over a period of 10 min
- Calcium channel blockers: amlodipine, nifedipine, verapamil, or diltiazem
- Magnesium sulphate: bolus 40–60 mg/kg, maintenance 1–2 g/h

Data from Lenders JW, Eisenhofer G, Mannelli M, Pacak K. Phaeochromocytoma. *Lancet* 2005; 366:665–675; Boutros AR, Bravo EL, Zanettin G, Straffon RA. Perioperative management of 63 patients with phaeochromocytoma. *Cleveland Clinic Journal of Medicine* 1990; 57:613–617; Weingarten TN, Cata JP, O'Hara JF, *et al*. Comparison of two preoperative medical management strategies for laparoscopic redelivery of phaeochromocytoma. *Urology* 2010; 76:508–511.

### Anaesthetic management

A multidisciplinary team consisting of an anaesthetist, endocrinologist, cardiologist, obstetrician, and surgeon should arrange a management plan to reduce risks in perioperative care. Surgical removal of phaeochromocytoma is usually performed by laparoscopy or laparotomy. If the tumour has been diagnosed during the first 24 weeks of gestation, it should be removed by laparoscopic adrenalectomy, after 10–14 days of medical preparation. The second trimester is the safest period to perform surgery in pregnancy.[127] Hypertension may persist after the surgical treatment in almost 50% of patients. The tumour recurrence rate during follow-up has been estimated to be 14% in adrenal disease and 30% in extra-adrenal disease.[128]

If the tumour is still *in situ*, caesarean delivery with immediate tumour removal is the best option, because catecholamine release and intra-abdominal pressure are higher in vaginal labour. The best anaesthesia option is a combination of GA and epidural. Hypotension should be avoided, if possible.

**Box 47.21** Drug therapy for treatment of post-resection hypotension during phaeochromocytoma surgery

- Norepinephrine
- Dopamine
- Phenylephrine

Data from Lenders JW, Eisenhofer G, Mannelli M, Pacak K. Phaeochromocytoma. *Lancet* 2005; 366:665–675; Boutros AR, Bravo EL, Zanettin G, Straffon RA. Perioperative management of 63 patients with phaeochromocytoma. *Cleveland Clinic Journal of Medicine* 1990; 57:613–617; Weingarten TN, Cata JP, O'Hara JF, *et al*. Comparison of two preoperative medical management strategies for laparoscopic redelivery of phaeochromocytoma. *Urology* 2010; 76:508–511.

**Box 47.22** Perioperative corticosteroid therapy in patients with phaeochromocytoma

- Prior to surgery: methylprednisolone 40 mg IV
- On the day of surgery: 40 mg (three times a day)
- Postoperative day 1: 20 mg (three times a day)
- Postoperative day 2: 10 mg (three times a day)
- Postoperative day 3: prednisone 5 mg orally + fludrocortisone 0.1 mg in the morning and prednisone 25 mg orally in the evening

Data from Lenders JW, Eisenhofer G, Mannelli M, Pacak K. Phaeochromocytoma. *Lancet* 2005; 366:665–675.

- Phenoxybenzamine should be withdrawn 48 hours prior to surgery. Alpha-adrenergic blockers therapy should be stopped the night before surgery.
- If surgery is performed on both glands, corticosteroid therapy should be started before the surgery.
- Premedication with an anxiolytic (benzodiazepine) is advised, but the neonatologist should be informed.
- Two large-bore IV cannulae, an arterial line for continuous monitoring of blood pressure, and central venous catheter for intravascular volume monitoring should be inserted preoperatively.
- A GA or a GA combined with epidural anaesthesia can be started. Intraoperative epidural analgesia can be achieved with an initial bolus of 10 mL bupivacaine 0.25% in divided doses, followed by a continuous infusion of bupivacaine (0.1%) and opiate (e.g. fentanyl 2 mcg/mL) at a rate of 6–12 mL/h.
- The hypertensive response to laryngoscopy should be avoided during induction of GA (as this may cause intracranial haemorrhage and myocardial failure).
- After the tumour has been removed, blood glucose and blood pressure may fall. Therefore, the infusion of glucose is necessary at the end of surgery. Hypotension should be treated by sympathomimetic adrenergic stimulation or vasoconstrictor drugs.
- These patients should be managed postoperatively in the intensive care unit.

Boxes 47.19, 47.20, and 47.21, summarize drugs which may be useful in controlling blood pressure and tachycardia. Perioperative steroids are necessary and a suggested regimen can be found in Box 47.22.

## Autoimmune diseases in pregnancy

Immunological response changes during normal pregnancy by transient immune tolerance of maternal cell-mediated immunity to protect the fetus, a genetically foreign body, from rejection. It was originally thought that the immune response was diminished, but recent data show that the change of ratio and function of leucocytes is the possible mechanism of reduced autoimmunity in pregnancy.

Immunomodulatory T-helper cells and their cytokines are found to be associated with pregnancy outcome. Type 1 CD4+ T cells (Th1) produce inflammatory cytokines including interferon-gamma (IFN-γ), interleukin (IL)-2, and TNF-α. Type 2 CD4+ T cells (Th2) produce IL-4, IL-5, IL-13, IL-10, and IL-6. Th 1 and Th 2 ratio play an important role in immunological maternal responses in early pregnancy.

Th1 cytokine domination and lack of adequate Th2 type response are associated with a greater incidence of miscarriages. Activation of the proinflammatory Th1 profile in late pregnancy may provoke preterm labour. Autoimmune diseases with predominant Th1 response, such as rheumatoid arthritis (RA), may improve during pregnancy. On the other hand, diseases with predominant Th2 response (e.g. systemic lupus erythematosus (SLE)) tend to worsen.[129,130]

Production of maternal alloantibodies to paternally inherited fetal HLA is the expected immune process during pregnancy. Mothers who carry histocompatible fetuses are at higher risk of pregnancy loss, due to lack of alloantibodies. Maternal alloantibodies against the trophoblast and its products may activate complement cascade. Complement activation is important in the pathogenesis of pre-eclampsia.

Successful pregnancy outcome depends on the balance of Th1/Th2-type lymphocytes response. The imbalance in the Th1/Th2 response could provoke an increase in natural killer (NK) cell levels. NK cells produce numerous proinflammatory cytokines (TNF-α, IFN-γ, and IL-10), which can cause recurrent spontaneous abortion.

## Rheumatoid arthritis

RA is a chronic autoimmune disorder that mostly affects synovial joints. The immune response is directed against an individual's own tissues, such as tendons, bones, lung, and kidney, resulting in inflammation and destruction. Extra-articular manifestations include vasculitis, subcutaneous nodules, pericarditis, peripheral neuropathy, lung disease, anaemia, and thrombocytosis. Progression of disease results in destruction of articular cartilage, ankylosis of the joints, and organ insufficiency.

The prevalence of RA is about 1% and increases with age. Onset is usually slow, over weeks or even months. Older age and female gender are risk factors both for the development of RA and for a worse outcome. It has been suggested that the largest genetic susceptibility to LA is associated with the *HLA-DRB1* gene.[131] Presence of antibodies against citrullinated peptides (ACPA) and rheumatoid factor (RF) precedes the development of clinical RA in genetically susceptible persons. Rheumatoid inflammation is mediated by activated pro-inflammatory Th1 cells. Immunomodulatory Th2 cells and their cytokines are rarely found.[132]

### Influence of pregnancy on RA

Immune tolerance in pregnancy is probably the most important factor of improvement of clinical symptoms and signs of RA. It is estimated that in 70% of patients, improvement of clinical signs or even remission have been found during pregnancy. Disparity in maternal and paternally inherited *HLA-DRB1* and *HLA-DQα* alleles is associated with improvement of the disease. Pregnancy-induced immune response towards an anti-inflammatory Th2 profile has been also suggested to have positive effects on RA symptoms.[133] Evidence suggesting that pregnancy may decrease the risk of RA is still controversial. On the other hand, exacerbation of the disease has been observed postpartum.

### Influence of RA on pregnancy outcomes

There are insufficient data of impact of RA on pregnancy outcomes. However, some authors suggest an increase in the rate of premature and small for gestational age infants in women diagnosed with RA.[134]

### Treatment of RA in pregnancy

The use of corticosteroids and non-steroidal anti-inflammatory drugs (NSAIDs) is approved in pregnancy, although the latter is stopped in the third trimester due to potential closure of the patent ductus arteriosus. Glucocorticoids modulate the immune response. They are the most potent inhibitors of pro-inflammatory cytokines and promote Th2 response. Cytostatic agents (methotrexate and leflunomide) and biologics (anti-TNF agents, rituximab, and abatacept) are not recommended for use in pregnancy.[135]

### Anaesthetic management of RA

NA for caesarean delivery is the preferable choice for RA patients. Some patients may find positioning for spinal or epidural insertion difficult due to limited or painful movement of the spine. Long-term treatment with NSAIDs has not been associated with higher risk of epidural haematoma.[136] If GA is performed, there is higher risk of atlanto- axial subluxation during intubation. In patients with temporomandibular joint involvement, mouth opening is restricted. Neck flexion or extension can also be restricted, making intubation challenging. Further details of anaesthetic management can be found in Chapter 46.

## Scleroderma

Systemic sclerosis (SS; systemic scleroderma) is an autoimmune disorder of connective tissue. Endothelial cells along with muscle cells of the small blood vessels (arterioles) in the skin and other organs have been destroyed by programmed cell death (apoptosis). These cells have been replaced by collagen. Further damage of the tissue is caused by inflammatory cell infiltration.

Scleroderma occurs predominantly in women and can be divided into two types—limited cutaneous scleroderma and diffuse cutaneous scleroderma. In limited cutaneous scleroderma, the severity of skin fibrosis is more important than the duration of the disease. Skin manifestations include Raynaud's phenomena, non-pitting oedema, and 'tight' skin. Diffuse cutaneous scleroderma is associated with organ involvement: the kidney, heart, and particularly lung.[137] In the severe disease, there may be renal insufficiency, cardiomyopathy, malignant hypertension, pericarditis, arrhythmia, pulmonary fibrosis, and malabsorption.[138] The aetiology of SS remains unknown but numerous risk factors have been suggested including various environmental agents, genetic influences, viruses, and more recently, microchimerism. Microchimerism is the presence of an increased number of circulating cells transferred from fetus to mother. These fetal cells lie dormant in the mother for many years and then initiate a host-versus-graft reaction.[139]

### Pregnancy and scleroderma

There is a relative paucity of literature concerning pregnancy and scleroderma. Women with scleroderma tend to have successful

pregnancies. Adverse pregnancy outcomes have been associated with severity of the disease. There is increased frequency of miscarriages, preterm births, and small-for-date babies. Careful antenatal surveillance is needed in these patients. Pregnancy does not seem to affect long-term prognosis of women with scleroderma.[140]

### Anaesthetic management

Multidisciplinary evaluation of the patient should be done prior to labour and delivery. Examination and investigation should be directed towards detection of underlying systemic dysfunction. An electrocardiogram (ECG) and an echocardiogram should be performed to assess cardiac function which, if reduced, may preclude NA. The skin over the lumbar area is usually devoid of the fibrous contractures so spinal, CSE anaesthesia, and epidural anaesthesia may be used with caution. Spinal anaesthesia is associated with higher risk of hypotension due to relative hypovolaemia and chronic vasoconstriction. If epidural anaesthesia is used, prolongation of motor and sensory blockade can be expected because of poor blood flow to the neural tissue and reduced local anaesthetic uptake. Patients with SS have been thought to be at a greater risk of difficult airway and/or difficult intubation, due to neck flexion contractures and restricted mouth opening. An awake fibreoptic intubation will be necessary if NA is contraindicated or unsuccessful.[141]

## Systemic lupus erythematosus

SLE is an autoimmune disease which may affect different organs and connective tissue in the whole body. It is more common in women of childbearing age. The course of SLE is unpredictable, with periods of remissions and relapses. Prognosis of SLE ranges from relatively benign to rapidly progressive and even fatal disease. The highest rates of prevalence have been reported in Italy, Spain, Martinique, and the United Kingdom, especially in the Afro-Caribbean population.[142]

SLE can involve the nervous system, lungs, kidneys, heart, blood vessels, liver, skin, and joints.[143] Lupus may imitate other diseases making the diagnosis extremely difficult. The signs and symptoms of SLE are summarized in Box 47.23.

These patients also have increased mortality from comorbidities such as infections, DM, atherosclerosis, coronary disease, lipid disorders, and malignancy.[144]

SLE is an illness of unknown aetiology. This autoimmune disease is characterized by the presence of antinuclear antibodies (ANAs) or anti-double-stranded DNA (dsDNA) antibodies. Acute lupus often flares following bacterial infections. Chronic infections may also induce lupus-like symptoms. Invading pathogens stimulate the immune system to proliferation and production of autoantibodies against the cell's nucleus.[145–147] Immune complexes form deposits in the microvasculature, on the basement membranes of skin and kidneys.

All patients with SLE are found to have serum ANAs. However, antibodies to native dsDNA are relatively specific for the diagnosis of SLE.[148,149]

**Box 47.23** Symptoms and signs of SLE

- Musculoskeletal:
  - Myalgia
  - Fatigue
  - Fever
  - Arthralgia
- Skin and mucosal:
  - Face rash—butterfly rash
  - Discoid skin lesion
  - Dry eyes
  - Skin and mucosal ulcers
- Lungs:
  - Shortness of breath
  - Chest pain
- Heart:
  - Endocarditis
  - Myocarditis
  - Pericarditis
- Renal:
  - Proteinuria
  - Haematuria
  - Lupus nephritis
- Neurological:
  - Headaches
  - Polyneuropathy
  - Cerebrovascular disease
- Psychiatric:
  - Depression
  - Psychosis
  - Cognitive dysfunction
  - Anxiety disorder
- Haematology:
  - Low white cell count
  - Low platelets
  - Anaemia

### Diagnosis

The American College of Rheumatology (ACR) has recommended criteria for SLE diagnosis, revised in 2012. According to this classification, SLE is diagnosed if the person has had biopsy-proven lupus nephritis with ANAs or anti-dsDNA antibodies or if four of the 11 diagnostic criteria, including at least one clinical and one immunological criterion, have been satisfied.[150] Increased levels of anti-dsDNA and decreased levels of complement (C3, C4, CH50) are specific for lupus flare. Diagnostic tests for SLE in pregnancy are listed in Box 47.24.

**Box 47.24** Diagnostic tests for SLE in pregnancy

- Increased anti-dsDNA levels
- Positive direct Coombs' test
- Red blood cells in the urine
- Antiplatelet antibodies in thrombocytopenic pregnant women
- Complement level—not specific in pregnancy due to oestrogen-induced synthesis

Data from Bertsias G, Ioannidis JP, Boletis J, *et al*. EULAR recommendations for the management of systemic lupus erythematosus. Report of a Task Force of the EULAR Standing Committee for International Clinical Studies Including Therapeutics. *Ann Rheum Dis* 2008; 67(2):195–205.

### Obstetric management

Pregnant women with SLE should be managed by a multidisciplinary team including a rheumatologist, obstetrician, and, if necessary, a nephrologist, neurologist, haematologist, cardiologist, and respiratory physician. Thrombophilia is often present. It is necessary to check platelets and other coagulation tests. Mild elevations of serum creatinine and blood pressure may be precursors of impending complications during pregnancy and daily proteinuria which exceeds approximately 200 mg is significant.[151] Pregnancy produces an environment of immune suppression in order to prevent fetal rejection, but cellular and humoral function has been modulated rather than suppressed. Diagnosis of SLE in pregnancy is a challenge for obstetricians. Many of these symptoms can be seen in normal pregnancy (e.g. backache, swollen ankles, and arthralgia). Pre-eclampsia and eclampsia can mimic lupus. Expectant mothers with lupus have a greater likelihood of miscarriage, intrauterine growth retardation, preterm birth, and intrauterine death. Lupus tends to worsen during pregnancy. However, maternal death is uncommon in pregnancies complicated by SLE. It can occur if active renal or central nervous system disease has been involved.

### Fetal outcome

This depends on placental pathology: ischaemia/hypoxia, decidual vasculopathy, decidual and fetal thrombi, chronic villitis, decreased placental weight and placental infarctions along with deposits of fibrin, immunoglobulin (Ig)-G, IgM, IgA, and C3 in the trophoblastic membrane.[152,153]

Previous history of lupus nephritis is not a contraindication to pregnancy, particularly if conception occurs 6 month after the nephritis. Patients with lupus nephritis with a previous renal transplant can have successful outcomes.[154]

Immunosuppressive medication required to control lupus disease should be continued despite a risk of minor fetal anomalies.[155] Corticosteroids are relatively safe. Prednisolone is the first-line treatment. Although methotrexate has been contraindicated, azathioprine, ciclosporin, and sulfasalazine might be used in combination with immunoglobulin therapy.[156] The presence of ANAs can produce congenital heart block. Thus, some tests should be performed at birth to exclude neonatal lupus (Box 47.25). Sun exposure is best avoided in infants of mothers with SLE.

**Box 47.25** Tests for neonates if the mother has SLE

- ECG
- Complete blood count
- Alkaline phosphatase test
- Transaminases

Data from Buyon JP, Clancy RM. Neonatal lupus: review of proposed pathogenesis and clinical data from the US-based Research Registry for Neonatal Lupus. *Autoimmunity* 2003; 36:41–50.

### Anaesthetic management

SLE parturients are likely to be on unfractionated heparin or LMWH and anticoagulation should be discontinued prior to delivery. Mode of delivery depends on the condition of the mother and baby. Delivery can be performed by the vaginal or caesarean route. Epidural and spinal analgesia has been considered safe for delivery provided sufficient time has elapsed between the heparin and epidural/spinal insertion (see Chapter 48). GA can be used in emergency situations.[157,158]

Corticosteroid therapy should be withdrawn gradually postpartum together with reintroduction of immunosuppressive therapy. Anticoagulant therapy should be continued for 3 months after the delivery. Breastfeeding is not recommended for these mothers.

## Antiphospholipid syndrome

Antiphospholipid syndrome (APS), also known as Hughes syndrome, is an autoimmune, hypercoagulable state, characterized by anticardiolipin antibodies and beta-2 glycoprotein I. APS causes non-traumatic thrombosis or thromboembolism, stroke, unexplained transient ischaemic attacks (including amaurosis fugax), autoimmune thrombocytopaenia, autoimmune haemolytic anaemia, and neurological and behavioural dysfunction. Antiphospholipid (APL) antibodies react against proteins on plasma membranes. Destruction of APL antibodies activates coagulation and produces blood clots in any organ system. APS has been commonly associated with other similar diseases, such as SLE (with which it shares many features).[159] During infectious disease processes (viral, bacterial, spirochetal, or parasitic) the disruption of cellular membranes may stimulate APL antibody production.

### Diagnosis

Diagnostic criteria include one clinical and one laboratory positive test (anticardiolipin antibodies, lupus anticoagulant, and/or anti-beta-2-glycoprotein I antibodies).[160,161] Patients with all three positive tests have been at greater risk for clinical events (thrombosis or pregnancy loss), when compared with patients with only one or two positive tests.[162] Activated partial thromboplastin time is prolonged but there is no evidence of coagulopathy.

### Obstetric management

Pregnant women with APS should be considered high-risk obstetric patients as they can have many complications (Box 47.26).

The rate of fetal loss due to placental infarction may exceed 90% in untreated patients with APS. Fetal ultrasonography has been

**Box 47.26** Effects of APL antibodies on pregnancy

APL antibodies may cause:

- Miscarriage
- Stillbirth
- Preterm delivery
- Severe pre-eclampsia

Data from Cowchock FS, Reece EA, Balaban D, Branch DW, Plouffe L. Repeated fetal losses associated with antiphospholipid antibodies: a collaborative randomized trial comparing prednisone with low-dose heparin treatment. *Am J Obstet Gynecol* 1992; 166(5):1318–23.

recommended monthly starting at 18–20 weeks of pregnancy. It is recommended to assess the presence of fetal growth retardation at 30–32 weeks of gestation. Multiorgan failure (Asherson's syndrome) has been described in pregnancy and during the postpartum period.[163,164]

A low dose of aspirin combined with prophylactic doses of LMWH have been recommended if there have not been thrombotic episodes in the past. Patients with a history of thrombotic episodes should be treated with therapeutic doses of LMWH—it can reduce the rate of fetal loss up to 25%. Splenectomy has been recommended in patients who suffer from the chronic form of idiopathic thrombocytopenic purpura.

### Anaesthetic management

The management of a patient with APS is not dissimilar to that of patient with SLE. The presence of lupus anticoagulant antibodies is not a contraindication for RA. Patients receiving anticoagulant therapy with heparins can receive NA provided an appropriate period has elapsed since the last dose of heparin (see Chapter 48).

In patients receiving or recently treated with corticosteroid therapy, supplementation is needed to cover the labour or caesarean delivery. Anticoagulant prophylaxis has to be continued for 6 weeks after the delivery.[165]

## Conclusion

Pregnancy itself influences specific endocrine changes caused by development of the fetoplacental unit. The function of this unique endocrine organ stimulates metabolic changes which can mimic endocrine diseases. Endocrine diseases, such as diabetes and thyroid disease, are not uncommon in pregnancy. If endocrine diseases remain untreated, they can have adverse effects on both mother and fetus. Therefore, early recognition and appropriate treatment during pregnancy is essential for good pregnancy outcome.

Immunological response is modulated during normal pregnancy and the course of autoimmune disease might be altered. RA may improve during pregnancy while SLE tends to worsen. Pregnant women with autoimmune disease are considered high risk. The rate of fetal loss is higher in these patients, especially in APS.

Every anaesthetist should have the basic knowledge of pathophysiology, diagnostic tests, and treatment of endocrine and autoimmune diseases. Anaesthetic management of these patients has significant differences when compared with healthy parturients.

# CHAPTER 48

# Obstetric haematology

Sapna Ladani, Beverley J. Hunt, and Sue Pavord

## Introduction

The aim of this chapter is to cover aspects of haematology of pregnancy, delivery, and postpartum that are not addressed in other chapters. Obstetric haematology is a vast and complex area, the importance of which has promoted the development of this as a unique subspecialty.

Thrombosis and bleeding, anaemia, and haemoglobinopathies still account for significant morbidity and mortality in pregnancy, despite improvements in recognition, prevention, and management. The management of postpartum haemorrhage is discussed in Chapter 35, while thrombosis and thromboprophylaxis is covered in Chapter 37. This chapter addresses the management of anaemia, haemoglobinopathies (mainly sickle cell disease), thrombocytopenia, microangiopathies, and the inherited bleeding disorders.

## Anaemia

Anaemia affects 1.62 billion people globally, corresponding to 24.8% of the world population.[1] Iron deficiency is the most common cause and even in the developed world an estimated 30–40% of preschool children and pregnant women have iron depletion. Other relatively common causes of anaemia in pregnancy in the United Kingdom include folate deficiency, haemoglobinopathies, and haemolytic anaemia.

Anaemia is defined as haemoglobin (Hb) less than 2 standard deviations below the mean for a healthy matched population. However, there is variation in what are considered normal values for pregnancy. The World Health Organization (WHO) defines anaemia in pregnancy as a Hb concentration of less than 110 g/L. However, in view of the relative plasma expansion being particularly marked in the second trimester, it would seem reasonable to take 105 g/L as the cut-off from 12 weeks, as suggested by the UK guidelines from the British Committee for Standards in Haematology.[2]

### Iron deficiency

Iron deficiency is the most common deficiency state in the world. Effective management is needed to prevent adverse maternal and pregnancy outcomes and avoidable blood transfusion. Iron deficiency represents a spectrum ranging from iron depletion to iron deficiency anaemia. In iron depletion, the amount of stored iron (measured by serum ferritin concentration) is reduced and there are insufficient iron stores to mobilize if the body requires additional iron. In iron-deficient erythropoiesis, transport iron (measured by transferrin saturation) is also reduced and the shortage of iron limits red blood cell production and results in increased erythrocyte protoporphyrin concentration. In iron deficiency anaemia, the most severe form of iron deficiency, there is shortage of iron stores, transport iron, and functional iron, resulting in reduced Hb in addition to low serum ferritin, low transferrin saturation, and increased erythrocyte protoporphyrin concentration. Tissue enzyme malfunction occurs even in the early stages of iron-deficient erythropoiesis and adverse effects have been described on maternal morbidity and mortality, fetal and infant development, and pregnancy outcomes.

#### Iron deficiency and its contribution to morbidity and mortality

Iron deficiency may contribute to maternal morbidity through effects on immune function with increased susceptibility or severity of infections, poor work capacity and performance, and disturbances of postpartum cognition and emotions. Mortality at delivery is potentially increased by the heightened bleeding risk, low reserves, and poorer tolerance of blood loss.

The fetus is relatively protected from the effects of iron deficiency by upregulation of placental iron transport proteins. However, evidence suggests that maternal iron depletion increases the risk of iron deficiency in the first 3 months of life, through a variety of mechanisms.[3] Impaired psychomotor and/or mental development are well described in infants with iron deficiency anaemia and it may be associated with adult-onset diseases[4]. There is some evidence for the association between maternal iron deficiency and preterm delivery, low birth weight, possibly placental abruption, and increased peripartum blood loss. However, further research on the effect of iron deficiency, independent of confounding factors, is necessary to establish a clear causal relationship with pregnancy and fetal outcomes.

#### Diagnosis of iron deficiency

Clinical symptoms and signs of iron deficiency anaemia in pregnancy are usually non-specific, unless the anaemia is severe. Fatigue is the most common symptom but patients may also complain of weakness, headache, palpitations, dizziness, dyspnoea, and irritability. Rarely pica develops where there is a craving for non-food items such as ice and dirt. Iron deficiency anaemia may also impair temperature regulation and cause pregnant women to feel colder than normal.

Storage iron is depleted before a fall in Hb and as iron is an essential element in all cells, symptoms of iron deficiency may occur even without anaemia; these include fatigue, irritability, poor concentration, and hair loss.

A full blood count (FBC) is taken routinely in pregnancy and may show low Hb, mean cell volume (MCV), mean cell

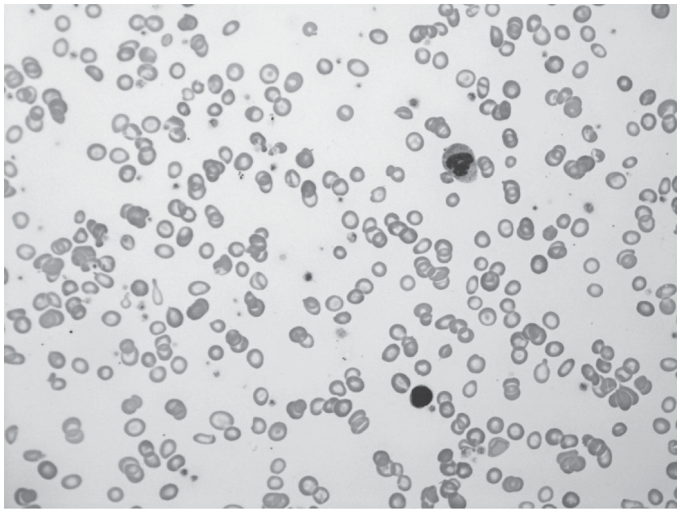

**Figure 48.1** A blood film of a patient with iron deficiency anaemia depicting microcytic hypochromic red cells and target cells.

haemoglobin (MCH), and mean cell haemoglobin concentration (MCHC). A blood film may confirm the presence of microcytic hypochromic red cells (Figure 48.1) and characteristic 'pencil cells'. However, microcytic, hypochromic indices may also occur in haemoglobinopathies. In addition, for milder cases of iron deficiency, the MCV may not have fallen below the normal range.

Some analysers will give a percentage of hypochromic red cells present. This is said to be a sensitive marker of functional iron deficiency, but is not available on all analysers, and there is little information on its use in pregnancy.

Other tests either assess iron stores or the adequacy of iron supply to the tissues.

### Serum ferritin

Serum ferritin is a stable glycoprotein which accurately reflects iron stores in the absence of inflammatory change. It is the first laboratory test to become abnormal as iron stores decrease and it is not affected by recent iron ingestion. It is generally considered the best test to assess iron deficiency in pregnancy,[5] although it is an acute-phase reactant and levels will rise when there is active infection or inflammation.

During pregnancy, in women with adequate iron stores at conception, the serum ferritin concentration initially rises, followed by a progressive fall by 32 weeks to about 50% of prepregnancy levels. This is due to haemodilution and mobilization of iron. The levels increase again mildly in the third trimester. Even though the ferritin level may be influenced by the plasma dilution later in pregnancy, a concentration below 15 mcg/L indicates iron depletion in all stages of pregnancy. In women of reproductive age, a level less than 15 mcg/L has shown specificity of 98% and sensitivity of 75% for iron deficiency, as defined by no stainable bone marrow iron. There are a variety of levels for treatment, quoted in different studies, but in general, treatment should be considered when serum ferritin levels fall below 30 mcg/L, as this indicates early iron depletion which will worsen unless treated. Van den Broek et al. found that serum ferritin is the best single indicator of storage iron provided a cut-off point of 30mcg/L is used, with sensitivity of 90%, and specificity of 85%.[5] Concurrent measurement of the C-reactive protein (CRP) may be useful in excluding inflammatory disease. The CRP concentration is largely independent of pregnancy and gestational age.

### Trial of iron therapy

A trial of iron therapy is simultaneously diagnostic and therapeutic and is both cost- and time-effective. Ferritin should be checked first if the patient is known to have a haemoglobinopathy but otherwise microcytic or normocytic anaemia can be assumed to be caused by iron deficiency until proven otherwise. Assessment of response to iron should be carried out at 2 weeks when a rise in Hb confirms iron deficiency. If haemoglobinopathy status is unknown, it is reasonable to start iron whilst screening is carried out immediately, in accordance with the UK NHS sickle cell and thalassaemia screening programme guidelines. Severe anaemia can affect the results of haemoglobinopathy testing, with a reduction in $HbA_2$ of up to 0.5%, but there is no justification for delay. If there has been no improvement in Hb by 2 weeks, referral should be made to secondary care to consider other causes of anaemia, such as folate deficiency.

### Dietary iron

The amount of iron absorption depends upon the amount of iron in the diet, its bioavailability, and physiological requirements. The main sources of dietary haem iron are haemoglobin and myoglobin from red meats, fish, and poultry. Haem iron is absorbed two to three times more readily than non-haem iron. Meat also contains organic compounds which promote the absorption of iron from other less bioavailable non-haem iron sources. However, approximately 95% of dietary iron intake is from non-haem iron sources. Vitamin C significantly enhances iron absorption from non-haem foods, the size of this effect increasing with the quantity of vitamin C in the meal. Germination and fermentation of cereals and legumes improve the bioavailability of non-haem iron by reducing the content of phytate, a food substance that inhibits iron absorption. Tannins in tea and coffee inhibit iron absorption when consumed with a meal or shortly after.

### Oral iron supplements

Education and counselling regarding diet may improve iron intake and enhance absorption but this is insufficient to correct established iron deficiency and medication is required.

Oral iron is an effective, cheap, and safe way to replace iron. Ferrous salts show only marginal differences between one another in efficiency of absorption of iron. Ferric salts are much less well absorbed. The recommended dose of elemental iron for treatment of iron deficiency is 100–200 mg daily. Higher doses should not be given, as absorption is saturated and side effects increased.

Available ferrous salts include ferrous fumarate, ferrous sulphate, and ferrous gluconate. The amount of elemental iron in each salt varies as detailed in Table 48.1. Combined iron and folic acid preparations may also be used but it should be noted that use of these preparations does not obviate the need to take the recommended dose of folic acid for prevention of neural tube defects preconception and during the first 12 weeks of pregnancy.

Oral iron supplementation should be taken on an empty stomach, as absorption is reduced or promoted by the same factors that affect absorption of dietary non-haem iron.

### Parenteral iron therapy

Parenteral iron therapy is indicated when there is absolute non-compliance with, or intolerance to, oral iron therapy or proven malabsorption.[6] It circumvents the natural gastrointestinal

**Table 48.1** Dose and elemental iron content per tablet of oral iron preparations

| Iron salt | Dose per tablet | Elemental iron |
|---|---|---|
| Ferrous fumarate | 200 mg | 65 mg |
| Ferrous gluconate | 300 mg | 35 mg |
| Ferrous sulphate (dried) | 200 mg | 65 mg |
| Ferrous sulphate | 300 mg | 60 mg |
| Ferrous feredetate (Sytron®) | 190 mg/5 mL elixir | 27.5 mg/5 mL |

regulatory mechanisms to deliver non-protein bound iron to the red cells.

Faster increases in Hb and better replenishment of iron stores in comparison with oral therapy have been demonstrated, particularly for iron sucrose and iron (III) carboxymaltose. A large retrospective study reported fewer postpartum transfusions in the group treated with intravenous (IV) iron.[7] However, there is a paucity of good quality trials that assess clinical outcomes and safety of these preparations.

As free iron may lead to the production of hydroxyl radicals with potential toxicity to tissues, iron deficiency should be confirmed by ferritin levels before use of parenteral preparations. Contraindications include a history of anaphylaxis or reactions to parenteral iron therapy, first trimester of pregnancy, active acute or chronic infection, and chronic liver disease. Facilities and staff trained in management of anaphylaxis should be available.

The IV iron preparations currently available in the United Kingdom and their properties are summarized in Table 48.2. The different preparations have not been compared to each other in pregnancy. Iron sucrose has a higher availability for erythropoiesis than iron dextran and experience suggests a good safety profile in pregnancy.[8] Its use is limited by the total dose that can be administered at any one time, requiring multiple infusions which may limit patient compliance. The newer preparations, iron III carboxymaltose and iron III isomaltoside, aim to overcome this problem, with single dose administration in an hour or less.

### Fast-acting intravenous iron preparations

Iron III carboxymaltose (Ferrinject®) is a ferric hydroxide carbohydrate complex, which allows for controlled delivery of iron within the cells of the reticuloendothelial system (primarily bone marrow) and subsequent delivery to the iron binding proteins ferritin and transferrin. It is administered intravenously, as a single dose of 1000 mg over 15 minutes (maximum 15 mg/kg by injection or 20 mg/kg by infusion). Randomized controlled trials have shown non-inferiority[9,10] and superiority[11] to oral ferrous sulphate in the treatment of iron deficiency anaemia in the postpartum period, with rapid and sustained increases in Hb. Animal studies have shown it to be rapidly eliminated from the plasma, giving minimal risk of large amounts of ionic iron in the plasma. By 28 days, in iron-deficient rats most of the iron has been incorporated into new erythrocytes.[12]

Iron III isomaltoside (Monofer®) is an IV preparation with strongly bound iron in spheroid iron-carbohydrate particles, providing slow release of bioavailable iron to iron binding proteins. There is rapid uptake by the reticuloendothelial system and little risk of release of free iron. An erythropoietic response is seen in a few days, with an increased reticulocyte count. Ferritin levels return to the normal range by 3 weeks as iron is incorporated into new erythrocytes. Doses of more than 1000 mg iron can be administered in a single infusion and it has been used safely in pregnancy.

### Intramuscular preparations

The only preparation available in the United Kingdom that may be given intramuscularly (IM) is low-molecular-weight iron dextran. However injections tend to be painful and there is significant risk of permanent skin staining. Its use is therefore generally discouraged but if given, the Z-track injection technique should be used to minimize risk of iron leakage into the skin. The advantage of IM iron dextran is that, following a test dose, it can be administered in primary care, although facilities for resuscitation should be available as there is a small risk of systemic reaction.

A recent Cochrane review on treatments for iron deficiency in anaemia[13] highlighted the need for good quality randomized controlled trials in this setting, in particular to assess clinical outcomes and adverse events. Pending further good quality evidence, centres should review their policies and systems for use of parenteral therapy in iron deficiency anaemia in pregnancy.

### Management of delivery in anaemic women

With good practice this situation should generally be avoided; however, there are instances when women book late, have recently come from abroad, or have not engaged with antenatal care. In these situations it may be necessary to take active measures to minimize blood loss at delivery. Consideration should be given to delivery in hospital, IV access, and blood availability. Whilst this should be done on an individual basis, a suggested cut off would be Hb less than 100 g/L for delivery in hospital, including hospital-based midwifery-led unit and less than 95 g/L for delivery in an obstetrician-led unit, with an intrapartum care plan discussed and documented.

The third stage of labour should be actively managed to minimize postpartum blood loss.

### Indications for and risks of blood transfusion

Concerns about safety, high costs, and availability of donor blood have promoted greater scrutiny of blood transfusion practice. Potential dangers of transfusion are numerous but most commonly arise from clinical and laboratory errors.[14] In addition, the potential for transfusion-induced sensitization to red cell antigens, confer a potential risk of fetal haemolytic disease.

Massive obstetric haemorrhage is widely recognized as an important cause of morbidity and mortality and requires prompt use of blood and components as part of appropriate management. Chapter 35 covers the multidisciplinary approach required, together with the implementation of intraoperative cell salvage as a transfusion sparing strategy. However, outside the setting of massive haemorrhage, audits indicate that a high proportion of blood transfusions administered in the postpartum period may be inappropriate,[15] with under-utilization of iron supplements.

### Postpartum anaemia

The WHO defines postnatal anaemia as Hb less than 10 g/dL. FBC should be checked within 48 hours of delivery in all women with

**Table 48.2** Summary of intravenous iron preparations available in the United Kingdom

| | Cosmofer® iron (III) hydroxide dextran complex | Venofer® iron (III) hydroxide sucrose complex | FerinJect® iron (III) carboxymaltose | Monofer® iron (III) isomaltoside |

an estimated blood loss greater than 500 mL and in women with uncorrected anaemia in the antenatal period or symptoms suggestive of postpartum anaemia. Where there is no bleeding, the decision to transfuse should77 be made on an informed individual basis. In fit, healthy, asymptomatic patients there is little evidence of the benefit of blood transfusion, which should be reserved for women with continued bleeding or at risk of further bleeding, imminent cardiac compromise, or significant symptoms requiring urgent correction. Women with Hb levels less than 100 g/L, who are haemodynamically stable, asymptomatic, or mildly symptomatic, should be offered elemental iron 100–200 mg daily for at least 3 months and a repeat FBC and ferritin to ensure Hb and iron stores are replete.

If, after careful consideration, elective transfusion is required, women should be fully counselled about potential risks, including written information, and consent should be obtained.

## Folate deficiency

Folate deficiency is an unusual cause of anaemia in pregnancy, largely due to the fortification of foods with folic acid and the wide-scale supplementation of low-dose folic acid in early pregnancy for the prevention of neural tube defects. It is found in a wide variety of food sources including green leafy vegetables, citrus fruits, nuts, bread, and dairy products; however, it is heat labile and often lost in the cooking process.

Body stores last for several months. It is absorbed mainly in the jejunum and will be affected by malabsorptive syndromes such as coeliac disease, although it is most unusual for these to first become manifest in pregnancy.

Secondary folate deficiency can result from increased erythropoiesis, as occurs in haemolytic anaemias and myeloproliferative disorders, and also from anticonvulsant therapy, which induces metabolic enzymes.

### Diagnosis of folate deficiency

Mean cell volume (MCV) rises in pregnancy by around 6 fL but an increase to over 100 fL is suggestive of vitamin $B_{12}$ or folate deficiency. Other clues on the blood film are the presence of oval macrocytes, hypersegmented neutrophils (Figure 48.2) and possible mild leucopenia or thrombocytopenia. If iron deficiency coexists the mean cell volume may be normal but the blood film shows dimorphism, with microcytes as well as macrocytes.

Red cell folate gives a more accurate assessment than serum folate but neither has particularly good sensitivity or specificity in pregnancy. Bone marrow examination would reveal the presence of megaloblasts, where there is loss of synchrony between nuclear

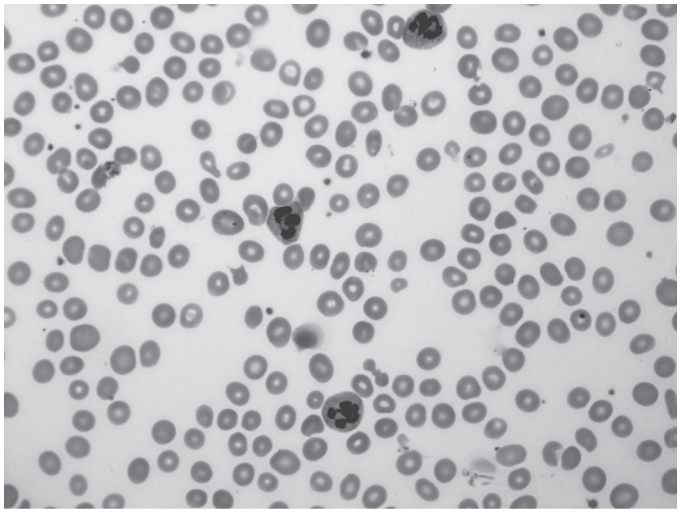

**Figure 48.2** A blood film from a patient with folate deficiency showing hypersegmented neutrophils and macrocytes.

**Table 48.3** Causes of haemolysis

| | Primary |
|---|---|
| Autoimmune | In association with connective tissue disorders or neoplastic disease |
| Hereditary | Disorders of Hb synthesis |
| | Red cell membrane disorders |
| | Enzymopathies |
| Mechanical | Mechanical heart valves |
| | Disseminated intravascular coagulation (DIC) |
| | Microangiopathic haemolytic anaemia (MAHA) |
| Drugs | Immune-mediated |
| | Oxidative stress |
| Infections | Bacterial enzymes, e.g. *Clostridium perfringens* |
| Paroxysmal nocturnal haemoglobinuria | Clonal disorder causing increased susceptibility to complement lysis |

and cytoplasmic maturation but the investigation is invasive and a trial of supplementation for suspected cases would be preferred. Proven folate deficiency requires treatment with 5 mg folic acid three times per day. The improvement in Hb levels can mask an undiagnosed $B_{12}$ deficiency and this should be excluded first.

### Vitamin $B_{12}$ deficiency

Vitamin $B_{12}$ deficiency is extremely rare in pregnancy but is often incorrectly diagnosed due to the physiological fall in serum $B_{12}$ levels as $B_{12}$ binding globulin increases. Genuine vitamin $B_{12}$ deficiency is usually associated with infertility and the most common cause, pernicious anaemia, usually develops after the age of 40 years. Vitamin $B_{12}$ is found in foods of animal origin, such as meat and dairy but even vegans rarely develop $B_{12}$ deficiency due to the synthesis of $B_{12}$ by bacteria in the gut or on legumes. In suspected cases, oral cyanocobalamin can be tried first but if IM hydroxycobalamin is thought necessary, proper investigation should be performed outside of pregnancy to avoid unnecessary lifelong supplements.

### Haemolytic anaemia

Haemolysis is defined as shortened red cell survival, the average lifespan of a red cell being 120 days. Mild haemolysis in compensated by an increase in bone marrow erythropoiesis and may not affect the Hb concentration, however anaemia will develop when the degree of shortened red cell survival exceeds the bone marrow's ability to compensate. Causes of haemolysis are listed in Table 48.3.

The most common cause is autoimmune haemolytic anaemia, either idiopathic or in association with underlying autoimmune disease such as systemic lupus erythematosus.

Laboratory markers of haemolysis include elevated lactate dehydrogenase (LDH), increased reticulocytes, fall in haptoglobins, and rise in bilirubin. Autoimmune haemolysis is characterized by a positive direct antiglobulin test (Coombs' test), giving evidence of antibody bound to the surface of erythrocytes.

Where there is intravascular haemolysis, such as in microangiopathic haemolytic anaemia (MAHA), free haemoglobin will be present in the urine and shed in tubal cells, showing as urine haemosiderin.

Management depends on the underlying cause. Autoimmune haemolysis can be treated with immunosuppressants such as steroids and immunoglobulin. Transfusion is sometimes necessary but provision of compatible donor units can be delayed by specialist investigation to identify the specificity of the antibody. Patients with cold haemagglutinin disease may benefit from receiving transfusion via a blood warmer.

## Haemoglobinopathies

### Introduction

The haemoglobinopathies are common genetic disorders. They may result in significant morbidity and mortality, affecting all age groups and genders. The abnormalities of haemoglobin can either be:

- *structural:* such as in sickle cell disease, where a single nucleotide change in the beta (β)-globin gene leads to the substitution of valine for glutamine at position 6 on the β-globin chain
- *disorders resulting from unbalanced globin chain production:* the thalassaemias, the globin chains produced are structurally normal but reduced in quantity.

It has long been known that morbidity and mortality in children with sickle cell disease is high in the first 5 years of life. The protective effects of high levels of fetal haemoglobin (HbF) in the newborn decline over the first 4–6 months of life, thereafter much of childhood mortality is due to pneumococcal septicaemia and acute splenic sequestration. Successful antibiotic prophylaxis, vaccination, and education programmes have all but eliminated these problems and are perhaps the single most important step in the improved survival of sickle cell disease. In adulthood, morbidity is predominated by end-organ damage from microvascular disease.

In β thalassaemia major, the failure of beta globin chain production results in a severe transfusion dependent anaemia which

is manifest as HbF levels reduce in the first few months of life. From this point on, the management of thalassaemia is based upon regular transfusion and iron chelation to reduce the risk of organ damage, particularly cardiac. Care of the patient with thalassaemia requires collaboration between haematologists, endocrinologists, diabetologists, cardiologists, and occasional input from other specialities such as hepatology. With appropriate care and good compliance, life expectancy may be normal. However, early cardiac death is common in those who do not comply with iron chelation.

## Sickle cell disease

The sickling disorders are a group of inherited chronic haemolytic anaemias with clinical manifestations occurring as a result of the polymerization of haemoglobin S. The disorders in which sickling occur are:

- homozygous sickle cell disease—HbSS. The most common and generally the most severe.

Compound heterozygous states associated with clinical disease include:

- haemoglobin SC disease
- haemoglobin Sβ thalassaemia
- haemoglobin SD Punjab
- haemoglobin SO Arab
- haemoglobin SLepore Boston.

Carriage of haemoglobin S is not associated with significant disease but its significance in pregnancy is in terms of genetic counselling and the need for partner testing.

Sickle cell disease is characterized by chronic intravascular and extravascular haemolysis; red cell lifespan is shortened from 120 days to 16–20 days. This chronic haemolysis leads to the liberation of free haemoglobin which mops up nitric oxide released from the vascular endothelium. This in turn leads to endothelial activation and vasoconstriction providing ideal conditions for adherence of cellular blood components. The combination of poorly deformable red blood cells, increased viscosity, endothelial activation and vasoconstriction causes ongoing vaso-occlusion in the microvasculature. The process is further exacerbated by leucocytosis, platelet activation, and increased levels of pro-inflammatory cytokines. Vaso-occlusion leads to both the acute complications of sickle cell disease, such as painful crises, as well as chronic organ damage, including cardiac and renal impairment seen in older patients.

Much of the published information on pregnancy in sickle cell disorders relates to homozygous (SS) sickle cell disease. This, and $S\beta^0$thalassaemia, are in general the most severe forms. Patients with milder sickle conditions such as SC disease and $S\beta^+$thalassaemia can also have complicated pregnancies though the risks are lower. All patients with sickling disorders should be jointly managed by an obstetrician and haematologist with interest and experience in these diseases. Since these pregnancies are high risk, patients will require frequent review by the multidisciplinary team. Twin and multiple birth pregnancies are associated with a higher rate of serious complications. Despite the potential complications, more than one-quarter of these pregnancies occur without problems.

Prior to the 1970s, 30–40% of women with sickle cell disease did not survive pregnancy, but recent decades have seen a marked improvement; currently mortality has been shown to be 1–2% in studies from the United States and Europe. A National Confidential Enquiry into Patient Outcome and Death (NCEPOD) report[16] highlights difficulties with death certification and autopsy in sickle cell disorders. Few pathologists have significant experience and non-specialist sickle clinicians are in a similar position. It is recommended that pathologists with appropriate experience perform such autopsies though there are now national guidelines for autopsy in sickle cell disease. Clinicopathological correlation is crucial, for example, in differentiating sickle chest from pneumonia or whether thrombosis is likely to have been *in situ* or embolic. These women may have complex coexisting medical problems which can make the management of their pregnancy even more challenging.

Perinatal mortality was reported to be as high as 50–80% prior to the 1970s. More recent studies in the United States and Europe have reported a perinatal mortality rate of between 1% and 8%. Since the 1970s, it has been known that women with sickling disorders are more likely to have premature deliveries. This has been reported at an average of between 34.1 to 38.5 weeks' gestation. In a recent Jamaican study, the mean gestational age was found to be 37.0 weeks compared to 38.7 weeks in controls. In African Americans, the mean gestational age was 37 weeks. Infants born to HbSS mothers are twice as likely to be preterm compared to HbSC mothers. Intrauterine growth retardation is a well-documented complication of sickle cell pregnancy. This is probably a consequence of maternal anaemia and impaired placental function resulting from vaso-occlusion in uteroplacental circulation. Histological studies have shown placental infarction with abruptions and villous oedema.

Seventy-seven per cent of infants born to mothers with sickle cell anaemia have a birth weight below the 50th centile, with 21% below the 10th centile. Neonates born to mothers with HbSS disease are significantly smaller than babies born to mothers with HbSC disease.

Patients with sickle cell disease have hyposplenism. Urinary tract infections are increased in normal pregnancies and can lead to pyelonephritis and premature labour. There may be a further increase in risk in sickle pregnancy. Other common sites of infection include chest and bone. Common pathogens include *Pneumococcus, Salmonella, Escherichia coli*, and *Mycoplasma*. Infection is a common precipitant of painful crises.

Pregnancy-induced hypertension and pre-eclampsia complicate one-third of pregnancies in sickle cell disease. There is an association between hypertension with proteinuria and simultaneous sickling complications. The pregnant patient with sickle cell disease should be regarded as at high risk of venous thromboembolism. Pulmonary embolism is difficult to diagnose in this setting but should be considered within the differential of a patient presenting with dyspnoea and chest pain.

### General management of sickle cell pregnancy

All couples should receive preconceptual advice. Maternal and fetal risks of pregnancy and availability of prenatal diagnosis should be discussed in the light of partner screening. Crisis prevention measures should be advised, including avoidance of cold, overexertion, and dehydration. Medications should be

reviewed, with assessment of risks versus benefits for individual drugs. Folic acid supplements and antibiotic prophylaxis are a necessity. Hydroxycarbamide should be discontinued at least 3 months before conception and the need for an antenatal top-up or exchange transfusion programme should be considered.[17]

Throughout pregnancy, women require continued health education and review of compliance with medications. The clinical condition of the patient, degree of haemolysis, and urine culture should be monitored regularly, along with fetal growth scans.

There should be a low threshold for admission especially if there is limb, bone, abdominal, or chest pain after 28 weeks' gestation, with a 24-hour admission policy and contact numbers if any features of sickle cell crisis develop. All women should have an appropriate plan for use of analgesia in pregnancy, aiming to avoid non-steroidal anti-inflammatory drugs (NSAIDs) after 34 weeks. The obstetric anaesthetist needs to be involved early to discuss management in labour. Transfusion should only occur after discussion with a haematologist.

The majority of severe crises occur in the third trimester often at the time of delivery. Often the complications of sickle cell disease precipitate labour rather than labour precipitating sickling complications. Crises in pregnancy are more common in women with HbSS pregnancies (30–80%) than in women with HbSC (30%). SC disease is generally a milder condition outside pregnancy but patients may present with pain, thrombosis, and other sickle complications in the third trimester.

Labour and early puerperium are risk periods for development of pain. This becomes more likely in the presence of infection, dehydration, or acidosis. Sickle patients have a renal concentrating defect from early childhood and pass large volumes of dilute urine. Attention to hydration status is therefore crucial. Crises in pregnancy often present as abdominal pain which can be difficult to distinguish from obstetric complications.

Those with a sickle cell crisis should be admitted only to an obstetric or haematology ward. In the final trimester, with the high risk of obstetric problems, the obstetric setting is most appropriate, and the patient should be rested and given adequate hydration of 3–4 L of fluid per 24 hours. Strict fluid balance is essential and oxygen if hypoxic. Pain relief should be initiated within 30 minutes, taking account of the previous analgesic history.[18] Regular paracetamol should be given and NSAIDs if the pregnancy is less than 34 weeks. However, subcutaneous opiates are often necessary. Pethidine is not recommended for the treatment of sickle pain, as it can induce seizures. Morphine, diamorphine, or oxycodone is appropriate. Linear analogue scales are used to assess pain control. Patient-controlled analgesia or subcutaneous pumps are occasionally required. Regular assessment of sedation and conscious level is essential if the patient is on strong opiates. Investigations should include a FBC, reticulocyte count, urea and electrolytes, group and screen, pulse oximetry and arterial blood gases if appropriate, a mid-stream specimen of urine, blood cultures and throat swabs, and a chest X-ray. Antibiotics are not routinely required unless there is evidence of infection. Low-grade fever of less than 38°C is common in painful crisis, even in the absence of infection. Low-molecular-weight heparin (LMWH) thromboprophylaxis and compression stockings should be given routinely. Indications for transfusion or exchange transfusion should be discussed with a haematologist. Chest physiotherapy including incentive spirometry will reduce the risk of a subsequent chest syndrome in patients with rib pain. Chest crises in pregnancy require even closer monitoring and the use of a broad-spectrum antibiotic. Transfusion, either exchange or top-up, should be considered in hypoxaemia ($SaO_2$ < 5% lower than patient's steady-state level), deteriorating clinical status, or progressive multilobe involvement.

### Labour and delivery

The aim should be to achieve a vaginal delivery, as there is no benefit from elective caesarean delivery. Induction leads to a higher caesarean delivery rate, with its own complications, plus the implication that future pregnancies will need a trial of scar and be associated with a risk of subsequent operative delivery. The mother needs to be kept warm and well hydrated, with IV fluids commenced at time of admission in labour, at a rate of 1 L 8-hourly, to maintain good urine output. Strict fluid balance should be ensured. A FBC, group and screen should be taken and continuous pulse oximetry used, with continuous cardiotocography monitoring throughout labour.

Epidural analgesia is the pain relief of choice. Therefore careful timing of LMWH should be taken into consideration if labour is induced. The woman should not be allowed to labour for more than 12 hours and prolonged rupture of membranes should be avoided as it increases the risk of infection and dehydration. If operative delivery is necessary, this should be discussed with the haematologist. Neuraxial (rather than general) anaesthesia reduces the likelihood of sickle crisis and postoperative acute chest syndrome. Thromboprophylaxis with LMWH and compression stockings is required postpartum and the neonatologist should be alerted.

### Postpartum

Baby and mother need close monitoring, with good hydration. The baby needs to be monitored for signs of respiratory depression if opiates have been used intrapartum.

### Prophylactic transfusion

The role of transfusion in sickle cell disease in pregnancy is controversial, although it is generally accepted that transfusion is not required as part of the management of uncomplicated sickle pregnancy. Transfusion should be reserved for high-risk pregnancies. This would include twin pregnancies, women with previous poor obstetric history, chest crises, recurrent pain, and severe anaemia. Cell salvage is contraindicated in women with sickle cell disease as the fragile cells are lysed in the machine.

### Summary

Maternal mortality is significantly increased for women with sickle cell disorders and the key to successful outcome lies in the close interaction between obstetric teams, the anaesthetist, and haematologists. Close monitoring and awareness of risks and complications is essential and the majority of pregnancies will have a successful outcome. Where possible, delivery should be allowed to proceed with minimal intervention; there being little evidence that transfusion or operative delivery are of any benefit in the majority of cases.

## Thalassaemia and pregnancy

The thalassaemias are almost always autosomal recessive disorders caused by mutations or deletions in the alpha (α)- or β-globin genes, leading to diminished or absent production of one or

more globin chains. The other globin chain is produced in relative excess and precipitates within erythroid precursors, causing chronic haemolysis and ineffective erythropoiesis.

### α thalassaemia

Four α-globin genes are inherited as a pair from each parent. The severity of the condition depends on the number of α-globin genes deleted.

### α-thalassaemia carrier (αα/––), (α–/α–) or (–α/αα)

Carriers of α thalassaemia are asymptomatic and are usually first detected at antenatal screening. Their haemoglobin is in the normal range or minimally decreased with low MCV and MCH.

### Haemoglobin H disease (––/–α)

Those affected by haemoglobin H disease have three non-functioning α-globin genes. The haemoglobin is commonly in the range 8–9 g/dL with microcytic, hypochromic red cell indices, and splenomegaly. HbH disease is a mild form of thalassaemia intermedia, those affected rarely need transfusion. The anaemia may worsen in pregnancy and with infection.

### Haemoglobin Bart's hydrops (––/––)

A complete absence of α chains is incompatible with life and results in the unopposed chains forming tetramers called haemoglobin Bart's. This is a common cause of stillbirth in areas with a high frequency of (––/αα) such as SE Asia and the Eastern Mediterranean. The fetus is stillborn at 34–40 weeks or dies soon after birth. The Hb Bart's binds oxygen poorly, impairing tissue oxygenation. The fetus appears oedematous and jaundiced with massive hepatosplenomegaly and ascites.

### β-thalassaemia carrier

Individuals are asymptomatic and diagnosed at antenatal screening or during investigation of microcytic, hypochromic indices. The haemoglobin is rarely less than 100 g/L. $HbA_2$ is raised. Iron replacement need not be given unless a deficiency state is proven by reduced serum ferritin.

### β-thalassaemia intermedia

A range of interacting genetic lesions may lead to a thalassaemic phenotype of varying severity. Some will be asymptomatic whilst others require intermittent transfusion. The haemoglobin is usually 100–120 g/L but can be as low as 50–60 g/L in severe forms. Hepatosplenomegaly may be present.

### Management in pregnancy

Carriers of α and β thalassaemia and those with HbH disease or other mild forms of thalassaemia intermedia can be managed as a normal pregnancy. Anaemia may worsen during pregnancy because of the normal physiological changes. Oral iron supplements should be given where there is a reduced ferritin but not for microcytosis and hypochromia alone.

It is important to identify couples at risk of a baby affected by Hb Bart's. This should be picked up by the antenatal screening programme and parents offered counselling, education and prenatal diagnosis. The mother may also develop 'mirror syndrome' a severe pre-eclampsia, and delivery of a hydropic fetus and placenta can cause obstetric problems.

β-thalassaemia major and severe forms of intermedia require careful multidisciplinary management in specialist centres. Cardiac and liver damage from iron overload should be assessed prior to pregnancy and organ function monitored. Transfusion regimens should be carefully reviewed as pregnancy proceeds and physiological haemodilution occurs and iron chelation therapy at delivery should be considered.

Neuraxial anaesthesia can be used for labour and delivery as long as there is no thrombocytopaenia,[19] which may occur if there is splenomegaly. Cell salvage can be used during caesarean delivery.[20]

## Normal haemostasis

Haemostasis is the process by which a fibrin platelet plug forms at the site of vascular injury. The reactions responsible for the formation of this haemostatic plug take place on phospholipid cell membranes, particularly endothelial cells, platelets, and monocytes, and are usually due to the expression of tissue factor (TF), which activates the coagulation pathway. In the resting state, the cells in contact with the blood do not support procoagulant reactions, but when activated, the negatively charged phospholipid, normally present on the inside of the cell, becomes exposed on the outside and provides a catalytic site for haemostatic reactions to occur. To further increase the procoagulant surface area, activated or apoptotic cells shed microparticles, pieces of membrane with exposed negatively charged phospholipid.

### Laboratory investigations

Laboratory screening tests of coagulation attempt to replicate haemostatic processes *in vitro*. However, this does not necessarily reflect the *in vivo* status and normal results do not exclude a bleeding disorder. Results should therefore be interpreted in conjunction with the bleeding history, particularly the response to haemostatic challenges and drug history. A coagulation screen will usually include the prothrombin time (PT) and activated partial thromboplastin time (aPTT). The thrombin time (TT) and fibrinogen level can also be easily measured.

The easiest way to understand *in vitro* tests of coagulation is to refer to the traditional cascade model of blood coagulation which uses a Y-shaped cascade of protease activation, with two pathways (intrinsic and extrinsic) converging to a final common pathway. Although this has little *in vivo* validity, it is a useful concept for interpreting laboratory tests. Figure 48.3 illustrates a simplified version of the coagulation cascade, and the factors which affect the PT and aPTT.

### Prothrombin time

The PT measures the extrinsic pathway. It is calculated by measuring the time taken for a clot to form after the addition of TF, phospholipid, and calcium to platelet-poor plasma.

### Activated partial thromboplastin time

The aPTT measures the intrinsic pathway. It is the time taken for a clot to form after addition of calcium to platelet-poor plasma, phospholipids, and a contact activator, such as kaolin, to activate factor XII (FXII).

### Thrombin time

The TT involves the addition of thrombin to platelet-poor plasma. It reflects the conversion of fibrinogen to fibrin but is also sensitive to the presence of inhibitors that may be present in the plasma (e.g. heparin).

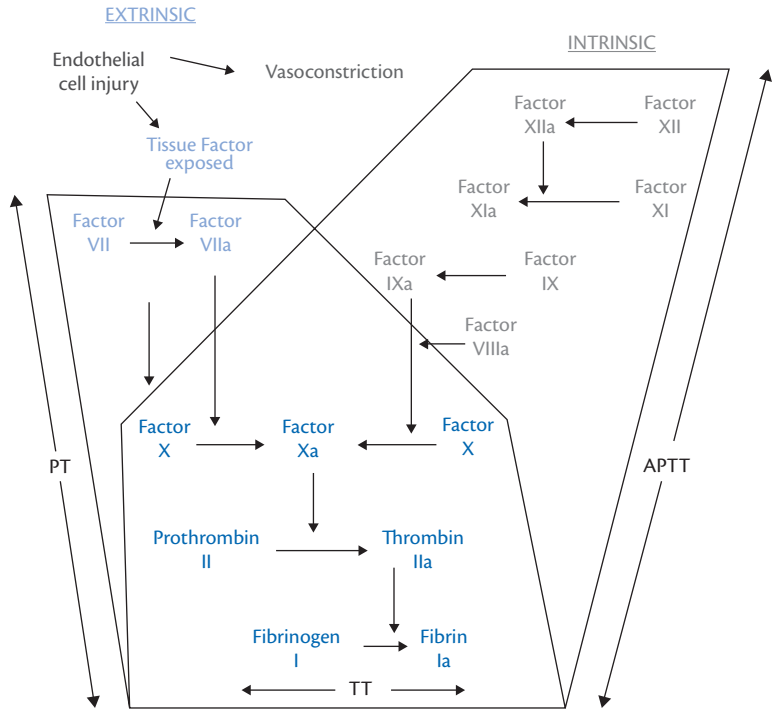

**Figure 48.3** A simplified model of the coagulation cascade.

## Fibrinogen

There are numerous methods of measuring fibrinogen levels. Most commonly performed is the Clauss assay, which is a functional or qualitative measure of fibrinogen. The immunological method measures the quantity of fibrinogen (fibrinogen antigen) and the comparison between the two can detect dysfibrinogenaemias.

The potential causes of abnormal coagulation tests are summarized in Table 48.4.

## Near-patient assessment of coagulation—thromboelastography (TEG®) and Rotational elastometry (ROTEM®)

Thromboelastography® (TEG®) and thromboelastometry (ROTEM®) provide a global assessment of clot formation, stabilization, and dissolution at the bedside. They give a dynamic assessment of coagulation compared to conventional methods, and assess the whole haemostatic process rather than isolated aspects. Near-patient testing allows rapid assessment.

**Table 48.4** Potential causes of abnormal coagulation tests

| Isolated prolonged PT | Isolated prolonged aPTT | Prolonged PT and aPTT | Prolonged TT | Decreased fibrinogen |
|---|---|---|---|---|
| Factor VII deficiency | Factor VIII deficiency | Vitamin K deficiency | Congenital and acquired deficiencies in fibrinogen | DIC |
| Warfarin therapy | Factor IX deficiency | Liver disease | Dysfibrinogenaemia | Liver disease |
| Vitamin K deficiency | Factor XI deficiency | DIC | Heparin | Massive transfusion |
| | Factor XII deficiency | Massive transfusion | Direct thrombin inhibitors | Inherited deficiencies including afibrinogenaemia, hypofibrinogenaemia, and dysfibrinogenaemia |
| | Lupus anticoagulant | Common pathway including factor V, factor X, prothrombin, and fibrinogen deficiencies | Elevated fibrin degradation products | |
| | Heparin therapy | Warfarin/heparin therapy | Paraproteinaemias | |
| | | Direct thrombin inhibitors | | |

aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; PT, prothrombin time; TT, prothrombin time.

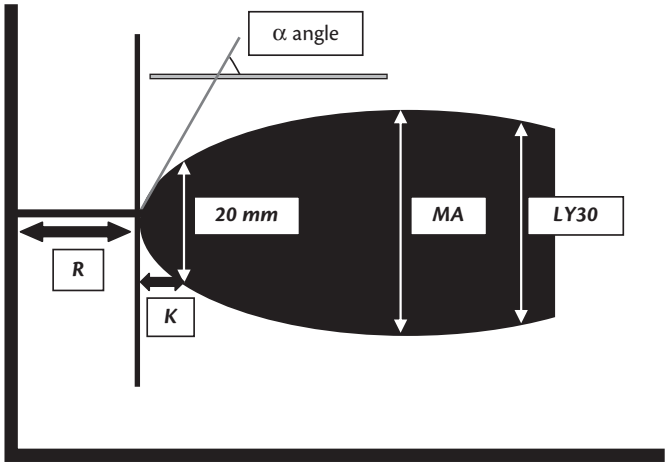

**Figure 48.4** A normal TEG® trace.
Reproduced from da Luz LT, Nascimento B, Rizoli S., Thromboelastography (TEG): practical considerations on its clinical use in trauma and resuscitation, *Scandinavian Journal on Trauma, Resuscitation and Emergency Medicine*., Volume 21: 29. 2013 © 2013 da Luz *et al.* This is an Open Access article distributed under the terms of the Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0), which permits unrestricted use, distribution, and reproduction in any medium, provided the original work is properly cited.

Classical thromboelastography (TEG®) involves placing a small sample of citrated blood into a cuvette which is gently rotated to imitate sluggish venous blood flow, activating coagulation. The blood is also recalcified to initiate coagulation, and an activator is added to standardize the test. The speed and strength of the clot is then measured, and a trace is formed. Four values which determine clot formation are measured in this test: the R time, the K value, the 'α' angle, and the maximal amplitude (MA). These are illustrated in Figure 48.4.

The R time represents the time from the start of test to the initial detection of the clot. The K time represents the time from the R time to the time taken for the clot to reach 20 mm in size. This represents the speed of coagulation. The 'α' angle is the tangent of the curve made as the K is reached and offers similar information to the K. The MA is a reflection of clot strength, assessing the properties of platelet and fibrin adhesion. The LY30 can also be calculated, which measures the percentage decrease in amplitude 30 minutes post MA, which gives a measure of the degree of haemolysis.

A heparinized cup can also be used with is sensitive to heparin. The use of paired plain and heparinized cups can be used to detect whether residual heparin is present. The generated curves and values can be used to detect and classify coagulopathies, and aid use of blood products, as suggested in Table 48.5. Some commonly seen curves are illustrated in Figure 48.5.[21]

ROTEM® uses similar principles to TEG®, but it is the sensor shaft rather than the cup which rotates. Formation of fibrin strands impedes the rotation of the sensor shaft and a trace is generated.[22]

## Inherited bleeding disorders

Women who are sufferers or carriers of a congenital bleeding disorder need to be carefully managed to allow them to cope with the haemostatic challenges of pregnancy, labour, and delivery. Cases should be managed in a multidisciplinary setting by experienced obstetricians, anaesthetists, and haematologists. Individually tailored management plans are needed, taking into account bleeding risks to mother and fetus, as well as obstetric risk factors. Key features in the management of mothers and babies at risk of bleeding disorders are listed in Boxes 48.1 and 48.2.

**Table 48.5** Potential causes of abnormal TEG® results

| Value | Causes | Suggested therapy |
|---|---|---|
| Increased R time | Factor deficiency, anticoagulation, severe hypofibrinogenaemia, severe thrombocytopenia | Fresh frozen plasma (FFP), consider cryoprecipitate if grossly prolonged |
| Increased K time | Factor deficiency, thrombocytopenia, thrombocytopathy, hypofibrinogenaemia | Do FibTem or functional fibrinogen to determine whether need of FFP and/or cryoprecipitate.<br>Give platelets if count <50 × $10^9$/L |
| Decreased α angle | Hypofibrinogenaemia, thrombocytopenia | Perform a FibTem or functional fibrinogen to determine whether need of FFP and/or cryoprecipitate,<br>Give 1 pool of platelets if platelet count is <50 × $10^9$/L |
| Decreased MA | Thrombocytopenia, thrombocytopathy, hypofibrinogenaemia | Perform a FibTem or functional fibrinogen and platelet count to determine if fibrinogen and/or platelet defect |
| Increased LY30 | Hyperfibrinolysis | Tranexamic acid |

The commonest disorders likely to be encountered are haemophilia A and B, and von Willebrand disease (VWD). However the rarer coagulation disorders also need to be considered.

### Haemostatic agents

Treatments available for women with inherited bleeding disorders are similar in the obstetric and non-obstetric setting. Most commonly used agents include tranexamic acid, desmopressin,

**Box 48.1** Management of mothers with bleeding disorders

- Care should be in a unit by a multidisciplinary team of obstetricians, anaesthetists, and haematologists with expertise in managing patients with bleeding disorders
- Plan of management should be discussed before pregnancy or as early as possible and a detailed labour plan documented during the third trimester
- Avoid IM injections
- Use NSAIDs with caution
- Avoid anticoagulation
- Establish baseline levels of deficiency/abnormality prior to intervention or labour
- Obtain good IV access during labour
- Ensure adequate haemostasis during labour and delivery with the use of appropriate therapy
- Avoid excessive genital or perianal trauma
- Active management of the third stage of labour
- Consider risk of thrombosis, especially postpartum
- Levels of deficient factor should be raised to at least 50 IU/dL before considering neuraxial anaesthesia

plasma-derived clotting factor concentrates, and recombinant factor concentrates.

### Plasma-derived and recombinant factor concentrates

If possible, plasma-derived clotting factors should be avoided, as although virucidal methods are used to eliminate the risk of HIV and hepatitis B and C there is a risk of transmission of hepatitis A and parvovirus infection. Fetal parvovirus infection can lead to hydrops fetalis and fetal death.[23] Recombinant factor concentrates are therefore preferred.

### Tranexamic acid

Tranexamic acid is an antifibrinolytic which competitively inhibits the activation of plasminogen to plasmin. It is a synthetic form of the amino acid lysine, and blocks the lysine binding sites on plasminogen and plasminogen receptors. Plasmin enzymatically breaks down many molecules and it especially effective in lysing fibrin, fibrinogen, and factor V. Tranexamic acid can be used prophylactically to reduce bleeding. It can also be used to treat bleeding. It is indicated in fibrinolysis which is diagnosed via thromboelastometry where fibrinolysis produces the classic 'tadpole' trace as seen in Figure 48.5. Fibrinolysis cannot be diagnosed by current standard laboratory tests. The dose is 1 g given slowly IV which can be repeated 8-hourly. Limited evidence on the use of tranexamic acid in pregnancy suggests it is safe[24] for pregnancy and breastfeeding. Currently the utility of tranexamic acid in managing postpartum haemorrhage is being assessed in the WOMAN study (Worldwide Maternal Antifibrinolytics Trial) randomizing 15,000 women with postpartum haemorrhage to tranexamic acid versus placebo.

Concurrent use of tranexamic acid with factor XI concentrate should be avoided, due to the potential risk of arterial or venous thrombosis that has been associated with factor XI concentrate.

**Box 48.2** Management of delivery for babies at risk of bleeding disorders

- Establish, if relevant, whether prenatal diagnosis has been made
- Avoid invasive monitoring
- Avoid prolonged labour
- Avoid ventouse extraction
- Avoid mid cavity forceps
- Obtain cord blood for baseline levels
- Avoid IM injections until cord results is known
- Give oral vitamin K rather than IM

### Desmopressin

Desmopressin (DDAVP®) can be used as prophylaxis or treatment of bleeding in carriers of haemophilia A, some subtypes of VWD, and some platelet function disorders. It has no effect in patients with haemophilia B. Desmopressin acts by stimulating exocytosis of Weibel–Palade bodies in endothelial cells, to release von Willebrand factor (VWF), and in some tissues also factor VIII (FVIII). FVIII levels rise approximately threefold after treatment with desmopressin. It also increases platelet responsiveness. The effect is maximal 30 minutes after IV administration, and 60 minutes after subcutaneous or intranasal treatment. The half-life of released FVIII is 8 hours. Repeated doses can be given, however tachyphylaxis occurs and the second dose can produce a rise of only 30% of the first. Desmopressin also has a fibrinolytic effect as it also stimulates the release of tissue plasminogen activator from the endothelium, so concurrent use of tranexamic acid is common. Lastly it has an antidiuretic activity, so fluid intake should be restricted for 24 hours.

There have been concerns about the safe use of desmopressin in pregnancy because of potential risks of placental insufficiency due to arterial vasoconstriction, and miscarriage or preterm labour due to an oxytocin effect.[23] A recent systematic review looked at 30 studies on the use of desmopressin in 216 pregnancies, in women with inherited bleeding disorders. They found that desmopressin was effective in preventing and reducing bleeding complications associated with pregnancy and delivery. There was one case of a water intoxication seizure, and one case of premature labour reported. There were no other maternal or fetal adverse outcomes.[25] Our practice is to use desmopressin in pregnancy where indicated (Box 48.3), but with careful attention to fluid balance.

## General measures

### Antenatal management

Antenatal management of women with a bleeding disorder, or at risk of a child with bleeding disorder, should include involvement by

**Box 48.3** Indications for DDAVP®

- Low factor VIII levels in carriers for haemophilia
- Type 1 VWD
- Some cases of type 2 VWD where response to DDAVP® is demonstrated
- Platelet function disorders

experienced obstetricians, haematologists, and anaesthetists. There are a number of haemostatic challenges in the antenatal period including miscarriage, termination of pregnancy, cervical cerclage, and prenatal diagnostic tests.[5,23,26,27] It is therefore essential to be aware of the level of the deficient or abnormal factor. The United Kingdom Haemophilia Centre Doctors' Organisation (UKHCDO) recommends measuring relevant coagulation factor levels at booking, and at 28 and 34 weeks' gestation.[28] They should also be checked prior to any intervention, and ideally after treatment to assess response.

Patients with factor XIII deficiency and afibrinogenaemia are at risk of early pregnancy loss and placental abruption[29–31] and often need prophylactic treatment throughout pregnancy. Patients with other inherited bleeding disorders do not usually need prophylaxis throughout pregnancy, but may do so before any interventions, delivery and during episodes of bleeding.

### Prenatal diagnosis

Prenatal diagnosis is often considered where the fetus is at risk of severe disease. This is usually performed by chorionic villus sampling at 11–14 weeks' gestation or amniocentesis between 16 and 20 weeks. These procedures may need to be covered with appropriate haemostatic support. Third-trimester amniocentesis is sometimes performed in women who are not considering termination of pregnancy, but wish to know whether the fetus is affected, to aid decisions made for delivery. For X-linked conditions such as haemophilia, it is clearly crucial to know the gender of the baby before planning delivery.

### Antenatal haemorrhage

Patients presenting with antenatal haemorrhage need assessment by the obstetric team to establish the cause. Conservative treatment is usually appropriate for most but those with severe bleeding disorders or severe bleeding may need factor replacement. Tranexamic acid is often effective in antenatal haemorrhage.[23]

### Labour and delivery

A detailed intrapartum care plan should be formulated by the multidisciplinary team during the third trimester for the management of labour and delivery. The mother's preferences with regards to caesarean delivery should be taken into account. It should include haemostatic measures that need to be taken and preferred mode of delivery. The plan should be made available for all involved, including the mother.

Women with moderate to severe haemophilia will need to be delivered in a unit with the necessary expertise in managing patients with bleeding disorders, and availability of appropriate coagulation assays and clotting factor treatments. Cell salvage is useful in these cases.

It is usually necessary to maintain haemostatic levels during labour and delivery up to those needed for major surgery because of the unpredictable need for emergency caesarean delivery.[31] If factor levels are not available in the acute setting, those obtained during the third trimester should be used. IV access should be obtained for patients with abnormal coagulation assays, and factor replacement is often needed to cover labour and delivery.

The mode of delivery can be controversial, and the decision should be made on a case-by-case basis. The aim is to minimize the risk of neonatal intracranial haemorrhage. A review of 117 deliveries of infants affected by haemophilia in Sweden reported rates of intracranial haemorrhage of 5.9%, 2.3%, and 0% among 17 ventouse deliveries, 87 spontaneous vaginal deliveries, and five emergency caesarean deliveries respectively.[32] There were eight elective caesarean deliveries, with one intracranial haemorrhage in a delivery at 27 weeks, where it was thought that the haemorrhage related to the prematurity of the neonate, rather than the coagulation defect.

The UKHCDO states that normal spontaneous vaginal delivery can be allowed, even for babies at risk of severe haemophilia, with early recourse to caesarean delivery if labour is prolonged or complicated. However, fear of a caesarean delivery becoming necessary in the second stage of labour prompts many to consider surgery electively. Furthermore, the decision to allow spontaneous vaginal delivery will often depend on the resources of the hospital, 24-hour availability of on-call senior obstetricians, anaesthetists and haematologists with experience in patients with haemophilia, and 24-hour laboratory support to allow processing of samples for factor assays. If these are not available, which may be the case in many hospitals, elective caesarean delivery may be a safer course of action.

Interventions such as fetal scalp monitoring, ventouse delivery, mid-cavity forceps, and forceps involving rotation of the head should be avoided in all male babies at risk of haemophilia, to minimize the risk of intracranial or scalp haemorrhage.

Care needs to be taken to avoid excessive maternal genital or perineal trauma to reduce the risk of excessive bleeding during delivery.[31]

### Neuraxial anaesthesia

Use of neuraxial anaesthesia in patients with bleeding disorders is a much debated issue. A systematic review in 2009 looked at the use of neuraxial techniques in obstetric and non-obstetric patients with bleeding disorders. A total of 507 procedures were included, 107 in patients with haemophilia, 74 in patients with VWD, and 326 in patients with idiopathic thrombocytopenic purpura (ITP), after review of 30 articles. Haemostatic treatments were not standardized. There was one case of spinal haematoma, which was in an infant with an undiagnosed haemophilia which resulted in paraplegia.[33]

Decisions on neuraxial anaesthesia should be made by the multidisciplinary team, after thorough counselling and consenting of the mother. The UKHCDO states that neuraxial anaesthesia is not contraindicated if the coagulation screen is normal, and the relevant factor level is above 50 IU/dL, either due to the spontaneous rise in pregnancy, or following prophylactic treatment (2006). The procedure needs to be performed by an experienced anaesthetist with meticulous technical skill. However, a non-traumatic insertion of a spinal or epidural cannot be guaranteed. The lowest concentration of local anaesthetic agent should be used to allow adequate analgesia but preserving motor function[32] and regular assessment of neurological function should be carried out to allow early recognition of complications. Suspicion of a spinal epidural haematoma should lead to an urgent MRI and surgical decompression if appropriate. As adverse neurological outcome is directly related to time interval to surgical decompression, early recognition is essential. Removal of epidural catheter is also associated with a risk of spinal epidural haematoma. Coagulation screen and factor assays should therefore be performed before removal of epidural catheter, and appropriate treatment given if abnormal.[31,34]

### Postpartum management

Women with inherited bleeding disorders are at significantly increased risk of primary and secondary postpartum haemorrhage especially those with severe disease. Perineal and vaginal haematomas are also more common at a rate of 1–6% versus 0.2% in the normal population,[35,36] Secondary postpartum haemorrhage is more common as coagulation factor levels return back to baseline after a rise in the third trimester.

Steps should be taken to reduce the risk of postpartum haemorrhage. The third stage of labour should be actively managed to reduce the risk of uterine atony. Agents used should be given IV rather than IM.

Normal factor levels should be maintained for 3–5 days after vaginal delivery, and 5–7 days after caesarean delivery. Close follow-up is needed after discharge, to identify and manage secondary postpartum haemorrhage.

Risk of thrombosis will need to be considered, particular in those receiving replacement therapy with FXI concentrate, recombinant activated factor VII and prothrombin complex concentrate. Antithrombotic measures such as hydration, early mobilization and the use of pharmacological thromboprophylaxis and antiembolic stockings should be considered in all.

### Management of the newborn

Early diagnosis of inherited bleeding disorders is essential to reduce the risk of complications. A cord sample should be taken for the appropriate factor assay in all neonates at risk. It should be remembered however that for mild and moderate disease, the result may not be representative, as some factors increase with the stress of delivery and some have not reached normal adult values. In these cases, the test may need to be repeated at a later stage. In neonates in whom haemophilia has not been excluded, IM injections including vitamin K should be avoided. The UKHCDO recommends cranial ultrasound for all neonates at risk of a severe or moderate bleeding tendency, prior to discharge,[37] however, for neonates with suspected intracranial haemorrhage, CT or MRI are more sensitive imaging modalities. Intracranial haemorrhage tends to occur at around 4 days of life, so parents should be warned which signs to look for.

## Haemophilia A and B

### Pathophysiology

Haemophilia A and B are due to a reduction in factor VIII and IX respectively. Factor VIII and IX together with factor X form the tenase complex, an essential component of the coagulation cascade, needed to produce the thrombin burst and ultimately the fibrin platelet plug. Lack of factor VIII or IX produces loose friable fibrin, which is susceptible to fibrinolysis. Fibrinolysis is further enhanced by the lack of the thrombin-activator fibrinolysis inhibitor, normally activated by the thrombin burst. The lack of thrombin burst leads to a failure to consolidate the primary haemostatic plug, causing the characteristic bleeding pattern of haemophilia A and B, which is delayed after trauma but prolonged.[38]

### Presentation

Haemophilia A affects approximately 1 in 10000 live births. Haemophilia B is rarer, affecting 1 in 50000 live births. Patients with haemophilia A and B tend to present in a similar fashion and suffer from similar clinical features. Patients are classified as mild, moderate or severe depending on factor levels (Table 48.6). Many infants are diagnosed because of a positive family history, where the mother is known to be a carrier. A cord sample for factor VIII or IX levels will establish a diagnosis. At least one third of cases have no family history and are due to new mutations. These patients may present with bleeding, such as a cephalohaematoma, after the trauma of delivery. They may otherwise present with bruises from minimal trauma, which can be misinterpreted as non-accidental injury, or with joint and muscle bleeds when the child starts walking. Patients with mild to moderate haemophilia may not suffer from spontaneous bleeding and may not present until later in life with bleeding after surgery or dental work.

**Table 48.6** Classification of haemophilia

| Severity | Factor VIII/IX level | Clinical features |
|---|---|---|
| Severe | < 1% | Spontaneous bleeds into muscle, joints, and internal organs |
| Moderate | 1–5% | Bleeding after minor trauma<br>Occasional spontaneous bleeding, |
| Mild | 5–49% | Bleeding after surgery or major trauma<br>Spontaneous bleeding very rare |

Data from White GC, Rosendaal F, Aledort LM, *et al.*, Definitions in haemophilia. Recommendation of the scientific subcommittee on factor VIII and factor IX of the scientific and standardization committee of the International Society on Thrombosis and Haemostasis. *Thromb Haemost*, volume 85, p. 560, copyright © 2001 Schattauer GmbH.

### Inheritance

The genes for factor VIII and factor IX are both encoded on the long arm of chromosome X and the conditions are inherited in an X-linked fashion. Daughters of men with haemophilia A or B are obligate carriers and are at risk of having an affected child. Their sons have a 50% chance of being a haemophilia sufferer and daughters have a 50% chance of being a carrier. Carrier females have on average 50% of normal levels and have a higher incidence of bleeding than non-carriers. Where lyonization is unbalanced, with skewed X-chromosome inactivation, baseline levels fall lower than 50% and bleeding risk is further increased.

In a similar manner to non-haemophiliac patients, factor VIII levels are expected to rise from 6 weeks' gestation, although Factor IX levels remain constant. FVIII levels start to fall from 48 hours postpartum.

### Outcomes

Of 90 pregnancies in 53 carriers of haemophilia A and B, between 1995 and 2005, there were 65 live births, 13 miscarriages and 12 terminations.[39] Neuraxial anaesthesia was performed in 25 pregnancies with no complications. The caesarean delivery rate was 47%. The incidence of primary and secondary postpartum haemorrhage was 19% and 2%, respectively. Two women required blood transfusion and all survived. There were two neonatal cranial bleeding complications associated with prolonged labour or instrumental delivery. Pregnancy and delivery therefore needs to be carefully managed to prevent bleeding in the mother and the child.

### Treatments for haemophilia A and B

Treatment options for the prevention or management of bleeds in women who are carriers of haemophilia include factor replacement, desmopressin, and tranexamic acid. These are in addition to other standard measures used to prevent or treat bleeding in obstetric patients. Decisions on treatment need to be made in conjunction with the haemophilia team.

### *Tranexamic acid*

Tranexamic acid is a very useful agent for carriers of haemophilia A or B. It can be used prophylactically to reduce bleeding prior to procedures, where it is often started the day before the procedure and continued for up to 5 days. It can be used to reduce risk of bleeding during delivery and the postpartum period, when it should be started at the onset of labour, with an initial IV dose of 1 g, followed by 1 g tds orally for at least 5 days. It can also be used as adjunctive therapy for treatment of bleeding in haemophilia carriers.

### *Desmopressin*

Desmopressin can be used as prophylaxis or treatment for carriers of haemophilia A, as well as male sufferers of mild to moderate haemophilia A. It has no effect in patients with haemophilia B. Mechanism of action, half-life, side effects and safety is covered earlier in the chapter. It should be remembered that desmopressin also acts as an antidiuretic, and therefore fluid intake should be monitored and may need to be restricted.

### *Recombinant factor concentrate*

Factor concentrate is needed for haemophilia B carriers with low Factor IX levels. It is only required for haemophilia A carriers with low factor VIII levels if there is contraindication to desmopressin, such as hypertensive disorders. Recombinant factor concentrate is used, so risk of transmission of blood borne infection is not a concern. The main complication of factor replacement is inhibitor formation but this is very rare when used in haemophilia A or B carriers. Dosage is based on weight and increment needed (Box 48.4).

## Antenatal management

Female carriers of haemophilia normally have factor levels of around 50 IU/dL. This level is usually sufficient to protect the patient from spontaneous bleeding and bleeding associated with surgery. However some carriers have lower Factor VIII or IX levels, due to unbalanced lyonization, and levels as low as 5 IU/dL have been seen in some patients.[39] Levels should be checked at booking and in the third trimester. They should be known before invasive procedures or delivery, and monitored during therapy. Therapeutic levels should be maintained for a suitable time period depending on the procedure. For minor antenatal procedures, usually 1–2 days of treatment is sufficient but for delivery normal values should be maintained for 3–5 days.

FVIII levels tend to increase during pregnancy, whereas FIX levels tend to remain constant. Chi et al. looked at 90 pregnancies of haemophilia carriers. Haemophilia A carriers had a significant rise in FVIII levels, with 92% achieving levels of greater than 50 IU/dL in the third trimester. Factor IX results were less consistent.[39]

Attempts are often made to establish the risk to the fetus so the pregnancy can be managed appropriately. Establishing the sex of the fetus is crucial. This can be done from 7 weeks' gestation by determining evidence of fetal Y chromosome in maternal blood, or by ultrasound scan at 12 weeks. If the fetus is female special precautions are not needed for delivery. For male fetuses, some women may accept prenatal diagnosis, by chorionic villus sampling or amniocentesis. If termination of pregnancy is not being considered, some parents opt for third trimester amniocentesis of male fetuses to aid decisions on management of labour.

A factor VIII or IX level of 50 IU/dL is necessary for procedures including chorionic villus sampling and amniocentesis. If the level is insufficient, treatment will be needed in the form of DDAVP® or factor VIII replacement for haemophilia A carriers, and factor IX replacement for haemophilia B carriers.

**Box 48.4** Dosage of recombinant factor VIII/IX

$$\text{Factor VIII dosage (units)} = [\text{weight (kg)} \times \text{increment needed (units dL)}] / 2$$

$$\text{Factor IX dosage (units)} = [\text{weight (kg)} \times \text{increment needed (units dL)}] / 0.8$$

## Management of labour and delivery

At the onset of labour a FBC, clotting screen and group and save should be taken. A factor assay should be taken if less than 50 IU/ dL at the last check. The majority of haemophilia A carriers do not need haemostatic support for delivery, as factor VIII levels usually reach the normal range spontaneously. However as factor IX does not rise in pregnancy these patients often need factor replacement.

As stated earlier, when considering the mode of delivery, factors to be taken into account include the maternal and fetal bleeding risks, other maternal complications and local resources such as availability of on-call senior obstetric, haematology and anaesthetic cover with experience in dealing with patients with bleeding disorders. Risk of intracranial haemorrhage is 4% in babies with severe haemophilias and special precautions need to be taken to avoid unnecessary trauma in potentially affected male babies. If vaginal delivery is opted for, use of ventouse extraction, mid cavity forceps and fetal scalp monitoring should be avoided. A prolonged second stage of delivery should also be avoided, with early recourse to caesarean delivery if necessary.

Neuraxial anaesthesia is considered safe providing the clotting screen is normal and factor VIII/IX levels are above 50 IU/Dl.[40] Levels should be checked again before removal of the epidural catheter as they may have fallen rapidly.

## Postpartum management

Postpartum patients should be closely monitored as levels are expected to fall. Levels should be maintained at least 50 IU/dL for 3–5 days, although longer if caesarean delivery has been performed.

Aspirin, NSAIDs, IM injections, and pharmacological thromboprophylaxis should be avoided in patients with factor VIII or IX levels less than 50 IU/dL.

## Management of the neonate

A cord sample should be taken to assess factor VIII or IX levels, although these may not be representative of the true baseline, as Factor VIII often rises in response to the stress of delivery and Factor IX does not reach true baseline levels until around 6 months of age. IM vitamin K should be withheld until the factor levels are known, or given orally if needed.

# Von Willebrand disease

## Pathophysiology

VWF is an essential part of the coagulation system. It is produced in the vascular endothelial cells and megakaryocytes in the bone marrow and binds to Factor VIII which inactivates rapidly in the absence of VWF. It is also important in platelet adhesion to wound sites.

VWF is released from the Weibel–Palade storage granules in response to a number of agonists including thrombin,

epinephrine, histamine and vasopressin. This can be taken advantage of therapeutically by the use of desmopressin to treat milder forms of VWD. Increased synthesis and secretion of VWF also occurs as part of an acute-phase response to injury, inflammation, infection, malignancy, emotional stress and also pregnancy. This needs to be kept in mind when managing a pregnant woman with VWD.[38]

For normal von Willebrand function, it must be present in normal amounts, have a normal multimeric structure, and an intact binding site for collagen and platelet glycoproteins GP1b and GPIIb/IIIa. VWD is most commonly inherited, with mutations affecting each of these different aspects leading to the six different subclassifications of inherited VWD (Table 48.7).

During pregnancy, there is a rise in VWF antigen (VWF:Ag). In women with type 1 VWD, this is also accompanied by a rise in VWF activity and FVIII:C, usually reaching normal ranges by term.

### Clinical features

The severity of bleeding varies from a mild to moderately severe bleeding tendency. Failure of platelets to adhere to injured vessel walls leads to failure of primary haemostasis and bleeding from small blood vessels in the skin and mucous membranes. Patients often present with bruising, epistaxis, menorrhagia and bleeding after surgery and dental extraction. Importantly, these patients are also vulnerable to postpartum bleeding. Patients with type 3 VWD have absent VWF and FVIII:C levels of 1-2%. These patients have a bleeding tendency similar to severe haemophilia A and suffer from haemarthrosis, muscle bleeds and life-threatening bleeding after trauma, as well as small vessel bleeding which is not normally a feature of haemophilia A.

### Outcomes

Women are at risk of bleeding early in pregnancy before VWF and FVIII levels have risen. In one case series 33% of pregnancies in mothers with VWD developed vaginal bleeding.[37] Major antenatal haemorrhage is rare, but can occur after miscarriage or termination. Up to 10% of terminations can be accompanied by excessive bleeding requiring transfusion.[37] Women are at risk of postpartum haemorrhage, as VWF and factor VIII levels fall. 16–29% of women with VWD will develop primary postpartum haemorrhage, and 20–29% of women will develop secondary postpartum haemorrhage.[41]

**Table 48.7** Subclassification of von Willebrand disease

| Subclassification | Pathology | Inheritance | Severity |
|---|---|---|---|
| Type 1 | Quantitative reduction in VWF | Autosomal dominant | Mild to moderate |
| Type 2a | Reduced high-molecular-weight multimers | Autosomal dominant | Mild to moderate |
| Type 2b | Increased GpIb binding leading to platelet aggregation and consumption | Autosomal recessive | Mild to moderate |
| Type 2m | Reduced GpIb binding | Autosomal recessive | Mild to moderate |
| Type 2n | Reduced VIII binding | Autosomal recessive | Mild to moderate |
| Type 3 | Quantitative complete absence of VWF | Autosomal recessive | Severe |

GP, glycoprotein; VWF, von Willebrand factor. Adapted from Sadler JE, Budde U, Eikenboom JCJ, *et al.*, Update on the pathophysiology and classification of von Willebrand disease: a report of the Subcommittee on von Willebrand Factor. *Journal of Thrombosis and Haemostasis*, volume 4, pp. 2103–14. copyright © 2006 John Wiley & Sons.

### Laboratory investigations

Investigation of VWD initially involves measurement of the FBC, APTT, von Willebrand factor antigen (VWF:Ag), von Willebrand factor ristocetin cofactor activity (VWF:RCo), von Willebrand collagen binding activity (VWF:CBA) and FVIII level (FVIII:C) (Table 48.8).

VWF:Ag is a quantitative measurement of VWF. VWF:CBA and VWF:RCo are functional measures of VWF activity. If an abnormality is found, further investigations including ristocetin-induced platelet aggregation (RIPA) which measures the ability of VWF to bind to platelets, and VWF multimer factor analysis are performed.

### Treatments for Von Willebrand disease

Patients with type 1 VWD and mild to moderate bleeding can often be treated with desmopressin, which acts to release VWF from Weibel–Palade storage granules, producing a brisk rise in VWF and FVIII levels, about 30 minutes after an IV infusion.[38] Desmopressin is less likely to be effective in patients with type 2 VWD due to the release of abnormal VWF. It is contraindicated in type 2b VWD as it will exacerbate platelet consumption and cause worsening thrombocytopenia. However it may be of benefit in type 2a, 2m and 2n VWD and a trial should be carried out before pregnancy. Desmopressin will be ineffective in patients with type 3 VWD.

For patients in whom desmopressin is ineffective or contraindicated, VWF concentrate is required. Intermediate and high purity concentrates are available which vary in the amount of VWF concentrate they contain and how well it is preserved, as well as the VWF/FVIII ratio. Following treatment with DDAVP® or VWF concentrate, FVIII:C levels, VWF:Ag, VWF:RCo, and if appropriate a FBC should be taken to assess response. Further levels may be required to assess if further treatment is needed.

### Antenatal management

A baseline FVIII:C level, VWF:Ag, VWF:RCo and FBC should be taken at booking, and at 28 and 36 weeks. Risks to the baby of inheriting VWD need to be determined, although prenatal diagnosis is rarely undertaken as patients with VWD are able to maintain a good quality of life with current treatments. However, where babies are at risk of type 3 VWD, mothers may wish to undergo antenatal diagnosis and the procedure may need to be covered with DDAVP® or von Willebrand concentrate to ensure levels of more than 50 IU/dL.

### Management of delivery

At the onset of labour a FBC, coagulation screen, FVIII;C level, VWF;Ag and VWF:RCo should be taken. Patients with type 1 VWD usually show a rise in VWF levels to within the normal range, giving no cause for concern at delivery. However the rise in VWF antigen levels leads to no improvement in activity for most patients with type 2 disease and those with type 2b VWD often develop a worsening of thrombocytopenia due to the heightened platelet binding. Patients with type 3 VWD have no increase in VWF.

**Table 48.8** Laboratory investigations in von Willebrand disease

| Subclassification | FBC | aPTT | VWF:Ag | VWF:RCo | VWF:CBA | FVIII:C | RIPA | Multimers |
|---|---|---|---|---|---|---|---|---|
| Type 1 | Normal | Normal or prolonged | Low | Low | Low | Normal or low | No reaction | Normal |
| Type 2a | Normal | Normal or prolonged | Normal or low | Low | Low | Normal or low | No reaction | Decrease in large multimers |
| Type 2b | Platelet count 75–100 | Normal or prolonged | Normal or low | Low | Low | Normal or low | Positive | Decrease in large multimers |
| Type 2m | Normal | Normal or prolonged | Normal or low | Low | Low | Normal or low | No reaction | Normal |
| Type 2n | Normal | Normal or prolonged | Normal or low | Normal or Low | Normal or Low | Low | No reaction | Normal |
| Type 3 | Platelet count reduced/ normal/increased | Prolonged | Absent | Absent | Absent | Low | No reaction | Absent |

Ag, antigen; aPTT, activated partial thromboplastin time; CBA, collagen binding activity; FBC, full blood count; RCo, ristocetin cofactor activity; RIPA, ristocetin-induced platelet aggregation; VWF, von Willebrand factor. Adapted from Laffan, M., *et al*, The diagnosis of von Willebrand disease: a guideline from the UK Haemophilia Centre Doctors' Organization. *Haemophilia*, Volume 10: issue 3, pp. 199–217. Copyright © 2004 John Wiley & Sons.

For labour, VWF activity levels and FVIII should be raised to 50 IU/dL. This can be achieved by the use of desmopressin, or if unsuitable, VWF concentrate. A delivery plan should have been made antenatally including the treatment agent of choice.

Neuraxial anaesthesia should only be used if FVIII;C level, VWF;Ag are above 50 IU/dL.[40]

The mode of delivery should be based on obstetric indications. Vaginal delivery is generally safe in type 1 and 2 VWD. Where the baby is at risk of type 2 or 3 VWD, a prolonged second stage of labour should be avoided, with early recourse to caesarean delivery. Interventions such as fetal scalp monitoring, ventouse delivery, mid cavity forceps and forceps involving rotation of the head should be avoided to minimize trauma to mother and baby, although the occurrence of intracranial haemorrhage is very low, even in patients with type 3 VWD.[42] The third stage of labour should be managed actively.

### Postpartum management of mother

Women with FVIII and VWF:RCo levels less than 50 IU/d Lare more likely to develop postpartum haemorrhage.[44] Levels should be maintained above 50 IU/dL for up to 5 days postpartum. This can be achieved with the use of desmopressin or VWF concentrate. If complications occur and treatment is needed for more than 3 days, VWF concentrate may be required in addition to desmopressin because of the potential of tachyphylaxis.

### Management of the neonate

A cord sample should be taken to establish FVIII:C, VWF:Ag and VWF:RCo levels. However, results may not be representative of true baseline levels as they can rise with the stress of delivery. Oral vitamin K should be given rather than IM, unless the cord sample shows normal levels.

## Factor XI deficiency

Inheritance of Factor XI deficiency is autosomal. Homozygotes have levels of less than 15–20 IU/dL. Heterozygotes are partially deficient and have levels ranging between 20 and 70 IU/dL. In Ashkenazi Jews heterozygosity is reported to be as high as 8%.[44]

FXI levels and the degree of bleeding tendency do not correlate and patients can be categorized into those with a non-bleeding phenotype and those at risk during haemostatic challenges. Bleeding intensity tends to be associated with the site of injury. Areas with high fibrinolytic activity such as the oral cavity or urogenital tract have a higher risk of bleeding and women are prone to menorrhagia and bleeding after childbirth. A severe bleeding phenotype is unusual and in many of these patients there is coexistence of other bleeding tendencies such as VWD or platelet function disorders.[31]

Factor XI levels do not rise in pregnancy but the incidence of spontaneous miscarriage or antepartum haemorrhage is no higher than for women with normal Factor XI levels. The risk of postpartum haemorrhage (PPH) is increased, although a study of 105 pregnancies in 33 women showed there to be a highly significant difference between women with a 'bleeding' phenotype compared to those considered to be 'non-bleeders', with a relative risk [RR] of 7.2 (CI 1.99–25.9).[45] A study of women with severe factor XI deficiency (factor IX < 17 IU/dL), found that 24% of 132 untreated vaginal deliveries were accompanied by excessive bleeding. 17% of the 12 women undergoing caesarean delivery without prophylaxis had increased bleeding but this did not occur in any of the 6 who received prophylaxis for surgery.[46]

Standard measures as outlined in Boxes 48.1 and 48.2 should be taken throughout pregnancy, during labour and delivery and the postpartum period. Decisions on prophylaxis for delivery should be made on an individual basis based on previous bleeding tendency, factor XI levels, and mode of delivery.

Treatment options include tranexamic acid, FXI concentrate and FFP. The UKCHDO advise that women with FXI levels between 15 and 70 IU/dL and no significant bleeding history can be managed expectantly, without prophylaxis.[40] Women with levels between 15–70 IU/dL and a significant bleeding history or no previous haemostatic challenges can be given a 3-day course of tranexamic acid, with the first dose being given during labour. Patients with severe deficiency (FXI levels < 10–20 IU/dL) are likely to require factor XI concentrate. As this is associated with an increased risk of thrombotic complications, low dose

therapy is usually used (around 10 IU/kg) to raise FXI levels to between 30 IU/dL and 70 IU/dL. Concomitant use of tranexamic acid should be avoided and antithrombotic measures should be used, including anti-embolic stockings, good hydration and early mobilization.

Neuraxial anaesthesia should be avoided unless an adequate response to treatment has been documented, with levels in the normal range. Recombinant activated factor VII has been used to prevent bleeding but this is an unlicensed indication and it is associated with increased thrombotic risk. All women with a bleeding phenotype should receive oral tranexamic acid for 2 weeks after delivery.

## Rare inherited bleeding disorders

Standard precautions (as in Boxes 48.1 and 48.2) for patients with bleeding disorders are required for women with a rare inherited bleeding disorder (Table 48.9).

Fibrinogen and FXIII are both needed to support a pregnancy. Therefore women with inherited fibrinogen abnormalities and FXIII deficiency are unique in needing prophylactic replacement therapy throughout pregnancy, from the outset.

Some women with dysfibrinogenaemia and hypofibrinogenaemia also have a paradoxical risk of thrombosis. Bleeding and thrombotic risk should be considered in all patients, and prophylaxis with LMWH is considered in some.

Although most rare inherited bleeding disorders are autosomal recessive, the risk of the fetus inheriting the disorder should be considered in consanguineous marriages.

## Analgesia for women with bleeding disorders

Normal analgesics used in the obstetric setting can be problematic for patients with bleeding disorders, due either to the side effects of the medication or its route of administration, and careful consideration should be given in choosing the most suitable form.

### Aspirin

Aspirin is commonly used in pregnancy, to prevent hypertensive disorders and placental insufficiency. It inhibits platelet aggregation and activation by inactivating the cyclooxygenase (COX) enzyme, responsible for the synthesis of precursors of prostaglandin and thromboxane. Prostaglandins are involved in transmission of pain sensation, inflammation and modulation of the hypothalamic thermostat. Thromboxane is a potent vasoconstrictor and enhances platelet aggregation and activation of new platelets. The inhibitory effect of aspirin is irreversible and thus persists for the lifetime of the platelet, approximately 7–10 days. Thus aspirin is not recommended for patients with bleeding disorders.

**Table 48.9** Summary of rare inherited bleeding disorders

| | Incidence | Inheritance | Coagulation results | Preferred therapeutic option | Other options |
|---|---|---|---|---|---|
| II | 1 per 2 million | Autosomal recessive | Prolonged aPTT and PT | Prothrombin complex concentrate | SD plasma |
| V | 1 per 1 million | Autosomal recessive | Prolonged AaPTT and PT, normal TT | SD plasma | Platelets and recombinant activated factor VII |
| VII | 2 per million | Autosomal recessive | Prolonged PT | Recombinant activated factor VII | Virally inactivated factor VII concentrate<br>Prothrombin complex concentrate or SD plasma—only recommended if alternatives not available |
| X | 1 per million | Autosomal recessive | PT and aPTT prolonged | Prothrombin complex concentrate | SD plasma |
| Combined V and VIII | 1 per million | Autosomal recessive | aPPT more prolonged than PT | SD plasma to raise FVII levels, and<br>Recombinant FVIII | FVIII concentrate |
| XIII | 1 per million | Autosomal recessive | Normal aPTT/PT/TT<br>Positive clot solubility test | FXIII concentrate | SD plasma |
| Fibrinogen | 1 per million | Autosomal recessive/ dominant | Afibrinogenaemia—fibrinogen unmeasurable by function (Clauss) method, and immunoreactive assays.<br>Hypofibrinogenaemia—low fibrinogen by functional and immunoreactive method.<br>Dysfibrinogenaemia—fibrinogen measured lower by functional method than immunoreactive assay | Virally inactivated fibrinogen | Cryoprecipitate only in emergencies |

aPTT, activated partial thromboplastin time; PT, prothrombin time; SD, solvent detergent; TT, prothrombin time.

### Non-steroidal anti-inflammatory drugs

NSAIDs also inhibit the COX enzyme, reducing production of thromboxane and prostaglandins but inhibition is competitively reversible. This the duration of the inhibitory effect is more dependent on the half-life of the drug. NSAIDs such as ibuprofen and diclofenac, ketoprofen and indomethacin have short half-lives of less than 6 hours, whereas naproxen, celecoxib, meloxicam, nabumetone, and piroxicam have half-lives of more than 6 hours and up to 60 hours. Pessaries and suppositories can have just the systemic effect as oral NSAIDs. Gastric ulceration can occur, both due to direct irritation of the gastric mucosa, and also due to reduction of protective prostaglandin.

NSAIDs are generally not recommended in patients with bleeding disorders. However, short-acting forms can be used with caution in women receiving haemostatic treatment.

### Intramuscular analgesia

NSAIDs or opiates are often given by the IM route. However in women with bleeding disorders this can be associated with muscle haematoma. IM injections are not recommended in women with factor levels less than 50%, or a platelet count less than $50 \times 10^9$/L.

### Patient-controlled analgesia

Patient controlled analgesia is a good option for analgesia in this cohort of women, allowing patients to manage their own analgesia. Long-acting opioids will affect the neonate, so short-acting opioids like remifentanil are more appropriate (see Chapter 13).

### Neuraxial anaesthesia

Use of neuraxial analgesia needs to be carefully considered. Epidural analgesia is more of a concern than spinal analgesia as the catheter is left *in situ* and the epidural needle is bigger and potentially causes more trauma. Removal of the catheter can be associated with a higher bleeding risk than insertion. Factor VIII or IX levels should be at least 50% for insertion and removal of the catheter and the platelet count should be at least $50 \times 10^9$/L and usually $80 \times 10^9$/L.

Spinal analgesia is often preferred as a smaller needle can be used and usually no catheter is left in place. Very rarely spinal catheters are used and would be contra-indicated in a patient with a bleeding tendency. Again a factor level of more than 50% is advised.

## Thrombocytopenia

Thrombocytopenia occurs in up to 10% of pregnancies, with gestational thrombocytopenia, MAHAs, and immune thrombocytopenias the most common causes. Figure 48.6 demonstrates the incidence of causes of thrombocytopenia. Box 48.5 lists rarer causes of thrombocytopenia.

### General considerations

Serious maternal haemorrhage is rare in those with thrombocytopenia. The bleeding risk depends on the cause of the thrombocytopenia, the level of platelet count, rate of fall and if there is an associated coagulopathy. For example, a patient with ITP will have younger more active platelets, and have a lower bleeding risk than a patient with disseminated intravascular coagulation (DIC) or a platelet function disorder.

Patients with a platelet count over $100 \times 10^9$/L can be monitored by the midwife or GP. Those with a platelet count less than

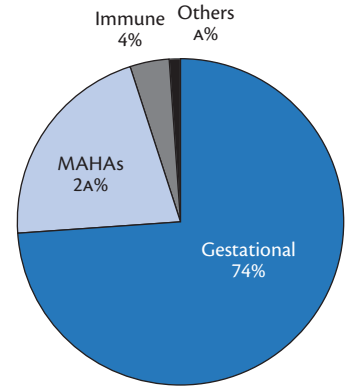

**Figure 48.6** Causes of thrombocytopenia in pregnancy.

$100 \times 10^9$/L usually need to be assessed in secondary care. Treatment aims to maintain a safe, rather than normal platelet count and is usually only required to cover invasive procedures and delivery.

### Anaesthesia

Use of neuraxial anaesthesia is often a source of debate and there is little evidence to support a safe platelet count. A threshold of more than $80 \times 10^9$/L is considered safe by most anaesthetists to insert and remove epidural anaesthesia, provided there is no associated coagulopathy, and the patient is not on anticoagulants or antiplatelet agents.[47] Some experienced anaesthetists would consider neuraxial anaesthesia in ITP patients with a platelet count above $50 \times 10^9$/L.[48] Patients with a platelet count of $50–80 \times 10^9$/L should be assessed on a case-by-case basis, and a detailed bleeding history should be established to help determine the bleeding risk.

### Mode of delivery

Mode of delivery should be based on obstetric factors, as there is no evidence to suggest caesarean delivery is safer than uncomplicated vaginal delivery.[45] If delivery is anticipated to be complicated, an elective caesarean delivery may be a better option.

### General considerations for the fetus

Neonatal thrombocytopenia with associated intracranial haemorrhage is the major concern for a baby with a thrombocytopenic mother and the cause of maternal thrombocytopenia needs to be considered. Gestational thrombocytopenia is a benign diagnosis for the fetus. However, maternal ITP can result in transplacental transfer of maternal immunoglobulin G (IgG) autoantibody,

**Box 48.5** Rare causes of thrombocytopaenia in pregnancy

- Folate deficiency
- Systemic lupus erythematosus/antiphospholipid syndrome
- Viruses
- Drugs
- Malignancies
- Splenomegaly
- Congenital platelet disorders

leading to thrombocytopenia in the fetus. Thrombocytopenia due to MAHA is not usually associated with thrombocytopenia in the fetus, but can cause placental infarction and high rates of morbidity and mortality.

Standard precautions should be taken for fetuses at risk of thrombocytopenia. This includes avoidance of fetal scalp monitoring, use of ventouse and rotational forceps, and prolonged labour. A cord sample should be taken to assess the platelet count. IM vitamin K should be avoided if the platelet count is less than $50 \times 10^9$/L, and can be given orally instead. Infants with a subnormal platelet count should be monitored, as the platelet count may continue to fall, with a nadir at 2–5 days.

Severe thrombocytopenia in infants is rare. Infants with a platelet count less than $20 \times 10^9$/L should be tested to exclude fetoneonatal alloimmune thrombocytopenia.

## Gestational thrombocytopenia

Gestational thrombocytopenia is the most common cause of thrombocytopenia in pregnancy and complicates 5% of pregnancies. There is approximately a 10% fall in platelet count from baseline, which tends to occur in the second half of pregnancy. The platelet count at term is more than $100 \times 10^9$/L in 95% of cases and it is rare for it to fall below $70 \times 10^9$/L. Other causes, namely ITP, should be considered if this is the case.

Gestational thrombocytopenia is a diagnosis of exclusion, and it can be difficult to distinguish severe forms of this from ITP. Table 48.10 summarizes the key distinguishing features.

Gestational thrombocytopenia is benign for both mother and baby, and is not associated with haemorrhagic complications. The thrombocytopenia usually resolves within 6 weeks after delivery. Use of neuraxial anaesthesia is considered safe in patients with gestational thrombocytopenia, as the platelet count rarely falls to below $70 \times 10^9$/L.

**Table 48.10** Differences between gestational and immune thrombocytopaenia

| Gestational thrombocytopenia | Immune thrombocytopenic purpura |
|---|---|
| No specific diagnostic test—diagnosis of exclusion | No specific diagnostic test—diagnosis of exclusion |
| No associated autoimmune diseases | Associated autoimmune diseases |
| Normal platelet count prepregnancy | Possible previous history of thrombocytopenia |
| Platelet count usually >100 × $10^9$/L, rarely < 70 × $10^9$/L | Median platelet count at delivery 85 × $10^9$/L |
| Not associated with maternal haemorrhage | Small risk of maternal haemorrhage |
| Occurs in second half of pregnancy | Can cause thrombocytopenia in the first and second trimester |
| No improvement with steroids | Improvement with steroids |
| No fetal haemorrhage | Small risk of fetal haemorrhage |
| Spontaneous resolution after delivery | Thrombocytopenia can persist after pregnancy |
| May recur in subsequent pregnancies | May recur in subsequent pregnancies |

## Immune thrombocytopenic purpura

Although ITP is one of the less frequent causes of thrombocytopenia in pregnancy, it is the most common cause of thrombocytopenia in the first and second trimester. It is due to antibodies against platelet surface glycoproteins, mainly glycoprotein IIb/IIIa and glycoprotein Ib/IX.

Severe bleeding complications are rare in patients with ITP as platelets tend to be younger and more active. Unlike gestational thrombocytopenia, ITP can cause haemorrhagic complications in the fetus as the IgG antibodies can cross the placenta.

### Outcomes

Webert et al. looked at 119 pregnancies in mothers with ITP.[49] Although 15.5% of women had a platelet count of lower than $50 \times 10^9$/L at the time of delivery, haemorrhagic complications were uncommon and not related to the platelet count. Four women had an estimated blood loss at delivery of more than 1 L and the platelet count in these women ranged from $54 \times 10^9$/L to $321 \times 10^9$/L. Neuraxial analgesia was used in 42 pregnancies, seven of whom had a platelet count of less than $75 \times 10^9$/L. No complications were reported. There was one fetal death related to thrombocytopenia. This was a stillbirth at 27 weeks in a mother with moderately severe ITP who had previously undergone a splenectomy.

### Treatments

Decisions on treatments for ITP should be based on the balance of risks of bleeding versus risks of side effects from treatments. The aim is for a safe platelet count for pregnancy, rather than a normal platelet count. Patients with a platelet count more than $20 \times 10^9$/L often do not need treatment until 36 weeks, or if delivery is imminent.

Table 48.11 suggests some maternal platelet counts which are generally thought to be acceptable.

Prednisolone is the usual first-line treatment, with 20 mg being a suitable starting dose in pregnancy. A response can be expected within 3–7 days. Patients unresponsive to steroids can be tried on IV immunoglobulin or higher-dose steroids. Other treatment options for ITP have limited use in pregnancy.

Splenectomy is rarely required for treatment of refractory ITP in pregnancy and is best undertaken in the second trimester. It can be performed laparoscopically before 20 weeks, after which the technique becomes difficult. Splenectomy in the first trimester is associated with increased risks of preterm labour.[50] The platelet count often does not need to be raised prior to splenectomy, as it can be expected to rise after the splenic artery is clamped.

Platelet transfusions are ineffective in the treatment of ITP as they are destroyed by the antibody, so are short lived. The only indication for use of platelets in the management of ITP is major

**Table 48.11** Acceptable platelet counts for various situations in women with idiopathic thrombocytopenic purpura

| Situation | Accepted platelet count |
|---|---|
| Antenatally | >20 × 109/L |
| Vaginal delivery | >40 × 109/L |
| Operational/instrumental delivery | >50 × 109/L |
| Epidural | >80 × 109/L |

haemorrhage or emergency surgery, when bleeding points can be transiently sealed. Concurrent use of IV immunoglobulin can extend the half-life of transfused platelets to some degree.

### Antenatal management

Women with a platelet count above 100 × $10^9$/L can usually be managed in the community with monthly blood counts by the midwife. Those with a platelet count below 100 × $10^9$/L should be referred to a specialized haematology obstetric clinic. In these patients, if the count is relatively stable monitoring can occur every 4 weeks until after 26 weeks, increasing to every fortnight and every week as term approaches.

Treatment for thrombocytopenia is not usually needed unless the platelet count is less than 20 × $10^9$/L, a procedure is planned, the patient is bleeding, or delivery is approaching. Potential side effects of treatment need to be considered, such as gestational diabetes, weight gain, or postpartum psychiatric disorders.

### Management of labour and delivery

Home delivery is not advised if the platelet count is less than 100 × $10^9$/L. Mode of delivery should be based on obstetric factors as there is no evidence that caesarean delivery is safer for the fetus. A blood count should be checked on arrival in labour and neuraxial anaesthesia avoided if the platelet count is too low. Standard precautions mentioned earlier should be taken to reduce the risk of neonatal haemorrhage.

### Postpartum management of the mother

Active management of the third stage of labour is recommended, with IV oxytocic drugs. Non-steroidal analgesia should be avoided due to the associated bleeding risk of haemorrhage. Oral tranexamic acid given for 14 days postpartum should be considered.

It needs to be remembered that 25% of mothers with ITP have antiphospholipid antibodies and therefore thromboprophylaxis may well be necessary.

### Management of the newborn

Babies born to mothers with ITP are at risk of thrombocytopenia. Reported incident of neonatal thrombocytopenia varies, but between 8% and 30% of infants will have platelet counts less than 50 × $10^9$/L, and 1–5% will have a platelet count below 20 × $10^9$/L.[51–53]

**Table 48.12** Common causes of microangiopathic haemolytic anaemias

| Specific to pregnancy | Not specific to pregnancy |
|---|---|
| Pre-eclampsia | Thrombotic thrombocytopenic purpura |
| HELLP syndrome | Haemolytic uraemic syndrome |
| Acute fatty liver of pregnancy | Disseminated intravascular coagulation |
| | Malignant hypertension |
| | Burns |
| | Vasculitides, e.g. Wegener's, systemic lupus erythematosus |
| | Certain infections, e.g. malaria, babesiosis, bartonellosis, *Clostridium perfringens* |

HELLP, haemolysis, elevated liver enzymes, low platelets.

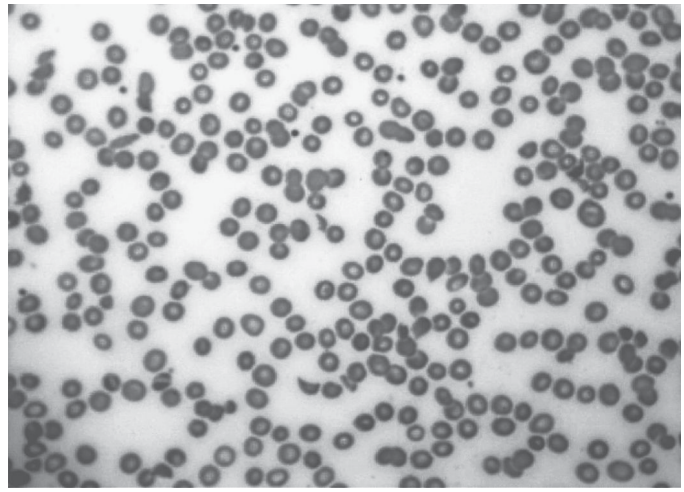

**Figure 48.7** A blood film from a patient with MAHA depicting polychromasia and schistocytes.

A cord sample should be taken to assess the platelet count and for those with thrombocytopenia, a repeat count should be considered at 2–5 days when platelets reach their nadir due to splenic development in the neonate.

## Microangiopathic haemolytic anaemias

MAHAs are a subgroup of haemolytic anaemias which involve physical destruction of red blood cells in blood vessels. Destruction can occur in the large vessels because of abnormal vasculature or cardiac valves, or more commonly in pregnancy in the small vessels due to deposition of thrombi. Destruction of red cells leads to anaemia and the presence of red cell fragments, known as schistocytes in the blood film (Figure 48.7). Consumption of platelets in deposited thrombi leads to thrombocytopenia

There is overlap in the presenting features of MAHAs, which can cause some diagnostic difficulty. Table 48.13 outlines some of the distinguishing features between the pregnancy-associated MAHAs. Delay in diagnosis, especially of thrombocytopenic purpura, can be life threatening, and often plasma exchange needs to be started immediately, before a diagnosis can be confirmed.

### MAHAs secondary to pre-eclampsia

The aetiology of the mechanical damage to red cells during pre-eclampsia is uncertain but is probably due to fracturing of red cells as they pass over microthrombi, reflecting coagulation activation, vasoconstriction, and/or endothelial dysfunction seen in this condition. Up to 50% of women develop thrombocytopenia, secondary to activation of coagulation and formation of microthrombi in the circulation. The severity parallels the pre-eclampsia (Box 48.6).

### Management

The FBC and coagulation screen should be monitored in patients with pre-eclampsia. Platelet transfusions should only be given if there is active bleeding, or if delivery is urgent. In this setting and in the presence of a DIC, platelets should be given to maintain a platelet count above 50 ×$10^9$/L.

Similarly, fresh frozen plasma should be used only if there is active bleeding.

**Table 48.13** Distinguishing features between the pregnancy-associated microangiopathic haemolytic anaemias

| | Pre-eclampsia | HELLP (haemolysis, elevated liver enzymes, and low platelets) | DIC (disseminated intravascular coagulation) | AFLP (acute fatty liver of pregnancy) | TTP (thrombotic thrombocytopenic purpura) | HUS (haemolytic uraemic syndrome) |
|---|---|---|---|---|---|---|
| Onset of symptoms | Third trimester | Third trimester | Any time | Third trimester | Third trimester | Postpartum |
| Central nervous system symptoms | +/– | +/– | +/– | +/– | +++ | +/– |
| Renal impairment | +/– | + | +/– | + | ++ | +++ |
| Fever | – | – | +/– | – | +/– | +/– |
| Liver impairment | +/– | +++ | +/– | +++ | +/– | +/– |
| Hypertension | +++ | +/– | – | + | +/– | ++ |
| Haemolysis | + | ++ | + | +/– | +++ | ++ |

| Prolonged clotting times | +/– | +/– | +++ | ++ | – | – |
| ADAMTS13 levels | Mildly reduced | Mildly reduced | Mildly reduced | Mildly reduced | Severely deficient (levels < 5%) | Mildly reduced |
| Resolution post delivery | Rapid | May take 2–3 days | Rapid | Can take weeks | Can take weeks | Can take weeks |

Myers B. Thrombocytopenia in pregnancy. *The Obstetrician & Gynaecologist*, volume 11, issue 3, pp. 177–183. copyright © 2009 John Wiley & Sons.

Neuraxial anaesthesia is only recommended if the platelet count is above $80 \times 10^9$/L and the coagulation screen is normal.

Thrombocytopenia, MAHAs, and coagulopathy associated with pre-eclampsia usually quickly resolve after delivery, but occasionally may worsen or even present postpartum and can continue for up to 14 days after delivery.

## HELLP syndrome

HELLP syndrome is characterized by haemolysis, elevated liver enzymes, and low platelets. It occurs in 0.5–0.9% of pregnancies and in 10–20% of cases of severe pre-eclampsia.[54] Seventy per cent of cases occur antenatally, usually in the third trimester, the remainder occur in the 48 hours postpartum (see also Chapter 36).

The pathophysiology of HELLP is thought to be similar to pre-eclampsia, with endothelial damage, possibly more marked in the liver vasculature, with local fibrin deposition and infrequently areas of liver infarction as a consequence. Haemolytic anaemia with the presence of schistocytes on the blood film, and thrombocytopenia are characteristic. Thrombocytopenia reflects the degree of severity and is used in the Mississippi classification of HELLP (Table 48.14). Liver function tests are abnormal and right upper quadrant pain can occur which is the result of obstructed blood flow in the hepatic sinusoids and hepatic necrosis. DIC complicates 80% of severe cases (Box 48.7).[45]

**Box 48.6** Haematological features of severe pre-eclampsia

- Thrombocytopenia
- Anaemia
- Reticulocytosis
- Presence of schistocytes and polychromasia in blood film
- Prolonged aPTT
- Increased fibrin degradation products
- Reduced antithrombin activity

HELLP has a maternal mortality rate of approximately 1%.[55] Perinatal mortality has been reported as between 7% and 34% and is mainly due to prematurity.[56–58]

### Haematological management

Mode of delivery should be guided by obstetric factors. Clotting screen results are usually normal in HELLP and as this is a prothrombotic condition blood products are rarely needed. Platelets should be avoided unless the patient is bleeding.

**Table 48.14** Mississippi classification of HELLP

| HELLP class | Mississippi classification |
|---|---|
| 1 | Platelets ≤ $50 \times 10^9$/L<br>AST or ALT ≥ 70 IU/L<br>LDH ≥ 600 IU/L |
| 2 | Platelets ≤ $100 \times 10^9$/L<br>≥ $50 \times 10^9$/L<br>AST or ALT ≥ 70 IU/L<br>LDH ≥ 600 IU/L |
| 3 | Platelets ≤ $150 \times 10^9$/L ≥ $100 \times 10^9$/L<br>AST or ALT ≥ 40 IU/L<br>LDH ≥ 600 IU/L |

ALT, alanine transaminase; AST, aspartate aminotransferase; LDH, lactate dehydrogenase.
Adapted from *American Journal of Obstetrics and Gynecology*, volume 195, issue 4, James N. Martin, Carl H. Rose, Christian M. Briery, Understanding and managing HELLP syndrome: The integral role of aggressive glucocorticoids for mother and child pp. 914–934, Copyright (2006), with permission from Elsevier.
Adapted from *American Journal of Obstetrics and Gynecology*, volume 180, issue 6, James N. Martin *et al.*, The spectrum of severe preeclampsia: Comparative analysis by HELLP (hemolysis, elevated liver enzyme levels, and low platelet count) syndrome classification pp. 1373–1384, Copyright (1999), with permission from Elsevier.

**Box 48.7** Complications of HELLP

- DIC (15%)
- Placental abruption (15%)
- Acute respiratory distress syndrome
- Hepatorenal syndrome
- Pulmonary oedema (8%)
- Subcapsular hepatic haematoma (1%)
- Hepatic rupture
- Maternal mortality (1%)
- Fetal mortality (7–34%)

Antiphospholipid syndrome is associated with HELLP and patients would benefit from testing for antiphospholipid antibodies after delivery, to guide management of future pregnancies.

Neuraxial anaesthesia is not without risk because of the associated coagulopathy, and should only be performed if the coagulation profile is normal or has been corrected, and the platelet count is above $80 \times 10^9$/L.

## Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP) is a rare condition with an incidence of less than six cases per million per annum. It has a 90% mortality if it not treated; 50% of deaths occur in the first 24 hours so early recognition is essential.[59] TTP is not unique to pregnancy, but 10–25% of cases can be associated with pregnancy. Presentation can be at any time in pregnancy, but is more common in the third trimester and postpartum. Pregnancy is a risk factor for relapse in women with known TTP especially those with congenital TTP.

TTP is due to a deficiency of the von Willebrand cleaving protein ADAMTS13. This is an enzyme which cleaves large molecules of VWF into smaller units. This deficiency can be due to a congenital deficiency (congenital TTP), or more commonly in adults, due to autoantibodies against ADAMTS13. Immune destruction of ADAMTS13 can be idiopathic/primary, or secondary to one of the conditions listed in Box 48.8. In the absence of ADAMTS13, high-molecular-weight VWF multimers under shear stresses will activate platelets and cause widespread platelet aggregates of clumps, which block vessels.

TTP is typically characterized by a clinical pentad of microangiopathic haemolytic anaemia, thrombocytopenia, renal dysfunction, fever, and neurological impairment, although diagnosis is hopefully made before the full pentad develops and should be considered in the presence of MAHA and thrombocytopenia alone, if there are no other obvious causes. Diagnosis is based on clinical signs and blood film appearances. Other laboratory investigations may be helpful (Box 48.8). A severely low ADAMTS13 of less than 5% is diagnostic of TTP, but this investigation is often not rapidly available. Signs and symptoms are due to widespread multiorgan thrombosis (Table 48.15). Thrombosis in the placenta also has detrimental effects for the fetus, causing intrauterine growth restriction or fetal death.

**Box 48.8** Conditions associated with TTP not always associated with low ADAMTS13 levels

- HIV
- Drugs including quinine, trimethoprim, and pegylated interferon
- Malignancy, particularly adenocarcinoma
- After bone marrow transplantation
- Pancreatitis
- Autoimmune disease

**Table 48.15** Clinical features of TTP

| | |
|---|---|
| Neurological | Seizures, headaches, drowsiness, confusion, focal neurological signs |
| Renal | Acute kidney injury, proteinuria, microhaematuria |
| Cardiac | Ischaemia/infarction |
| Respiratory | Pulmonary embolism |
| Haematology | Bruising, haemorrhage, jaundice due to haemolysis |
| Gastrointestinal | Abdominal pain |
| Non-specific | Fever, pallor, fatigue, arthralgia, myalgia |
| Fetal | Miscarriage, intrauterine growth restriction, intrauterine death, pre-eclampsia |

### Management

The diagnosis of TTP is a medical emergency; patients must be prioritized to receive plasma exchange as soon as possible as delays can be life-threatening for the mother. In the last two triennial Confidential Enquiries, TTP accounted for 1% of all maternal deaths due to late diagnosis or delayed treatment resulting in myocardial infarction.[60] Patients presenting with a MAHA and thrombocytopenia which cannot be easily explained by another pregnancy-related MAHA should be assumed to have TTP and treated as such.

### Investigations

Investigations listed in Table 48.16 should be performed to aid diagnosis. It is essential that the ADAMTS13 level and antibodies are taken prior to the infusion of plasma products, as this will invalidate the result. A low ADAMTS13 level will confirm the diagnosis of TTP, which is particularly important when the clinical diagnosis is uncertain. The presence of antibodies against ADAMTS13 suggests immune-mediated or acquired TTP, rather than congenital TTP. In addition, a virology sample for HIV and hepatitis B and C should be taken as a baseline prior to infusion of plasma products. A troponin should also be measured to assess for cardiac involvement which is a poor prognostic sign.

### Treatment options

Plasma exchange will infuse ADAMTS13, and remove the ADAMTS13 antibody. If there is any delay in plasma exchange, a plasma infusion should be given, ideally solvent detergent plasma if available, otherwise fresh frozen plasma is acceptable. As a new presentation of TTP in this age group is usually immune in nature, immunosuppressants in the form of oral prednisolone or IV methylprednisolone should also be commenced. Although most patients present with thrombocytopenia, platelet transfusions are contraindicated as they will increase the risk of thrombosis. Treatment with plasma exchange and immunosuppressants

**Table 48.16** Diagnostic investigations of TTP

| | |
|---|---|
| Haemoglobin | Reduced—usually 80–100 g/L |
| Platelet count | Reduced—usually 10–30 × $10^9$/L |
| Reticulocyte count | Increased |
| Lactate dehydrogenase | Increased |
| Bilirubin | Increased |
| Haptoglobin | Reduced |
| Direct coombs test | Negative |
| Clotting screen | Usually normal |
| Urea and electrolytes | Can be abnormal if renal involvement. Acute kidney injury requiring haemodialysis is more indicative of HUS |
| Blood film | Presence of schistocytes, polychromasia, thrombocytopenia, left shift |
| ADAMTS13 level | Reduced |
| ADAMTS13 antibodies | Present in acquired/immune TTP, absent in congenital TTP |

should lead to an increase in the platelet count within a few days. Regular plasma exchange should be continued throughout pregnancy, and also in the postpartum period. In the rarer scenario of the mother being found to have congenital rather than immune TTP, they should attend a specialist centre and receive ADAMTS13 supplementation regularly throughout pregnancy and the postpartum period.

### Management of delivery

Ideally patients should be stabilized with plasma exchange. Neuraxial anaesthesia should be avoided if the platelet count is below 80 × $10^9$/L. It should be remembered, however, that, unlike MAHA associated with pre-eclampsia, TTP is slow to resolve after delivery and treatment needs to be continued.

### Supportive care

As TTP is a prothrombotic condition, aspirin and prophylactic LMWH should be commenced once the platelet count is above 50 × $10^9$/L. Folic acid is required to support increased erythropoiesis, to compensate for the haemolysis but red cell transfusion is only needed if significant uncontrolled anaemia develops.

### Management of patients with a previous history of TTP in pregnancy

Patients with a previous history of TTP are at risk of recurrence during subsequent pregnancies and require preconceptual counselling about potential risks of future pregnancies and the use of the combined oral contraceptive pill. These patients need close monitoring during pregnancy in a joint haematology and obstetric clinic. ADAMTS13 levels can be used to predict likelihood of relapse, and guide prophylactic treatment

## Haemolytic uraemic syndrome

Haemolytic uraemic syndrome (HUS) is the clinical trial of a microangiopathic haemolytic anaemia, acute kidney injury, and thrombocytopenia. It is divided into diarrhoea associated due to a toxin produced by *Escherichia coli* and occasionally pneumococci. In atypical HUS, there is no prodrome of diarrhoea and recent research shows the majority relate to a defect in the complement system or occasionally due to antiphospholipid syndrome. The disease most commonly presents in the late postpartum period. It is often associated with a poor outcome with 76% of patients developing end-stage renal failure.[60]

Management of diarrhoea-associated HUS is supportive, plasma exchange has little benefit except in the very old or very young. Atypical HUS is diverse in its response to plasma exchange and some cases do respond to eculizumab. HUS is best managed by experts in this field.

**Table 48.17** Common causes of disseminated intravascular coagulation

| Pregnancy related | Non-pregnancy related |
|---|---|
| Placental abruption | Severe sepsis |
| Amniotic fluid embolism | Trauma and burns |
| Pre-eclampsia | Malignancy |
| Acute fatty liver of pregnancy | Acute promyelocytic leukaemia |
| Septic abortion | Organ destruction, e.g. pancreatitis |
| | ABO incompatible transfusion reaction |
| | Liver failure |
| | Vascular abnormalities |
| | Massive haemorrhage |

## Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare complication of late pregnancy, or the postpartum period (see also Chapter 36). Presentation is with nausea, vomiting, right upper quadrant pain, and liver failure. Haematological laboratory findings include a low platelet count, prolonged PT, low fibrinogen, and low antithrombin levels. The associated coagulopathy is due to reduced production of clotting factors by the liver, rather than consumption.

Treatment for AFLP includes fresh frozen plasma, platelets, and cryoprecipitate if the patient is bleeding. Careful attention needs to be paid to fluid balance and use of analgesia and anaesthesia.[61] Early delivery should be considered, as this can correct some of the clinical and laboratory abnormalities.[62]

## Disseminated intravascular coagulation

DIC refers to a pathological intravascular activation of coagulation, with severe consumption of coagulation factors and platelets. Deposition of fibrin in small vessels can lead to a MAHA. DIC is a clinicopathological diagnosis, that is, it cannot be made from a set of blood tests but requires a clinical overview to make the diagnosis.

Some of the numerous causes of DIC are listed in Table 48.17. Laboratory features suggestive of DIC are listed in Box 48.9, although not all features are always present.

Thromboelastometry is diagnostic with prolonged clotting time and reduced angle and clot strength. Definitive treatment of

**Box 48.9** Laboratory features suggestive of disseminated intravascular coagulation

- Prolonged aPTT
- Prolonged PT
- Thrombocytopenia
- Low fibrinogen
- Increased fibrin degradation products

DIC is to treat the underlying cause. Plasma products and platelet transfusions should be given if there is active bleeding or if delivery is imminent.

## Conclusion

Haematological disorders in pregnancy can be varied but often present unique and complex challenges. There is a need for these pregnancies to be carefully managed within the multidisciplinary team to improve maternal and fetal outcomes.

# CHAPTER 49

# Peripartum psychiatric disorders

Roch Cantwell

## Epidemiology of mental illness in relation to pregnancy and childbirth

Mental illness is common. Depression has a lifetime prevalence of 4–10% in the general population, with women having a rate 1.5–2.5 times that of men.[1] Bipolar affective disorder and schizophrenia each affects approximately 1% of the population. Pregnancy offers little protection against the continuation or development of mental illness, although risk of suicide[2] and admission to inpatient psychiatric care is reduced at this time.[3] Minor mental illness may be more common in early pregnancy and nearer to delivery. However, the early postpartum period places a woman at greater risk of severe psychiatric disorder and admission to psychiatric care than at any other time in her life. For some women, this risk can be identified, allowing for preventative interventions to be put in place.

## Normal emotional changes in early pregnancy

Some 50% of pregnancies are unplanned,[4] and a proportion of those, unwanted. Rates of unplanned pregnancy are even higher among women with severe mental illness. Even in much wanted pregnancies, ambivalence about the pregnancy, health-related anxieties, and fears about inability to cope (especially in first-time mothers) are typical and normal. Increased emotional lability is common in the first trimester, and may be exacerbated by the physical changes typical of early pregnancy. Such emotional changes are largely bound up with the psychological adjustments typical to pregnancy but may be contributed to by hormonal alterations. It is important to be able to distinguish these changes from those more clearly associated with mental illness.

Oates[5] describes certain groups as having particular needs for increased support in relation to childbearing:

- Very young, single, and unsupported mothers, and women who themselves have poor experiences of mothering, may be especially vulnerable. Their own needs may conflict with those of their babies and early planning to provide appropriate support is essential to help develop the woman's ability to care for her baby.
- Older mothers who may have over-idealized expectations of pregnancy and delivery, and have problems adjusting to life changes after the birth.
- Women who have complicated pregnancies, including those with previous pregnancy loss, those who have undergone assisted conception, and those who require an emergency caesarean delivery.

Women also face an increased risk of domestic violence in pregnancy. Fifteen per cent of women report abuse during their pregnancy and 30% of domestic violence begins during pregnancy.[6] It is recommended that women should be seen alone on at least one occasion during their antenatal care, enquiries about violence should be routinely included in the antenatal history, and information provided on legal rights and available supports. In over 50% of cases of domestic abuse, children are also directly abused. All professionals involved in the care of pregnant women should be aware of how to recognize signs of abuse.[7]

## Pre-existing mental illness

### Bipolar affective disorder

Bipolar disorder is estimated to have a lifetime prevalence of 0.4–1.6%, with peak age of onset for women during reproductive years. Lifetime prevalence is likely to reach 4% when less severe forms of the disorder are included. It is characterized by episodes of elevated (termed mania or hypomania, depending on severity) or depressed mood, and altered behaviour, with relative well-being between periods of illness. Psychotic symptoms (delusions, hallucinations) are typical during episodes, but not essential to the diagnosis. Bipolar disorder is conventionally subdivided into types I and II, depending on the presence or absence of psychotic symptoms or marked behavioural disturbance. Genetic factors play an important role in aetiology, with heritability accounting for approximately 85% of the variance,[8] but episodes of illness may be triggered by stressful life events. Women with bipolar disorder are likely to be on maintenance therapy, which can include lithium, mood-stabilizing antiepileptics, and second-generation antipsychotics. There are teratogenic risks associated with lithium and with the mood-stabilizing antiepileptics, sodium valproate and carbamazepine, but high risk too with regard to relapse of illness on discontinuation. Viguera et al.[9] found that 71% of bipolar women who discontinued prophylactic lithium treatment at onset of pregnancy relapsed at some point during that pregnancy, a two-fold greater risk than for those continuing treatment. Decisions regarding continuation, stopping, or alteration of treatment (for part, or all, of the pregnancy) should be made on an individual basis and with the woman's fully informed involvement. Factors to be taken into account include the previous natural history of the disorder (number, severity, and time interval between episodes of illness), response to previous treatment discontinuations, and time taken to recovery.

Relapse of bipolar disorder in pregnancy (whether with mania, depression, or a mixed presentation) is likely to require use of antipsychotics, antidepressants, mood stabilizers, or sedatives, alone or in combination, depending on the severity and nature of the mood disturbance. Inpatient care is often indicated and, occasionally, electroconvulsive therapy (ECT) may be used. This is discussed more fully later in the chapter.

Pre-existing bipolar disorder is one of the greatest risk factors for postpartum psychosis. Seventy per cent of women with bipolar disorder will experience relapse in the first 6 postnatal months if not taking mood-stabilizing agents.[10] Irrespective of decisions about medication during pregnancy, all women should be offered prophylactic medication (usually lithium or a mood-stabilizing antipsychotic) immediately following delivery. Given that most women with bipolar disorder return to full health between episodes, there is little evidence that they are any less able to care appropriately for their children, except during the acute phase of the illness.

## Schizophrenia

Schizophrenia is an enduring mental illness, characterized by *positive symptoms* such as bizarre delusions, hallucinations, and disrupted thinking reflected in speech (thought disorder), and *negative symptoms* such as social withdrawal, blunted affect, and lack of motivation. It affects approximately 1% of the general population, and is slightly more common in men. Fertility is lowered among women with schizophrenia[11] but the move away from institutional care, and increased use of second-generation antipsychotic drugs, which have a lower propensity to elevate prolactin, may contribute to increasing rates of pregnancy in this group. Women who switch from older drugs may not be aware of this and may place themselves inadvertently at risk of unwanted pregnancy. Women with schizophrenia are more likely to have unplanned and unwanted pregnancies and less likely to engage well with routine antenatal care. They have more adverse outcomes of pregnancy including increased risk of pregnancy loss and neonatal death.[12] Some of this increased risk may be due to confounders such as high rates of smoking and poorer physical health.

There is an increased risk of relapse of schizophrenia in the postnatal period, but the pattern of relapse into illness does not show the very early high risk found in bipolar disorder.[13] This may be explained by the likelihood that precipitants to relapse relate more to the psychosocial and emotional demands of increased contact with health and social care professionals, and caring for a developing child. Although not universally poor, the outcome in terms of the mother remaining the primary carer for her child is often unfavourable,[14] leading to great distress for the mother and for those (including health professionals) who support her. Appropriate supports, including social services, should be engaged at an early stage in pregnancy to ensure sufficient help is available to the mother and her family. It is often difficult for women with schizophrenia to cope with frequent contact with health professionals during pregnancy and there is a risk that they will receive suboptimal care due to failure to attend antenatal care.

Most women with schizophrenia will be on maintenance antipsychotic medication. The implications of relapse during pregnancy are severe for both mother and child, and, unless there are strong reasons to the contrary, treatment should continue, with appropriate monitoring, throughout pregnancy. Difficult decisions may have to be made regarding the relative advantages and problems associated with continuing a well-established regimen involving newer antipsychotics or switching to older medication, where the risks associated with pregnancy are better known.

## Depressive and anxiety disorders

Depressive disorder is characterized by a triad of symptoms groupings including disturbed mood, negative thinking, and somatic or behavioural change, which may include reduced appetite and energy, disturbed sleep, impaired enjoyment, and difficulty with concentration and memory. Suicidal thoughts, planning, or acts may be present in more severe illness. Given a lifetime prevalence of 4–10%, with rates higher in women than men, many women may have a pre-existing depressive disorder at conception. Studies suggest that 2–10% of women are taking prescribed antidepressant treatment at the time of conception. Women are most likely to discontinue treatment, without consultation, on discovering a pregnancy.[15] This may place them at greater risk of relapse of illness. A past history of depressive illness is one of the strongest risk factors for antenatal depression, which in turn is predictive of postnatal depression. Although depressive symptoms are probably as common in pregnancy as in the postnatal period they often remain undetected.

For anxiety disorders, the course in pregnancy is likely to be related to the severity of illness preconceptually. Physiological changes in respiratory function during pregnancy may lead to an increased propensity to panic and anxiety and panic may worsen in the postnatal period. These disorders may also significantly compromise antenatal care. Women with severe needle phobia are likely to be referred to anaesthetic services to assist in blood taking. The Confidential Enquiry into Maternal Deaths 2006–08 reported one case of refusal to have bloods taken in pregnancy or thromboprophylaxis postnatally in a woman who died of thromboembolism.[16] Such patients require early referral and intervention, using behavioural techniques.

Non-pharmacological treatments include *cognitive therapy* and *behavioural techniques*, such as anxiety management, teaching the patient about the nature and genesis of symptoms, and engaging in relaxation exercises to reverse them. Drug treatments include selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants. Beta blockers should not be used as first-line treatment.[17]

## Eating disorders

Core features of eating disorders (anorexia nervosa and bulimia) include distorted body image and a morbid fear of fatness with efforts at weight loss, such as food restriction, excessive exercising, self-induced vomiting, and use of appetite suppressants, laxatives, and diuretics. Bulimic symptoms (binge eating followed by vomiting) are a core feature of bulimia but may also be present in anorexia nervosa. Amenorrhoea is essential to the full anorexic syndrome, but many women have partial syndromes (commonly termed EDNOS (eating disorders not otherwise specified)), which may include presentations where ovulation continues, or returns when weight loss is not so extreme. Eating disorders, including EDNOS, have some of the highest mortality rates of any psychiatric disorder.

Eating disorders (including partial syndromes) affect 5–7% of women of childbearing age.[18] There is some evidence that eating

disorder symptoms may improve in pregnancy, but the postnatal period can be associated with a worsening of symptoms, as efforts are made to lose weight gained in pregnancy. With regard to the impact of a pre-existing eating disorder on pregnancy, there is evidence from some studies of intrauterine growth restriction, miscarriage, and preterm delivery.[19,20] Self-induced vomiting may lead to electrolyte imbalance, and severe weight restriction to delayed wound healing after delivery.

The fertility of anorexic women is significantly reduced. Women with bulimia may have menstrual irregularities despite a normal body mass index. During and after pregnancy, women with eating disorders are more likely to experience comorbid depressive disorder. They struggle more with breastfeeding.

Early detection and referral to eating disorders services, where available, is core to management. Guidance on expected weight gain in pregnancy, healthy eating, and bodily changes in pregnancy are of particular importance in this group. Rarely, inpatient refeeding may be required. In the postnatal period, specific enquiry about depressive symptoms and worsening or return of eating disorder should be made.

### Substance use disorders

Details of specific substance abuse can be found in Chapter 51. Women with alcohol or drug problems often engage poorly with antenatal care and their impaired physical health, and increased risk of blood-borne virus infection, may place them and their pregnancy at risk. An increasing number of drug-using women contribute to cases reported to the Confidential Enquiries into Maternal Deaths.[21]

As with other maladaptive behaviours, excessive alcohol use tends to decrease during the antenatal period. Physical complications of alcohol misuse, which can threaten or complicate pregnancy, include nutritional deficiencies, liver disease, and pancreatic disease. Withdrawal complications such as delirium tremens and seizures pose particular risk.

Fetal alcohol syndrome, and the more encompassing term, fetal alcohol effects, is characterized by craniofacial abnormalities, growth retardation, and neurodevelopmental abnormalities, including impaired IQ, in the presence of maternal alcohol consumption.[22] The pathway for adverse effects on fetal development is complex but there is evidence that alcohol is a direct teratogen and there appears to be a dose-related response. Animal studies suggest that binge pattern drinking in pregnancy is particularly harmful, but there is no consensus about whether there may be a safe lower limit for consumption in pregnancy.

Other drug use effects vary depending on the properties of the specific drug, although it is important to recognize that patients may frequently use a combination of substances and research in the area is not extensive. Pregnant women who misuse drugs should receive specialist support, with the aim of stabilizing, minimizing, or, where appropriate, stopping their use. Abrupt discontinuation of drug use is not recommended. Although women may be more motivated to stop drug use in pregnancy, there is significant risk of relapse in the postnatal period with potentially serious adverse child welfare consequences. Early involvement of child care social work is an essential component of alcohol and drug misuse management in pregnancy. The children of many of these women are taken into care and some may enter a vicious cycle of repeated pregnancies in an attempt to retain at least one of their children. Contraceptive advice should be a priority postpartum.

### Personality disorder

Personality disorders are deeply engrained and enduring patterns of behaviour, resulting in inflexible responses to a broad range of personal and social situations. They are stable and unchanging, usually present from adolescence, and often cause the person, or those around them, to suffer. There are often difficulties in forming and/or sustaining relationships, and this may extend to health professionals involved in the person's care. In one epidemiological study, the prevalence of personality disorder in pregnancy was 6.4%.[23] Of the group of personality disorders, the emotionally unstable type is perhaps the most commonly diagnosed in young women. It is characterized by emotional instability, impulsivity, dysphoric mood, disturbances in self-image, chronic feelings of emptiness, and self-destructive behaviour, including recurrent self-harm, and drug or alcohol misuse. Such difficulties cause high levels of anxiety among health and social care professionals, and may interfere with effective antenatal care. Impaired forward planning and tolerance of distress may increase anxieties regarding child welfare. Effective management is usually provided through good joint working and communication between professionals, and a clear and consistent treatment plan to which the patient agrees. There may be a role for specific psychological and drug therapies.

## Newly arising mental disorder

### Tocophobia

Tocophobia is a morbid fear of childbirth.[24] Primary tocophobia pre-dates pregnancy and may be associated with previous abusive experiences. Secondary tocophobia arises from previous traumatic delivery. Tocophobia may also present as a symptom of depressive disorder in pregnancy. For some women, the dread of delivery is such that they will proceed to termination despite the pregnancy being wanted. Other women will plan, from the outset, for elective caesarean delivery. Interventions will usually take the form of cognitive therapy and anxiety management techniques, but there is a higher incidence of caesarean delivery even where such approaches are used.

### Postpartum psychosis

Psychotic disorders arise after 1 in 500 births. Although the absolute risk for any woman is low, relative to other times in a woman's life, this period carries the highest risk of psychosis and psychiatric hospital admission.[25] The illness has its onset in the early postnatal period, 90% occurring within the first month. Despite the name, a small proportion of cases have onset in late pregnancy. Almost all cases are affective in nature, that is, they present predominantly with mood disturbance in addition to the characteristic symptoms of psychosis—delusions, hallucinations, marked behavioural disturbance, and loss of insight. Non-affective or schizophrenia-like presentations are much less common. Typically, the presentation is one of rapid fluctuations of mood (often with a mixture of manic and depressive symptoms), perplexity, confusion, and markedly altered behaviour. Ideas of self-harm may be driven by delusions of guilt, self-worthlessness, or hopelessness. Thoughts of harm concerning the baby or other children are rare but should always

be assessed. Initial symptoms may be non-specific, often including anxiety and labile mood. Failure to recognize such prodromal symptoms, coupled with rapid progression to frank illness over a short period of time, is a recurrent theme in psychiatric deaths reported to the Confidential Enquiry.[21]

Several factors have been identified that significantly increase the risk of psychosis. Of greatest importance is a previous history of postpartum psychosis or bipolar disorder. A first-degree relative with bipolar disorder or previous postpartum psychosis increases this risk further. With one or more of these risks, a woman may have a greater than one in two risk of developing postpartum psychosis. Identification of risk is particularly important, as there is evidence that preventative interventions, when started in the immediate postpartum period, are effective in reducing progression to illness. Interventions include lithium, mood-stabilizing antipsychotic drugs, and measures to protect sleep.

All women with postpartum psychosis should be managed by psychiatric services. Most will require admission to hospital. Where specialist mother and baby facilities are available, her baby will usually accompany her. Treatment consists of a combination of antipsychotic medication, antidepressants, or mood stabilizers depending on the specific presentation. ECT is also an effective and rapid treatment. Supervised support for the patient's care of her infant and help for the family are crucial to good management. Recovery usually takes place over a period of 1–2 months but there is great individual variation. Prognosis for the episode is very good and most women will make a complete recovery, but remain at a one in two risk of future postpartum episodes. There is also a significantly increased risk, perhaps as high as 60%, of non-postpartum recurrence, in which case criteria are likely to be met for bipolar disorder.

The aetiology of postpartum psychosis remains uncertain. The dramatic, early presentation is suggestive of a link with major hormonal changes normally occurring after childbirth. The strong association with bipolar disorder implies a genetic predisposition, and evidence has emerged of a specific familial risk for postpartum episodes in bipolar disorder.[26] It has been suggested that the rapid reduction in oestrogen levels is linked to the development of dopamine receptor hypersensitivity, which in turn may trigger the onset of psychosis in predisposed individuals.[27] Serotonergic neurotransmitter systems have also been implicated in causation. So far, however, there is very limited evidence for the use of hormonal treatments in routine management.

### Antenatal and postnatal depression

In contrast to postpartum psychosis, non-psychotic depression often presents later in the postnatal period, with a peak occurrence at around 6 weeks. While there is some evidence of a telescoping in the incidence of depression in the first postnatal weeks, the overall prevalence of 10–15% in the first year is not very different from the prevalence of mild to moderate depression at any other time in a woman's life, including in pregnancy. Similarly, the symptoms of depression in the antenatal and postnatal period do not differ greatly from those at other times, depression usually presenting with a combination of the triad of affective, cognitive, and behavioural symptoms mentioned earlier. Some studies suggest a greater predominance of obsessional symptoms in postnatal depression. For some women, these may take the form of obsessional worries or fears that she may cause harm to her baby. Much less commonly, there may be true infanticidal thoughts. Thoughts of self-harm are not uncommon and should be followed up with sensitive enquiry as to the depth and strength of these feelings.

The majority of depressions occurring at this time are mild and do not require specific psychiatric intervention. Most will be uncovered during routine antenatal and postnatal screening by the midwife, general practitioner (GP), or health visitor. For postnatal depression, the provision of extra support and non-directive counselling by health visitors is usually adequate to bring about resolution. A smaller number of women, approximately 3–5%, will benefit from antidepressant medication, but fewer than half that number will require referral to psychiatric services. Of these, only a small number will be admitted to psychiatric care, though it is important to identify those with the most severe disorders. While previously advocated, there is no evidence that progesterone or synthetic progestagens are effective treatments for postnatal depression.

Unlike postpartum psychosis, where risk factors are largely biological, psychosocial factors play the greatest part in the development of non-psychotic depression. Most important are a past history of depression, psychological problems during pregnancy, poor social support, lack of a confiding relationship, and recent adverse life events.[28] Weaker associations have been found with obstetric complications, history of abuse, lower socioeconomic status, and perception of poor obstetric experience. Unfortunately, these risk factors have poor specificity and so, while allowing for heightened awareness, cannot be used to accurately predict the development of depression in any one individual. Untreated postnatal depression is also closely associated with disturbed mother–baby interaction and with adverse effects on infant cognitive and emotional development.

## Psychological aspects of miscarriage, stillbirth, and abortion

Around one in five pregnancies will end in spontaneous loss before 20 weeks. Early loss is often not associated with the same acknowledgement and support attending stillbirth or neonatal death. In the absence of an obvious cause, miscarriage may also lead to a greater sense of self-blame and guilt. Around 40% of women will go through a typical bereavement process, similar to that following stillbirth or neonatal death, with emotional reactions that may include numbness, disbelief, social withdrawal, anger, guilt, sadness and anxiety, leading eventually to acceptance and resolution. Depressive symptoms are present, at a rate two to four times that of the general population in the first 6 months,[29] and anxiety symptoms are similarly elevated. In most cases, symptoms have returned to background levels by 1 year. However, some women may experience an abnormal or prolonged grief reaction, depressive or anxiety disorder.

Interventions to reduce the risk of psychological morbidity are poorly researched. Women consistently say they wish for greater access to psychological support, and there is some evidence for the benefit of psychological interventions. Where benefit has been demonstrated, it has mostly been for interventions targeted at those displaying early difficulties, rather than for general approaches to all women who miscarry. However, an empathic approach, and acknowledgement of the significance of the loss, is important for all women.

Late pregnancy and early neonatal loss is likely to result in a normal grief reaction. Some controversy surrounds the common practice of encouraging parents to spend time with, hold, and dress their dead infants. One study found an increased risk of depression,

anxiety, and post-traumatic stress disorder in subsequent pregnancy, where women had time with their infants, and that greater exposure was correlated with more subsequent problems.[30] Best practice is to allow parents to decide for themselves whether they wish contact with their dead infants, without assumption from staff that such exposure is the correct or desired option.[31]

The link between induced abortion and mental health is shrouded in controversy. The most recent, and extensive, review of the literature to date suggests that for women with an unwanted pregnancy, the risk of adverse mental health is the same, whether the outcome is an induced abortion or term delivery.[32] Certain factors, such as a negative attitude to abortion, or pressure from a partner to have an abortion, may increase the risk of adverse mental health outcomes. Overall however, the most reliable predictor of mental health problems post abortion is having a history of mental health problems before the abortion.

## Maternal mental illness, child welfare, and infant development

Infanticide is a very rare outcome of maternal mental illness. However, some mental illnesses, such as schizophrenia, may compromise a woman's ability to engage with antenatal care, increasing the risk of adverse outcomes for the pregnancy. Furthermore, persistent anxiety in pregnancy, and untreated postnatal depression, may be linked to impaired social and cognitive development in children as they grow up.[33] Antenatally, this may be mediated through disruption of the fetal hypothalamic–pituitary–adrenal axis. In the postnatal period, maternal depression may alter the quality of interaction between mother and child, leading to poorer social interaction.

The majority of women with mental health problems care for their children without difficulty. Where there are concerns that care may be compromised by severe illness or substance misuse, early involvement of social services is essential, ideally during pregnancy, to allow for a full evaluation of risk and for support, if required, to be coordinated.

## Biological management of psychiatric disorder in pregnancy and breastfeeding

The research base for psychotropic medication effects in pregnancy is limited but ever changing. For this reason, it is not possible to give definitive advice. The National Institute of Health and Care Excellence (NICE)[34] and the Scottish Intercollegiate Guidelines Network (SIGN)[35] provide some general principles which should govern prescribing in pregnancy. These are summarized in Box 49.1. NICE and SIGN also recommend that access to psychological therapies, where appropriate, should be promptly available.

### Antidepressants

Coincidental antidepressant prescribing at conception is common and SSRI antidepressant use is now more established in pregnancy. There is some evidence of an increased risk of cardiac anomaly, but the absolute risk is likely to be less than 1%. Some studies suggest a greater risk with paroxetine but research to date is imperfect and poorly controlled for potential confounders, such as smoking and alcohol use. There remains uncertainty about whether SSRIs are associated with an increased risk of persistent pulmonary hypertension in the neonate, if given after 20 weeks. A recent meta-analysis suggests an odds ratio of 2.5–2.8, against a baseline risk of 1.9/1000.[36] Again,

**Box 49.1** Principles of prescribing in pregnancy

- Involve the woman, and her family where appropriate, in all decisions about treatment, including an individualized assessment of benefit versus risk
- Be aware that not treating mental illness in pregnancy or the postpartum period may in itself be associated with adverse outcomes for the woman, her pregnancy, and her infant
- Establish a clear indication for drug treatment (ie the presence of significant illness in the absence of acceptable or effective alternatives)
- Choose treatments with the lowest known risk
- In choosing medication in pregnancy consider the implications for breast feeding and the benefits of avoiding the need to switch drugs (including the minimization of withdrawal effects)
- Use treatments in the lowest effective dose for the shortest period necessary
- Be aware of potential drug interactions, particularly with non-psychotropics, and aim for monotherapy
- Where there is no clear evidence base that one drug is safer than another, the safest option is not to switch. The only drug with a clear indication for switching on safety grounds is valproate
- Be aware of the potential effects of pregnancy and childbirth on drug pharmacokinetics and pharmacodynamics (eg the need for dose adjustments as pregnancy progresses and specific risks during labour and following birth)
- Be aware that although knowledge of teratogenic effects of psychotropic drugs is increasing, understanding of the long-term neurodevelopmental effects of such medications in pregnancy and breast feeding is extremely limited
- Be aware of the need for close monitoring for change in mental state where a woman decides to cease her usual medication. Stopping medication may lead to relapse of illness
- Where there is known risk, ensure that women are offered appropriate fetal screening and monitoring of the neonate for adverse effects. This may include involvement of neonatal and or paediatric services
- Be aware that premature or ill babies are more at risk of harmful drug effects
- Monitor the infant for specific drug side effects as well as feeding patterns, growth and development
- Caution women against sleeping in bed with the infant, particularly if taking sedative drugs.

the absolute risk remains low. Similarly, there is limited evidence for growth retardation and premature delivery. Neonatal poor adaptation is increased threefold against background rates. Typical symptoms include irritability, constant crying, shivering, increased tone and tremor, poor feeding and, rarely, seizures. Infants are at increased risk of special care admission and of lower Apgar scores at birth. More recent evidence suggests a possible association between SSRIs and autistic spectrum disorder. Although more research is required, even if increased, the attributable risk remains very low.

Tricyclic antidepressants are likely to have a similar adverse side effect profile in pregnancy. While they have been available for a much greater period of time than the SSRIs and consequently any greater adverse effects might be expected to have emerged, systematic reporting of exposure is less extensive than with the SSRIs and so quality of evidence is poorer. Monoamine oxidase inhibitors may be associated with early teratogenicity and the risk of blood pressure abnormalities, particularly with tyramine-related food interactions, make them unsuitable in pregnancy.

While an evaluation of the risks and benefits of continuing already prescribed antidepressants in pregnancy should be made with the woman, there are also risks of relapse with sudden discontinuation. Women should usually be advised not to abruptly discontinue, but to arrange an early review with their GP. Decisions on new prescribing in pregnancy should take into account the severity of illness, previous treatment response and breastfeeding intentions. Different SSRIs are present in breastfed babies in very varying concentrations.

## Antipsychotics

Many antipsychotics raise prolactin levels and reduce fertility. Some are associated with excessive weight gain and impaired glucose tolerance. Because of this, it is recommended that women on antipsychotics be regarded as at increased risk of gestational diabetes and managed accordingly.[37] The evidence of any association with fetal malformation is very limited. Where these drugs are prescribed for the management of severe and enduring mental illness (i.e. schizophrenia and related disorders), the risks of discontinuing will usually outweigh any risks of medication to the developing fetus. In the majority of cases, usual practice would be to continue medication throughout pregnancy. Long-acting depot medication can persist in the neonate for considerable periods and it may be possible to change to an oral preparation during the pregnancy to avoid this risk. Such decisions need to take individual circumstances into account, particularly the significant risk of relapse of illness. There is a theoretical risk of blood dyscrasia in the neonate where clozapine is used in pregnancy but, again, risks for the woman from discontinuation may be very high.

## Mood stabilizers

These drugs, most commonly prescribed for prophylaxis of bipolar disorder, include lithium, and the antiepileptics valproate, carbamazepine, and lamotrigine.

Lithium has a narrow therapeutic to toxic ratio and is monitored by regular blood level assay. In early pregnancy, lithium has been associated with an increased risk of cardiac malformation, notably Ebstein's anomaly. The relative risk of Ebstein's anomaly may be increased 10–20-fold, but the absolute risk remains low, at 0.05–0.1%. Overall, risk of cardiac anomaly may have been overestimated in earlier retrospective studies.[38] In later pregnancy, lithium is associated with neonatal complications, including hypotonia, neonatal hypothyroidism, and nephrogenic diabetes insipidus. Lithium crosses the placenta with ease and levels in the neonate are equivalent to those in the mother. There is a close correlation between maternal/neonatal levels, and neonatal complications.[39] Pharmacokinetic changes in pregnancy result in lithium levels lowering, for the same oral dose, from mid trimester. Doses may need to be increased to maintain therapeutic levels, but there is then a risk of toxicity in the mother and neonate after delivery.

Lithium levels should be monitored monthly in pregnancy, and weekly from 36 weeks. It should be discontinued at onset of labour, and some authorities would suggest reducing the dose in late pregnancy, aiming for levels at the lower end of the therapeutic range, particularly where there is a history of rapid delivery or other indicators of early delivery (e.g. twin pregnancy). Other precipitants of toxicity, which may be relevant in pregnancy, include dehydration occurring in hyperemesis or prolonged labour, pre-eclampsia, impaired renal function, and sodium-restricted diets. Drug interactions with diuretics, non-steroidal anti-inflammatory agents, angiotensin-converting enzyme inhibitors, and calcium channel blockers may also cause toxicity.

Sudden lithium discontinuation is associated with greatly increased risk of relapse in bipolar disorder and specialist advice should be sought urgently if a woman presents, on lithium, in early pregnancy.

The antiepileptic mood stabilizers carbamazepine and valproate are associated with a risk of neural tube defects (0.5% for carbamazepine; 1–2% for valproate), including spina bifida. They are also associated with cardiac, gastrointestinal, and facial anomalies, along with a range of other minor malformations. Given that many pregnancies will not be confirmed until after the neural tube closes (day 28), reducing this risk is dependent on preconceptual advice and management. This may include high-dose folate (5 mg/day) from at least 12 weeks prior to conception, although its prescription has not been shown directly to reduce the rate of neural tube defects in women on antiepileptics. For valproate, there is evidence of a dose relationship, with greater risk at doses above 1000 mg/day. Valproate has also been linked to a significant impairment in cognitive function, with 22% of children noted to have exceptionally low verbal IQ, compared with an expected rate of 2% in the general population.[40] Given these concerns, it is recommended that valproate is not prescribed to bipolar women of childbearing potential unless there are no effective alternatives. In such circumstances, women should be on long-acting contraception. Some studies suggest that lamotrigine is associated with increased rate of cleft palate, but findings are conflicting. Lamotrigine is also subject to significantly lowered bioavailability as pregnancy progresses and levels should be monitored in each trimester.

## Anxiolytics and hypnotics

Evidence for teratogenicity associated with benzodiazepines is conflicting, with some, but not all, studies suggesting an increased risk of oral cleft. In late pregnancy, there is an increased risk of neonatal sedation or withdrawal. Ideally, doses should be tapered nearing delivery and the infant monitored for withdrawal effects.

## Electroconvulsive therapy

Despite a somewhat controversial reputation, ECT is a well-established treatment with a good evidence base for effectiveness in

**Box 49.2** Indications for referral to mental health services in pregnancy

- Woman with current illness where there are symptoms of psychosis, severe anxiety, severe depression, suicidality, self-neglect, harm to others, or significant interference with daily functioning. Such illnesses may include psychotic disorders, severe anxiety or depression, obsessive–compulsive disorder, and eating disorders.
- Woman with a history of bipolar disorder or schizophrenia.
- Woman with previous serious postpartum mental illness (postpartum psychosis).
- Women on complex psychotropic medication regimens.
- Referral should be considered for women with illness of moderate severity if developing in late pregnancy or the early postpartum period.
- Referral should be considered for women with current illness of mild or moderate severity where there is a first-degree relative with bipolar disorder or puerperal psychosis. In the absence of current illness, such a family history indicates a raised, but low absolute, risk of early postpartum serious mental illness. Where identified, information should be shared with primary care and any evidence of mood disturbance during pregnancy or in the postpartum period should lead to referral.
- Women with previous periods of inpatient mental health care should be screened by mental health services (either by assessing case records or seeing the woman).
- Maternity services need to ensure that appropriate communication with primary care, and social services where necessary, takes place for women who decline referral to specialized mental health services.

Reproduced from Royal College of Obstetricians and Gynaecologists, *Management of Women with Mental Health Issues during Pregnancy and the Postnatal Period*. Good Practice Paper No. 14. London: RCOG; 2011, with the permission of the Royal College of Obstetricians and Gynaecologists.

severe depressive disorder where, in certain circumstances, it may be the treatment of choice. Less commonly, it is used to manage mania and catatonia. It is also an effective treatment for postpartum psychosis. ECT is most likely to be used where there is a need for rapid recovery because of significant distress, self-neglect, or suicidality, or where there has been a previous good ECT response. There are clear guidelines about the use of ECT, including the use of general anaesthesia and availability of resuscitation and recovery facilities.[41]

The evidence base for the use of ECT in pregnancy is sparse. One case series suggested that the overall risk is low, with 3.2% of fetal or neonatal complications, and 5.3% of maternal complications, attributable to the treatment. The commonest fetal complication was transient cardiac bradyarrhythmia.[42] Modifications to standard ECT administration in pregnancy, particularly in the second and third trimester, include additional fetal monitoring, measures to counteract increased risk of aspiration such as histamine $H_2$ receptor antagonists, for example, ranitidine, sodium citrate, a rapid sequence induction, cricoid pressure, intubation, antiemetics, avoiding excessive hyperventilation, and positioning of the patient to prevent aortocaval compression.[43]

## Managing risk

Guidance for risk management is outlined in NICE[34] and SIGN[35] guidelines on perinatal mental illness.

### Prepregnancy

Women who are planning a pregnancy should be asked about a history of significant mental illness. Those at greatest risk of adverse consequences include women with bipolar disorder or schizophrenia (risk of relapse of illness postnatally), and women with schizophrenia, substance misuse, or personality disorder (who may struggle to cope with the challenges of pregnancy and childcare, without appropriate support). Women currently prescribed complex psychotropic regimens should be given advice regarding any known teratogenicity, and specialist review to establish the safest and most effective treatment in advance of pregnancy.

### Pregnancy

First contact with maternity services provides an important opportunity to identify women with pre-existing mental illness, or those with a raised risk of postnatal mental illness. All women should be asked about:

- personal history of postpartum psychosis, other psychotic disorders (especially bipolar disorder and schizophrenia), and severe depressive disorder
- family history of bipolar disorder or postpartum psychosis.

Women confirming any of these risk factors should be referred for assessment and management of risk, and should have a detailed plan for their management in late pregnancy and the early postnatal period, which is shared with the woman and all those involved in her care. Services should also respond promptly to any change in mental state reported in late pregnancy or the early postnatal period.

Enquiry should also be made about depressive symptoms at booking and, if there are ongoing concerns, at all subsequent contacts.

Box 49.2 outlines situations where referral to mental health services is indicated during pregnancy.[44]

## Conclusion

Pre-existing mental illness presents services with particular challenges during pregnancy, labour, and the postnatal period. Disorders may compromise access to care (such as with schizophrenia or needle phobia), predispose to comorbid physical illness (such as with eating disorders or substance misuse), or result in treatments which require expert management during pregnancy and delivery (such as with lithium or ECT). In addition, the development of early severe postpartum mental illness is, in a substantial proportion of cases, a predictable risk which can be identified and prevented by careful clinical enquiry. All clinicians have a role in the prevention, early detection, referral, and initial management of such disorders.

# CHAPTER 50

# Chronic maternal infections

Kristel Van Calsteren

## Introduction

Pregnant women diagnosed with chronic infections are a worldwide problem. In developed countries, the most frequently encountered are hepatitis B and C (see Chapter 43), toxoplasmosis, syphilis, herpes simplex, and *Cytomegalovirus* infections. In developing countries, human immunodeficiency virus (HIV) and malaria are also seen commonly in pregnant women. Maternal infections are associated with various complications in pregnant women, but also with congenital infections with or without structural anomalies and long-term sequelae, fetal growth restriction, preterm delivery, and perinatal mortality.

Moreover, increasing evidence suggests that maternal infection during pregnancy affects the developing immune system of the fetus independently of the vertical transmission of pathogens.[1]

In this chapter, I discuss the pathogen characteristics, ways of transmission, clinical presentation, diagnostic options, treatment, and, if relevant, prophylaxis for the most common infections in pregnant women.

## Human immunodeficiency virus

### General information

An infection with HIV is a life-long infection that can lead to the acquired immunodeficiency syndrome (AIDS).

The official first registration of the disease occurred in the summer of 1981 when the US Centers for Disease Control and Prevention (CDC) reported on a cluster of *Pneumocystis jirovecii* (previously *carinii*) pneumonia (PCP) in five homosexual men.[2] Soon thereafter, additional gay men developed a previously rare skin cancer called Kaposi's sarcoma (KS).[3,4] However, there is substantial evidence that HIV first crossed the simian–human species barrier much earlier. The identification of a cytopathic retrovirus in 1983 and development of a diagnostic serological test for HIV-1 in 1985 have served as the basis for developing improvements in diagnosis.

HIV is a lentivirus, a slow-replicating retrovirus, that infects vital cells in the human immune system such as helper T cells (specifically CD4+ T cells), macrophages, and dendritic cells.[5] Lentiviruses are transmitted as single-stranded, positive-sense, enveloped RNA viruses. Upon entry into the target cell, the viral RNA genome is converted (reverse transcribed) into double-stranded DNA by a virally encoded reverse transcriptase that is transported along with the viral genome in the virus particle. The resulting viral DNA is then imported into the cell nucleus and integrated into the cellular DNA by a virally encoded integrase and host co-factors. Once integrated, the virus may become latent, allowing the virus and its host cell to avoid detection by the immune system. Alternatively, the virus may be transcribed, producing new RNA genomes and viral proteins that are packaged and released from the cell as new virus particles that begin the replication cycle anew.

Two types of HIV have been identified: HIV-1 and HIV-2. HIV-1 is more virulent, more infective,[6] and is the cause of the majority of HIV infections globally. The lower infectivity of HIV-2 implies that fewer of those exposed to HIV-2 will be infected per exposure. Because of its relatively poor capacity for transmission, HIV-2 is largely confined to West Africa.

HIV infection leads to low levels of CD4+ T cells through a number of mechanisms including apoptosis of uninfected bystander cells, direct viral killing of infected cells, and killing of infected CD4+ T cells by CD8 cytotoxic lymphocytes that recognize infected cells. When CD4+ T cell numbers decline below a critical level, cell-mediated immunity is lost, and the body becomes progressively more susceptible to opportunistic infections (Figure 50.1).

### Transmission

Infection with HIV occurs by the transfer of blood, semen, vaginal fluid, pre-ejaculate, or breast milk. Within these bodily fluids, HIV is present as both free virus particles and virus within infected immune cells. If their mothers have HIV, infants can become infected during the pregnancy, during labour and delivery, and, to a lesser degree, through breastfeeding.

### Diagnosis

HIV testing is performed by immunoassays (ELISA or combination antibody and antigen immunoassays) and analysed in duplicate. If the result of either duplicate test is reactive, the specimen is reported as repeatedly reactive and undergoes confirmatory testing with Western blot.

When the possibility of an acute HIV infection is considered or the serology is positive, viral load is determined by reverse transcription polymerase chain reaction (RT-PCR) and CD4 cell count is measured.

Testing post exposure is recommended initially and at 6 weeks, 3 months, and 6 months since the time interval between infection and test positivity is 20–45 days for immunoassays, 35–60 days for Western blot, and 5–15 days for viral load.[7]

Many HIV-positive people are unaware that they are infected with the virus. Therefore, it is strongly recommended that all pregnant women undergo serological screening for HIV.

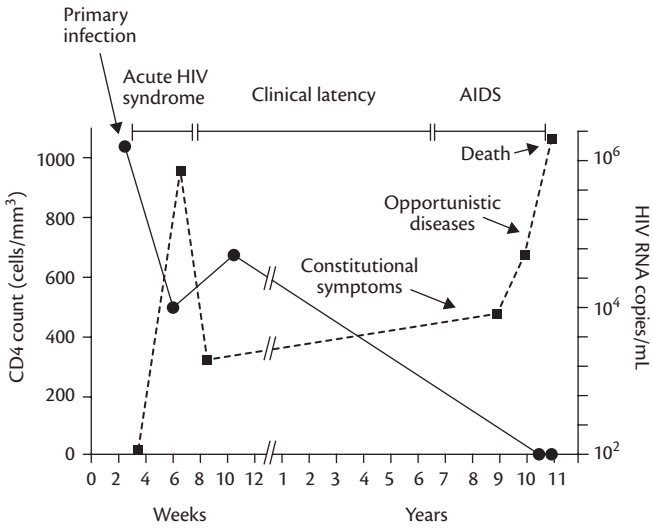

**Figure 50.1** HIV infection: CD4 count and viral load throughout disease progression.

## Clinical presentation

Ten to 60% of patients with early HIV infection will not experience symptoms. In acute symptomatic HIV infection, a variety of symptoms can be seen: fever, lymphadenopathy, sore throat, rash, myalgia/arthralgia, headache, and diarrhoea. These findings are not specific for acute HIV, but prolonged duration of symptoms and the presence of mucocutaneous ulcers are suggestive of HIV. The usual time from HIV exposure to the development of symptoms is 2–4 weeks.

AIDS is a disease characterized by progressive failure of the immune system allowing life-threatening opportunistic infections and cancers to thrive.

## Treatment

At diagnosis, and at regular time intervals, viral load, CD4 T cell count and side effects of medication should be monitored. HIV drug-resistance studies are advised to be performed before starting or modifying antiretroviral regimens in all pregnant women whose HIV RNA levels are above the threshold for resistance testing (above 500–1000 copies/mL).[8] The importance of adherence to prescribed antiretroviral medications should be stressed to reduce the potential for development of resistance.

During pregnancy, all women with HIV are advised to take combination antiretroviral regimens using three HIV drugs. Combination antiretroviral drug regimens will maximally suppress viral replication, which is the most effective strategy for preventing development of resistance and minimizing risk of perinatal transmission.

The 2013 World Health Organization guidelines recommend initiation of a once-daily, fixed-dose combination of tenofovir (300 mg), lamivudine (300 mg) (or emtricitabine (200 mg)), and efavirenz (600 mg) in all HIV-infected pregnant women. Alternative agents are zidovudine to replace tenofovir and nevirapine to replace efavirenz in the three-drug regimen. There are extensive safety and efficacy data on the use of zidovudine and nevirapine in pregnant and breastfeeding women.[9]

Studies suggest that women who start HIV medications earlier in pregnancy are more likely to have a low amount of virus in the blood by the time of delivery. However, some women may prefer to start after the first trimester of pregnancy to avoid unnecessary drug exposure to the embryo. Once started, HIV medications are continued throughout pregnancy.

There are several HIV medications that should not be used in pregnancy. Nevirapine is generally not started in women with a CD4 count higher than 250/mm$^3$, since it is associated with hepatic toxicity and hypersensitivity reactions. Efavirenz is associated with fetal malformations (neural tube defects), so should not be started during the first few weeks of pregnancy. However, women who become pregnant while taking efavirenz can continue that medication.

## Obstetric care

HIV-positive patients are at increased risk for spontaneous abortions and stillbirths, growth restriction, preterm delivery, and perinatal mortality and appear to have a lower risk of pre-eclampsia.[10,11] The latter has been linked to the HIV-1-related immune deficiency and indicates the pivotal role of the immune system in the pathogenesis of pre-eclampsia.[12]

A detailed ultrasound is usually recommended at 18–20 weeks of pregnancy to screen for structural anomalies, especially when antiretroviral drugs were administered in the first trimester of pregnancy. A follow-up ultrasound is often recommended during the third trimester to monitor the fetal growth.

The advised mode of delivery depends on the viral load at that time.[8,9]

Pregnant women with HIV who have been taking HIV medications throughout pregnancy and have an *undetectable HIV viral* load at 34–36 weeks of pregnancy may choose to have a vaginal delivery. The risk of transmission during a vaginal delivery is than very low, and a caesarean delivery has not been shown to decrease this risk any further.

Women with an HIV viral load *between 0 and 1000 copies/mL* who have been taking HIV medications during pregnancy may choose between a vaginal or caesarean delivery. Data are insufficient to evaluate the potential benefit of caesarean delivery used solely for prevention of perinatal transmission in women with HIV RNA levels less than 1000 copies/mL, and given the low rate of transmission in these patients, it is unclear whether scheduled caesarean delivery would confer additional benefit in reducing transmission.

Pregnant women with HIV who have taken HIV medications throughout pregnancy but have a *viral load above 1000 copies/ mL* at 34–36 weeks of pregnancy (or unknown HIV levels and newly diagnosed disease) are advised to have a planned caesarean delivery (at 38 weeks) rather than a vaginal delivery. For these patients it is advised to administer zidovudine intravenously (IV) to reduce the risk of HIV transmission, next to their combination HIV medications which they should continue to take on schedule to provide maximal protection to the mother and infant and to minimize the risk that the mother could develop drug resistance due to a missed dose of medication.[8] Women with newly diagnosed disease or unknown HIV levels at the time of delivery should also have a caesarean delivery and zidovudine IV.

It is not clear whether caesarean delivery after rupture of membranes or onset of labour provides benefit in preventing perinatal transmission. Management of women originally scheduled for caesarean delivery who present with ruptured membranes or in labour must be individualized at the time of presentation based on duration of rupture and/or labour, plasma HIV RNA level, and current antiretroviral drug regimen.[8]

Transmission-increasing procedures, like amniocentesis, artificial rupture of membranes, use of fetal scalp electrodes/scalp pH, operative delivery with forceps/vacuum, and episiotomy, should be avoided unless there are clear obstetric indications.

In case of postpartum haemorrhage resulting from uterine atony, the current antiretroviral drug regimen should be taken into consideration. In women who are receiving a cytochrome P450 (CYP)-3A4 enzyme inhibitor such as a protease inhibitor, methylergometrine should be used only if no alternative treatments are available. If methylergometrine is used, it should be administered in the lowest effective dose for the shortest possible duration. In women who are receiving a CYP3A4 enzyme inducer such as nevirapine, efavirenz, or etravirine, additional uterotonic agents may be needed because of the potential for decreased methylergometrine levels and inadequate treatment effect.

### Postpartum care

Decisions about continuing antiretroviral drugs after delivery should take into account current recommendations for antiretroviral therapy, current and nadir CD4 T-lymphocyte counts and trajectory, HIV RNA levels, adherence issues, whether a woman has an HIV-uninfected sexual partner, and patient preference.

Women with HIV who breastfeed can pass HIV to the infant. In one study of over 600 mother–infant pairs from Malawi, the risk of transmitting HIV to the infant through breast milk was 7% for infants who breastfed for 1 year and 10% for infants who breastfed for up to 2 years.

In resource-rich countries, clean water and infant formulas are readily available and are safe alternatives to breastfeeding. Therefore, in resource-rich countries, HIV-positive patients are recommended not to breastfeed their babies, even if the woman is taking HIV medications. While risk of HIV transmission through breast milk can be lowered by HIV medications, HIV can still be transmitted through breast milk. The same advice cannot be given to women in resource-poor countries because safe alternatives to breast milk may not be consistently available.

Newborns of women with HIV should receive post-exposure prophylaxis to prevent transmission from exposure to HIV during delivery/breastfeeding with 6 weeks of zidovudine or nevirapine. Zidovudine or nevirapine should be initiated as close to the time of birth as possible, preferably within 6–12 hours of delivery.

Infants born to HIV-infected women who have not received antepartum antiretroviral drugs should receive prophylaxis with zidovudine given for 6 weeks combined with three doses of nevirapine in the first week of life (at birth, 48 hours later, and 96 hours after the second dose), begun as soon after birth as possible. A longer duration of infant prophylaxis is reasonable in breastfeeding infants in certain circumstances that increase the likelihood of absent or delayed viral suppression in the mother, such as when women do not receive antepartum antiretroviral drugs. The use of antiretrovirals other than zidovudine and nevirapine cannot be recommended in premature infants because of lack of dosing and safety data.[8]

HIV antibody tests are not accurate in infants since HIV antibodies may be transferred from the mother to the baby. This may result in the infant having a positive HIV antibody test. However, this does not mean that the baby necessarily has HIV infection.

For this reason, in infants an HIV PCR test that directly measures the virus itself should be performed to determine whether or not the baby is infected with HIV.

### Long-term follow-up of children

Studies of infants who were exposed to zidovudine and who did not become infected with HIV have not shown any increased risk of serious problems with growth, the immune system, brain function, cancers, or other problems for up to 6 years.[13] However, long-term data regarding the safety of HIV medications during pregnancy, particularly combination regimens, are not available.

## Prophylaxis

Pregnancy does not appear to worsen HIV or increase the risk of death from HIV. For the baby, patients should understand that the risk of transmission is much lower with an undetectable viral load. Therefore it is important to take HIV medication adequately.[8]

For serodiscordant couples who want to conceive, it is important to recognize that treatment of the infected partner may not be fully protective against sexual transmission of HIV.

For HIV-infected females with HIV-uninfected male partners, the safest conception option is artificial insemination, including the option of self-insemination with a partner's sperm during the periovulatory period.

For HIV-infected men with HIV-uninfected female partners, the use of sperm preparation techniques coupled with either intrauterine insemination or *in vitro* fertilization should be considered if using donor sperm from an HIV-uninfected male is unacceptable.

For serodiscordant couples who want to conceive, initiation of antiretroviral therapy for the HIV-infected partner is recommended. Periconception administration of antiretroviral pre-exposure prophylaxis (PrEP) for HIV-uninfected partners may offer an additional tool to reduce the risk of sexual transmission. The utility of PrEP of the uninfected partner when the infected partner is receiving antiretroviral therapy has yet not been studied.

Partners should be screened and treated for genital tract infections before attempting to conceive.

Perinatal transmission can be reduced by antiretroviral drugs by lowering maternal antepartum viral load and providing infant pre- and post-exposure prophylaxis.

## Anaesthetic management

Patients with HIV infection have early HIV virus infection of the central nervous system (CNS). Hence the initial fear of epidural or spinal anaesthesia transferring the virus to the CNS, are unfounded and regional anaesthesia should not be withheld.[14] Also the use of an epidural blood patch whenever indicated seems to be safe.

HIV patients may have mild thrombocytopenia. Hence platelet levels should be tested.

# Malaria

## General information

Malaria is caused by five species of the protozoan genus *Plasmodium*: *P. vivax, P. falciparum, P. malariae, P. knowlesi*, and *P. ovale*. The infection is maintained in nature by female mosquitoes of the genus *Anopheles*, in which the parasites' multiplication occurs.

Malaria is an endemic disease in parts of Asia, Africa, Oceania, and Central and South America, where environmental factors including temperature, humidity, and standing water support the breeding of mosquitoes in close contact with humans.

The mosquito feeds on human blood, in which the *Plasmodium* life cycle is completed.

## Transmission

When a female *Anopheles* mosquito bites an infected human, male and female gametocytes are ingested into the mosquito stomach. The sexual reproductive cycle produces sporozoites in about 2 weeks' time, which accumulate in the mosquito salivary glands and are infectious for humans. When the mosquito bites again, the sporozoites are infected into the bloodstream. The sporozoites infect liver parenchymal cells during this clinically inapparent pre-erythrocytic or exoerythrocytic phase. After several days merozoites are released into the bloodstream. This form of the parasite is capable of red blood cell invasion and multiplication, a process called schizogony, which lead to red blood cell lysis. When enough parasites are in synchrony, periodic fevers manifest themselves coincident with rupture of red blood cells and release merozoites. The cycle takes 36–72 hours.

Certain haemoglobinopathies and erythrocyte enzyme defects render patients less susceptible to severe complications of malaria. Patients with sickle haemoglobin acquire falciparum malaria as frequently but the clinical disease is attenuated, possibly because the parasite is less able to divide in the abnormal erythrocyte. Certain black populations are less susceptible to *P. vivax* infections because of the absence of Duffy blood group antigen, which acts as an erythrocyte receptor for *P. vivax* merozoites.[15]

Immunity to clinical malaria is acquired gradually as a result of repeated exposure to the infection. In endemic areas, this process takes 5–10 years to develop and immunity is partial, meaning that the parasites are present intermittently in the blood of semi-immune subjects.[16] The development of antibodies and cell-mediated immunity contribute to the pathogenesis of some of the clinical features of chronic malaria such as nephrotic syndrome and tropical splenomegaly. Disruption of the host–parasite balance by malnutrition, pregnancy, or introduction of new strains of parasite, may precipitate recrudescence and clinical manifestations in the semi-immune host.

All types of malaria can be transmitted congenitally, but congenital disease is most often associated with *P. vivax* and *P. falciparum*. In immune mothers, the risk of transplacental transmission of malaria appears to be small (0.1–1.5% had cord blood positive for parasites and clinical disease), when overt attacks occurred during pregnancy the risk was 1–4%.[17] In contrast, in semi-immune or non-immune mothers, transplacental antibody transfer may be deficient, and the incidence of congenital infection appears to be higher (7–10%).[18]

Primiparous women in endemic areas seem to be more susceptible to recrudescent infections than multiparous women.

## Diagnosis

Diagnosis is made by Giesma-stained thick and/or thin peripheral blood smears or a rapid diagnostic test. The highest level of parasitaemia will be demonstrable several hours after a rigor and serial thick and thin slides may be needed to demonstrate parasitaemia. It is important to point out that women may have placental parasites that are not circulating in the peripheral blood, and hence, the blood film would be negative. Yet, no reliable peripheral biomarker for the presence of placental malaria has been identified.

## Clinical presentation

Patients with acute malaria usually present with rigors and fever (which may or may not be periodic), often associated with headache and myalgia. Non-specific symptoms include malaise, dry cough, abdominal pain, diarrhoea, nausea, anorexia, or vomiting. Physical examination reveals fever, tachycardia, respiratory distress, hepatomegaly, splenomegaly, pallor, and sometimes jaundice.

Fever and related symptoms gradually subside over several weeks in untreated *P. vivax, P. ovale*, and *P. malariae* malaria. Months or years after initial exposure, dormant forms of the parasitic (hypnozoites) may emerge from the liver and cause relapses. With *P. falciparum*, serious complications such as coma, severe haemolytic anaemia, disseminated intravascular coagulation, acute kidney injury, and acute pulmonary oedema may develop rapidly in the non-immune host; however, once eradicated from the blood *P. falciparum* does not relapse.[15]

Compared to non-pregnant women, pregnant women experience more severe disease, severe anaemia (60%), more hypoglycaemia, and more respiratory complications (pulmonary oedema, acute respiratory distress syndrome).[19]

Adverse perinatal outcomes associated with malaria include miscarriage, fetal growth restriction, preterm birth, low birth weight, fetal and maternal anaemia, and congenital infection. Each year, 50 million women living in malaria-endemic areas become pregnant. It is estimated that 10,000 women and 200,000 infants die as a result of malaria infection during pregnancy; severe maternal anaemia, prematurity, and low birth weight contribute to more than half of these deaths.

In endemic areas, it can be difficult to distinguish malaria acquired congenitally from that acquired as a newborn, particularly in infants of asymptomatic mothers. The onset of symptoms is usually at 2–8 weeks of age and includes poor feeding, fever, vomiting, diarrhoea, and irritability. Anaemia, thrombocytopenia, and hyperbilirubinaemia are common. Splenomegaly is more common than hepatomegaly.

## Treatment

Acute malaria in the unexposed, pregnant host is a medical emergency requiring immediate treatment.

Patients with malaria during pregnancy should be admitted and started with drug treatment (artesunate, quinine, clindamycin, chloroquine, atovaquone–proguanil) (Table 50.1).[20] Paracetamol (maximum 4 g/day provided the patient is >50 kg) should be started for fever and screening for anaemia should be performed.

These patients should be monitored for hypoglycaemia, pulmonary oedema, acute respiratory distress, and secondary bacterial infection should be screened for if the patient becomes hypotensive. (Exchange) Transfusion might be necessary for anaemia.

Uncomplicated malaria in pregnancy is not a reason for induction of labour.

**Table 50.1** Royal College of Obstetricians and Gynaecologists guidelines for treatment and prophylaxis of malaria in pregnancy[20]

| Severity | Indication | Drug and dosage |
|---|---|---|
| Severe or complicated malaria | Any species | Artesunate IV 2.4 mg/kg at 0, 12, and 24 hours, then daily thereafter. When the patient is well enough to take oral medication she can be switched to oral artesunate 2 mg/kg (or IM artesunate 2.4 mg/kg) once daily, plus clindamycin. If oral artesunate is not available, use a 3-day course of Riamet® or Malarone® or a 7-day course of quinine and clindamycin at 450 mg 3 times a day 7 days |
| | | Alternative:<br>Quinine IV 20 mg/kg loading dose (no loading dose if patient already taking quinine or mefloquine) in 5% dextrose over 4 hours and then 10 mg/kg IV over 4 hours every 8 hours plus clindamycin IV 450 mg every 8 hours (maximum dose quinine 1.4 g). When the patient is well enough to take oral medication she can be switched to oral quinine 600 mg 3 times a day to complete 5–7 days and oral clindamycin 450 mg 3 times a day 7 days (an alternative rapid quinine-loading regimen is 7 mg/kg quinine dihydrochloride IV over 30 minutes using an infusion pump followed by 10 mg/kg over 4 hours)<br>*Note*: quinine dosing should be reduced to 12-hourly dosing if IV therapy extends more than 48 hours or if the patient has renal or hepatic dysfunction. Quinine is associated with severe and recurrent hypoglycaemia in late pregnancy. |
| Uncomplicated malaria | *P. falciparum* | Oral quinine 600 mg 8-hourly and oral clindamycin 450 mg 8-hourly for 7 days<br>*or* Riamet® 4 tablets/dose for weight > 35 kg, twice daily for 3 days<br>*or* Malarone® 4 standard tablets daily for 3 days |
| | Vomiting but no signs of severe or complicated malaria | Quinine 10 mg/kg dose IV in 5% dextrose over 4 hours every 8 hours plus IV clindamycin 450 mg every 8 hours. When the patient is well enough to take oral medication she can be switched to oral quinine 600 mg 3 times a day to complete 5–7 days and oral clindamycin can if needed be switched to 450 mg 3 times a day 7 days |
| Non-falciparum malaria | *P. vivax, P. ovale, P. malariae* | Oral chloroquine (base) 600 mg followed by 300 mg 68 hours later. Then 300 mg on day 2 and again on day 3 |
| | Resistant *P. vivax* | As for uncomplicated malaria *P. falciparum* |
| | Preventing relapse during pregnancy | Chloroquine oral 300 mg weekly until delivery |
| | Preventing relapse after delivery | Postpone until 3 months after delivery and G6PD testing |
| | *P. ovale* | Oral primaquine 15 mg single daily dose for 14 days |
| | *P. vivax* | Oral primaquine 30 mg single daily dose for 14 days |
| | G6PD (mild) for *P. vivax* or *P. ovale* | Primaquine oral 45–60 mg once a week for 8 weeks |

Reproduced from Royal College of Obstetricians and Gynaecologists, *The diagnosis and treatment of malaria in pregnancy*. Green-top Guideline No. 54b. London: RCOG; 2010, with the permission of the Royal College of Obstetricians and Gynaecologists.

Peripartum malaria is an indication for placental histology and placenta, cord, and baby blood films to detect congenital malaria at an early stage.

### Prophylaxis

Pregnant travellers should be advised to defer travel until after delivery whenever feasible. For pregnant women who cannot defer travel, mosquito avoidance measures should be used in conjunction with chemoprophylaxis.

Chloroquine or hydroxychloroquine are considered safe to use in all trimesters of pregnancy. Mefloquine is the agent of choice for chloroquine-resistant areas, and evidence suggests it is not associated with an increased risk to the fetus. Although the atovaquone–proguanil drug combination is not currently recommended for use during pregnancy, limited data suggest that it is not harmful to the fetus. Doxycycline and primaquine are not recommended during pregnancy.[21]

## Syphilis

### General information

Syphilis is a chronic infectious disease caused by the spirochaete, *Treponema pallidum*. It is a sexually transmitted disease that can cause long-term complications and/or death if not treated correctly. Symptoms in adults are divided into four stages: primary, secondary, latent, and late syphilis.

### Transmission

Syphilis is transmitted by direct contact with a syphilitic ulcer during anal, vaginal, or oral sex. Ulcers can be found on the penis, vagina, lips, and in the rectum and mouth.

The disease can be found at any stage in a pregnant woman and *T. pallidum* can cross the placenta to infect the fetus, resulting in congenital disease or stillbirth. The risk of congenital syphilis is directly related to the stage of syphilis in the mother and the risk is extremely high for the first 4 years after maternal acquisition of infection when spirochaetaemia is common. Perinatal transmission occurs in 50% of patients with primary or secondary syphilis, with fewer congenital infections among women with early latent (40%), late latent (10%), and tertiary disease (10%).[15]

### Diagnosis

Available tests are divided into screening and confirmatory tests.

For screening, a non-treponemal antibody test (Venereal Disease Research Laboratory (VDRL) test and the Rapid Plasma

Reagin (RPR) test) is performed on serum. Positive tests are usually reported as antibody titre and can be used to follow the response to treatment in many patients. These tests are relatively inexpensive, easy to perform, and can also be done on other body fluids, such as cerebrospinal fluid (CSF). Confirmatory tests (treponemal antibody tests) detect antibodies specifically directed at treponemal cellular components (fluorescent treponemal antibody absorption (FTA-ABS), microhaemagglutination assay for antibodies to *T. pallidum* (MHA-TP), and *T. pallidum* particle agglutination assay (TPPA)). These tests are sensitive and specific, but expensive. Furthermore, they remain positive despite treatment and therefore correlate poorly with disease activity.

Lumbar puncture is required for any patient with clinical evidence of neurological involvement and is strongly recommended for patients with coexistent HIV or with latent syphilis for more than 1 year.

In all pregnant women, it is advised to screen for syphilis during the first prenatal medical visit. If the patient is considered to be at high risk this screening should be repeated in the third trimester.

For the diagnosis of congenital syphilis, the VDRL or RPR test should be performed. A thorough physical examination should be performed for evidence of congenital syphilis. Direct visualization of *T. pallidum* by darkfield microscopy or fluorescent antibody staining of infected body fluids (e.g. nasal discharge) or lesions, placenta, or umbilical cord can be performed.

PCR has been used on neonatal blood and CSF for diagnosis of congenital syphilis, but these tests are not widely available.[22]

## Maternal clinical presentation

*Primary syphilis* presents as a papule, which is typically painless, at the site of inoculation (genital or extragenital).[23] This soon ulcerates to produce the classic chancre(s) of primary syphilis. The chancre is a 1–2 cm painless ulcer with an indurated margin, which is associated with regional lymphadenopathy. Chancres heal spontaneously within 3–6 weeks, even in the absence of treatment. The primary stage of syphilis is often missed in women because the lesion is on vaginal or cervical mucosa.

*Secondary syphilis* is a disseminated systemic process that begins 6 weeks to 6 months after the appearance of the chancre in approximately 25% of untreated patients. This stage of disease is characterized by a generalized maculopapular skin rash involving the palms and soles and mucous membranes, but usually sparing the face. The rash is usually not itchy. Other symptoms that can accompany the skin rash include generalized lymphadenopathy, fever, pharyngitis, weight loss, patchy hair loss, headaches, muscle aches, and fatigue, as well as genital condylomata lata. Although spirochaetes can be found in the CSF of around 40–50% of patients with early syphilis, neurological manifestations are rare. The rash of secondary syphilis typically resolves spontaneously within 2–6 weeks. Secondary syphilis is commonly the stage when women present to a healthcare provider.

*Latent disease* is usually subclinical, although clinical relapses, particularly of lesions of secondary syphilis, may occur. If syphilis is not treated, it can remain present for years without any signs or symptoms.

*Tertiary syphilis* occurs in approximately one-third of untreated patients, but is now rarely seen since most patients are treated either deliberately or inadvertently when receiving penicillin for other indications. Tertiary syphilis can occur 10–30 years after the infection begun, or 5–20 years after the disease has become latent. This stage is characterized by slowly progressive signs and symptoms. Clinical manifestations include gumma formation (15%), cardiovascular disease (10%) (aortic aneurysm), and neurosyphilis (6.5%) (general paresis, numbness, blindness, dementia, tabes dorsalis).

## Congenital syphilis

The clinical spectrum of congenital infection includes perinatal death, preterm delivery, low birth weight, non-immune hydrops, early congenital syphilis, and late congenital syphilis.

Two-thirds of live-born neonates with congenital syphilis are asymptomatic at birth. Clinical manifestations in untreated infants usually appear by 3 months of age, most often by 5 weeks.[24]

Characteristic findings for early congenital syphilis include a maculopapular rash, hepatosplenomegaly and jaundice, fever, neurosyphilis, pneumonitis, rhinitis or 'snuffles', lymphadenopathy, chorioretinitis, anaemia, thrombocytopaenia, and osteochondritis which may lead to pseudoparalysis. Also condylomata lata and nephrotic syndrome have been described. Chancres do not occur.[25]

If untreated, late congenital syphilis will develop. Manifestations of late congenital syphilis are facial features (frontal bossing, saddle nose, short maxilla, protuberant mandible), oropharyngeal anomalies (Hutchinson's teeth, mulberry molars, perforation of hard palate), ophthalmologic damage (interstitial keratitis, chorioretinitis, secondary glaucoma, corneal scarring, optic atrophy), sensorineural deafness, gummas, skeletal anomalies (saber shins: anterior bowing of the tibia, Higoumenakis sign: enlargement of the sternoclavicular portion of the clavicle, Clutton joints: painless arthritis) and lesions of the CNS (intellectual disability, arrested hydrocephalus, seizures, juvenile general paresis).[25]

Late congenital syphilis develops in approximately 40% of infants born to women with untreated syphilis during pregnancy. Some manifestations of late congenital syphilis can be prevented by treatment of the mother during pregnancy or treatment of the infant within the first 3 months of life. However, other manifestations (e.g. keratitis and saber shins) may occur or progress despite appropriate therapy.

## Treatment

Benzathine penicillin G cures maternal infection and prevents congenital infection in 98% of cases.[26] Alternative therapy with other non-penicillin regimens is not recommended for pregnant patients because of treatment failures in preventing congenital infection, especially with erythromycin (Table 50.2).[27] Tetracycline is not recommended because of discolouration of fetal teeth and bones, but may represent a reasonable choice if no other alternatives are available. Ceftriaxone is also effective in adults for the treatment of early syphilis, but there is no information about its efficacy in preventing congenital syphilis.

If non-penicillin alternative regimens are used during the pregnancy, the neonate should be very carefully evaluated for active disease and treated with a single dose of benzathine penicillin G (50,000 units/kg IM).

Patients with a history of penicillin allergy should receive skin testing for the presence of anaphylactic antibodies to both the major determinant antigen, penicilloyl polylysine, and to the minor determinant antigens, benzylpenicillin G and benzyl penicilloic acid. About 90% of patients giving a history of

**Table 50.2** Guidelines for treatment of syphilis

| Stage of disease | Recommended treatment |
|---|---|
| Early syphilis (primary, secondary or latent syphilis of <1 year duration) | Benzathine penicillin G 2.4 million units IM in a single dose<br>*Alternatives*:<br>Tetracycline 500 mg orally 4 times daily for 2 weeks<br>Erythromycin 500 mg orally 4 times daily for 2 weeks<br>Ceftriaxone 1 g IM daily for 10 days |
| Late latent syphilis (>1 year duration and cardiovascular syphilis) | Benzathine penicillin G 2.4 million units IM weekly for 3 consecutive weeks<br>*Alternative*:<br>Tetracycline 500 mg orally 4 times daily for 4 weeks |
| Neurosyphilis | Aqueous crystalline penicillin G, 3–4 million units IV every 4 h for 10–14 days, followed by benzathine penicillin G 2.4 million units IM weekly for 3 consecutive weeks<br>*Alternative*:<br>Aqueous procaine penicillin G 2.4 million units IM daily and probenecid 500 mg orally 4 times daily, both for 10 to 14 days |

penicillin allergy do not in fact have a true immunoglobulin (Ig)-E-mediated anaphylactic reaction and can be treated with penicillin. Patients who do have an IgE-mediated allergic reaction should be offered penicillin desensitization, as proposed by Wendel et al.[28]

Occasionally, pregnant patients with early syphilis may experience a Jarisch–Herxheimer reaction after therapy. This reaction generally consists of fever 2–12 hours after initiation of therapy for active syphilis. However, cardiovascular collapse, seizures, and death also have been reported. The Jarisch–Herxheimer reaction is thought to be produced by the release of endotoxin-like compounds during penicillin-mediated lysis of *T. pallidum*. Since fever may initiate preterm labour, hospitalization should be considered for these patients.

### Follow-up

After treatment, quantitative RPR or VDRL titres should be followed closely until negative (or stable at a low titre of generally less than 1:4 for late latent syphilis). In general, the quantitative titre should decline fourfold by the third or fourth month after therapy for primary and secondary syphilis. Patients should be evaluated for neurosyphilis and retreated for persistently high titres after 3 months, or for a fourfold increase in titre.[29]

## Toxoplasmosis

### General information

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*. It is an obligate intracellular parasite that exists in three forms: the oocyst, which is shed only in cat faeces; the tachyzoite, a rapidly dividing form observed in the acute phase of infection; and the bradyzoite, a slow-growing form observed within tissue cysts.

Cats play an important role in the spread of toxoplasmosis. Eating infected rodents, birds, or other small animals infects them. The parasite is then passed in the cat's faeces in oocyst form. During a primary infection, a cat can shed millions of oocysts daily for a period of 1–3 weeks. These oocysts become infective 1–5 days later and may remain infectious for over a year, especially in warm, humid environments. Cats typically develop immunity after a primary infection; therefore, recurrent infection with passage of oocysts is unlikely. Other animals (including pigs, chickens, lambs, and goats) and humans become infected by contact with contaminated soil or water or eating soil-contaminated fruit or vegetables, resulting in meat containing tissue cysts.

Once a person is infected, the parasite lies dormant in neural and muscle tissue and will never be eliminated.[30]

### Transmission

There are three principal routes of transmission of *Toxoplasma*:

1. *Foodborne transmission*. This is the main source of human infection in developed, temperate climate countries. People become infected by ingestion of bradyzoites contained in undercooked meat, by eating undercooked contaminated meat or by handling it and not washing hands thoroughly, or by eating food that was contaminated by knives, cutting boards, or other foods that had contact with raw contaminated meat.
2. *Animal-to-human (zoonotic) transmission*. Hereby, people become infected by ingestion of oocysts from contact with contaminated soil or water or eating soil-contaminated fruit or vegetables.
3. *Mother-to-child (congenital) transmission*. A woman who is infected with *Toxoplasma* during pregnancy can pass the infection to her unborn child. Transmission to the fetus occurs predominantly in women who acquire their primary infection during gestation. In rare cases, congenital transmission has occurred in chronically infected women whose infection was reactivated because of their immunocompromised state (e.g. from AIDS or treatment with corticosteroids for their underlying disease). The incidence of maternal infection during pregnancy ranges from 1 to 8/1000 susceptible pregnancies, with the highest reported rates in France.[31]

   The risk of fetal infection increases with advancing gestational age at the time of maternal infection. Meta-analysis of all available cohorts estimated the risk of transmission to be 15% when the mother seroconverted at 13 weeks, 44% at 26 weeks, and 71% at 36 weeks.[32]
4. *Rare instances of transmission*. Rarely, people become infected by receiving infected blood via transfusion or by receiving an organ transplant from a *Toxoplasma*-positive donor. Laboratory workers who handle infected blood can also acquire infection through accidental inoculation.

### Diagnosis

Diagnosis is usually achieved by serology. The presence of IgG antibodies shows that a person has been infected. To try to estimate the time of infection, IgM is measured and an avidity test is performed. An IgG avidity test measures how tightly the antibody

binds to the antigen. Over time this value increases, so a low avidity means that the infection was recent, a high avidity suggests that the infection was more than 3–4 months ago.

Interpreting serology results of toxoplasmosis is often confusing. A positive IgM is not indicative for an acute infection since the IgM response lasts a median of 10–13 months. Depending on the type of test used, there is substantial variation in duration between individuals, and about one-quarter of infected women have a persistent IgM response lasting years. Although high IgG avidity is a hallmark of latent infection, low avidity is not diagnostic of acute infection; low IgG avidity can persist for years in some women.[33,34] For women whose first prenatal test at 13 weeks of gestation was IgM and IgG positive, the probability that their infection occurred after conception is 1–3%, depending on the test used.

The most accurate diagnosis of a maternal infection is based on seroconversion from negative to positive toxoplasma-specific IgM or IgG. Serial testing can be offered in susceptible asymptomatic pregnant women. Monthly or 3-monthly retesting schedules operate in parts of Europe, while in the United States and Canada, universal screening for toxoplasmosis in pregnancy is not performed.

Apart from serology, diagnosis can be made by direct observation of the parasite in stained tissue sections, CSF, or other biopsy material. These techniques are used less frequently because of the difficulty of obtaining these specimens. Parasites can also be isolated from blood or other body fluids (e.g. CSF) but this process can be difficult and requires considerable time.

Ocular disease is diagnosed based on the appearance of the lesions in the eye, symptoms, course of disease, and often serological testing.

Diagnosis of congenital infections can be achieved by detecting *T. gondii* DNA in amniotic fluid using molecular methods such as PCR; however, accuracy varies among laboratories and techniques and sensitivity is lower in early (<18 weeks of gestation) than in late pregnancy.

### Clinical presentation

Most pregnant women with acute acquired infection do not experience obvious symptoms or signs. A minority may experience mild flu-like symptoms (e.g. malaise, low-grade fever, lymphadenopathy, and muscle aches) that last for several weeks. Up to 1% of infected individuals will present with visual changes due to toxoplasmic chorioretinitis as a result of recently acquired infection or reactivation of a chronic infection.[35]

In the fetus and neonate, toxoplasmosis infection presents with chorioretinitis, microcephaly or ventriculomegaly/hydrocephaly, intracerebral calcifications, and mental retardation or other evidence of parenchymal brain damage, hepatosplenomegaly, myocarditis, pericardial and pleural effusion (TORCH syndrome). The later in pregnancy, the less severe the fetal damage of a toxoplasmosis infection will be. The risk of developing clinical signs of infection in the offspring is 60%, 25%, and 10% in the first, second, and third trimesters, respectively.[36]

Of all infected fetuses, 70% are born without obvious lesions, 10% suffer only ocular manifestations, and the remaining 20% have the classic TORCH syndrome.[30]

### Treatment

Most healthy persons recover from toxoplasmosis without treatment. In pregnancy, antibiotic treatment will be started to protect and treat the fetus.

In the case of a primary maternal infection before 18 weeks of gestation, spiramycin (3 g/day to the mother) should be started since it reduces the risk of transmission to the fetus by about 60%.[37] The longer the interval between maternal seroconversion and the start of spiramycin, the greater the likelihood of fetal damage. Spiramycin therapy, even over a long period, appears to have no significant maternal or fetal toxicity. Since spiramycin does not readily cross the placenta, it is not reliable for treatment of infection in the fetus.

Therefore, if fetal infection is confirmed by positive PCR of amniotic fluid (at/after 18 weeks) or structural anomalies on prenatal ultrasound, it is recommended to switch treatment to pyrimethamine, sulfadiazine, and folic acid. Because of the high transmission rates observed after 18 weeks of gestation, treatment with pyrimethamine, sulfadiazine, and folic acid is also used for patients who have acquired the infection after 18 weeks of gestation. Pyrimethamine is not used earlier because it is potentially teratogenic.

If ultrasound examination reveals congenital anomalies indicating congenital fetopathy, the option of termination of pregnancy should be discussed with the parents.

## *Cytomegalovirus*

### General information

*Cytomegalovirus* (CMV) is a DNA virus and member of the herpes family of viruses. The rate of seroconversion (primary infection) during pregnancy ranges from 1% to 7%.[38] Like other herpesviruses, CMV establishes latency after the host is initially infected. Non-primary infection, also sometimes called recurrent or secondary infection, may be due to reactivation of latent virus or reinfection with a new strain.

### Transmission

Person-to-person transmission usually occurs by contact with infected nasopharyngeal secretions, urine, saliva, semen, cervical and vaginal secretions, breast milk, tissue, or blood, including transfusion of blood and bone marrow and transplacental transfer. The risk of seroconversion is highest in households with young children in daycare centres.[39]

Transmission of CMV from the mother to the fetus or newborn can occur in several ways. Most commonly, CMV infects the placenta (placental cytotrophoblasts are permissive to CMV replication) and is then transmitted to the embryo/fetus, where the virus is replicated in multiple tissues, including renal tubular epithelium.[40] Ascending infection from the maternal genital tract is thought to be rare antepartum, but possible.[41] Intrapartum and postnatal transmission can occur via ingestion/aspiration of cervicovaginal secretions during delivery or via breastfeeding. Rates of cervical CMV excretion vary depending upon various factors, including age, socioeconomic status, and geography of the populations studied.[42]

Perinatal transmission of CMV occurs in 5–8% when the infection occurred within 3 months before conception, in 10–20% when a periconceptional infection occurred, in 30% when the infection occurred in the first trimester, and 40–60% when infection occurred in the second to third trimester of pregnancy.[43] Although perinatal transmission may increase as gestation advances, sequelae in offspring appear to be less severe the later in gestation transmission occurs.

## Diagnosis

Diagnosis is made by viral culture from urine, nasopharynx, or blood, or by serology.

Seroconversion of CMV-specific IgG is diagnostic for a new acute infection. The presence of CMV IgM is not helpful for timing the onset of the infection because it usually remains present until 4–8 months after the primary infection, but can persist at low titre for years or increase periodically in women with reactivation or reinfection with a different strain. Therefore determination of the avidity of IgG is used to determine the acuity of the infection, and thus the risk of *in utero* transmission. High avidity (>65%) suggests that the primary infection occurred more than 6 months in the past; low avidity (<30%) suggests a recent primary infection in the last 3 months.[44,45]

Reactivation or reinfection can be suspected when there is a fourfold rise in IgG and presence of IgM titres and patients with positive IgG on former blood analysis.

When CMV infection is diagnosed periconceptionally or in the first trimester of pregnancy, that is, patients at risk for serious abnormalities, an amniocentesis is offered to determine whether or not the fetus is infected based on a PCR analysis for CMV DNA of amniotic fluid. Critical to obtain an adequate sensitivity is to perform the amniocentesis after 21 weeks of gestation and with a time interval of at least 6 weeks between the maternal infection and the amniocentesis.[46,47]

For maternal infections late in gestation, PCR for CMV is performed on a urine sample of the newborn.

## Clinical presentation

The most common manifestation of CMV infection is the lack of any demonstrable disease (90%).

Primo-infection in the *immunocompetent* (pregnant) adult may develop a mild febrile illness, atypical lymphocytosis, some malaise (rhinitis, pharyngitis, myalgia, arthralgia, headache, fatigue), mild lymphadenopathy, but generally has a benign course. Rarely, serious complications of the acute infection occur including interstitial pneumonitis, hepatitis, the Guillain–Barré syndrome, meningoencephalitis, myocarditis, thrombocytopenia, and haemolytic anaemia.

The virus may be excreted for weeks, months, or years after a primary infection and can be cultured from urine. A latency period eventually occurs, but reactivation and reinfection are common. Reinfection with a different strain of CMV or reactivation of virus in women with pre-existing antibody generally does not cause clinical illness.

CMV infection in the *immunosuppressed patient* (immunosuppressive drugs, organ transplant, AIDS patients) can be serious. Most commonly is a mononucleosis-like syndrome. The next most frequent manifestation is interstitial pneumonia, which may progress rapidly from asymptomatic to fatal, often in association with pneumocystis infection in AIDS patients. Also frequent are myocarditis, hepatitis, gastrointestinal disease with ulceration leading to haemorrhage and perforation, and meningoencephalitis.[30]

*Congenital CMV* infection occurs in 5–60% of the maternal primo-infections. The rate of maternofetal transmission increases linearly with the gestational age at infection, while the sequelae in the infected newborn decrease with the gestational age at infection. Twenty to 25% of infected fetuses develop sequelae and 10–15% will be symptomatic at birth or diagnosed prenatally on ultrasound (Table 50.3). These newborns have a mortality rate of about 5%, and 50–60% of survivors will develop severe long-term neurological morbidity (progressive hearing/visual loss and cognitive impairment). Although fetal infection can be detected, there is no way to accurately predict whether or not the fetus will develop significant sequelae. Serial ultrasound examinations every 2–4 weeks can be useful to detect development of sonographic abnormalities. Persistent changes, such as ventriculomegaly, periventricular calcifications, growth restriction, microcephaly, and hydrops, suggest the presence of severe disease and high risk of long-term neurodevelopment impairment. For these patients the option of termination of the pregnancy should be discussed. Magnetic resonance imaging (MRI) may provide additional information about anomalies, particularly neurological abnormalities.[48] However, normal ultrasound and MRI imaging does not exclude the possibility of hearing loss.[49]

Five to 15% of infected fetuses are asymptomatic at birth, but will develop neurodevelopmental damage (learning disabilities, hearing loss) within the first 3 years of life.[50] Non-primary infection results in symptomatic disease at birth in 0.2–2% of cases; perinatal death is rare.[51]

## Treatment

Treatment of the acute symptomatic CMV infection in immunocompetent patients consists of supportive care for symptomatic relief.

In immunocompromised patients and neonates, antiretroviral drugs such as ganciclovir, foscarnet, and cidofovir reduce

**Table 50.3** Ultrasonographic and clinical signs of congenital CMV infection

| Ultrasonographic markers | Clinical symptoms |
|---|---|
| Periventricular echogenicity | Small for gestational age |
| Periventricular (pseudo)cysts | Microcephaly |
| Periventricular calcifications | Chorioretinitis |
| Cerebral ventriculomegaly | Hepatosplenomegaly |
| Microcephaly | Thrombocytopenia |
| Polymicrogyria | Petechiae |
| Large cisterna magna | Sensorineural hearing loss |
| Cerebellar hypoplasia | Pneumonitis |
| Branching linear echogenic areas in the thalami corresponding to arteries in the basal ganglia and thalamus | Visual impairment |
| Intraventricular adhesions | |
| Hyperechogenic fetal bowel | |
| Hepatosplenomegaly | |
| Fetal growth restriction | |
| Ascites and/or pleural effusion | |
| Hydrops | |
| Placental enlargement | |

Data from various sources (see references).

mortality and morbidity. However, antiretroviral drugs have not been shown to decrease perinatal transmission.

Pre-existing maternal antibodies to CMV is the most important protective factor against congenital CMV infection.[53] Studies using passive immunization with specific anti-CMV immunoglobulin reveal promising results, but are still investigational.[54]

Better than the available treatment is prevention by practising good personal hygiene thorough pregnancy and use of CMV-negative blood products when transfusing seronegative pregnant women and newborns. The demonstrated benefits of breastfeeding outweigh the minimal risk of acquiring CMV from an infected breastfeeding mother. There is progress in the development of a specific CMV vaccine; however, it will take several more years until it will be available for use in humans.

## Herpes simples virus

### General information

The herpes simplex viruses (HSV) are DNA viruses of the herpes family. HSV-1 has been considered to cause orolabial herpes and HSV-2 genital herpes infection; however, there is an important overlap. Up to one-third of the genital herpes infections are caused by HSV-1.

### Transmission

Primary orolabial herpes is mainly a disease of childhood, children acquiring the infection from family members through close contact. Genital herpes may occur after sexual contact either genital–genital or orogenital, with an infectious person. The incubation period is less than a week and persons transmitting the virus may be asymptomatic themselves.[55]

Transmission of HSV to the fetus or neonate occurs mostly during labour and delivery as a result of direct contact with virus shed from infected sites (vulva, vagina, cervix, perineal area). The concentration and duration of viral shedding are higher with primary versus non-primary disease and in HSV-2 versus HSV-1 infection. On the other hand, viral shedding can also occur when maternal symptoms and lesions are absent. Rarely *in utero* infection occurs as a result of transplacental or ascending transmembranous infection.[56,57]

### Diagnosis

HSV infection can be diagnosed by viral culture, PCR, direct fluorescent antibody testing, and type-specific serological tests. PCR is more sensitive than culture and is becoming the preferred test for diagnostic testing in symptomatic patients and for detecting viral shedding. Serological testing for HSV is of little clinical use since a large proportion of pregnant women are positive. Only a seroconversion and the presence of HSV-specific IgM confirm the diagnosis.[58]

### Clinical presentation

Although 90–95% of *primary oral infections* are asymptomatic, a few may consist of a rather florid vesiculoulcerative outbreak in the oropharynx and lips about a week after exposure. Adenopathy and viraemia, along with fever and malaise, may persist for a week or two, with viral shedding for up to 6 weeks. Thereafter, antibody production limits the virus such that it remains dormant, occasionally flaring up as localized blisters on the lips in times of stress, sunburn, or febrile systemic illness. During recurrent disease, viral shedding lasts up to a week.[59]

*Primary genital HSV infection* can be severe with painful genital ulcers, pruritus, dysuria, tender inguinal lymphadenopathy, and systemic symptoms of fever, malaise, myalgia, and headache. Disseminated infection, mostly in immunosuppressed patients, can lead to death from HSV encephalitis and hepatitis.[60] Lower motor neuron and autonomic dysfunction may lead to bladder atony and urinary retention. Viral shedding occurs for nearly 3 weeks in severe cases. Local disease may reoccur weeks or months later, especially if the offending virus is HSV-2, which recurs more often than HSV-1 does, especially in the genital area.[61] In patients who develop lesions, prodromal symptoms, such as pruritus, burning, or pain, may occur before the lesions are visible. The genital lesions may be non-tender or atypical in appearance (e.g. fissure, vulvar irritation). The duration of lesions and viral shedding during recurrent infection are shorter than that seen during the primary episode.

Disseminated HSV infection to the fetus can lead to abortion, prematurity, and fetal/neonatal infection.

Systemic illness and fever may stimulate preterm contractions. The fetus acquiring HSV, especially if the mother suffers an acute, primary infection,[62] may sustain severe neonatal morbidity including chorioretinitis, meningitis, encephalitis, mental retardation, seizures, and death. Primary infection early in pregnancy, perhaps due to a viral endometritis ascending from cervical infection, may end in spontaneous abortion.

### Treatment

Recurrent infections are mild and little symptomatic intervention is necessary. Many practitioners recommend topical aciclovir for pregnant patients on the grounds that it is not significantly absorbed. It is unclear whether it is helpful.

Pregnant women with a significant primary HSV infection or a genital non-primary infection should be treated, regardless of the timing in pregnancy. Aciclovir is administered orally (200 mg five times a day for 7–10 days) or IV (5 mg/kg every 8 hours for the same period).

Active lesions at the time of labour is considered to be an indication for caesarean delivery, although the risk is less with recurrent disease. If there are no active lesions and no prodromal symptoms at the time of labour, vaginal delivery is allowed. Women with preterm premature rupture of the membranes and active lesions are considered individually taking into account gestational age and other relevant factors. It should not, however, be assumed the fetus is infected just because of prolonged rupture of membranes.

In women with symptomatic infection during pregnancy, the American College of Obstetricians and Gynecologists recommends suppressive therapy with aciclovir (400 mg orally three times daily) at 36 weeks of gestation through delivery rather than no therapy. Suppressive therapy reduces the risk of clinical recurrence of HSV and asymptomatic viral shedding at delivery, and thus the need for caesarean delivery. However, the clinical impact on neonatal HSV is unknown.[63]

## Conclusion

The impact of the maternal infections discussed in this chapter are both for the mother and the fetus potential life-threatening

events which may lead to chronic complications, sometimes lasting throughout life.

This stresses the importance of adequate patient information. The way of transmission of the most common infections—and so the way of prevention—should be discussed preconceptionally. Furthermore, systematic screening for the most important infections should be offered at the first pregnancy consultation. In case an infection is diagnosed, the appropriate treatment and a multidisciplinary follow-up are required to reduce the risk of congenital infections and long-term sequelae.

# CHAPTER 51

# Substance abuse

Ross Junkin and Elizabeth M. McGrady

## Introduction

Substance abuse can be simply defined as a pattern of harmful use of any substance for mood-altering purposes that deviates from medically or socially accepted use. If prolonged, it can lead to physical or psychological dependence. This dependency is characterized by:

- intermittent or continuous impaired control over substance self-administration (despite awareness of adverse effects)
- preoccupation with substance acquisition
- distortions of mental capacity, most notably denial.

Various attendant terms have also been defined in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV)[1], see Table 51.1. Illegal drugs are not the only substances that can be abused. Alcohol, prescription medication, solvents, caffeine, and tobacco can all be implicated. The line between use and abuse can sometimes be difficult to determine especially when the patient may not even recognize a problem or indeed admit to it.

### Social implications of substance abuse in pregnancy

Substance abuse in pregnancy is a cause of morbidity and mortality with 13 deaths directly related to substance abuse highlighted in the 2006–2008 Confidential Enquiry into Maternal Deaths in the United Kingdom.[2] It is easy to focus on the medical complications of substance abuse in pregnancy but there are also wide-ranging general health, social, and psychological problems which are as important, if not more so. The main characteristics of substance-abusing women who died either from medical or psychiatric complications of their abuse were that they were most often young, single, unemployed, and socially deprived. It is difficult to regard substance abuse in isolation without some consideration of the socioeconomic environment and social background with which substance abuse is associated.

Antenatal care is often inadequate in women who misuse drugs because of late presentation. Reasons for this include a chaotic lifestyle and a reluctance to have involvement with social services. Women who misuse substances are often excluded from mainstream society and, on becoming pregnant, feel guilty about their drug misuse and the potential effects this could have on their unborn baby. These women are vulnerable in many ways and agencies must ensure that they are not excluded from antenatal care.[3] The prevalence of antepartum drug abuse is higher in unbooked parturients and has been reported in up to 70% in some centres in the United States.[4,5] One UK study demonstrated increased rates of emergency caesarean deliveries and reduced rates of elective caesarean deliveries in drug-abusing parturients.[6] This may reflect lack of antenatal preparation among the other increased risks in pregnant women who misuse substances.

### Extent of the problem

Accurate prevalence statistics regarding drug abuse rates of illicit substances are difficult to ascertain when measuring those engaged in a largely covert or socially unacceptable activity, which may be further heightened by the pregnant state. Health professionals do not always ask specifically about drug abuse and when they do, pregnant women often fail to disclose it. Epidemiological data from the general non-obstetric population are available. Data collected by the Centers for Disease Control and Prevention (CDC) in the United States are displayed in Table 51.2.[7]

The trends suggest that substance abuse is most prevalent among young adults with variation between ethnic groups. Although there is often a male sex preponderance, the problem will also transfer into the obstetric population of young women of child-bearing age. Table 51.3 collates data reported by the European Monitoring Center for Drugs and Drug Addiction (EMCDDA) from population surveys specific to young women who report recent drug use (within the 30 days prior to survey completion).[8]

Direct techniques tend to underestimate the extent of drug use and the incidence of substance misuse in the United Kingdom varies widely by geographical location. Three per cent of under-35s are said to have a drug problem in the United Kingdom, with Data from the UK National Treatment Agency for Substance Misuse (NTASM) estimating overall rates of 8.93/1000 in the general population using heroin and/or crack cocaine with the highest rates in people aged 25–34.[9] Twenty-five years ago, there were relatively few problem drug users in the United Kingdom. Since then, the numbers have increased dramatically. No part of the country has been spared, although inner city areas and especially London, Glasgow, Liverpool, and Manchester have traditionally been considered hotspots. For example, the number of known heroin addicts and the number of heroin confiscations by police increased 10-fold and 15-fold respectively between 1980 and the late 1990s.

In England and Wales, estimates from the 2010/2011 British Crime Survey, which relies upon anonymous questionnaire self-reporting, show that around one in three adults aged 16–59 (36.3%) had used illicit drugs in their lifetime (almost 12 million people) and 8.8% (2.9 million) had used illicit drugs in the last year.[10] The national surveys have consistently shown the highest drug prevalence among young adults (20.4% of 16–24-year-olds in 2010/11) and especially in males (Figure 51.1).

**Table 51.1** Definitions of substance-related disorders

| Substance use disorder | Definition |
|---|---|
| Tolerance | Increasing doses of the substance used over time is required to achieve a consistent or desired effect. Equally, persisting with the same dose will result in a lessening effect |
| Substance abuse | A pattern of substance use which leads to harm, as manifested by ≥1 of the following, occurring within 1 year:<br>◆ Repeated substance use impacting on ability to fulfil work, school, or home/family commitments<br>◆ Repeated substance use in situations in which it is dangerous, e.g. driving, work environments<br>◆ Repeated substance-related legal problems<br>◆ Repeated social or interpersonal problems caused or exacerbated by the effects of the substance |
| Substance dependence | A pattern of substance use which leads to harm. Evidence of physiological dependence and the substance use taking a prominent position in the user's life. Manifested by ≥ 3 of the following, occurring within 1 year:<br>◆ Tolerance<br>◆ Withdrawal<br>◆ Increasing dose and duration<br>◆ Persistent desire or unsuccessful efforts to cut down or control substance use<br>◆ Prominent substance seeking and associated behaviours requiring significant time and effort acquiring the substance or recovering from it<br>◆ Social harm—impact on work and career or recreational pastimes reduced because of substance use<br>◆ Knowing the harmful effects but continuing to use the substance |

Data from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, 2000, American Psychiatric Association.

Class A drugs represent those deemed most dangerous and carry the harshest criminal punishment as outlined in the United Kingdom Misuse of Drugs Act 1971.[11] The long-term trends in the use of different drugs in England and Wales show variation in the levels of Class A drug use since 1996 (Figure 51.2). Of note, cocaine use appears to have been increasing recently to a peak in 2008/2009.

In Scotland, the most recently available official statistics from the information services division (ISD)[12] uses the 2013 European Standard Population (ESP2013) to calculate the European Age-Sex Standardised Rates (EASRs) regarding hospital admissions directly related to drug misuse. It is based on nationally available information routinely drawn from hospital administrative systems across the country and relate to all patients, both obstetric and non-obstetric. The publication reveals an overall general substance-misuse-related hospital admission rate of 107/100,000 population in Scotland in 2012/2013. In the period 2008/2009 to 2012/2013, the general hospital discharges with a diagnosis of drug misuse increased among older age groups (35 years and over) and decreased among younger age groups. Despite these reductions, the highest rates of drug misuse persisted in the young adults of potentially child-bearing age (Figure 51.3).

The relative proportions of male (around two-thirds) to female (around one-third) have remained roughly the same for 5 years and are consistent with findings from the rest of the United Kingdom.

In 2012/2013, the majority of drug-related general hospital discharges were associated with opioids (67%), followed by multiple/other drugs (14%; includes hallucinogens, volatile solvents, multiple drug use, and use of other psychoactive substances), cannabinoids (11%), and cocaine (6%).

Data subsets specifically concerning pregnancy show that the rate of drug misuse reported per 1000 maternities in Scotland has increased recently to a peak of 19.7/1000 (see Table 51.4[13]). Opiates were the most frequently recorded substance of abuse with 8–9/1000 maternities consistently across the records. The drug using parturients were more likely to come from more deprived areas with 42% residing in the most deprived areas. The rates of preterm and lower birth weight babies were also increased compared with non-drug using parturients.

Maternal use of illicit and prescription drugs is additionally associated with considerable neonatal morbidity. Lifestyle factors, such as illicit substance exposure, have been implicated in restricting fetal growth and causing the onset of preterm birth.[14] Low birth weight and preterm birth are associated with short- and long-term morbidities. One North American study retrospectively examined 669,451 births over an 8-year period (2000–2008) identifying 9024 neonates with prenatal drug exposure. In this cohort, both illicit and prescription maternal drug use was associated with increased risk of prematurity, lower mean birth weight, longer birth hospitalization, feeding problems, and respiratory conditions.[15]

The UK Home Office report entitled 'Hidden Harm' estimates that there are between 200,000 and 300,000 children living in England and Wales where one or both parents have serious drug problems.[16] This represents about 2–3% of children under 16. Only 37% of fathers and 64% of mothers were still living with their children. The more serious the drug problem, the less likely it was for the parent still to be living with the child. Most children not living with their natural parents were living with other relatives and about 5% of all children were in care. In Scotland, the estimated situation is worse still, with between 41,000 and 59,000 children with a problem drug-using parent. This represents about 4–6% of all children under 16 years.

Obstetric anaesthetists may become involved in the care of substance-abusing parturients in controlled settings antenatally when planning labour and delivery or in the emergency setting

**Table 51.2** Use of illicit drugs in the past month among persons aged 12 and over by age, sex, race, and ethnic origin in the United States

*Estimates are considered unreliable. Data not shown if the relative standard error is greater than 17.5% of the log transformation of the proportion, the minimum effective sample size is less than 68, the minimum nominal sample size is less than 100, or the prevalence is close to 0% or 100%.

[1]Any illicit drug includes marijuana/hashish, cocaine (including crack), heroin, hallucinogens, inhalants, or any prescription-type psychotherapeutic drug used non-medically.

[2]Non-medical use of prescription-type psychotherapeutic drugs includes the nonmedical use of pain relievers, tranquilizers, stimulants, or sedatives and does not include over-the-counter drugs.

[3]Persons of Hispanic origin may be of any race. Data on race and Hispanic origin were collected using the 1997 Revisions to the Standards for the Classification of Federal Data on Race and Ethnicity. Single-race categories shown include persons who reported only one racial group. The category 2 or more races includes persons who reported more than one racial group.

Reproduced from National Center for Health Statistics. *Health, United States, 2012: With Special Feature on Emergency Care.* Hyattsville, MD. 2013.

where substance abuse may be known or indeed covert. Drug abuse is often associated with poor nutrition, poor hygiene, generalized immunosuppression, difficult intravenous access, and altered drug metabolism. Substance abuse therefore poses specific challenges for the obstetric anaesthetist with regard to the delivery of anaesthesia and the management of pain around the peripartum period. Identification of the substance-abusing parturient is difficult when the denial of such abuse is common[17] and clinical signs of illicit drug use can lead to serious obstetric complications and even mimic other diseases such as pre-eclampsia.[18] Local knowledge of obstetric services' catchment areas, specific regional illicit drug prevalence, and popular modes of drug administration will be helpful in recognition of the drug-abusing parturient and the associated co-morbidities.

Substance abuse is thus a major problem facing our society and in particular the young adult population. About half of substance-using women may continue substance use during pregnancy[19] and so form an important subgroup that warrants specific care and attention.

**Table 51.3** Population survey data displaying recent (within 30 days) drug use in young women in countries across Europe

Tolerance and addiction to drugs in pregnancy creates potential problems for the parturient, her fetus, and the wide range of healthcare professionals involved in her care. Extra vigilance is required in the care of these patients as they are a high risk both to themselves, the fetus, and to healthcare workers.

## Screening, assessment, and treatment

Motivation to change unhealthy or harmful behaviours is increased during pregnancy and it is an ideal time to intervene with women who have substance abuse problems.[20] The cessation of substance abuse in pregnancy is a potentially reversible cause of adverse birth outcomes. All pregnant women regardless of socioeconomic status should be screened for past/current alcohol, smoking, and illicit drug use. This should be in a private setting with a non-judgemental tone.

Previous healthcare professionals' attitudes towards pregnant patients who use substances, particularly alcohol and/or illicit drugs, were largely negative and few routinely screened their patients for substance abuse.[21–23] More recently, increased awareness of the importance of this issue among healthcare

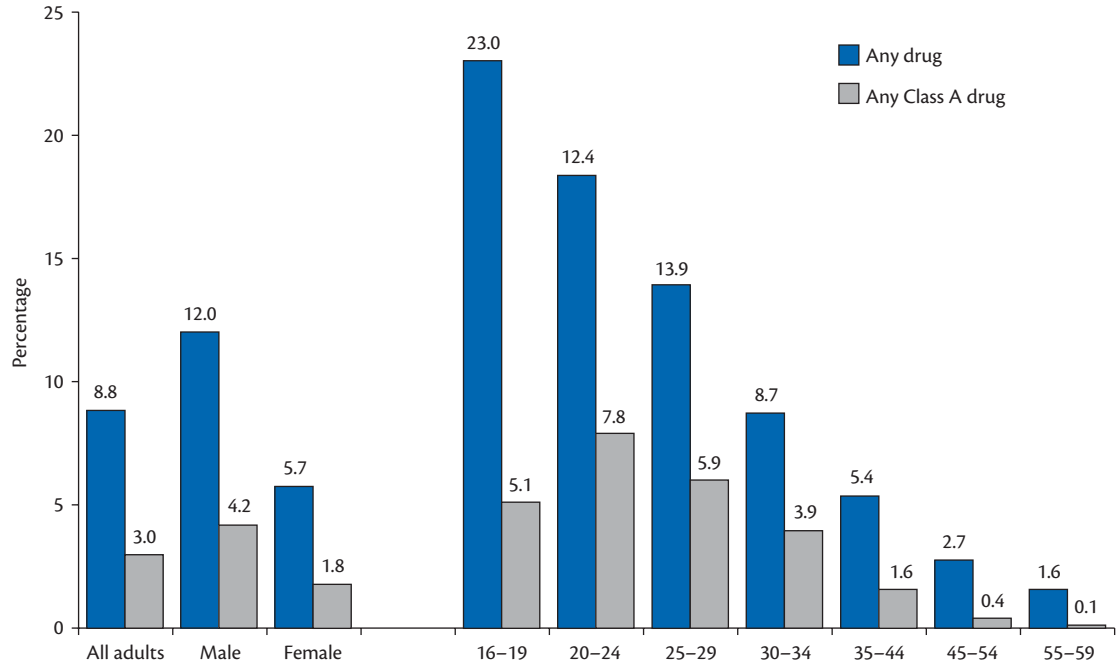

**Figure 51.1** Proportions of 16–59-year-olds in England and Wales self-reporting use of any drug by age group and sex in the 2010/2011 British Crime Survey.

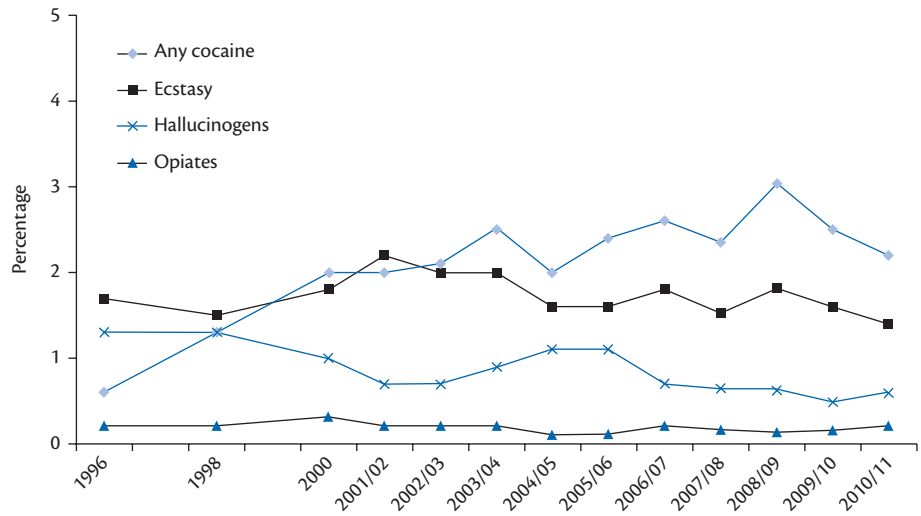

**Figure 51.2** Trends in individual class A drug use in England and Wales in 16–59-year-olds.
Smith K and Flatley J. *Drug Misuse Declared: Findings from the 2010/11 British Crime Survey,* England and Wales. http://www.statistics.gov.uk

providers has led to actively asking about tobacco, alcohol, and illicit drugs.[24,25]

Identification of substance abuse most often depends on a history given voluntarily by the patient. Questions about alcohol, smoking, and illicit substances should be routine at the initial prenatal visit. Previous as well as present drug use should be explored including questioning regarding frequency, patterns, quantity, and route of administration. Serum or urine drug screening, hepatitis B and C, and HIV testing may be considered after informed consent from the patient. The CAGE questionnaire[26] or the TACE Screening Tool are often used to assess alcohol use (see Box 51.1).

Polysubstance abuse is common, with single agents rarely used in isolation. Pregnant women who use illicit drugs may be more likely to use a combination of drugs rather than a single drug.[27] Random anonymous testing of all patients now raises several legal and ethical issues including the right to privacy and admissibility of test results.[28] Despite this, anonymous screening of both newborns and mothers has previously been conducted and may be more accurate than reliance on self-reporting rates. A large multisite study based in the eastern United States tested meconium specimens of 8527 newborns for illicit drugs and on average found positive results for cocaine/opiate exposure in 10.7%. The mothers had denied drug

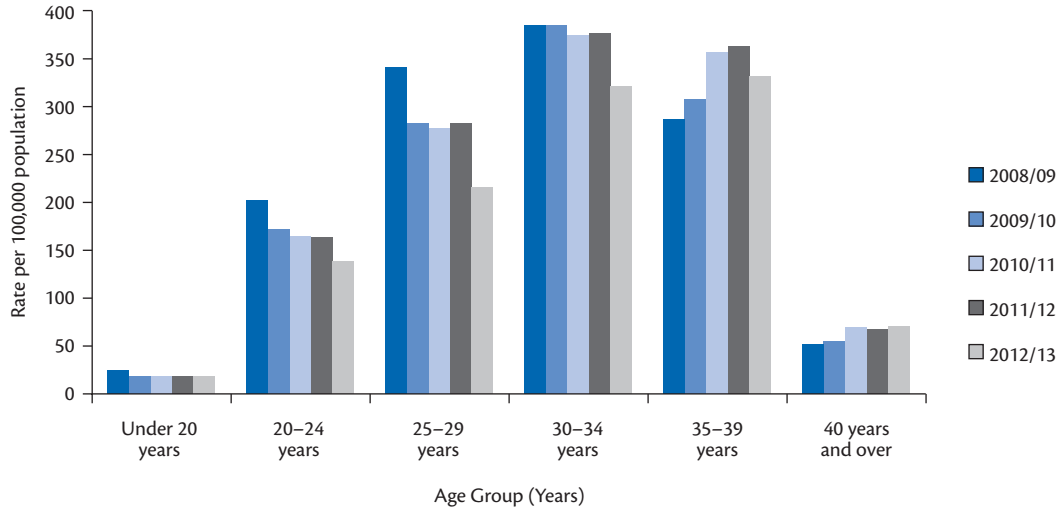

**Figure 51.3** Scottish Information Services Division (ISD) data depicting rate per 100,000 population of general acute inpatient and day-case hospital admissions related to drug misuse.
ISD Scotland.

use in 38% of these cases.[29] Geographical variations were demonstrated across different sites with inner city populations again highlighted as having higher prevalence. Prospective screening of newborns in a high-risk urban population in the United States revealed that 44% of babies tested positive for opiates, cocaine, or cannabis.[30] Screening anonymized urine samples of pregnant women in inner city clinics in the United Kingdom has revealed rates of 10.7%[31] to 16%[32]. Substances tested for included cannabinoids, opiates, amphetamines, cocaine, and benzodiazepines.

Rapid urine dipstick testing for multiple illicit drugs can be easily achieved at the bedside and various kits are available.[33] Urine sampling demonstrates high rates of false-negatives, however. Except for chronic marijuana use, most substances or their metabolites are only measurable in urine for less than 72 hours and alcohol for less than 12 hours. It is therefore easy to miss substance abuse on testing unless frequent sampling is carried out. A single negative result may not necessarily be reassuring. Hair analysis of mother or newborn can be used to test for cocaine and opiates. The benefit of hair analysis is the retrospective window of detection that is able to show the trend of a habit over time and identify what drugs were used, serving as a 'diary' of usage. It improves on identification of drug use by random testing, making evasion of detection very difficult if not impossible.[34]

**Table 51.4** Year-on-year rates per 1000 Scottish maternities where drug misuse has been recorded

| Year of dataset | Rate of drug misuse per 1000 maternities |
|---|---|
| 2006/7–2008/9 | 9.9 |
| 2007/8–2009/10 | 11.9 |
| 2008/9–2010/11 | 15.8 |
| 2009/10–2011/12 | 18.9 |
| 2010/11–2012/13 | 19.7 |

Data from ISD Scotland: Scottish Morbidity Records (SMR02).

The most accurate screening method is analysis of meconium, but this is not undertaken routinely in the United Kingdom. Drug metabolites accumulate in meconium by direct deposition from bile or by ingestion of metabolites in the amniotic fluid (or both). Meconium is not usually excreted antenatally and accumulates throughout gestation, thus its composition reflects not only recent drug use but a prolonged antenatal period. It can only be sampled post delivery, is retrospective, and may in effect

**Box 51.1** TACE Screening Tool to assess possibility of alcoholism

A total score of 2 or greater indicates potential risk for the purposes of Pregnancy Outreach Program identification of prenatal risk:

**Tolerance**

1. How many drinks does it take to make you feel high?
   0. Less than or equal to 2 drinks
   1. More than 2 drinks

**Annoyance**

2. Have people annoyed you by criticizing your drinking?
   0. No
   1. Yes

**Cut down**

3. Have you felt you ought to cut down on your drinking?
   0. No
   1. Yes

**Eye opener**

4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover?
   0. No
   1. Yes

only represent a missed opportunity for antenatal drug counselling and support.

### Antenatal substance abuse management

Substance abuse management may involve behavioural therapy, support groups (e.g. Alcoholics Anonymous and Narcotics Anonymous), nutritional therapy (e.g. replacement of thiamine which is often deficient in alcohol abusers due to malabsorption), close monitoring for complications (e.g. placental abruption), and inpatient or outpatient pharmacotherapy (e.g. methadone to prevent withdrawal symptoms that may affect the fetus).

## Drug-specific issues

Substance abuse in pregnancy may be obvious, openly admitted, or occult. It is also subject to geographical variations in the availability of the substance in question and its locally preferred route of administration. The ranges of substances which are abused are diverse chemically, pharmacologically, and physiologically with each bringing with it its own unique subset of challenges. The anaesthetic implications are summarized in Table 51.5.

### Smoking

Smoking-related morbidity and mortality affects millions of individuals throughout the world. It is well established that smoking is harmful to general health but it is a socially tolerated form of substance abuse. Since 1998 to present, when *Smoking Kills: A White Paper on tobacco*[35] was published, cigarette smoking prevalence among adults in the United Kingdom has gradually declined from 28% to 21%. Estimates from the 2011 report regarding self-reporting of tobacco smoking among English women in the age range 16–44 years has fallen to a rate of 20–22%.[36] United States CDC data[7] also reveals similar reduction trends in smoking rates over time although they lag behind that seen in the United Kingdom with higher rates overall (see Table 51.6).

Overall there is evidence of a gradual decline in smoking rates over study periods stretching back over the last two decades in the general population. Regarding the obstetric population, Scottish ISD data for maternal smoking rates at booking over the last decade are depicted in Figure 51.4, and similarly demonstrate a small overall decline.[37]

Smoking in pregnancy is decreasing in high-income countries[38] and increasing in low- to middle-income countries.[39] It is strongly associated with poverty, low educational attainment, poor social support, low socioeconomic status, and psychological illness.[40] Figure 51.5 depicts Scottish smoking rates at first booking and their association with degree of maternal deprivation.[41] Depressed women are up to four times more likely to smoke during pregnancy than non-depressed women.[42]

Tobacco smoking remains a preventable factor associated with complications in pregnancy. Educational programmes are well established in pointing out the risks to maternal health and fetal well-being but despite this it has proved very difficult to introduce preventative strategies as nicotine is highly addictive and only a minority will stop smoking when they become pregnant. Smoking in pregnancy has been studied extensively. Mothers should be counselled to reduce and/or stop smoking altogether in early pregnancy; however, approximately 80% of mothers who smoke prior to pregnancy continue to do so when pregnant[43] and of those that do manage to quit around half will resume smoking by 2 weeks postpartum.[44] A meta-analysis of randomized controlled trials where smoking cessation was the primary aim of the intervention included 72 trials and over 25,000 patients. Interventions ranged from maternal counselling, information on fetal well-being, provision of nicotine replacement therapy, and social support. Overall only six women in every 100 stopped smoking.[45]

#### Smoking: pathophysiology

There are over 4800 substances isolated from cigarette smoke of which nicotine and carbon monoxide are well known. Others include nitrogen oxides, volatile aldehydes, alkenes, and the toxin hydrogen cyanide.

Cigarette smoking causes transient mild hypoxia, cough, mucous hypersecretion, and airflow obstruction progressing to chronic obstructive pulmonary disease in the long term. Morbidity and mortality from smoking is largely related to the effects on cardiovascular disease although increased risk of thromboembolic events and cancer, particularly of the lung, are also prevalent. Passive smokers also have an increased incidence of adverse events.

#### Smoking: impact on the mother

It appears that actively smoking mothers have reduced incidences of pregnancy-associated hypertension and pre-eclampsia.[46]

**Table 51.6** United States Centers for Disease Control and Prevention (CDC) data showing smoking rates among persons age 12 and over by age, sex, race and ethnic origin

| Age, sex, race, and Hispanic origin | Any tobacco[1] | | | Cigarettes | | | Cigars | | |
|---|---|---|---|---|---|---|---|---|---|
| | 2002 | 2009 | 2010 | 2002 | 2009 | 2010 | 2002 | 2009 | 2010 |
| | Percent of population | | | | | | | | |
| 12 years and over | 30.4 | 27.7 | 27.4 | 26.0 | 23.3 | 23.0 | 5.4 | 5.3 | 5.2 |
| Age | | | | | | | | | |

However, if a smoker does develop pre-eclampsia, she is considerably more likely to develop the more severe early-onset form[47]. Additionally, it is likely that any beneficial reduction in the overall pre-eclampsia rate is superseded by the many other harmful effects of smoking. Encouragingly, if a woman stops smoking during her pregnancy, the deleterious outcomes all decrease.[44] This is an important observation for those caring for pregnant women and supports active promotion of smoking cessation.

Women who smoke are more likely to have preterm rupture of membranes and preterm delivery. The mechanism is not fully understood but is possibly related to a smoking-induced increased sensitivity of the myometrium to oxytocin.[48] Risk of placental abruption and placenta praevia are also increased.[49]

Chronic obstructive pulmonary disease may well be present in women of child-bearing age if they have been heavy smokers from an early age.[50] Chronically impaired respiratory function is further compromised by the gravid uterus due to reduction in functional residual capacity and can be demonstrated by reduced measured performance in pulmonary function tests.

### Smoking: impact on the fetus

Carbon monoxide has a much higher affinity for haemoglobin than oxygen resulting in decreased oxygen delivery to the fetus. Nicotine decreases placental blood flow due to vasoconstriction and contributes to development of fetal hypoxia.[51] Smoking during pregnancy increases the risk of miscarriage, preterm labour,

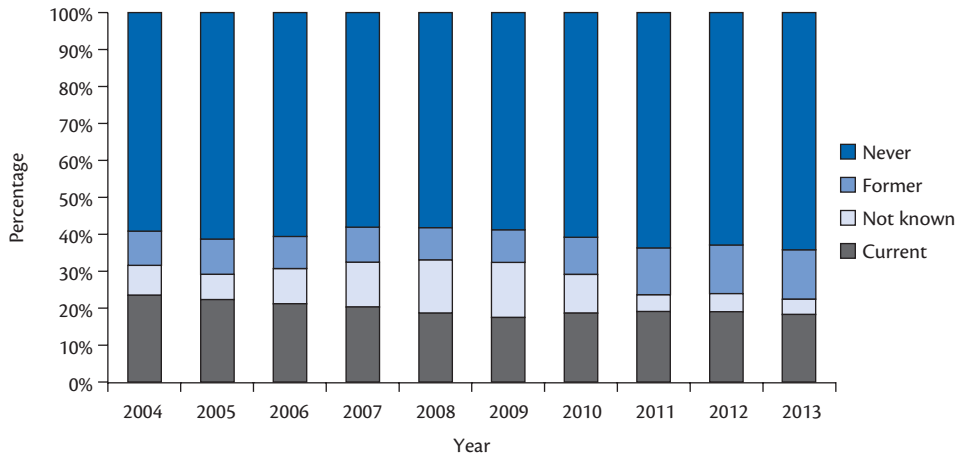

**Figure 51.4** A decade of trends in smoking rates (%) in Scottish mothers at booking.
ISD Scotland.

low birth weight, stillbirth, and newborn death. The number of low birth weight neonates increase in proportion to the number of cigarettes smoked[52] and is also influenced by passive smoking.[53] Maternal third-trimester cigarette consumption is the strongest predictor of low birth weight with an estimated 27 g reduction in birth weight with each additional cigarette per day.[54] These reductions in fetal weight may have lifelong consequences with evidence pointing to significant paediatric and adulthood morbidity associated with the reduced birth weight.[55]

Maternal smoking is associated with modestly increased risk of congenital heart defects in the newborn (relative risk 1.11), especially septal defects (relative risk 1.44).[56] Passive smoking also increases the risk of congenital malformations and stillbirth.[57]

### Smoking: implications for anaesthesia

Smoking is a risk factor for intraoperative pulmonary complications and a wide range of postoperative pulmonary, cardiovascular, and wound-related complications.[58] If general anaesthesia is required, adequate anaesthesia should be administered for intubation to minimize the risk of provoking bronchospasm.

Neuraxial anaesthesia is well established as the technique of choice in obstetric anaesthesia and has additional advantages for patients who smoke avoiding instrumentation of an airway which may display increased reactivity and postoperative respiratory morbidity.

Long-term smoking-related comorbidities including underlying ischaemic heart disease, chronic obstructive pulmonary disease, and hypertension should be considered and labour analgesia/anaesthesia administered following consideration of these risks on an individual patient basis.

Smokers are usually asked to abstain for at least 24–48 hours before anaesthesia for elective caesarean delivery is administered. Clearly labour is often not predictable in its onset although women should be told not to smoke when imminent labour is suspected or once contractions have started.

## Caffeine

Caffeine is a central nervous system (CNS) stimulant and is the most widely consumed drug in the world since it is present in coffee, tea, many carbonated drinks, and some medications. Additional unrecognized caffeine consumption can occur in certain energy drinks and fortified foods.

### Caffeine: pathophysiology

Caffeine is a methyl xanthine of which the main action is competitive antagonism of the inhibitory neurotransmitter adenosine.

### Caffeine: impact on the mother

Excess caffeine intake can produce a syndrome similar to that of anxiety neurosis including:

- irritability
- nervousness
- excitement
- muscular twitching and tremor
- insomnia
- headache
- myocardial stimulation—tachycardia, inotropy, increased ectopic beats

The most consistent symptom of caffeine withdrawal is headache and typically occurs within 24 hours of abstinence.[59] Indeed, medical-grade caffeine is commonly combined with other simple analgesics for treatment of migraine.[60]

### Caffeine: impact on the fetus

Caffeine has not been shown to be teratogenic[61] and does not appear to influence birth weight or length of gestation.[62,63] The effect of caffeine intake during pregnancy has been studied for the past 30 years with inconsistent results. Even though the evidence is limited, it is, however, recommended that very high intakes of caffeine in pregnancy should be avoided due to potential increased risk of stillbirth.[64]

Caffeine can be tested for in the serum and urine of neonates with neonatal caffeine withdrawal presenting with excessive levels of feeding difficulties, vomiting, crying, irritability, and poor sleep. The prevalence of fetal caffeine withdrawal is difficult to estimate due to the non-specific nature of the symptoms.

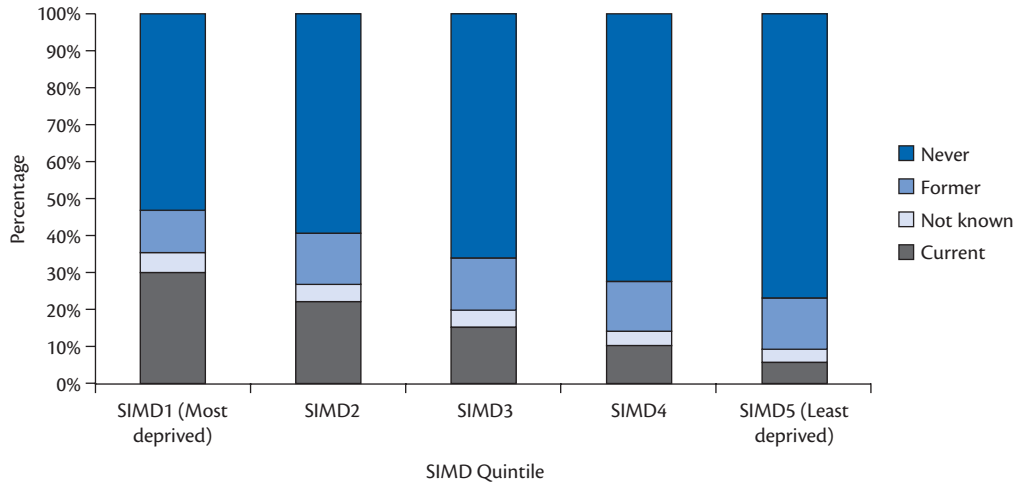

**Figure 51.5** Scottish Information Services Division (ISD) data from 2010 showing maternal smoking rates at first booking and its association with degree of deprivation (SIMD= Scottish Index of Multiple Deprivation).
ISD Scotland.

Caffeine administration (either oral or intravenous) is a therapeutic option used in management of the apnoea of prematurity in neonates.[65]

### Caffeine: implications for anaesthesia

Caffeine withdrawal has been associated with postoperative headache.[66] Caffeine withdrawal may form part of the differential diagnosis of postpartum headache in mothers who have received neuraxial anaesthesia. Patients may abruptly cease consumption of caffeine which can be either enforced (fasting prior to theatre, nausea, prolonged labour) or voluntary (concerns about breastfeeding etc.). This can often be identified with thorough history taking and be easily rectified by caffeine consumption and alternate diagnoses explored if non-resolution of symptoms. Caffeine administration was also a recognized treatment for headache caused by dural puncture, having been shown to both decrease persistence of headache and need for other therapeutic interventions[67] but its evidence base is poor.[68]

## Alcohol

Alcohol use is common and causes problems as a result of both acute intoxication and the health effects of chronic consumption. Most women who drink alcohol before pregnancy tend to reduce or abstain when they become pregnant. Studies have demonstrated pre-pregnancy rates of alcohol consumption (average one drink per day) falling from 44% to 4.6% during pregnancy.[69] Psychological and educational interventions might increase abstinence from alcohol and reduce alcohol consumption among pregnant women.[70] Alcohol addiction can be more subtle and difficult to detect in the pregnant patient than the other illicit drugs.[71]

### Alcohol: pathophysiology

Alcohol ingestion causes acute intoxication and liver damage with chronic usage. The spectrum of liver damage ranges with worsening prognosis from normal liver to fatty liver, steatohepatitis and fibrosis or cirrhosis. The severity of disease does not always correlate with the amount of alcohol intake, and environmental and genetic factors likely play a crucial role in alcoholic liver disease development.[72,73] Women appear to be more susceptible to cirrhosis for any given level of alcohol intake developing liver disease after the ingestion of less than half the amount of the equivalent male alcohol intake.[74]

Excessive alcohol intake has many adverse effects on all body systems:

- Haematological—complications result from both direct bone marrow toxicity and indirect associations such as nutritional deficiencies. Results include macrocytic anaemia, poor immunity and impaired platelet production/function
- Cardiac—arrhythmias, dilatational cardiomyopathy, hypertension
- Pancreatitis—chronic and acute
- Brain—mood/behaviour change, Wernicke's encephalopathy, Korsakoff's psychosis, seizures, and cerebral atrophy
- Osteoporosis
- Cancer—associated as a risk factor for various cancers including oropharyngeal, oesophageal, liver, and breast.

### Alcohol: impact on the mother

Acute alcohol intoxication causes ataxia, confusion, stupor, and eventually coma. Risks from aspiration of gastric contents are increased as alcohol ingestion increases gastric volume and acidity whilst reducing the ability to protect the airway. Other acute presentations of alcohol abuse include hypoglycaemia, acute or chronic hepatic failure, and Wernicke's encephalopathy. Wernicke's encephalopathy often results from inadequate intake or absorption of vitamin $B_1$ and is characterized by the classic triad of:

- confusion
- ophthalmoplegia (paralysis of one or more extraocular muscles)
- ataxia.

Alcohol withdrawal may result from physiological dependency and produce blackouts, tremor, hallucinations, delirium, seizures, and cardiac failure. Acute withdrawal occurs around 48 hours after cessation but can occur up to 10 days after.[75]

Chronic alcohol consumption may result in malnutrition, liver disease, altered drug metabolism, coagulopathy, pancreatitis, oesophageal varices, and cardiomyopathy.[76]

### Alcohol: impact on the fetus

Alcohol readily crosses the placenta and is the most widely recognized teratogen (chemical causing malformation) among abused substances in pregnancy. The fetal alcohol syndrome (FAS) describes a group of features caused by *in utero* alcohol exposure and may be as infrequent as 4% among heavy daily users.[77] FAS is one of the most severe effects of alcohol use during pregnancy and remains the leading cause of mental retardation in the United States.[78,79] It is a syndrome of mental and physical defects with characteristic features described in Box 51.2.

Acute alcohol intoxication in the mother causes fetal distress. Moderate chronic alcohol use increases the risk of small for gestational age babies (three or more drinks per week)[80] and is associated with increased risk of stillbirth (five or more drinks per week).[81] Use of alcohol in pregnancy also adversely effects exposed children later in life causing poor coordination, behavioural problems such as hyperactivity, learning, and developmental problems.[82,83]

Regardless of gestational period, alcohol causes adverse fetal effects and abstinence appears the safest approach in pregnancy.[84]

### Alcohol: implications for anaesthesia

Alcohol-abusing pregnant patients may present to obstetric services acutely intoxicated, acutely withdrawing, or suffering other ill effects of chronic alcohol abuse.

Neuraxial anaesthesia can be safely performed in alcohol-abusing parturients. Contraindications, however, include coagulopathy, platelet dysfunction, and infection. Direct alcohol toxicity and nutritional deficiencies have been implicated in the development of peripheral neuropathy.[85] Alcoholic neuropathy is characterized by spontaneous burning pain, hyperalgesia, and allodynia. Examination and documentation of any pre-existing lower limb peripheral neuropathy should be performed prior to consideration of neuraxial anaesthetic techniques.

Chronic alcohol abuse may result in bleeding tendency. Direct alcohol toxicity can produce thrombocytopenia and alcoholic liver disease may produce a prolonged prothrombin time. Monitoring of prothrombin time and albumin levels are good markers of synthetic liver function, although only really encountered in end-stage disease. Laboratory clotting studies should be checked to ensure acceptable platelet counts and coagulation. Full blood count may reveal anaemia of chronic disease or macrocytic anaemia. Liver transaminases (aspartate transaminase (AST) and alanine transaminase (ALT)) are raised in alcohol abuse. Biochemical and haematological findings of alcoholic liver disease can be confused with those encountered on the spectrum of HELLP syndrome (*H*aemolysis, *E*levated *L*iver enzymes and *L*ow *P*latelet count). A high index of suspicion should prompt reassessment of the patient's alcohol history and clinical examination.

When general anaesthesia is required, acutely intoxicated patients are already partially anaesthetized and will require dose reductions in some anaesthetic agents. Chronic alcohol abuse per se does not alter the requirement, pharmacokinetics, and pharmacodynamics of thiopentone.[86] Chronic alcohol excess induces tolerance to other general anaesthetic agents. Induction dose requirements of propofol have been studied in alcoholic patients and have found to be increased, albeit in the non-obstetric population.[87] Acute intoxication may cause vomiting, hypoglycaemia, and delayed gastric emptying. Risk of aspiration of stomach contents is increased and appropriate airway management should assume a full stomach. Antacid pharmacoprophylaxis should be administered.

Alcoholic cardiomyopathy is characterized by a dilated hypokinetic heart with reduced ejection fraction. The increased cardiac output of pregnancy, together with increased fluid retention and hypoalbuminaemia may present as peripartum congestive cardiac failure. Pregnancy in the cardiomyopathy patient is high risk.[88]

Patients at risk of alcohol withdrawal should be identified on admission to hospital. They may abscond from medical care in order to continue drinking if withdrawal is imminent. Symptoms can be suppressed by benzodiazepine administration in accordance with local policies or resumption of alcohol consumption. Intravenous B vitamin supplementation may be required. Delirium tremens is a potentially life-threatening condition. Alcohol withdrawal should be considered in the differential diagnosis of seizures in the pregnant patient and could potentially mimic eclampsia. Reduced serum potassium and magnesium predispose to alcohol-related seizures.

## Marijuana

Marijuana is a naturally occurring preparation of the plant *Cannabis sativa* and has been smoked for its hallucinogenic properties and used both as a recreational psychoactive and medicinal drug. It contains many chemicals classified as cannabinoids but by far the most important and potent agent found is tetrahydrocannabinol (THC). Marijuana has been the most frequently used of

**Box 51.2** Characteristic features of fetal alcohol syndrome

- Growth deficiency, both pre- and postnatally
- Central nervous system disturbances that affect intellect and behaviour
- Decreased muscle tone and poor coordination
- Abnormal facial characteristics:
  - Low-set unparallel ears
  - Short, flat philtrum
  - Elongated midface
  - Small upper jaw
  - Small head
  - Small eyes with large epicanthic folds
  - Short upturned nose
- Malformation of major organs, especially heart (VSD and ASD) and skeletal deformities.

the illicit drugs in pregnancy,[89] with varying rates of 9.5–27%[90] of parturient usage described in the United States.

Marijuana is obtained in a variety of preparations such as dried leaves, resins, and oils. It goes by many street names including pot, weed, and herb. Hash, a concentrated form of the drug, is short for hashish. It is most frequently consumed by inhalation through smoking (rolled in paper with tobacco and termed a 'joint') or vaporization (through various dedicated pipes). It may also be consumed orally in any form and its use has been described in cookery and teas.

### Marijuana: pathophysiology

High fat-solubility of cannabinoids leads to rapid accumulation in adipose tissue from which they are slowly released into the brain with elimination half-lives up to 7 days. The high lipid-solubility results in their persistence in the body for long periods of time. As a result they can be detected in the body for weeks or longer.

Cannabinoids undergo hepatic metabolism to numerous metabolites all of which have psychoactive properties. They seem to exert their effects by agonist action at cannabinoid receptors in the brain and peripherally. THC indirectly increases dopamine release to produce its psychotropic effects.

Most users take marijuana for its mood altering effects—feelings of 'high' or 'stoned', but the US National Institute on Drug Abuse describes the main psychological effects as quite variable and including euphoria, calmness, anxiety, or paranoia. Aside from a subjective change in perception and, most notably mood, the most common short-term physical and neurological effects include:

- myocardial depression, low blood pressure, increased heart rate
- increased respiratory rate
- red eyes
- dry mouth
- increased appetite and consumption of food
- slowed reaction time.

These effects are reduced after about 3–4 hours.

### Marijuana: impact on the mother

Although marijuana usage in pregnancy appears common, the effects are unclear, perhaps due to the close association and combination abuse with alcohol, tobacco, and other drugs.[91] It is seen as a gateway drug which may lead to harder drug abuse.

Studies suggest that medicinal cannabis use may in fact be beneficial for treatment of pregnancy-related nausea and vomiting.[92]

### Marijuana: impact on the fetus

Prenatal marijuana use is not associated with increased rates of birth defects, spontaneous abortion, or stillbirth.[93] Most investigators have concluded that marijuana is not an established human teratogen and does not produce structural defects or that insufficient data exists. Evidence regarding adverse neurobehavioural effects is inconclusive but associations with sleep disturbance, hyperactivity, inattention, poorer visual problem-solving skills, and delinquency in children have been suggested [94]. Heavy prenatal marijuana use (≥ 1 cigarette/day) is associated with decreased intelligence scores in children at age 6 years.[95] An association between childhood cancers, most notably leukaemia, has been reported.[96]

Marijuana remains in the baby's fat cells for 7–30 days and can be detected on drug screening.

### Marijuana: implications for anaesthesia

Acute cannabis intoxication may augment the sedative and hypnotic effects of anaesthetic agents when co-administered and require relative dose reductions. Similarly chronic marijuana usage can lead to cross-tolerance with alcohol, barbiturates, opioids, benzodiazepines, and phenothiazines.[97] The cardiovascular effects of myocardial depression and tachycardia may be enhanced by the vasoactive side effects of anaesthetic agents and emergency drugs.

Smoking cannabis also leads to effects on the lungs and airways very similar to that of tobacco smoking. Marijuana smoking may lead to oropharyngitis and airway oedema and thorough airway examination should take place.

A careful drug history should be taken, enquiring for use of other more harmful drugs, and general reduction of use should be encouraged.

## Solvents/inhalant abuse

Recreational inhalation of solvents causes intoxication, euphoria, and addiction. National surveys in the United States report that nearly 20% of young people have experimented with inhalants at least once.[98] Solvents are a range of chemicals which include almost any household cleaning agent or propellant:

- Aliphatic hydrocarbons (butane): lighter fuels, spray paint, paint thinner, hairspray, deodorants
- Alkyl halides: paint stripper, solvent
- Aromatic hydrocarbons (benzene, toluene): glue, spray paint, nail polish remover.

The method of delivery is inhalation of a solvent from its container ('sniffing'), a soaked rag ('huffing'), or a bag ('bagging'). Rebreathing from a closed bag causes hypercapnia and hypoxia which intensifies the effect of the inhalant.[99] Solvent-abusing patients may be identified by the characteristic odour from their breath or clothes, evidence of solvent residue, or presence of drug-taking paraphernalia. No specific laboratory tests confirm solvent inhalation.

### Solvents/inhalant abuse: pathophysiology

These compounds are rapidly absorbed and excreted through the lungs. They are very lipid-soluble and rapidly reach the CNS producing the desirable acute effects. Chronic exposure can lead to permanent CNS damage such as toluene leucoencephalopathy characterized by dementia, ataxia, corticospinal tract damage, brainstem signs, and cranial neuropathies.[100] Chronic inhalant abuse can also cause changes in autonomic cardiac function, ventricular fibrillation, and myocardial infarction.[101,102] Renal and hepatic damage have also been described.

### Solvents/inhalant abuse: impact on the mother

Acute respiratory distress, increased airway resistance, pulmonary hypertension, adult respiratory distress syndrome, and liver toxicity have all been reported in pregnant women exposed to solvents.[103] Arrhythmias, hypotension, bronchospasm, seizures, and chronic neurological symptoms are all implicated.

### Solvents/inhalant abuse: impact on the fetus

Evidence suggests that the risk for pregnancy problems, as well as developmental delays and neurobehavioral difficulties, is higher

for the children of women who have been exposed to high concentrations of organic solvents during pregnancy than for those who have not.[104] There are more than 100 cases reported in the literature of children born to solvent-abusing mothers. Many of these children were small at birth and some have craniofacial abnormalities not unlike that seen in children with FAS. In the few studies reporting the findings of follow-up in these children, some evidence has been obtained for retardation in growth, development and for residual deficits in cognitive, speech, and motor skills.[105]

### Solvents/inhalant abuse: implications for anaesthesia

There are no reversal agents for inhalant intoxication and treatment of complications is generally supportive. Like other illicit drugs, the obstetric anaesthetist could be faced with the challenges of dealing with an acutely intoxicated patient. The chronic background neuropathy association with solvent abuse should necessitate accurate documentation of neurological examination prior to neuraxial anaesthesia.

## Opioids/heroin

Opioids are strong analgesic drugs with associated recreational properties amenable to abuse. Frequent and regular administration is associated with physical dependence and physical tolerance. Medical-grade opioids are available in a variety of formulations and are typically used to treat severe pain or opiate withdrawal symptoms. Opioid analgesic drugs may be divided into:

- Naturally occurring alkaloids (e.g. morphine and codeine)
- Semisynthetic drugs (e.g. diamorphine and dihydrocodeine)
- Synthetic drugs (e.g. pethidine, fentanyl, and alfentanil).

Each drug has slightly different effects on the body but in general is similar to morphine. They may be abused both legally when prescribed by a medical practitioner and illegally when obtained without prescription. Non-medically processed illicit opioids are also available as street drugs.

Heroin is the name attributed to diamorphine when it is discussed in its illegal (street) form and is also colloquially known by a huge variety of names including H, dope, smack, brown, and tar among many others. Illegally obtained heroin is often supplied in freebase form which has a duller appearance than the bright white powder of diamorphine, has a lower boiling point, and is amenable to smoking. It can also be dissolved in water when mixed with an acid (usually citric acid or lemon juice) and heated to provide a mixture suitable for intravenous injection. Oral use of heroin as a means of recreation is less common due to the lack of a 'rush' associated with the rapid rise in blood concentration. Additionally, combining heroin with other illicit drugs is common practice and there are also locally accepted terminologies to describe these (e.g. snowball—heroin and cocaine, speedball—heroin and amphetamine).

### Opioids/heroin: pathophysiology

Opioids mimic the action of the endogenous opioid peptides and are agonists binding to mu-, delta-, and kappa-opioid receptors throughout the CNS. Excessive use leads to receptor down-regulation and tolerance. Heroin readily crosses the placenta.

Classic effects include:

- analgesia
- sedation/euphoria/dysphoria
- respiratory depression
- nausea and vomiting
- constipation
- histamine release causing hypotension, bradycardia, bronchospasm and rash
- meiosis (pinpoint pupils).

Methadone is a long-acting opiate agonist that reduces heroin craving, drug-seeking, and other high-risk behaviours.

### Opioids/heroin: impact on the mother

It is difficult to separate out the ill effects of heroin from the coexisting effects of additional agents, multiple diseases, and lifestyle factors among heavy opioid users. Heroin may be contaminated with other substances during preparation (lactose, glucose, mannitol, starch, quinine, amphetamines, strychnine, procaine, or lidocaine among many others). Serious infections can occur due to both biological contamination of heroin batches with bacteria, viruses, or fungi and transmission of blood-borne viruses between individuals sharing needles. Serious recent outbreaks of unusual infections with high mortality rates as a by-product of contaminated heroin use in the United Kingdom have been described. These include anthrax,[106] botulism,[107,108] tetanus,[109] and *Clostridium novyi*[110] infections. Injecting users sharing needles have well-established blood-borne virus transmission, most commonly hepatitis C, but also hepatitis B and HIV.

Opioid withdrawal is characterized by sweating, lacrimation, pyrexia, nausea, vomiting, diarrhoea, abdominal pain, tachycardia, and hypertension. These symptoms peak at 36–72 hours after the last dose. Aims of treatment should be provision of analgesia, prevention of opioid withdrawal, and management of abnormal drug-taking behaviour. Opioid abuse is linked to irregular menstrual cycles and together with chaotic lifestyles, women may not even realize that they are pregnant contributing to lack of antenatal care. The early signs of pregnancy can even be misinterpreted as opioid withdrawal symptoms. Unintended pregnancy is common in these women with 86% of pregnant opioid-abusing women reporting that their pregnancy was unintended in one study.[111] Methadone maintenance has become the 'gold standard' for the management of pregnant heroin users and UK guidelines support its use.[112]

The treatment of opioid dependence with methadone or buprenorphine decreases opioid and other drug abuse, reduces criminal activity, and improves individual functioning and decreases HIV transmission rates.[113] The purpose of substitution therapy is to replace illicit opioid use by the medically controlled oral use of a synthetic opioid. Unfortunately, these medically controlled agents can also be subject to a phenomenon known as pharmaceutical leakage and they themselves appear on the illicit market for abuse.[114] Methadone maintenance is used in the treatment of opioid dependence in pregnancy. Methadone maintenance given during pregnancy reduces maternal illicit opiate use and fetal exposure, enhances compliance with obstetrical care and is associated with improved outcomes like heavier birth weight.[115]

Buprenorphine is a partial agonist–partial antagonist synthetic opioid with around 72 hours; action that has also been used to treat opioid dependence in pregnancy both in Europe and the United States.[116] Buprenorphine's effectiveness during pregnancy as maintenance therapy has not been proven although neonatal withdrawal may be shorter and less severe with buprenorphine than with methadone.[117] Subutex (buprenorphine combined with naloxone to reduce side effects) may also be taken for mild to moderate withdrawal.

### Opiates/heroin: impact on the fetus

Heroin rapidly crosses the placenta entering fetal tissues within 1 hour of administration. This can affect the fetus directly (opioid effects). Birth weight is reduced in the offspring of heroin (mean reduction 489 g) and methadone (279 g) users,[118] possibly as a result of malnutrition and frequent infections. Intrauterine growth retardation and intrauterine fetal distress are established consequences.[119] Postnatal growth deficiency, microcephaly, neurobehavioural problems, increase in neonatal mortality, and a 74-fold increase in sudden infant death syndrome have been described.[120] There are no direct teratogenic effects on the fetus but direct harm is caused to the fetus by the associations of high-risk maternal opioid use. These include severe malnutrition, lack of obstetric care, inhabiting a risky environment, and sequelae of medical complications such as infectious diseases, endocarditis, abscesses, and sexually transmitted disease.[121]

Fluctuating opioid concentrations in the maternal blood may lead to cyclical fetal overdose and withdrawal. Maternal drug withdrawal is thus equally experienced by the fetus both *in utero* and post delivery. Around 48–94% of fetuses exposed to *in utero* opioids develop clinical signs of withdrawal following delivery, termed neonatal abstinence syndrome (NAS).[122] There is some correlation between dose and severity of withdrawal[123].

Apart from NAS, many of these health risks to the fetus can be avoided in principle by opioid substitution treatment[124,125] and lifestyle changes. Methadone replacement substantially minimizes the peak and trough in maternal serum opioid levels that typically occur with repeated use of short-acting opioids (i.e. heroin) reducing harm to the fetus of repeated maternal intoxication and withdrawal.[126]

Methadone treatment may well stabilize the maternal lifestyle but one study in Glasgow of 450 drug-dependent mothers prescribed substitute methadone found that 45.5% of infants needed pharmacological treatment for NAS.[127] Neonatal intensive care unit admission was required in 48.8% of infants born to methadone users. The reasons for admission included prematurity (15.8%), respiratory distress (12.6%), and a range of social reasons (13%). Infants born to drug-misusing mothers constituted 2.9% of hospital births, but occupied almost a fifth of neonatal cot days. A prolonged postnatal stay is recommended to help healthcare professionals observe for signs of NAS, conduct social work assessment, and arrange for parenting and community support for the mothers prior to discharge. Additionally, researchers showed that encouraging breastfeeding in mothers, who are established on the lowest dose of methadone to remain stable, helps to protect against the risk of developing NAS.

### Opiates/heroin: implications for anaesthesia

Polydrug use is common in opioid-abusing patients and history and examination should reflect this. Heavy users are at risk of acute withdrawal when admitted to hospital and may abscond from medical care in order to continue drug-seeking behaviour. There may be obvious signs of recent needle marks or local skin infection which may require explanation if history taking seems unreliable. It will be difficult to judge appropriate pain management and dosing when illicit opioid drugs have complicated analgesic requirement.

Pregnant patients may present acutely with signs of acute opioid overdose including respiratory depression. Opioid-related hypoxia will be both more rapid and more severe in advanced pregnancy due to the alterations in cardiorespiratory physiology. Patients who present for obstetric reasons acutely under the influence of opioids may require a reduction in the dose of anaesthetic drugs. Similarly patients who are severely malnourished may have unexpectedly low body weights and caution should be noted when calculating appropriate local anaesthetic and non-opioid analgesic safe dosages.

Treatment of acute pain in women with opioid abuse disorders can be very challenging. The pain of many opioid-agonist-maintained patients is often underestimated and undertreated[128] with behavioural and social responses worsening the pain experience. There are common misconceptions when treating the non-opiate naive patient experiencing acute pain (see Box 51.3).

Hyperalgesia is observed in patients with heroin use and this is not altered by maintenance methadone or buprenorphine. Tolerance is one factor that explains why these patients derive little pain relief from long-term maintenance opioids. Pain is subjective, making assessment of its severity objectively difficult. Medical staff experience concern about being manipulated by drug-seeking patients but this can only be reduced by careful clinical assessment. A multimodal analgesic regimen[129] including regular short-acting opioid medications, non-opioid simple analgesics,[130] and neuraxial anaesthesia/analgesia where appropriate will be required in addition to maintenance opioid therapy to achieve adequate acute pain control.[131] It can be difficult to predict response to opioid analgesics in an opioid abusing patient but frequent regular dosing with frequent review seems logical to ascertain a dose–effect relationship in an individual.

In a labouring patient or elective delivery, methadone therapy should be timed wherever possible to avoid peak drug concentration occurring around delivery time of the fetus. Maintenance

**Box 51.3** Common misconceptions in the non-opioid naïve patient experiencing acute pain

1. Maintenance medication (e.g. methadone) provides pain relief
2. Opioids prescribed for acute pain will cause a relapse
3. Opioids prescribed for acute pain, in addition to maintenance doses, may cause respiratory depression
4. Acute pain may be assumed to acquire prescribed opioid medication.

Data from Alford D, Compton P and Samet J. Acute pain management for patients receiving maintenance methadone or buprenorphine therapy. *Ann Intern Med* 2006; 144:127–134.

opioid medication is usually inadequate for labour pain management. Neuraxial anaesthesia can provide adequate pain relief in women receiving methadone or buprenorphine for both labour and delivery and is the technique of choice. The dose of opioid in the epidural or spinal should be similar to that in opioid-naïve patients. Patient-controlled analgesia can be used as a mode of opioid administration but settings may need to include a background infusion and a higher bolus dose. The aim is to eventually discharge patients on no more opioid than was used before admission.

The partial agonist (buprenorphine or subutex) maintenance dosing can complicate pain management during labour and delivery. The slow dissociation and low intrinsic activity at the mu receptor[132] result in a favourable safety profile, but also complicate pain management by preventing acute pain medications adequately reaching their target receptors. Another option for consideration is to discontinue partial agonists in advance of delivery and substitute with regular full agonist opioid analgesics, titrating to effect to avoid withdrawal and then to later achieve adequate analgesia as required. Otherwise, higher doses than typical may be required to competitively displace buprenorphine from mu opioid receptors.[111]

Chronic opioid users may be relatively immunosuppressed due to alteration of cell-mediated immune pathways, poor nutrition, and pregnancy. They may also be more likely to be exposed to infectious pathogens through self-administration of contaminated drug, heavy smoking, and breaching of the skin with contaminated needles. Systemic infection may be present due to local cellulitis, endocarditis, and abscesses related to injection sites. Neuraxial anaesthesia may be contraindicated in a systemically septic patient. Chronic opioid-abusing patients have notoriously poor dentition and this should also be examined as part of a thorough airway assessment.

Blood sampling and peripheral venous cannulation (PVC) may be extremely technically difficult in the chronic intravenous drug-abusing patient. This is compounded by the prevalence of blood-borne viruses present in this patient group which increases the infection risk via needlestick injury to healthcare professionals. This represents a significant concern to healthcare professionals performing exposure-prone procedures and universal precautions must apply to all staff in the delivery suite and obstetric theatre. Obstetric patients can have life-threatening emergencies which can be unpredictable and fast paced with time-critical responses needed to prevent morbidity.[133] Emergency resuscitation and/or delivery of the fetus could be delayed when faced with difficult or impossible PVC. Intravenous access traditionally and ultimately falls to the labour ward anaesthetist in the most difficult of patients.

Antenatal anaesthetic assessment may reveal that some patients have required multiple previous central venous catheters on separate occasions during previous medical treatments. Long-term intravenous drug abusing patients are often expert self-phlebotomists and evidence of multiple skin popping (failed venous injection or intentional subcutaneous injection of drug) may herald lack of venous access. These patients should be regarded as high risk of difficult intravenous access when they later present for management of labour and delivery (see Box 51.4).

Management plans regarding vascular access prior to labour should be discussed and equipment such as ultrasound and central venous access catheters be made available. Ultrasound has been recommended for safe placement of central venous access[134] and more recently has gained recognition for its use in siting peripheral venous cannulae.[135] Individual risk assessment should reflect the need for vascular access with particular consideration given to risk factors for sudden massive haemorrhage and/or potential requirements for large volume resuscitation. Pre-existing large-bore vascular access should be optimal in these circumstances permitting appropriate flow rates.

When antenatal assessment is not met, similar assessment of patients at risk of difficult venous access should occur in early labour and vascular access secured appropriately. Difficulty may arise when an intravenous drug abusing patient with difficult access presents with a life-threatening obstetric emergency. If PVC attempts fail, and access must be expedited, intraosseous (IO) access is one alternative to central line insertion which may provide significant time savings,[136] has been used successfully in a previous obstetric emergency[137] and has been recommended in national guidelines.[138,139] A recent national survey of UK obstetric anaesthetists revealed that 81% of respondents would consider the use of IO access in a life-threatening obstetric emergency after failed PVC attempts.[140] The technique of IO needle insertion appears easy to learn among delivery suite staff with a high first-pass success rate demonstrable following simulation training.[141] In our institution, inhalational induction of general anaesthesia in a mother with very difficult venous access has been used rarely to facilitate an emergency caesarean delivery because of immediate threat to life of mother or fetus (category 1 caesarean delivery according to the Lucas et al. classification[142]). A laryngeal mask airway was inserted, and a central line sited once the baby was delivered. Individual risk assessment to all parties including mother, baby, and healthcare professionals in emergency settings should take place.

Once vascular lines are in place it should be remembered that they can be used for 'main-lining' and therefore patients should not be allowed off the ward with them *in situ* and they should be removed as soon as they are no longer medically needed.

## Cocaine

Cocaine (benzoylmethylecgonine, $C_{17}H_{21}N_{O4}$) is an alkaloid derived from the plant *Erythroxylon coca*. It is legally available as a topical local anaesthetic but its illegal/recreational use as a CNS stimulant far exceeds the medicinal use. It is illegal for non-medicinal use in almost every country.

Route of administration includes snorting, smoking, ingestion, and injection. It is presented in the following forms:

- Coke—pure cocaine which is a white powder generally snorted through the nasal mucosa.
- Crack—the alkalinized form or free base, known as 'crack' has increased bioavailability, is more dangerous, and is highly

**Box 51.4** Risk factors for difficult intravenous access in intravenous drug abusers

- Needle marks in the dominant arm or groins
- Evidence of skin/muscle popping
- Central vein cannulation in previous hospital admission
- Lack of antenatal blood sampling results

addictive.[143] It is produced by mixing cocaine crystal or powder with water and baking soda (sodium bicarbonate, $NaHCO_3$). The mixture is boiled until the water evaporates leaving brown and white rocks which are very hard/brittle. The origin of the name 'crack' comes from the crackling sound that is produced when the cocaine and its impurities (i.e. water and sodium bicarbonate) are heated past the point of vaporization. Crack cocaine is widely smoked throughout the world,[144] usually through special glass pipes or from foil, although it can also be injected when reconstituted with water.

### Cocaine: pathophysiology

Cocaine is absorbed rapidly into the bloodstream producing a 'high' in approximately 6–8 minutes and lasts around 30 minutes to an hour, with variations depending on route of intake. Cocaine is a potent nervous system stimulant, readily crossing the blood–brain barrier and acting as a serotonin–norepinephrine–dopamine reuptake inhibitor, also known as a triple reuptake inhibitor (TRI). It is a sympathomimetic, causing an exaggerated response to these chemical messengers. Through this mechanism, prolonged adrenergic stimulation is produced with the following physical manifestations:

- increased motor activity
- tremors
- convulsion
- tachycardia
- generalized vasoconstriction
- hypertension
- hyperpyrexia.

With excessive dosage, tremors, seizures, and increased body temperature are observed.[145]

Mood-altering effects of cocaine produce euphoria by promotion of dopamine's activity in the limbic system. Feelings of high energy, alertness, increased competence, and general well-being are experienced. Anxiety, paranoia, and restlessness are also frequent. Sudden withdrawal of the drug results in fatigue, mental depression, and psychological craving.

### Cocaine: impact on the mother

In common with other illicit drug use in pregnancy, denial of use is a likely response to direct questioning. Heavy use may be associated with exhaustion, dehydration, and poor nutrition. Since it is often smoked, it can affect others due to passive smoking which has implications for other family members nearby including the newborn and other children.

Binge cycles are a particular problem and reflect the chaotic lifestyle. Bingeing is associated with preterm birth and an increased incidence of acute complications.[146] Use of cocaine in pregnancy can result in systemic and focal vasoconstriction and abnormal uterine contractions due to increased sensitivity to catecholamines. Cocaine also indirectly increases uterine contractility by promoting endometrial prostaglandin production. Overdoses cause hyperthermia, a marked elevation of blood pressure and seizures which can be life-threatening.

Maternal complications of cocaine ingestion include increased likelihood of placenta-associated syndromes such as placental abruption[147] and infarction.[148] Uterine rupture has been described in association with cocaine abuse in both women who have had previous caesarean delivery (scar rupture)[149] and even in a primigravid unscarred uterus.[150] Preterm labour, hepatic rupture,[151] rhabdomyolysis,[152] cerebral haemorrhage,[153] cardiac arrhythmias, and death[154] are all recognized. Cocaine-induced cardiovascular complications do not seem to be dose dependent, and even small recreational doses can lead to significant morbidity and mortality in an otherwise healthy parturient. The cardiovascular toxicity of cocaine is significantly increased in pregnancy.[155] Increased myocardial oxygen demand together with coronary vasoconstriction and enhanced platelet aggregation can lead to myocardial ischaemia and chest pain. This is most likely to occur within 1 hour after ingestion when blood levels of cocaine are at their highest.[156]

Acute cocaine intoxication in the third trimester can mimic pre-eclampsia and eclampsia. A case series of 11 pregnant women has been described in a report from the United States where patients presented with hypertension, blurred vision, abdominal pain, or seizures in the third trimester, but with a positive urine test for cocaine.[157] All women had a diastolic above 90 mmHg but which returned to the normal range within 45–90 minutes after admission. In these patients all laboratory investigations (liver and renal function tests) for pre-eclampsia were negative and the clinical syndrome improved as the drug wore off. A similar case of acute cocaine intoxication mimicking pre-eclampsia has also been described in the postpartum period.[158] Hypertension, proteinuria, and oedema can all occur with acute cocaine intake. In these cases, the diagnosis was aided by rapid result bedside urine toxicology testing. Normal laboratory testing may be a key differential.

Persistent cocaine abuse is associated with more chronic problems such as small-for-gestational-age infants, systemic infections, anaemia, and low maternal body weight.[142]

Cocaine and other illicit drugs should also be considered in the differential diagnosis of commonly encountered postpartum headache.[159]

### Cocaine: impact on the fetus

Cocaine is rapidly transferred across the placenta by simple diffusion.[160] There is no convincing evidence of teratogenic effects although this is difficult to isolate from other attributable factors in 'at-risk' mothers.[161] Infant outcomes in early studies consistently associated prenatal cocaine use with decreased birth weight, prematurity, and decreased fetal growth.[162] These finding have been reinforced by a more recent meta-analysis including 31 studies and accumulating data from nearly 40,000 patients.[163] Links to delayed cognitive development[164] and behavioural problems[165] later in childhood are also present.

Fetal cocaine withdrawal occurs around day 3 of life, with many discharged home before symptoms. Cocaine can be detected in fetal meconium.[166]

### Cocaine: implications for anaesthesia

Cocaine abuse is often denied by the pregnant patient and associated risk factors may include cigarette smoking, late booking, and premature labour.[167] A high index of suspicion is required. Cocaine effects should be considered when mothers present with new-onset cardiac arrhythmias or signs of myocardial ischaemia and no previous cardiac history or risk factors. Management of cocaine-induced arrhythmias are usually similar to that in the

non-pregnant women but with added consideration of fetal effects and safety profiles.[168]

Excessive uterine activity may result in fetal compromise or abruption and requirements for emergency resuscitation and delivery. Delivery suite anaesthetists should be aware of the increased risks of complications associated with cocaine abuse. High prevalence of obstetric emergencies in cocaine-abusing mothers results in the occasional necessity to expedite delivery of a cocaine-intoxicated patient. Mode of anaesthesia for delivery should be individualized to the specific set of problems presented by a cocaine-abusing parturient.

When neuraxial anaesthesia is selected, combative behaviour, altered pain perception, cocaine-induced thrombocytopenia, and ephedrine-resistant hypotension may be encountered. Phenylephrine should be used for hypotension associated with neuraxial anaesthesia. Neuraxial anaesthesia is still recommended as per non-cocaine abusing mothers but individual consideration should be given to the cardiovascular effects of cocaine use. Changes in opioid receptor densities and alteration in endorphins may result in perception of breakthrough pain despite adequate spinal and epidural blocks.[169,170] Chronic cocaine abuse leads to increased need for opiate analgesia in treatment of acute pain.

If general anaesthesia is required, consideration should be given to obtund the hypertensive response to laryngoscopy which may be exaggerated and anaesthetic volatile agents may worsen incidence of cardiac arrhythmias. Cardiac arrhythmias, hypertension, and myocardial ischaemia may be encountered under general anaesthesia.[171] Myocardial infarction and chest pain are caused by cocaine-induced vasospasm together with increased myocardial oxygen demand. Chest pain should be treated with oxygen, nitrates, benzodiazepines, and consideration of angioplasty.

Beta blockade to obtund cardiovascular responses in cocaine-abusing parturients may be relatively contraindicated due to the resultant unopposed alpha-adrenergic stimulation which can worsen hypertension. Hydralazine has been used but the decrease in systemic vascular resistance may cause reflex tachycardia[172] which is undesirable in cocaine intoxication. Labetalol is a combined alpha and beta blocker which has been widely used in pre-eclampsia treatment and has also been recommended for treatment of cocaine toxicity.[173,174]

## Amphetamines

Amphetamine is one compound within its own class of drugs. They are addictive stimulants. Derivatives range from 3,4-methylenedioxy-*N*-methylamphetamine (MDMA) known as ecstasy, to the *N*-methylated form methamphetamine known as 'crystal meth' and to medical decongestants such as ephedrine. Another common street name is 'speed' but there are many others. Population surveys across Europe suggest widespread use in the general population (Figure 51.5),[175] with the Czech Republic highest at 3.2%. Amphetamine use across Europe is generally stable, with most countries reporting broadly constant levels since the 1990s.

In the United States, it has been estimated that 5% of all pregnant women have used methamphetamines[176] and hospitalizations due to amphetamine abuse in pregnancy are increasing.[177] In the United Kingdom, amphetamines are regarded as Class B drugs.[11]

Physical effects reflect its action as a stimulant and include:

- hyperactivity
- pupil dilatation
- hypertension
- tachycardia and palpitations
- headache
- tachypnoea
- fever
- sweating
- conjunctival injection
- tremor
- convulsions.

Users also experience prominent psychological effects which can include euphoria, increased alertness, concentration, energy, confidence, and self-esteem. However, these effects occur on a spectrum also including anxiety, aggression, grandiose behaviour, paranoia, and psychosis. Tolerance to the drug is developed rapidly.

Withdrawal symptoms produce fatigue, mental depression, and somnolence. Amphetamine overdose is fairly common, which is probably due to abusers' ever-increasing need for more and more of the drug (tolerance). Unintentional overdose is a sign of increasing tolerance.

Amphetamine is administered orally, by smoking, by snorting, and by injection. Oral administration in tablet or powder form is the commonest method of recreational use.[178] In some areas amphetamine is also available in a paste which can be mixed with water and drunk. Oral ingestion effects appear within 15–60 minutes and peak at 2–3 hours.[179] Amphetamine can be smoked by heating to vaporization in glass pipes or aluminium foil. Snorting involves inhaling drug in fine powder form into the nose where it is rapidly absorbed through mucus membranes producing effects within minutes but with a shorter duration. If not already in powder form the drug may first be prepared by crushing. Injection is the most dangerous method of administering amphetamine and is prepared by dissolving in water and drawing up through a cigarette filter. This route produces the highest bioavailability and the sensation of an immediate 'rush' but with faster offset of effects. Regional variations among illicit users are seen in choice of route of administration.[180] Polydrug use is common among amphetamine users.[181] Potentiation of both effects and side effects can result from combining amphetamine with other drugs.

### Amphetamines: pathophysiology

Amphetamines enhance neurotransmitters in the brain including dopamine, serotonin, and norepinephrine, increasing their concentrations in synaptic clefts. Ecstasy (MDMA) is a derivative of methamphetamine. It causes accumulation of serotonin and dopamine at the synapses and has additional hallucinogenic properties.

Amphetamine and its derivatives, methamphetamine and MDMA, are slowly metabolized and easily distributed to the CNS.

### Amphetamines: impact on the mother

Stimulant effects of amphetamine resemble and appear to have significant crossover with those seen in cocaine abuse.

Although the medical literature on the adverse maternal and infant outcomes of cocaine abuse during pregnancy is substantial, less research has been done on amphetamine abuse during pregnancy; however, the reported effects are similar.[188] When cocaine and amphetamine abusing groups are compared with each other, obstetric diagnoses associated with infant morbidity such as premature delivery and poor fetal growth are more common in the cocaine-abusing women, whereas vasoconstrictive effects such as cardiovascular disorders and hypertension complicating pregnancy are more common in the amphetamine-abusing mothers.[175] Amphetamine injection increases the risk of emergencies such as placental abruption.[182]

Patient cooperation and safe positioning for neuraxial anaesthesia may complicate attempts at neuraxial analgesia/anaesthesia in a patient experiencing acute hallucinogenic effects of MDMA. Adverse cardiovascular events have been reported in amphetamine-dependent parturients undergoing operative delivery under both neuraxial and general anaesthesia.

MDMA intoxication has been associated with hyperthermia (> 39° C), disseminated intravascular coagulation, and severe dehydration. Excessive antidiuretic hormone (ADH) release may cause hyponatraemia leading to coma and death. Serum electrolytes should be measured and care taken with fluid administration

### Amphetamines: impact on the fetus

Amphetamine abuse during pregnancy has potential fetal side effects as the drugs are fat-soluble and can easily cross the placental barrier.[183] It has been postulated that amphetamines will decrease uterine blood flow and increase uterine vascular resistance in a dose-related manner. Its use in pregnancy is associated with increased risk of adverse pregnancy outcomes such as increased neonatal mortality and worsened Apgar scores at 1 minute and 5 minutes.[184] The problems of amphetamine exposure in pregnancy include intrauterine growth restriction,[185] preterm labour,[186] and low birth weight.[187] One study found a 3.5-fold increased risk of fetal growth restriction among babies of women using methamphetamine in pregnancy.[188] Long-term effects include reduction in childhood growth, intellectual performance,[189] and behavioural problems.[190]

Methamphetamine exposure was also associated with neonatal withdrawal symptoms of agitation, vomiting, and tachypnoea.[191] This withdrawal syndrome is relatively mild and only requires medical intervention in approximately 4% of cases.[192]

Preterm birth rates in amphetamine abusing mothers have been quoted around 26–28.6%.[193,194] As per previous studies, the exact causes are multifactorial and it is difficult to extrapolate whether it is a direct effect of amphetamine itself or associated factors in the substance abusing parturient such as anaemia, poor nutrition, and social factors. Fetal and infant deaths have also been reported in relation to amphetamine abuse.[195]

### Amphetamines: implications for anaesthesia

Amphetamine intoxication presenting with seizures, proteinuria, and/or hypertension may be mistaken for pre-eclampsia/eclampsia and is similar to cocaine intoxication in this respect. Psychedelic effects, psychosis, and hallucinations may cause difficulty with cooperation required for siting neuraxial blockade. Caution should be demonstrated with sympathomimetic

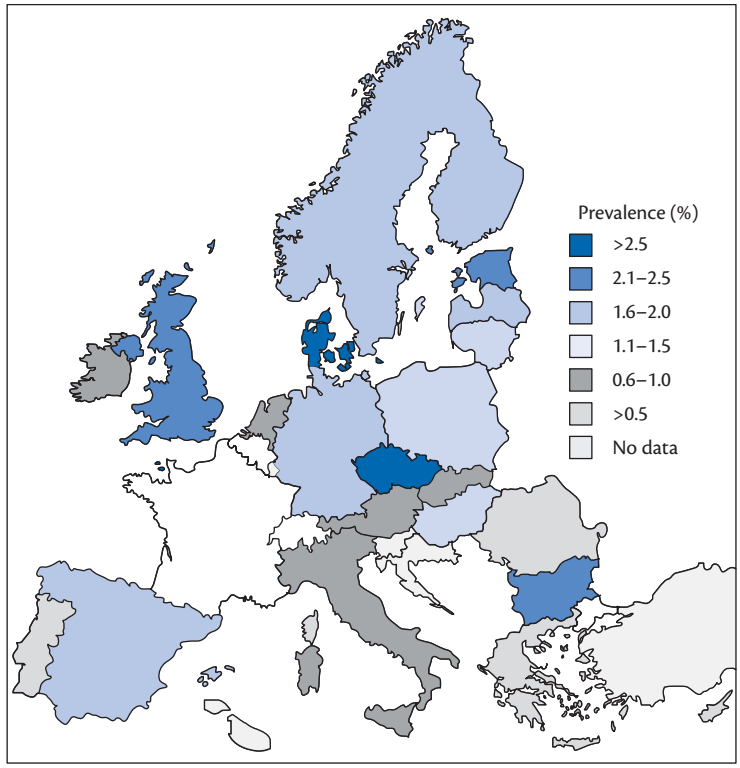

**Figure 51.6** Report of population surveys suggesting prevalence of amphetamine use among young adults (15–34 years) in Europe.

drugs due to exaggeration of hypertension, arrhythmias, and myocardial ischaemia. Acute amphetamine intoxication tends to increase minimum alveolar concentrations of anaesthetic agents, while chronic usage tends to decrease anaesthetic dose requirements. Electrolytes should be monitored together with careful fluid balance as seizure-induced hyponatraemia has been associated with extreme thirst and ingestion of large volumes of water.

One study has shown that 35% of amphetamine-abusing mothers are anaemic on screening, compared to nearly 8% in the non-substance abusing group.[196] The increased risk of this complication may well result from poor nutrition and lack of antenatal iron supplementation in a patient group demonstrated to have higher incidences of lack of obstetric care. Screening for anaemia should be undertaken.

## Conclusion

Substance abuse in pregnancy is a significant problem faced by the obstetric anaesthetist which adds a layer of complexity to the management of labour and delivery. It is difficult to quantify the true extent of the problem given the often socially unacceptable, illegal, and covert nature of this activity although it appears significant, particularly in inner city regions.

Substance abuse may be obvious, openly admitted, or occult. It is also subject to geographical variations in the availability of the substance in question and its locally preferred route of administration. The ranges of substances which are abused are diverse chemically, pharmacologically, and physiologically with each bringing with it its own unique subset of challenges.

Substance-abusing mothers tend to default on antenatal care, present with obstetric and non-obstetric emergencies directly related to drug abuse, mimic other obstetric disease states, and have a tendency towards preterm labour. Neonates tend to be premature, small for gestational age, at risk of stillbirth, at risk of withdrawal, and have behavioural problems which continue into childhood and adult life. Local knowledge and experience together with a high index of suspicion among obstetric care providers is invaluable in supporting substance-abusing mothers throughout their pregnancy to obtain the most favourable outcomes for both mother and baby.

PART 10

# Recent advances in obstetric anaesthesia

# CHAPTER 52

# Genetics

Ruth Landau and Clemens Ortner

## Introduction

Since the completion of the Human Genome Project over a decade ago, the medical community has been somewhat disillusioned after the promise that pharmacogenomics would transform their practice and result in personalized medicine.[1–4] Undeniably, recommendations based on pharmacogenetic testing to ensure effective and safe analgesia and anaesthesia are still awaited. The National Institutes of Health's Pharmacogenetics Research Network developed a Pharmacogenomics Knowledge Base (PharmGKB)[5] with the goal 'to collect, encode, and disseminate knowledge about the impact of human genetic variations on drug response, curate primary genotype and phenotype data, annotate gene variants and gene–drug–disease relationships via literature review, and summarize important pharmacogenetic genes and drug pathways'. In line with their goals, the Clinical Pharmacogenetics Implementation Consortium (CPIC)[6] was launched in 2011 to establish clinical recommendations for dosing based on genetic testing providing information on genotype–test interpretations and on the scientific evidence supporting the evidence of these tests. Since its inception, genetic/drug dosing guidelines have been established for eight different drugs, out of which only codeine prescription according to cytochrome P450 (CYP)-2D6 genotype[7] may be relevant to the practice of anaesthetists, pain doctors, paediatricians, obstetricians, or perinatologists.

This chapter describes a selection of association studies that have examined the contribution of genetics to (1) preterm labour and the progression of labour, (2) labour analgesia, (3) haemodynamics and vasopressor response during spinal anaesthesia for caesarean delivery, and (4) post-caesarean pain and analgesic response to opioids. Numerous genes influence the overall experience of labour and delivery, but we will focus on the most well-studied genes in the clinical context of obstetric anaesthesia and perinatology: the μ-opioid receptor gene (*OPRM1*), the catechol-*O*-methyltransferase gene (*COMT*), the $\beta_2$ adrenergic receptor gene (*ADRB2*), the oxytocin receptor gene (*OXTR*), the ATP-binding cassette, subfamily B, member 1 (*ABCB1*) gene, and the genetics of CYP2D6 metabolism (Table 52.1).

## Preterm labour and the progression of labour

The influence of these genetic variants on preterm delivery, preterm labour, as well as the progress of labour has been the focus of several clinical studies in the last decade. The preterm birth phenotype is defined as having five components (maternal conditions that are present before presentation for delivery, fetal conditions that are present before presentation for delivery, placental pathological conditions, signs of the initiation of parturition, and the pathway to delivery),[8] therefore the exact contribution and the weight carried by each genetic variants is probably not very high and remains to be determined.

The beta-2 ($\beta_2$)-adrenergic receptor gene (*ADRB2*) and in particular two common polymorphisms found in strong linkage disequilibrium, p.16Arg/Gly and p.27Gln/Glu, have been extensively evaluated in a number of anaesthesia-related studies with relevant clinical effects described in the context of airway responsiveness[9] and cardiac perioperative outcomes.[10] All in all, these two single nucleotide polymorphisms (SNPs) have been studied over the last decade in only a handful of reports evaluating uterine quiescence and the progression of labour.

Homozygosity for Arg16 of *ADRB2* was first shown to confer protection from preterm delivery in a small association study in a North American cohort [11], followed by other studies suggesting that the Glu27 variant of *ADRB2* increases the risk for preterm delivery.[12,13] Thereafter, the response to hexoprenaline, a $\beta_2$-agonist administered for tocolysis in a cohort of Swiss women diagnosed with idiopathic preterm labour between 24 and 34 weeks gestation, was found to be more effective in the presence of Arg16 homozygosity,[14] demonstrating a pharmacogenetic effect. This improved response to tocolysis had a significant impact on neonatal outcomes, with higher birth weights and fewer neonatal admissions to the intensive care unit for respiratory or other complications due to prematurity in babies born to mothers with that genotype.

In a larger trial evaluating the impact of *ADRB2* genotype/haplotype on preterm labour, a subanalysis confirmed the hypothesis that Arg16 homozygosity of *ADRB2* is associated with a slower rate of labour progress in successful term and late-preterm labour when compared to women with all other genotypes.[15] In this North American cohort, women Arg16Arg–Gln27Gln (double homozygous) progressed at the slowest rate of active labour ('slow haplotype'), and women Gly16Gly–Glu27Glu (double homozygous) progressed with the fastest cervical rate ('fast haplotype').

Using the previously validated non-linear mixed effects modelling (NONMEM) to predict the pain and labour progress of the first stage of labour in nulliparous women, another smaller study from the same North American group, to evaluate the effect of *ADRB2* and *OPRM1* genotypes on the progress of labour and labour pain demonstrated that women homozygous for the variant Gln27 allele had a slower transition into the active phase labour, resulting in prolonged labour compared to women with the other genotypes.[16] Genotype was strongly correlated with

**Table 52.1** Selected genes, genetic variants, and associated phenotype of interest to obstetric anaesthesia and perinatology

| Gene | Variant | Phenotype | Anaesthetic and obstetric outcome | Reference |
|---|---|---|---|---|
| *OPRM1* | p.118A/G | Pain perception and response to opioids | Labour analgesia<br>(G118 associated with decreased median effective dose of spinal fentanyl and epidural sufentanil) | 40–43 |
| | | | Post-caesarean analgesia<br>(A118 associated with decreased IV PCA morphine use) | 41,47,54 |
| | | | Neonatal exposure to opioid (NAS)<br>(neonatal G118 associated with shorter hospital stay and less medication) | 69 |
| *COMT* | p.472G/A<br>(Val158Met) | Pain perception and response to opioids | Labour analgesia<br>(Met158 associated with poor response to IV fentanyl) | 43 |
| | | | Neonatal exposure to opioid (NAS)<br>(neonatal Val158 associated with shorter hospital stay and less medication) | 69 |
| | | Uterine activity | Labour progress<br>(rs4633 associated with slow labour progress) | 17 |
| *ADRB2* | Arg16Gly–Gln27Glu | Uterine activity | Preterm labour and delivery<br>(Arg16 associated with protection from preterm delivery; Glu27 associated with increased risk for preterm delivery) | 11-13 |
| | | | Tocolysis efficacy ($\beta_2$-agonist)<br>(Arg16 associated with better response to $\beta_2$-agonist tocolysis) | 14 |
| | | | Labour progress<br>(Arg16–Gln27 associated with slow labour progress) | 15-17 |
| | | Response to ephedrine | Spinal hypotension during caesarean<br>(Gly16–Glu27 associated with increased response to ephedrine) | 64–66 |
| | | | Neonatal acidosis<br>(neonatal Arg16 associated with protection from ephedrine-induced neonatal acidosis) | 64 |
| *OXTR* | rs53576 A/G | Uterine activity | Labour progress<br>(G allele at rs53576 associated with slower progress of labour) | 17 |
| *ABCB1* | p.1236C/T<br>p.2677T/A<br>p.3435C/T | Pain perception and response to opioids | Chronic post-caesarean pain<br>(T allele of C3435T associated with increased trend for chronic post-caesarean pain) | 61 |
| | | | Neonatal exposure to opioid (NAS)<br>(no impact of neonatal *ABCB1* genotype on hospital stay) | 69 |

NAS, neonatal abstinence syndrome; PCA, patient-controlled analgesia.

Data from various sources (see references).

ethnicity (none of the Asian women included in the study were Glu27 homozygous), and labour was indeed found to be slower among Asians. The study was underpowered to detect an effect of *OPRM1* genotype on labour pain, but identified that cold sensitivity was the pain modality that may predict the intensity of labour pain.

Using the same model to evaluate the progression of labour, eight SNPs in three different genes, *ADRB2, COMT*, and *OXTR* were examined in a cohort of 233 Saudi Arabian nulliparous women.[17] Three different SNPs of *COMT* were evaluated, and one of them (region sequence rs4633) along with one SNP of *OXTR* (region sequence rs53576) were associated with increased duration of the latent phase of first stage of labour, resulting in longer labours (in the order of 5 hours for *COMT* and 2 hours for *OXTR*). These findings contrast with results from other studies that found no effect of *OXTR* SNPs on the duration of first-stage labour[16]

or risk of dystocia.[18] In addition, *ADRB2* genotype/haplotype was not associated with labour progress once demographic factors were accounted for. Data combining all the genetic variants (joined allelic combination) for each woman in the cohort was not reported, so one cannot infer the overall importance of a genetic contribution to the progress of labour.

Taken together, all studies evaluating obstetrical outcomes based on *ADRB2* genotype reported that women carrying Arg16 and/or Gln27 are conferred protection from preterm delivery and have a more 'quiescent' uterus, resulting at the time of labour and delivery in a slower progression and prolonged labour duration. Overall though, factors influencing the progress of labour are multiple, including ethnicity and maternal weight, and genetic variability, out of which *ADRB2* is only one of many candidate genes, is unlikely to contribute in a major manner.

A variety of genomic studies have examined the influence of genetic variants and validation of biomarkers to identify women at risk for preterm labour and delivery is ongoing.[19,20] On the other extreme of the clinical spectrum, a genome-wide scan study in Sweden has identified at least six loci that appear to contribute to the risk of women requiring a caesarean delivery for dystocia,[18] and further prospective studies will need to validate these findings.

## Labour analgesia

Clearly, the pain of childbirth is the most severe pain most women will endure in their lifetimes.[21] Nonetheless, despite undeniable advances in our understanding of the physiology of labour pain that have resulted in the ability to provide safe and effective labour analgesia to the majority of women in the developed world, evaluating and measuring labour pain and the response to analgesia remains a remarkable challenge.[22] Therefore, it is no surprise when one realizes that a standard tool such as a numeric pain score, used in all clinical pain studies, does not capture very well the essence of labour pain. Other challenges that are specific to obstetric pain relate to the dynamic nature of labour and labour progress and the consequent changes in nociception that occur over time; pain of first-stage labour is conducted by thin afferent, *visceral* sympathetic fibres, entering the spinal cord at thoracic and lumbar roots (T10–L1) while second-stage labour pain is conducted via thicker *somatic* nerve fibres entering the spinal cord at sacral roots S2–4. The dynamic component of labour pain has been integrated in a recent mathematical modelling technique that attempts to integrate multiple parameters to predict the intensity of pain over the course of labour.[23] Nonetheless, one of the major hurdles in labour pain studies relies on the subjective, individual ability of women to quantify their pain during labour.

We have made numerous assumptions in our attempts to evaluate labour pain and women's response to labour analgesia. We have assumed that asking women to score their pain on a 0–10 scale would result in a meaningful and relevant response, that if women experienced severe pain they would request an epidural, that if women requested an epidural earlier in the process of labour they were surely hurting more than women requesting an epidural at a later stage in labour, that if women required more analgesic medication they may have a poorer response to analgesia, and finally that if women had not requested any medication, they either had better coping skills or hurt less. We have also assumed that we could accurately measure pain scores, average these scores for each woman enrolled in a study, that we could compare these averaged scores between women and infer into which category (more pain, less pain) women belong. Last, analysing and interpreting findings from such studies is a gruelling and perplexing task for the obstetric anaesthetist invested in evaluating labour pain and analgesia. Ultimately, obstetrical factors greatly influence the amount of medication and analgesia women will want to take and agree to receive, based on the belief that the ability to effectively push and deliver the baby may come at the expense of some discomfort and pain. Therefore, any study that has considered overall analgesic consumption during labour and delivery, whether by means of systemic opioids or neuraxial analgesia, as a surrogate to measure pain during childbirth is likely to be meaningless and misconstruing the complexity of the labour pain experience. Labour pain and analgesic requirements in the peripartum period may well be the most intricate pain phenotype to evaluate and surely requires multidimensional tools not yet widely utilized to evaluate obstetrical or acute postoperative pain as clinical models of acute pain. This may in part explain why genetic association studies that have attempted to predict the consumption of opioids in any clinical setting have been disappointing;[24] genotyping is probably useless if the phenotype cannot be well defined and measured.[25]

Among the myriad of candidate genes that have been considered important in opioid response, *OPRM1* is probably the most studied [26]. A common polymorphism of *OPRM1* is a single nucleotide substitution at position 118, with an adenine substitution by a guanine (p.118A/G) reported to occur with an allelic frequency of 10–30% among Caucasians,[27] a higher prevalence among Asians,[28] and a lower one in African Americans.[29] Despite numerous studies in the last two decades to identify the mechanism by which the altered receptor influences opioid analgesia, several hypothesis remain unconfirmed. *In vitro* studies have suggested that p.118A/G of *OPRM1* affects receptor binding characteristics[30,31] or messenger RNA expression levels;[32] however, under some experimental conditions no effect on function[33] or expression levels[34] was confirmed. In a recent humanized mouse model exploring signal transduction pathways that mediate opioid pharmacology, sensory neurons expressing G118 homozygosity displayed reduced morphine (but not fentanyl) potency and efficacy compared with the A118 homozygous version of the gene, suggesting an effect at the level of the sensory neurons.[35]

In a study evaluating the response to different experimental modalities in healthy individuals, there was no significant effect of *OPRM1* genotype on pain sensitivity in the entire sample, but when examining each ethnic group separately (Caucasians, Hispanics, and African Americans), a lower pain sensitivity was found among Caucasians carrying the G118 allele, while there was a trend in the opposite direction among Hispanics and no measurable effect among African Americans (the G allele is under-represented in this ethnicity); of note, there were no Asian women in that study.[36] Also, since the G118 variant allele is extremely common among Asians, studies comparing pain sensitivity between Caucasians and Asians will be of interest. It remains to be determined whether haplotype structure, gene–gene interactions, or DNA methylation[37] rather than the A118G genotype itself are key to explain these inter-ethnic differences in pain sensitivity; nonetheless this ethnicity-dependent genetic association may contribute to some

of the discrepancies reported in clinical studies as underlined in the paragraphs that follow.

In a large cohort of Swedish women, labour pain-related behaviours, characterized by the cervical rate upon arrival in the labour room and the use of any type of analgesia (nitrous oxide, epidural, systemic opioids, and acupuncture) were not found to be associated with a particular genotype of *OPRM1*.[38] In other words, women did not seem to have different thresholds for labour pain or epidural request based on p.118A/G genotype, but the response to labour analgesia once provided was not evaluated. Of note though, the overall epidural rate was relatively low (30%) and the epidurals were placed at a relatively advanced stage in labour (at approximately 6 cm of cervical dilatation); therefore the lack of difference in epidural use is more likely to reflect a local clinical practice than a lack of genetic contribution. The same authors also reported that a previously described pain-protective haplotype related with three SNPs of the guanosine triphosphate cyclohydrolase gene (*GCH1*) did not appear to drastically alter labour pain-related behaviours.[39]

The first clinical study evaluating any genetic influence on labour pain and searching for a pharmacogenetic effect in response to labour analgesia is most likely the one conducted in a Swiss cohort of nulliparous women requesting neuraxial analgesia early in labour evaluating p.118A/G of *OPRM1*. Using the up-down sequential allocation model to identify differences in analgesic requirement according to A118G genotype, women carrying the less common G118 variant allele required substantially *lower* doses of spinal fentanyl, with a 1.5-fold difference compared to A118 homozygous women (Figure 52.1).[40] This finding was replicated with a different pharmacological study design using random-dose allocation, with a twofold difference between genetic groups.[40] Of note, cervical dilatation at the time of analgesia request was significantly *less* in A118 homozygous women than that in women carrying one or two variant alleles (A118G heterozygotes or G118 homozygotes). The finding of lower analgesic requirements at a more advanced stage in labour at the time of the analgesic request suggests that women carrying the G118 variant allele have a *higher* pain tolerance, which allows them to wait longer before requesting analgesia. This is of interest because women received the combined spinal–epidural analgesic when they requested pain relief, in other words at the time they experienced painful contractions. Since it has previously been demonstrated that epidural analgesic requirements increase with progress of labour and cervical dilatation, the expectation would be that women carrying the G118 allele should have greater analgesic requirements due to the greater cervical dilatation at which they requested analgesia; the finding that these women required *less* fentanyl may actually underestimate the true effect of genotype. Since provision of optimal labour analgesia remains an ongoing challenge for obstetric anaesthetists with minimal motor impairment and opioid-related side effects such as pruritus and fetal bradycardia (which appear to be dose dependent), this significant difference in median effective dose ($ED_{50}$) according to genotype may be relevant from a clinical standpoint. Therefore, one may presume that genotyping may well help improve the delivery of neuraxial labour analgesia because a 1.5–2-fold difference in spinal fentanyl dose is not trivial. Meanwhile, another clinical study in a North American cohort determined that the duration of spinal fentanyl analgesia is not influenced by p.118A/G.[41] Taken

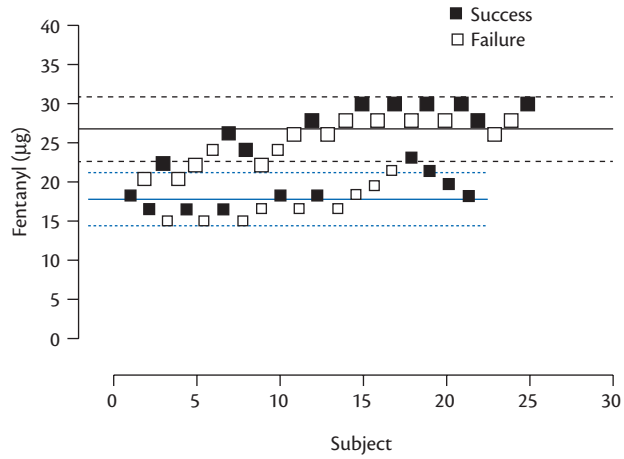

**Figure 52.1** Influence of p.118A/G of *OPRM1* on spinal fentanyl dose for labour analgesia. Median effective dose ($ED_{50}$) of spinal fentanyl according to p.118A/G genotype of *OPRM1* was evaluated using the up-down sequential allocation method. Data show effective (success) and ineffective (failure) analgesic outcome according to genotype; A118 homozygotes are represented within the upper dotted bars, women heterozygous (118A/G) or 118G homozygotes are represented within the lower dotted bars, with solid bars representing $ED_{50}$ and dotted bars representing 95% confidence intervals. $ED_{50}$ of spinal fentanyl was 26.8 mcg (95% CI 22.7–30.9) in women A118 homozygotes (per-protocol analysis, n = 25) versus 17.7 mcg (95% CI 13.4–21.9; P < 0.001) for women heterozygous (118A/G) or 118G homozygotes (per-protocol analysis, n = 19). $ED_{50}$ ratio (A:G) for genotype is 1.51 (95% CI 1.18–2.01), P = 0.009.
Adapted with permission from Landau R, Kern C, Columb MO, Smiley RM, Blouin JL., Genetic variability of the μ-opioid receptor influences intrathecal fentanyl analgesia requirements in laboring women, *Pain*, Volume 139, pp. 5–14, Copyright © 2008 Wolters Kluwer Health, Inc.

together, these studies suggest that this common polymorphism of *OPRM1* influences spinal fentanyl potency without affecting the duration of analgesic action.

Using the same methodology, another recent study in Caucasian women demonstrated a similar pharmacogenetic association of p.118A/G with opioid potency during labour analgesia, although with a more modest clinical effect. In nulliparous women receiving early epidural analgesia, a lower dose requirement ($ED_{50}$) for epidural sufentanil was found among those carrying the G allele.[42]

The benefits of intravenous (IV) fentanyl for labour analgesia have not been well studied, but fentanyl is offered to women trying to delay or avoid altogether receiving neuraxial analgesia. The rationale for studying the influence of p.118A/G in this clinical context would be to examine the hypothesis that the analgesic response to IV versus spinal fentanyl, under similar clinical conditions (i.e. labour pain) may be influenced differently by this genetic variant. A recent study attempted to explore this question, and determine whether the response to IV fentanyl, and subsequently spinal fentanyl if women went on to request a combined spinal–epidural analgesic would be different according to *OPRM1* genotype alone or in combination with p.472G/A (158Val/Met) of the *COMT* gene.[43] In this North American cohort, most women were Caucasian, and IV analgesic success was found to be relatively low (only 20% of women reported a pain score of <10/100 at 15 minutes after dosing). The average decrease in pain scores 15 minutes after a unique dose of IV fentanyl was only modestly

influenced by *OPRM1* genotype, but was found to be lowest among Met/Met158 women compared with women carrying Val/Met or Val/Val of *COMT*; that genotype with the poorer analgesic response was carried by 31% of women. Genotypes of p.118A/G of *OPRM1* in combination with p.472G/A (158Val/Met) of *COMT* seemed to have an impact on the analgesic outcome; IV fentanyl was least effective in women with the A/A–Met/Met combination of *OPRM1* and *COMT,* which was carried by 18% of women in this cohort. The study was ultimately insufficiently powered to explore the hypothesis that spinal and systemic opioid dynamics are different and determine whether enhanced analgesia in response to spinal fentanyl in the presence of the variant *OPRM1* G118 allele may not exist in response to IV fentanyl. Nonetheless, such findings may have useful clinical implications, such as not offering IV fentanyl in labour to women who will most likely not benefit from it.

Overall, findings in labouring women are in disagreement with most if not all other studies examining p.118A/G and opioid analgesia,[24] whether one evaluates postoperative IV fentanyl consumption,[44–46] spinal morphine for post-caesarean pain,[41,47] IV morphine for postoperative pain,[48,49] or oral morphine for chronic cancer pain.[50–52] Potential explanations other than ethnicity for such discrepant results are that labour pain is different from that experienced in other clinical settings (experimental, postoperative or chronic pain), or that the response to systemic rather than spinal fentanyl, is affected differently by *OPRM1* genotype. One could speculate that human spinal cord receptor function and signal transduction is selectively more altered by the G118 variant than supraspinal receptors. Another potential explanation and factor to bear in mind is the different nature of the nociceptive stimulus in labour versus other painful syndromes. Indeed, similar disparate results in human genetic studies of pain sensitivity have been shown to occur with other polymorphisms commonly assessed in pain studies.[53]

## Post-caesarean delivery pain and response to postoperative analgesia

The effect of p.118A/G of *OPRM1* on post-caesarean analgesia after spinal and IV *morphine* was evaluated in three studies.[41,47,54] In a North American cohort, the amount of post-caesarean rescue analgesia after a spinal solution of 150 mcg morphine and 15 mcg of fentanyl according to genotype was examined and there was no difference in the duration of spinal morphine analgesia or need for analgesic supplementation over 72 hours in women carrying the G118 allele.[41] The total median morphine equivalent dose was 68 mg (interquartile range; 37–97) in women A118 homozygotes (n = 78) and 75 mg (interquartile range; 37–90) in women carrying at least one G118 variant allele (n = 22 118A/G heterozygotes and n = 3 G118 homozygotes). The time for first opioid rescue analgesia was 22 hours (interquartile range; 12–24) in women A118 homozygotes, and 22 hours (interquartile range; 15–24) in women carrying at least one G118 variant allele. The incidence of nausea was similar between groups; however, pruritus was less frequent in carriers of the G118 variant allele during the first 24 hours.

Sia et al. from Singapore reported that in women undergoing caesarean deliveries under spinal anaesthesia with a morphine spinal dose of 100 mcg, carriers of the G118 variant allele exhibited *increased* 24-hour postoperative consumption of morphine via IV patient-controlled analgesia (PCA).[47,54] In both studies, women were given upon arrival in the post-anaesthesia care unit (PACU) a morphine IV PCA pump (1 mg bolus) and no other analgesics were prescribed. In a first publication reporting on 588 Chinese Singaporean women, 24 hours postoperative morphine IV PCA consumption was lowest in women A118 homozygotes (n = 288) with a mean dose of 5.9 mg (95% confidence interval (CI) 5.1–6.8) versus 8.0 (95% CI 6.9–91) in women 118A/G heterozygotes (n = 234) and 9.4 mg (95% CI 7.3–11.5) in women G118 homozygotes (n = 82) (P = 0.0017).[47] Distribution of morphine use over time (doses were recorded in 4-hour time intervals) demonstrated that most of morphine use occurred in the PACU during the first 4 hours after spinal anaesthesia. It is possible that this early IV morphine use reflects lack of analgesia upon arrival in the PACU; indeed onset of analgesia procured by spinal morphine is known to be slow and has been shown to occur up to 45 minutes after its administration.[55] Consequently, initial differences in IV morphine use may be due to differences in pain perception rather than impaired spinal morphine analgesia in women carrying the G118 variant allele, while differences of morphine use at 24 hours reflect either differences in spinal morphine duration and/or efficacy or more likely differences in IV morphine efficacy. The overall incidence of nausea was low; nonetheless incidence of nausea was higher in women A118 homozygotes versus the other two groups (9.6% vs 5.6% and 1.2% for women 118A/G heterozygotes and G118 homozygotes, respectively; P = 0.02). Since pain scores were lower in women A118 homozygotes, it was concluded that nausea was unlikely to have discouraged women from using the IV PCA morphine button.

In a second publication by the same authors, 994 women from the three main ethnic groups in Singapore were evaluated (n = 617 Chinese, n = 241 Malays, and n = 136 Indians).[54] The overall genotype distribution in the women was 39% A118 homozygotes, 44% 118A/G heterozygotes, and 17% G118 homozygotes, with significant differences between ethnic groups (G118 homozygosity more prevalent among Malays and Indians). The average amount of self-administered morphine was 8.9 mg ± 9.6 over 24 hours. The authors report a large inter-individual range with 65 women not using any, 129 using only one dose, while another 122 administered two doses. The highest amount recorded was 62 mg followed by 55 mg; the remainder of women (n = 676) used between 3 and 40 mg. Total IV morphine use over the first 24 hours was significantly higher in women G118 homozygotes, and incidence of nausea was again lower in women with this genotype. In a multiple regression analysis, the most important factor contributing to morphine usage was maximum pain score, followed by ethnicity and p.118A/G. After correction for *OPRM1* genotype, ethnicity was still a significant contributing factor, with Indian women reporting higher pain scores and using higher doses of IV morphine.

This apparent discrepancy between the North American study reporting no effect of p.118A/G of *OPRM1* on spinal morphine analgesia and the Singaporean findings of a pharmacogenetic effect of this polymorphism, may be explained by differences in study design and primary outcomes. In Sia et al.'s studies evaluating Asian women, the spinal solution did not include fentanyl therefore it is possible that onset of spinal analgesia occurred after women arrived in the PACU. Since women were given IV PCA morphine as the initial rescue analgesic (rather than ibuprofen as

in Wong et al.'s study), such study design was more likely to evaluate the effect of p.118A/G of *OPRM1* on IV morphine analgesia rather than the analgesic effect of spinal morphine, at least for the early morphine doses. Another obvious explanation may be that *OPRM1* genotype interacts differently with opioid analgesia in different ethnic groups, as may be suggested by the recent finding of an ethnicity-dependent genetic association for p.118A/G of *OPRM1* recently described in healthy volunteers evaluated with an experimental model of pain.[36]

Finally, the risk for developing chronic pain after childbirth and in particular after caesarean delivery, a topic of interest and subject of several recent publications,[56–60] has been associated with SNPs of the *ABCB1* gene in an Asian cohort of women evaluated in Singapore.[61] Such findings need to be validated with studies evaluating prospectively chronic pain, with pain outcomes that include neuropathic pain descriptors, across multiple ethnicities.

## Haemodynamics and vasopressor use during caesarean delivery

The response to vasopressor agents (α- and β-adrenergic agonists) to prevent and/or treat hypotension during spinal anaesthesia for elective caesarean delivery has been extensively studied.[62] Ephedrine is a sympathomimetic amine, the principal mechanism of its action relies on its direct and indirect actions on the adrenergic receptor system (both an α- and β-adrenergic agonist). For decades, ephedrine has been considered the safest and probably the sole acceptable agent in pregnant women, based on a seminal study in the pregnant ewe that suggested deleterious effects of pure α-adrenergic agonists on uteroplacental blood flow.[63] Ephedrine has been widely used in a variety of regimens (different bolus doses, infusions, and in combination with phenylephrine) although no definitive consensus has ever been achieved as to which of these modes of administration provides the most reliable and effective response.

To date, only three studies have evaluated the effect of *ADRB2* genotype/haplotype on maternal haemodynamics and vasopressor requirement during caesarean delivery under spinal anaesthesia.[64–66] In a North American cohort of healthy pregnant women (N = 170), the incidence and severity of maternal hypotension after spinal anaesthesia for caesarean delivery and the response to treatment was clearly affected by *ADRB2* genotype/haplotype.[66] Women Gly16 homozygous and carrying one or two Glu at position 27 (Gln27Glu heterozygous or homozygous for the Glu27 variant allele) were found to require significantly *less* vasopressors (ephedrine) for treatment of hypotension during spinal anaesthesia. The two haplotypes that seemed to 'protect' women from requiring higher doses of ephedrine are relatively common in Caucasians, and in this study 20% of the women carried either one of these haplotypes.

In a small Brazilian cohort (N = 50), homozygosity for Arg16 was suggested to confer protection from hypotension and ephedrine requirements were lower in women with that genotype.[65] Finally in a cohort of Asian women, as expected, the haplotype distribution for p.16Arg/Gly and p.27Gln/Glu was found to be substantially different from that described in Caucasian individuals; the two haplotypes found to be associated with lower ephedrine requirements in the North American study mentioned above[66] were under-represented among Asian women and *ADRB2* genotype/haplotype was not found to influence ephedrine dosage in that study evaluating Asian women.[64]

Further studies would be required to confirm this genetic and pharmacogenetic effect of *ADRB2* genotype/haplotype on maternal hypotension and ephedrine requirement; however, current clinical practice warrants prevention of hypotension with phenylephrine, either given as a bolus or by means of a continuous infusion, therefore this question will most likely remain unanswered. Nonetheless, this possible pharmacogenetic effect may explain in part why two decades of multiple studies trying to define one single optimal strategy (fluid loading, ephedrine, or phenylephrine) to prevent or treat hypotension during spinal anaesthesia for caesarean delivery have failed to identify that one regimen that would 'fit all'.

## Fetal and neonatal effects of maternal medication

### Neonatal acidosis after maternal ephedrine

The direct effects of ephedrine on the fetus have been revisited.[67] Evidence that ephedrine crosses the placenta to a greater extent and undergoes less early metabolism and redistribution than phenylephrine (a direct α-adrenergic agonist) causing direct fetal metabolic acidosis has made ephedrine less desirable as a first-line treatment.[68] The proposed mechanism is that direct fetal β-adrenergic stimulation increases anaerobic glycolysis and causes a hypermetabolic state. The hypothesis that neonatal *ADRB2* genotype may directly influence the degree of neonatal acidaemia in response to ephedrine given to the mother prior to delivery has been explored. The most clinically relevant and intriguing finding of a study conducted in Asian women was that umbilical artery (UA) pH was overall higher and UA lactate was lower in neonates that were Arg16 homozygous as compared to neonates with the two other genotypes of *ADRB2*.[64] Furthermore, among babies born to mothers receiving ephedrine, ephedrine dose was associated with neonatal acidaemia (decreased UA pH) only in neonates carrying a Gly16 allele, but not in neonates who were Arg16 homozygous. Since there was no significant difference in ephedrine concentration as determined by maternal and umbilical cord assays among genetic groups, any difference in metabolic markers are unlikely to have resulted from differential transplacental transfer of drug or a pharmacokinetic effect. Arg16 homozygous neonates seem to be protected from the risk of developing acidaemia when exposed to ephedrine, irrespective of the dose given to the mother. These findings provide interesting insight on fetal acidosis and metabolic responses in neonates born to mothers who have received β-agonists (ephedrine and/or other β-stimulants prescribed for tocolysis or bronchodilation) prior to delivery.

### Neonatal abstinence syndrome after maternal opioids

In a recent prospective cohort study conducted in the Unites States, 86 mother–infant pairs were studied to evaluate the association

between p.118A/G of *OPRM1*, p.472G/A (158Val/Met) of *COMT* genes, and three SNPs of the *ABCB1* gene and the risk for neonatal abstinence syndrome (NAS) in neonates exposed *in utero* to methadone or buprenorphine.[69] Neonates carrying the variant G118 allele of *OPRM1* had a shorter length of hospital stay and were less likely to require medication compared to neonates A118 homozygotes. Neonates carrying one or two alleles of the Val158 variant were also protected from a longer hospital stay and the need for medication. There was no effect of any *ABCB1* SNPs and neonatal outcome. The study was truly underpowered to evaluate the joined allelic combination for both SNPs.

This is the first study to evaluate the influence of fetal/neonatal genotype on neonatal outcomes after fetal exposure to opioids, and while epigenetic studies will be of interest as well, these findings do provide some insight into the mechanisms underlying NAS.

## Neonatal death after maternal codeine

Codeine was initially prescribed because of the belief that this weak opioid would not result in adverse outcomes. For that reason, codeine has been considered a safe alternative to other opioids for outpatient pain management, and is still available in some countries as an over-the-counter medication, either alone or in combination with paracetamol (acetaminophen). Current use of codeine includes paediatric patients,[70] and treatment of postoperative pain, although large-scale evidence on efficacy is sparse and has been challenged by a meta-analysis.[71] Codeine is a pro-drug, and requires *O*-demethylation catalysed by CYP2D6 to be converted into morphine and become analgesic; this metabolic pathway accounts for 10% of codeine clearance. The conversion of codeine into norcodeine by CYP3A4 and into codeine-6-glucuronide by glucuronidation represents approximately 80% of codeine clearance. Morphine is further metabolized into morphine-6-glucuronide (M6G) and morphine-3-glucuronide; both morphine and M6G display opioid activity. Individuals with an UM phenotype carry the risk for respiratory depression with codeine, particularly if CYP3A4 activity is inhibited by concomitant use of antibiotics or in the context of kidney dysfunction.[72]

In a recent pilot study, the relationship between CYP2D6 genotype, post-caesarean pain scores, codeine consumption, and side effects were evaluated.[73] The two extremes in CYP2D6 genotype seemed to predict pain response and or adverse effects. Several reports of fatalities after codeine prescription in paediatric cases have been published in recent years.[74] The most striking report is that of the death of a breastfed 13-day-old neonate following a morphine overdose because his mother was taking codeine after childbirth.[75] Toxic blood levels of morphine or its active metabolite M6G may arise in mothers and neonates that are CYP2D6 ultra-rapid or extensive metabolizers. The mother was categorized as a CYP2D6 ultra-rapid metabolizer and her breast milk had a morphine concentration of 87 ng/mL—the typical range being 1.9–20.5 ng/mL at doses of 60 mg codeine every 6 hours. The infant was categorized as a CYP2D6 extensive metabolizer (extensively metabolizing the pro-drug codeine to morphine) and postmortem toxicology tests using gas-chromatography mass spectrometry revealed blood concentrations of morphine at 70 ng/mL. A daily codeine dose of 60 mg for postpartum pain normally results in maximum morphine plasma concentrations of 2.2 ng/mL in breastfed neonates[76] and neonates prescribed morphine for analgesia display serum morphine concentrations in the range of 10–12ng/mL.[77] Codeine and morphine clearance in breastfeeding mothers and their relation to *CYP2D6* genotypes have been extensively evaluated and commented on.[78–86] Since 2007, the US Food and Drug Administration (FDA) requires manufacturers of prescription codeine products to state in the 'Precautions' section of the drug label the risks of prescribing codeine to breastfeeding mothers.[87] An FDA-approved genetic test (AmpliChip CYP450, Roche Diagnostics, Palo Alto, CA, USA) is commercially available to test genetic variants of *CYP2D6*.[88] Overall, the level of evidence linking gene variation (*CYP2D6*) to phenotype (increased biotransformation of

**Table 52.2** Codeine therapy recommendations based on CYP2D6 phenotype

| Phenotype | Implications for codeine metabolism | Recommendations for codeine therapy | Classification of recommendation for codeine therapy |
|---|---|---|---|
| Ultra-rapid metabolizer (CYP2D5 activity score >2) | Increased morphine formation<br>Higher risk of morphine toxicity | Avoid codeine use (potential for toxicity)<br>Consider alternative such as morphine or non-opioid<br>Consider avoiding tramadol | Strong |
| Extensive metabolizer (CYP2D6 activity score = l–2) | Normal morphine formation | 15–60 mg every 4 h as needed for pain<br>(label recommendation) | Strong |
| Intermediate metabolizer (CYP2D6 activity score = 0.5) | Reduced morphine formation | Start at 15–60 mg every 4 h as needed for pain<br>If no response, consider alternative analgesics<br>Monitor tramadol use for response | Moderate |
| Poor metabolizer (CYP2D6 activity score = 0) | Greatly reduced morphine formation<br>Insufficient pain relief | Avoid codeine use (lack of efficacy)<br>Consider alternative such as morphine or a non-opioid<br>Consider avoiding tramadol | Strong |

codeine into morphine) is significant; however, there is no randomized clinical trial assessing the benefits of genetic testing prior to codeine therapy at large. In addition, while insufficient morphine formation from codeine resulting in failure of analgesia can currently be well predicted, extremely high morphine formation still requires the effort of combining genotyping with phenotyping.[89] Finally, the CIPC published guidelines in 2012 based on a focused review and interpretation of the literature by experts in the field (Table 52.2).[7] Because of a wide inter-ethnic genotype distribution not only for CYP2D6 but also of most SNPs assessed in this chapter (Table 52.3), it is important to identify the cohorts in which pharmacogenetic effects and genetic association have been reported, and avoid generalizing findings from one study to different ethnicities.

## Conclusion

Overall, whether in the perioperative period or in a more chronic setting, defining relevant clinical outcomes in pain and analgesia studies—or, in other words, identifying meaningful differences in pain perception and opioid response—remains the problem to solve; [25] this has proven to be even more complex in the context of obstetric pain.[22,90] Phenotyping is key in all association studies and designing clinical studies to assess the genetic contribution to pain is challenging. In addition, interpreting results, particularly when multiple genes are evaluated, requires large sample sizes and appropriate statistical analysis to avoid misconstrued findings.[91,92] Last but not least, the genetic contribution to labour pain or even that of pharmacogenetics to explain differences in analgesic response is probably not simple and straightforward,[90] and we are at the beginning of our explorations. On the positive side, these pharmacogenetic studies have enlightened us and have taught us that one should no longer design clinical studies with the sole goal to find 'the one dose for one drug that will fit all' because genetic variants do influence drug response in ways that have clinical implications. Unfortunately, firm recommendations to tailor opioid regimens based on patients' individual genetic profile are not available and are unlikely to become available in the near future other than for the prescription of codeine.[93]

The concept of mathematical modelling of labour progress is certainly promising, and may in the future allow identification of some of the genetic contributions that are important for the progression of labour and the risk for dystocia and will perhaps one day predict labour outcome and labour pain perception. Large prospective studies, well designed, and interpreted with the necessary caution are needed to thoroughly investigate this fascinating topic; meanwhile genome-wide association studies or exome sequencing to examine well-known and yet undiscovered genetic variants resulting in women being outliers for the various phenotypes during labour will be of interest.

# CHAPTER 53

# Simulation

Mark Wigginton, Miguel Garcia, Timothy J. Draycott, and Neil A. Muchatuta

## An introduction to simulation

Simulation enables healthcare professionals to acquire knowledge, attitudes and skills in an environment that is safe both for them and for patients. It is 'a technique to replace or amplify real-patient experiences with guided experiences, artificially contrived, that evokes or replicates substantial aspects of the real world in a fully interactive manner'.[1]

*Primum non nocere*: 'Above all, do no harm'. This cornerstone principle of medical practice is undone when patients are exposed to avoidable error.[2] In 1999, the Institute of Medicine in the United States produced the landmark report *To Err is Human* which revealed that up to 98,000 deaths a year occurred as a consequence of medical error.[3] Medical simulation aims to reduce errors by improving individual and team performance, and offering the opportunity to improve systems. In obstetric anaesthesia, simulation has been used widely from routine task training to multidisciplinary teamwork training for high risk, rarely occurring events.[4]

## History of simulation

It is a common misconception that simulation training in anaesthesia, obstetrics, and medicine is a late twentieth-century concept that has been refined and improved to produce the high-fidelity mannequins in use today. On the contrary, the history of simulation has a long and complex story, to the extent that much of its earliest use has been irrevocably lost to time. When reviewing the history of simulation for which records still remain, it is useful to make a distinction between purely anatomical models and those interactive simulation models that allow an element of feedback to the trainee.

### Anatomical models

Anatomical stone sculptures exist from approximately 24,000 years BC but it is difficult to separate the educational value of early models from their likely artistic, religious, or entertainment objectives.[5] The ancient Egyptian and Mayan civilizations produced partially dissected human models in a variety of media displaying good knowledge of anatomy but their use was most likely to be spiritual in nature.[5] Similarly, *memento mori* are carved dissected or skeletal figures, popular throughout the eighteenth and nineteenth centuries, intended primarily as a reminder of the transient and fragile nature of life.[5]

The first anatomical models used specifically for medical training purposes were probably from the Chinese Song dynasty. Wang Wei-Ye (987–1067), the imperial physician, was responsible for standardizing the teaching of acupuncture. He commissioned two life-sized bronze figures with organs; it is believed that the figures were then covered in wax. Students would have to identify acupuncture points from the surface anatomy, and were rewarded if the needle passed through a hole in the bronze structure and emerged with a drip of fluid from the mannequin.[5]

The European development of anatomical models was stimulated by the publication of *De Humani Corporis Fabrica Libri Septum* by Andrea Vesalio in 1543.[6,7] The artistry of wax and bronze models produced after this time compares favourably with models of today. A detailed understanding of anatomy was considered essential training for renaissance artists. Therefore, throughout the seventeenth and eighteenth centuries, European medical students were instructed using *écorché* ('flayed man' models) in addition to cadaveric dissection.[7] By the end of the seventeenth century, the use of polychromatic wax in decaying figures created by Gaetano Giulio Zumbo were said to be so realistic as to 'evoke a sense of overwhelming stench'.[5]

The practice of casting anatomical detail in a variety of media has continued. In some cases, pathological details were cast directly from patients. Wealthy medical schools across the world have built up large collections; some are still used for teaching purposes, whilst others have been consigned to antiquity.

### Interactive models

To practise a specific task, or to evaluate the consequences of one's actions using simulated physiology, is clearly an entirely different concept to pure anatomical teaching. What we might now refer to as task trainers or physiological simulators are intended for this purpose. These creations frequently appear far simpler in outward appearance than anatomical models but the ingenuity of internal design or their suitability for a specific training need is what gives them value.

Obstetric simulation has a particularly rich history in the development and widespread use of task trainers. The eighteenth and nineteenth centuries were a prolific era with the introduction of the first simulators to address an identified training need, and also the first recognized regional simulation programme. In 1739, the first British maternity hospital opened with a promise that the students would be taught using an obstetric simulator whereby 'all the inconveniences which might otherwise happen to women from pupils practising too early on real objects will be entirely prevented: for by this method and contrivance each pupil will become

in a great measure proficient in his business before he attempts a real delivery'.[5]

Mid-eighteenth-century surgeon Giovanni Antonio Galli was concerned that surgical trainees had theoretical knowledge but limited practical experience and that the midwives assisting with births may also have very limited practical experience. He developed a birthing simulator consisting of a glass uterus in a pelvis with a flexible fetus. This was designed specifically to address a training need and was also used for assessment as students were made to deliver the fetus blindfolded.[5]

No history of simulation could be considered complete without mentioning Angélique Marguerite Le Boursier du Coudray. Tasked by Louis XV to stem the decline in the population of rural France, she developed and ran two-month courses comprised of 40 sessions with an accompanying course manual. For practical training she developed life-sized mannequins with removable uterus, interchangeable nulliparous and multiparous os which could simulate dilatation by means of a silk drawstring, and sponges which released red or clear fluid to simulate blood or amniotic fluid. From 1760, Madame du Coudray toured the country for two decades with her 'machines' and, to facilitate repeated training, left courses running in various places with regional supervisors.[8]

By 1831, we have evidence of sophisticated obstetric simulators in use which are in many ways comparable to some of today's high-fidelity models. Dr Ozenne presented to the French Royal Academy of Medicine a whole-body simulator that had a uterus with radial and longitudinal fibres able to contract. The strength and rate of contractions could be controlled manually. It also had an amniotic sac and an artificial fetus with fontanelles.[5]

By the latter half of the nineteenth century, obstetric simulation had made its way into American medical schools. However, by the start of the twentieth century, damning reports were published on the state of simulation equipment around the country. The *Medical Education in the United States and Canada* report, published in 1909, referring to Southwestern University Medical College, Texas, remarked 'in a corner of one [lecture theatre] is an abused manikin'.[9] This comprehensive report was critical of large sections of the North American medical school system, and served as a damning indictment of medical education as a whole. These attitudes towards medical education were reflected in a neglect of simulation as a teaching modality. An era sometimes referred to as 'the dark age of simulation' began. For much of the twentieth century medical advances were made by practice on real patients. Mistakes and adverse outcomes may have been commonplace but it is difficult to be critical when materials and facilities were made scarce by the ravages of two worldwide conflicts.

During the second half of the twentieth century, there was recognition that significant improvements in safety achieved by the airline industry came as a result of highly technical and realistic simulation training.[10] Medicine again looked to simulation in order to emulate these safety improvements. Resusci-Anne is a mannequin developed by Laerdal, a toy manufacturer, in the 1960s.[11] It has been widely used to teach cardiopulmonary resuscitation (CPR) since then and probably represents the early stages of a simulation resurgence that has subsequently gathered pace and momentum. The 1960s also saw the development of the first computer-controlled patient simulator; although Sim One, as it was called, may have been ahead of its time and never became commercially available.[12]

Since then simulation centres, point-of-care simulation, multidisciplinary team training, and physiological remote-controlled mannequins have become commonplace terms in the burgeoning simulation field. Up-to-date educational theory is now incorporated into courses and instructors are tutored on effective methods of instructing. There is a small but growing evidence base for the usefulness of simulation in reducing adverse events and improving outcome, as well as evidence of its limitations.[13–16] To refer to the latest simulation technology as high-fidelity leaves little scope for superlatives to describe future innovations in a rapidly evolving field. Medicine, art, engineering, and computer technology have come together, working in synergy to produce experiences as close as possible to the real thing. Nevertheless, the human body is potentially the most complex and heterogeneous machine known. To simulate it fully will take many more years of development, and could well prove impossible.

## Simulation technology for obstetric anaesthesia

Simulators provide the physical interface between the simulation and its user. Whilst simulators are commonly thought of as a piece of expensive high-technology equipment, tools for simulation form a wide spectrum. At one end are increasingly complex, computer-driven mannequins that can replicate maternal anatomy, physiology, and pathology; at the other are verbal techniques, such as role-play and narrative discussions.[17]

Simulators can be categorized in a number of ways, such as by the way the user interacts with them, by the skill they are used to examine, and by the participants involved.[18–21] Gaba described a spectrum that is based on the technology employed:[17]

- Verbal (role play)
- Standardized patients (actors)
- Part-task trainer (physical or virtual reality)
- Computer patient (screen based)
- Electronic patient (mannequin based)

There have always been examples that cross between these categories, and the march of modern technology is blurring the boundaries still further. Each technique has its own particular advantages, and their relative strengths and weaknesses will help the operator decide which best to employ.

### Role play

Verbal role play forms the basis of much of the teaching that occurs in labour wards and obstetric theatres on a daily basis, such as getting a trainee to work through an invented problem or discussing 'what ifs'. By projecting a mental scenario for the learner to temporarily inhabit, the trainer can achieve many of the benefits of a full-scale simulation without relying upon a physical simulator or props.

### Standardized patients

Standardized patients, or patient actors, are people who have been coached to portray a specific patient. They appear in medical education literature from the early 1960s[22] and are most commonly

used to teach communication skills, although they can also used to teach clinical skills.[23] One of the recent drivers for their use in medical training is an increasing focus on the patient's perspective of the medical care they receive.[24]

Using a patient actor can be at least as effective as using a high-fidelity mannequin. In one study of eclampsia training, groups trained with a patient actor and those trained with a high-end simulator both improved their performance to a similar degree.[25] The same investigators looked at the simulated management of postpartum haemorrhage, where training using patient actors and mannequins were compared.[26] Again the teams improved similarly in terms of clinical outcomes, but the perception of safety and communication were significantly improved in the group trained using a patient actor.

Standardized patients enable a degree of fidelity that is not currently possible with mannequin technology. They can be used to simulate a wide variety of physical findings, although there can be limitations in their use in terms of performing invasive or embarrassing procedures. More recently, patient actors have been combined with part-task trainers to enhance fidelity and patient interaction whilst performing medical interventions, thus creating a convincing learning environment.[27,28] An obstetric part-task trainer has recently been developed which has been specifically designed for use with patient actors (Figure 53.1). It can be used to replicate a variety of obstetric conditions such as postpartum haemorrhage, and further blurs the boundary between patient actors, part-task trainers, and mannequins.

The efficacy and cost-effectiveness of standardized patients, especially when combined with part-task trainers, is an important consideration during times of budgetary constraint. This is particularly true in the developing world, where access to expensive technology is impractical, but effective training is particularly crucial.[29]

## Part-task/skills trainers

Part-task trainers are simulators that recreate only a portion of the process or system being examined. They are traditionally used to practice psychomotor skills, but have also been successfully employed to improve higher-level skills such as teamwork and clinical judgement. They have been used to allow the participant to focus upon a particular facet of a scenario, thereby building simple tasks into a complex skill.[30] Part-task trainers are available in a range of levels of complexity; an example of the lowest level could include using the palm of the hand to simulate structures in the palate encountered whilst inserting a laryngeal mask airway,[31] whilst highly complex examples include some virtual reality devices. They can be used for a number of applications relevant to obstetric anaesthetists:

### Epidural trainers

Epidural insertion is a core obstetric anaesthetic skill, and many trainees learn or refine their skills whilst on the delivery suite. A simulated spine has the potential to allow novices to safely practise epidural insertion without putting patients at risk. A number of homemade and commercially available devices have been described,[32–34] although few studies have evaluated them against alternatives means of training. One study compared the use of a homemade device with a high-fidelity mannequin to train junior anaesthetists in epidural insertion, and then went on to observe them carrying out epidurals on patients.[35] They were able to show that the homemade version was as good for training as the high-end device.

**Figure 53.1** Example of an obstetric part-task trainer that can be combined with a patient actor to enhance simulation fidelity.
Reproduced with permission by Laerdal.

Although no study has yet established whether there is an advantage to training with an epidural trainer over traditional patient-based training methods, one study of junior physicians training for lumbar puncture showed improved skills after training with a similar device.[36]

### Estimating maternal haemorrhage

Maternal haemorrhage remains an important cause of maternal death in the United Kingdom,[37] and is a leading cause of preventable maternal death worldwide.[38] The successful management of obstetric haemorrhage relies upon an accurate estimation of blood loss. Studies have shown that clinicians underestimate blood loss using visual inspection by as much as 33–50%.[39] Simulation has been used both to demonstrate this discrepancy, and to train staff in how to better recognize the degree of haemorrhage. Bose et al.[40] used simulated stations (Figure 53.2) to replicate the blood lost at the time of delivery; all groups underestimated, with their assessments becoming less accurate with worsening degrees of haemorrhage. Toledo et al.[41,42] demonstrated that simulation stations, both live and web-based, could improve the estimation of blood loss to a clinically insignificant degree of error. However these improvements decayed by 9 months, suggesting that training of this nature needs to be regularly repeated.[43]

### Airway trainers

A decline in the use of general anaesthesia for caesarean delivery,[44,45] and the increased risk of failed intubation in the obstetric population,[46,47] means that maintaining competent airway skills in this setting is especially vital. Simulators have been used

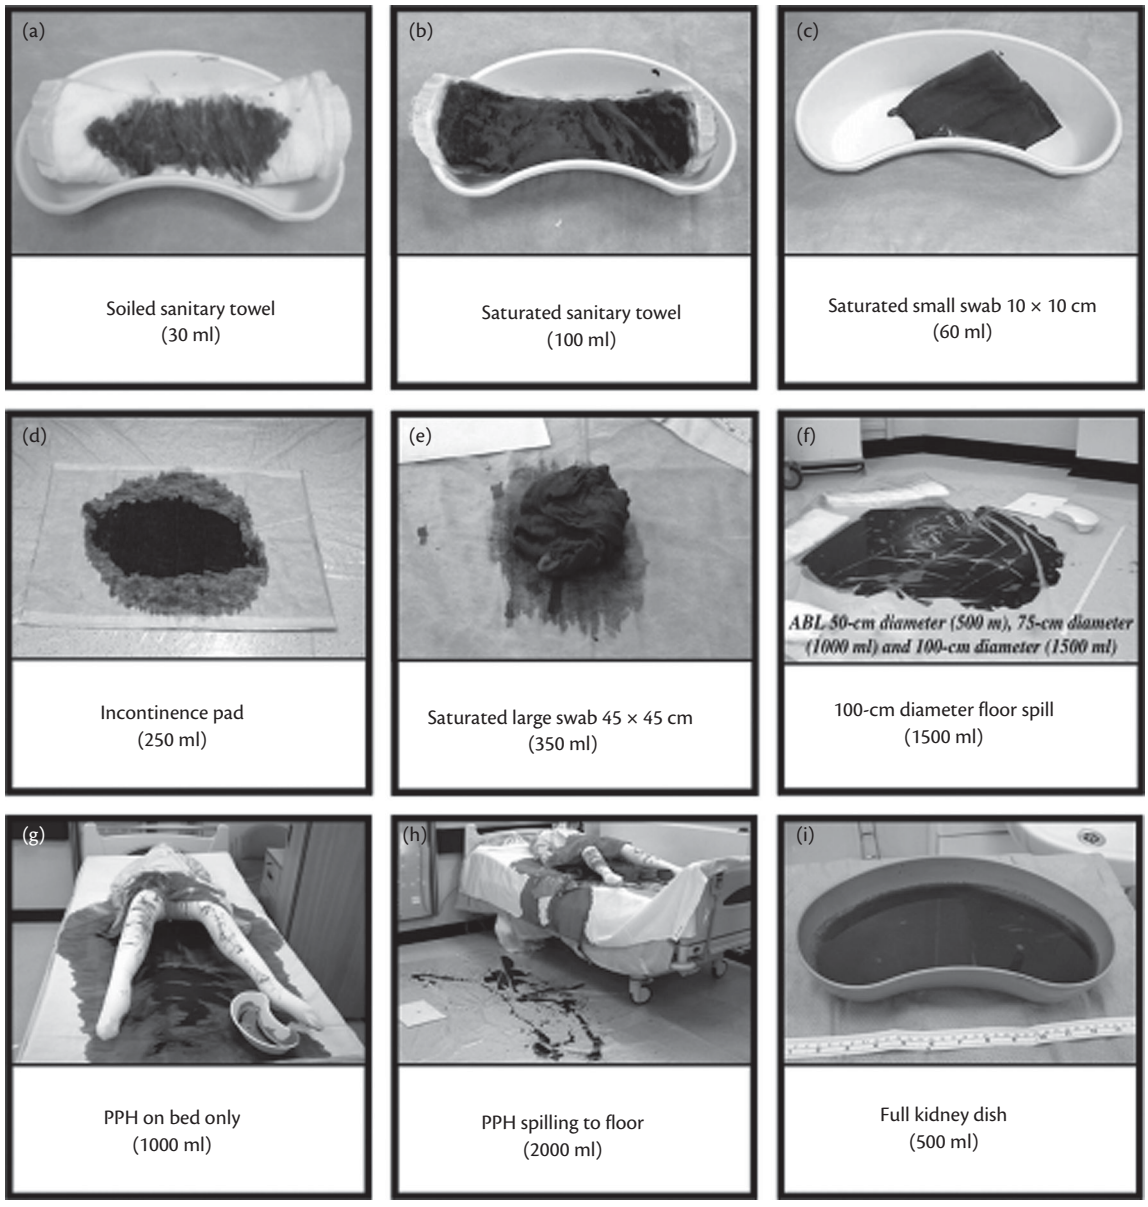

**Figure 53.2** Simulation tools used to replicate varying degrees of obstetric blood loss.

to assess and train all aspects of airway management relevant to obstetrics, including to teach the correct application of cricoid pressure.[48]

Goodwin and French [49] used a part-task simulator to assess trainees' management of failed intubation during caesarean delivery. The initial results were mediocre, but improved significantly following training using the simulator. Similarly, using simulators to train for cricothyroidotomy in the event of 'can't intubate can't ventilate' scenarios improved anaesthetists' management of this life-threatening crisis,[50,51] including with real patients.[51] Investigators have found that a single simulation session improved skills for at least 1 year in one study,[50] although this degree of persistence of learning has not been replicated universally.

There are numerous airway trainers available, with complexities ranging from a disposable plastic coffee cup[52] to high-fidelity devices designed to replicate all aspects of airway anatomy. Truly accurate replication of airway anatomy may not be achievable even with the most expensive devices;[53] however, current evidence suggests that it is the quality of the training, rather than the technology employed, that allows effective learning to take place.[54,55]

### Cardiopulmonary resuscitation in pregnancy

Studies that have looked at CPR in pregnancy have demonstrated that even experienced clinicians have inconsistent knowledge,[56,57] and that the performance of CPR in simulated scenarios is often poor.[58] However, there is evidence emerging that simulation can be successful in improving the management of simulated maternal cardiac arrest,[59] and possibly in the management of cardiac arrest in real patients.[60] As a result there are calls to further improve resuscitation in pregnancy by developing a simulation-based life support course especially designed for obstetrics.[61] MOET (Managing Obstetric Emergencies and Trauma) is one such course, and has been credited with improving knowledge of managing obstetric emergencies and contributing to an increased use of perimortem caesarean delivery at maternal cardiac arrest.[60]

### Ultrasound for epidural insertion

The use of ultrasound is becoming ubiquitous in anaesthesia, and the National Institute for Health and Care Excellence (NICE) in the United Kingdom has suggested that it might be helpful in achieving correct placement of epidural catheters for labour.[62] Evidence suggests that 'phantoms', part-trainers for the acquisition of skills in ultrasound-guided techniques, can facilitate the training of anaesthetists in ultrasound for regional anaesthesia.[63] Further research is needed to see whether the phantoms for epidural insertions that have recently been developed can be successfully used in obstetric anaesthesia.

### Virtual reality devices

Virtual reality simulators, in which screens or specialized headsets replicate a physical environment, have been used successfully to train surgical trainees and interventional radiologists for real operations and procedures.[14] Their earliest application within anaesthesia came in the form of vascular access trainers,[21] and they are now used to train for airway management, resuscitation, and spinal anaesthesia.[64–66] One of the pitfalls of virtual reality simulations has been providing convincing haptic (touch) feedback, which is becoming a key area of research and development.[67] Whilst still a relatively nascent form of technology it holds much promise, and further research will help determine its place amongst other available simulation modalities.

## Screen-based simulators

Screen-based technology has been used as a simulation tool in a number of ways, ranging from interactive tutorials to whole-body simulators.[21] Numerous websites provide access to simulation programmes, and simulation applications ('apps') for smartphones and tablet computers are now becoming well established. The use of electronically supported learning ('e-learning'), which often includes elements of simulation, has also become widespread within medicine.

The use of screen-based technology seems to provide more effective learning than traditional didactic teaching when preparing for the successful management of medical emergencies.[68–70] It has also been used successfully as a bridging tool for learners before exposing them to a higher-fidelity environment.[68] Indeed the technology has the potential to be at least as effective as highly complex simulation mannequins when training for certain key anaesthetic emergencies.[71]

The widespread use of smartphones and tablets has increased the accessibility and portability of simulation technology significantly, with many apps that support simulation being free or readily affordable. They can also be effective, with studies showing that they can help improve resuscitation skills over traditional teaching methods.[72,73] Some apps allow a smartphone or tablet to replicate a patient monitor, thereby allowing users to create a high-fidelity environment using a low-fidelity mannequin.[74] Such accessible, portable, and affordable technology has the potential to transform the way that simulation is delivered, although its familiarity should not prevent application-based tools being assessed and researched as vigorously as any other simulation modality.

## Mannequin-based simulators

The use of patient mannequins has a long history in obstetrics, as the life-sized mannequins used by Madame du Coudray to teach the art of childbirth to doctors in the eighteenth century French court attest. The use of highly technological mannequins to deliver simulation for anaesthesia has grown rapidly from Sim One, a one-off computerized patient mannequin designed and constructed in the 1960s,[12] to the plethora available from various manufacturers today. As mannequin technology has expanded and become more complex, the taxonomy to describe them has become equally complicated.[21] Terms such as high- and low-fidelity are often described, but are variably used, and are often relative to the technology of the era.

All mannequins share the same basic hardware: a life-sized patient model. Those designed for use in anaesthesia typically have a realistic head, an airway that can accept airway devices and adjuncts, and lungs that can be ventilated. More complex models may also allow cannulation of peripheral, central, and arterial vessels; airways that can be manipulated to simulate airway obstruction and failed intubation; chests that permit decompression of pneumothoraces; and many more features. Modern mannequins for obstetrics may combine a full-body anaesthetic simulator with a female pregnancy simulator (Figure 53.3), further enhancing the realism as well as making multidisciplinary interaction more practicable.

**Figure 53.3** Example of a high-fidelity obstetric and anaesthetic mannequin.
Reproduced with permission by Laerdal.

The software that drives the simulation can also vary in complexity. Many mannequins have no intrinsic software; they rely on the use of display screens, verbal cues, pre-prepared graphics, or other simulating devices to present their physiology.

For mannequins that do have software, the physiological parameters are usually computerized.[21] These can be script-controlled, where the changes occur according to a predetermined script or plan, and can be altered in response to the interventions of the participant. This allows the user to retain a degree of control of the simulation and its intended objectives. Alternatively they can be model controlled, where a mathematical model determines the mannequin's physiology and its response to interventions. This can result in a more accurate physiological response, but is sometimes unpredictable and therefore having a manual override available may be helpful.

## Fidelity

Fidelity is the degree to which a real environment is simulated.[75] This can be applied in a number of domains, of which the simulation tools themselves form only one part (Figure 53.4). Therefore simulation technology on its own cannot be the key to successful simulation. Equal thought needs to be given to the environment in which the simulation occurs, and the preparation of the participants and those running it.

The ideal level of fidelity for effective simulation is unclear,[76] and most evidence would suggest that increasing the fidelity of the simulator itself does not improve the intended outcomes.[18,35,54,55,77] Concentrating on the complexity of the simulator may be the wrong priority: ultimately, it is the learning requirements that drive the choice of simulation tool. The key to effective simulation is in successfully marrying these.

## Conclusion

As technology advances, the options available for simulation are increasing exponentially. Life-sized patient mannequins are able to replicate human anatomy and physiology with ever increasing levels of accuracy and sophistication. Innovative uses for patient actors, part-task trainers, and combinations of both continue to be found. However, it is within screen-based technology that the next explosion of developments is likely to emerge. Smartphones

and portable computing devices have become commonplace in healthcare environments, and developers are feeding the frenzy for novel ways to incorporate them into simulation. Since the programming software that creates applications is relatively accessible, this places the future of simulation technology into the hands of people who run simulation.

This is a responsibility as well as an opportunity. The choice of simulation tool must be determined by the learning objectives, and evidence needs to be sought as to how this technology should best be applied. Further research needs to focus on how best to apply the myriad tools available within simulation to improving patient outcomes.

## Simulation delivery methods

### Simulation centres

Simulation can take place in specifically purpose-built facilities or in any other space refurbished or adjusted to accommodate a simulation facility. Simulation centres are expensive to build and develop. They can usually accommodate many different types of simulation training such as part-task training, full-scale mannequins, and computer-based simulation. In addition, more advanced simulation training for laparoscopic procedures, robotic surgery, or using virtual reality devices may also be available. They sometimes focus on different specialties depending on clinical leadership, local interests, and politics.[78] The Swiss Centre for Medical Simulation at the University Hospital in Basel, Switzerland was amongst the first simulation centres to be established in Europe in 1994.[79] Since then simulator centres have become commonplace, and are available in most major cities in the United Kingdom.

Simulation centres can vary from single rooms placed within a hospital to an entire building with rooms that accommodate different methods of simulation delivery. Rooms designed for full-scale simulation are often flexible allowing them to be converted into different areas such as theatres, emergency resuscitation rooms, or ward bays. This flexibility allows setting up multiple scenarios when performing simulation. Rooms are usually equipped with functioning oxygen and suction equipment. The simulation room may have video and audio links to a control room, which is typically fitted with a one-way mirror (smoked glass) so that the operator or simulation technician can visualize the entire room. Whilst the scenario is being run, the operator can manage the mannequin's physiology, control its voice, and allow the simulation to respond appropriately to the participant's actions. Video and sound equipment are often used to capture images in order to give feedback to participants. Multiple video camera recordings can be synchronized with monitor readings to make the debriefing process more efficient.[80]

### Simulation *in situ*

*In situ* simulation is arguably as old as the medical profession where apprentices would be observed interrogating patients, following the instructions of their masters. In modern medical educational terms, *in situ* simulation is simulation that is physically integrated into the normal clinical environment. *In situ* simulation has enabled the transfer of simulation into hospitals; this allows the potential benefits of training using the environment, equipment, and clinical teams that might be encountered when dealing with real patients. *In situ* training has the potential to enhance individual and team learning experiences, with the additional benefit of allowing organizations to test their safety systems without exposing patients to potential harm.

One of the main advantages of *in situ* simulation over the use of a simulation centre is its low cost. Compared with traditional simulation, it often involves a wider range of participants, potentially including allied health professionals, porters, clerks, and administrators. In contrast with simulation centres, the primary audience is usually practising providers rather than trainees.[81]

Simulating in the normal working environment has the potential to unmask organizational factors that contribute to latent errors, thereby promoting a culture where safety is paramount.[82] It has been shown to be an effective tool to improve organizational performance in trauma as shown by Steinmann and colleagues, with a 76% improvement in task completion and 16% improvement in resuscitation times.[83] It has also shown benefits in obstetrics: Riley and colleagues showed a reduction in perinatal mortality in hospitals trained with *in situ* simulation alongside teamwork training, when compared to hospitals who trained with the teamwork training alone.[84]

In the United Kingdom, the SaFE study (Simulation and Fire drill Evaluation) compared training for obstetric emergencies using high-technology training at simulation centres with *in situ* training. Both teams improved their performance after training. However, training in the simulation centre conferred no additional benefit. Following the SaFE study, the investigators continued to do their obstetric team training *in situ*. Their continued use of in-house simulation has been credited with a reduction in brachial plexus injuries in neonates born following deliveries with shoulder dystocia.[85] Since instituting the training, they have also found a reduction in babies born with low Apgar scores and a decreased incidence of hypoxic-ischaemic encephalopathy.[86–88] This is a powerful demonstration of the potential for successful *in situ* simulation training to translate to improved patient outcomes.

## Simulation as a teaching tool

Teaching professionals can be difficult, and using simulation as a teaching tool for professionals is a potentially complex issue. Unlike schoolchildren, adult learners attending a simulation course often do so because they want to learn and improve their skills. They are invariably highly motivated. The common mistake made when teaching professionals is to assume that a lack of learning is due to a lack of motivation and therefore a little inspiration (i.e. simulation) will solve the problem. In fact, perhaps more than any other modality of teaching, simulation must have a secure footing in educational theory. Candidates are placed in potentially stressful situations; they may be tested beyond their current level of expertise in the company of their peers. This combination of circumstances can be potentially damaging. Professionals are used to being successful; consequently they can have great difficulty learning from their own errors. Reactions to errors made in stressful situations include anxiety, embarrassment, and 'defensive reasoning'.[89] Defensive reasoning describes the action of justifying errors by looking at them as the inevitable result of external circumstances or the actions of others. The term was coined by Chris Argyris, an acclaimed educational thinker. Much of his educational theory is relevant to simulation, as are other educational theories too numerous to cover fully here. However it is possible to

illustrate with examples some of the educational theory relevant to teaching with simulation.

Behaviourism describes perhaps the most basic of learning strategies; the classic example being Pavlov's conditioning experiments in which the association of the sound of a bell with food eventually lead to the physiological response in dogs of salivation at only the sound of the bell.[90] Operant conditioning introduces the concept of reward and punishment. If an operator performs a task repeatedly and receives reward for doing so then they are conditioned to perform that task again in the same way. This way of learning can often be seen when using task trainers.

Obviously, this is an oversimplification. Cognitive learning, where conceptual knowledge and experience from other areas influence the learning process, also plays a role. Nevertheless, it has been demonstrated that even novice practitioners, who would be expected to have a limited internal cognitive structure upon which to base the learning, will increase their skill at performance on a task trainer with repeated attempts. Crucially though, this does not necessarily translate to increased skill at performance of the task on real patients. Clearly real patients are much more heterogeneous than the average part-task trainer.

One might expect that the higher fidelity the trainer is, the more likely it would be to increase performance on real patients. This is not necessarily the case; Freidman and colleagues[35] took 24 anaesthetic trainees and randomized them into two groups. One group received epidural training with a high-fidelity, anatomically correct, commercially produced simulator that was coupled with a virtual reality display of the needle progression. The other group practised their loss-of-resistance technique by inserting needles into a banana. Blinded expert examiners, utilizing a validated manual skills checklist and global ratings scale, found no difference in subsequent performance of epidural insertion in actual patients between the two groups.

Simulation is often used to increase a participant's knowledge or to train them for a particular skill. It can also be used to train teams of clinicians in crisis resource management (CRM) or 'human factors' training. This type of training has gained popularity due to the realization that decision-making, interpersonal behaviour, and team management can have just as significant an effect on outcome as an individual's knowledge of the algorithms involved.[91]

Different teaching modalities tend to suit different learning environments, candidate selection, and scenario set-up. For example, whilst running knowledge-based teaching scenarios, candidates that will be involved in the scenario at a later stage can benefit from being wallflowers in the room. Conversely, for CRM or human factors training, part of the educational objective is often to examine the flow of information through different members of the team. Obviously this will not happen in a realistic manner if a candidate has been in the room watching the scenario unfold. However, regardless of the simulation modality, the mechanism of learning probably adheres to a similar structure.

In 1984, David Kolb published his experiential learning styles model.[92] It suggests that the learning process cycles through four separate stages and also that people have different learning styles (see Figure 53.5). Kolb proposed that in order to learn it was not sufficient to have the experience, but that reflecting on that experience is a necessity. Learners can engage in the learning process at any part of the cycle. The part of the cycle in which they are likely to engage, and the scale of this engagement, may relate to the type of learner. The Kolb cycle has been elaborated, augmented, and criticized since its inception. The stages may be less distinct than the cycle suggests and learners probably have many styles of learning rather than a clear predilection for one.[93] However, by mapping the stages of simulation to the Kolb cycle, it should be possible to engage all types of learners and complete the learning cycle.

As important as addressing people's learning styles and the learning cycle, is creating an environment in which learning is possible. Maslow's hierarchy of needs (Figure 53.6) is a well-established psychological theory, which asserts that for self-actualization to take place an individual must first have physiological well-being, feel safe, be satisfied in interpersonal relationships and have a sense of self-esteem.[94] It can be argued that many of our most vivid memories are from emotionally charged experiences where in fact we feel unsafe.[95] Indeed many clinicians might attest that much of the 'traditional' practice of medical teaching seemed to be based on seniors undermining their student's sense of self-esteem. Teaching by humiliation is thankfully dying out but, if set up incorrectly, simulation can be equally humiliating.

The aim of increased fidelity is to achieve a situation as close as possible to the real thing. Suspension of disbelief is a term used in the literary, film, and television industries. For example, if a viewer is not able to suspend disbelief and look upon something as 'real' then they will never truly engage with a film. Conversely, if they can view the action as real, then not only will the filmmaker be able to truly immerse them in the story, but may also elicit actual physiological and emotional responses along the way. The same is true for simulation. During high-fidelity simulation, candidates can become anxious and stressed, relieved when things go well, and frustrated even saddened when things go badly. The key is to be able to moderate these feelings to such an extent that learning can take place.

To help understand this there are a number of emotional models: Russell's circumplex model of affect is an accessible and useful example (Figure 53.7).[96] Studies have demonstrated that stimuli that create either an arousal or valence response can lead to increased memory retention.[95] Valence in this respect refers to a scale of positive or negative feeling. For example, feeling happy has a positive valance response, whereas feeling excited would have both positive valance and arousal. High arousal states can be as damaging to effective learning as those in the low end of the spectrum, such as sleepiness or boredom. If candidates become overstimulated by a perceived excess of information, their attention and focus can become narrowed to the extent that they miss the relevant teaching points of the scenario. So the aim is to create realism in simulation that stimulates both arousal and a positive emotional response; to design simulation that will be challenging, but not to the extent that anxiety interferes with the educational objectives.

An interesting case study in this regard is the Managing Emergencies in Paediatric Anaesthesia (MEPA) course that is in widespread use in the United Kingdom and now taught in several centres around the world. The scenarios for MEPA are based on real events and, as occurred in real life, if a certain cue is missed in a scenario, the stress level will build as the simulated patient progressively deteriorates. This can be frustrating, even distressing, for the candidate for whom the scenario is going badly. From the previous discussion it might be assumed that this situation

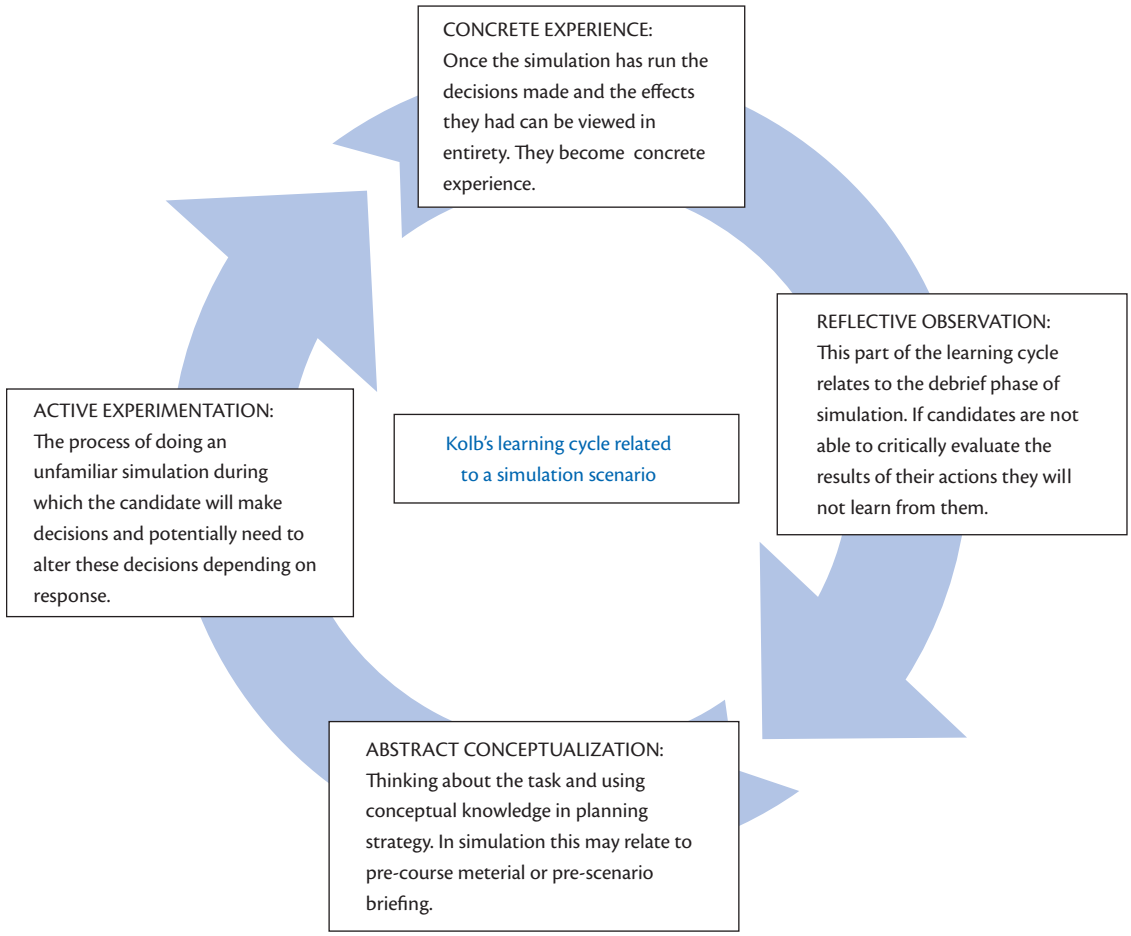

**Figure 53.5** Kolb's cycle of learning.
Kolb, David A., *Experiential Learning: Experience as a Source of Learning & Development, 1st*, ©1984. Printed and Electronically reproduced by permission of Pearson Education, Inc., New York, New York.

is less than ideal on a simulation course. However, the learning objectives of the scenario are to teach the cues for that particular adverse event, to localize the cause of the problem using a systematic method, and to warn of the dangers of task fixation in high-stress situations. Therefore, despite the poor outcome, the arousal and emotion has helped encode and consolidate the learning point. Nevertheless in the eyes of the candidate that outcome may be seen as a failure. As previously stated, professionals and high achievers can have great difficulty learning from failure. How then is it possible to address inevitable failures of judgement and action that will arise during simulation scenarios? This is achieved through debriefing.

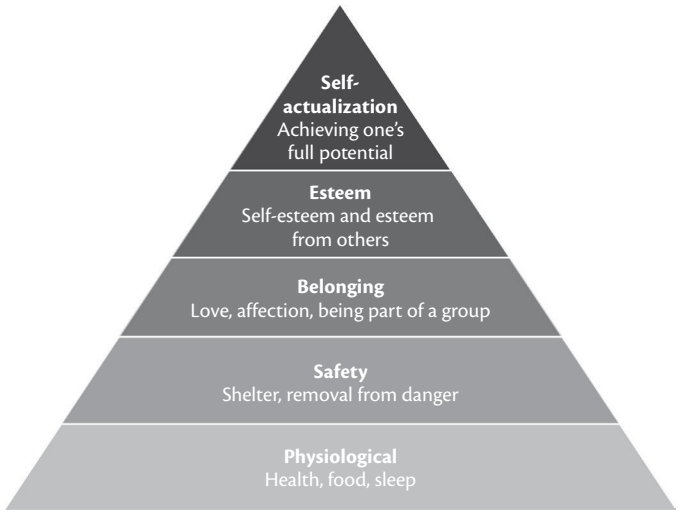

**Figure 53.6** Maslow's hierarchy of needs.
Maslow A, A theory of human motivation, *Psychological Review*, Volume 50, Issue 4, pp. 370–96, Copyright © 1943 American Psychological Association. Reprinted with permission.

The debrief is one of the most crucial aspects of simulation,[76,97] and as Kolb suggested, it is an integral part of the learning process. There are some basic practical points to be borne in mind when considering how to debrief effectively. From a time allocation perspective, an effective and thorough debrief should run for approximately the same duration as the scenario itself. Ideally it should take place away from the area of simulation so that candidates are not constantly distracted by the equipment and faculty setting up for the next group. From the instructor's perspective, the aim of the debrief is firstly to understand the candidates' perceptions of their own actions and then to understand their reasons for acting as they did, before facilitating a group understanding of how things can be done differently to achieve a different result.

This process is more complex than it sounds. Often when someone is asked their reasons for doing something, they will often respond with an 'espoused' theory.[98] That is, they respond with

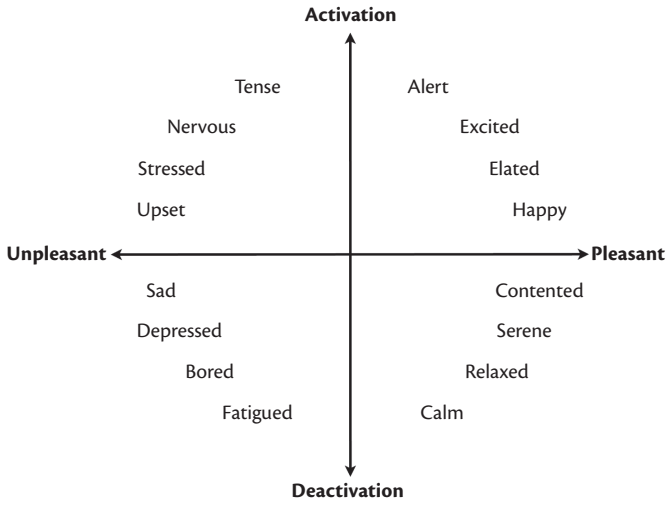

**Figure 53.7** Russell's circumplex model of affect.
Russell J, A Circumplex Model of Affect, *Journal of Personality and Social Psychology*, Volume 39, Issue 6, pp. 1161–78, Copyright © 1980 American Psychological Association. Reprinted with permission.

the theory that they think is the correct answer to the question rather than the 'theory-in-use', which is their underlying personal reason for their actions. For example, if an anaesthetic trainee is asked, 'Why did you use an ultrasound machine to identify vessels for central venous cannulation?' they may respond 'Using ultrasound for this purpose is associated with a reduced risk of inadvertent arterial cannulation'. Which is correct; but it is an espoused theory. The real reason may be that it is the only method they know for identifying the vessel location. To identify the theory-in-use is critical in order to understand the motivation of the candidates. Without an appreciation of a candidate's motivation, a debrief will be didactic and may never serve to change actions in real life.

In 2006, Jenny Rudolph et al. published a debriefing strategy they termed 'debriefing with good judgment'.[99] In essence, the instructor is advised to establish a genuine stance of curiosity in order to elicit the knowledge, assumptions, and feelings that drive the trainee's actions. Following this disclosure the instructor is then able to reframe those feelings and generalize them, which opens up the discussion making it relevant for the entire group, before examining ways of addressing the misapprehensions and if necessary altering behaviour.

Video debriefing has a particular role to play in CRM or human factors training scenarios. Candidates' perception of what happens in high-stress scenarios can differ significantly from that of the impartial observer. Video footage can illustrate this, sometimes quite spectacularly. For this, specialist equipment and a smooth information technology interface is required. Often there is insufficient time when debriefing to scroll through minutes of footage to find a particular incident. Despite the challenges, video debriefing has its enthusiasts.

Simulation as a teaching tool is the topic of various 'Train the Trainers' courses. Teaching theory, mannequin/equipment set-up and use, and lecture and debriefing skills are all covered to varying degrees. Such courses signal that the incorporation of educational theory into simulation design should now be considered a necessity for instructors.

## Simulation as an assessment tool

### Assessing healthcare providers

Assessments for healthcare providers are generally divided into summative and formative. Formative assessment is a self-reflective process that highlights an individual's strengths and weaknesses, and in simulation typically involves direct observation followed by feedback. Summative assessment is a formal assessment of learning with a specific end point and includes exams, accreditation, and revalidation.[100] Fitness to practice based on simulation assessment is a developing field but to date it is not supported by the current state of simulation knowledge and simulation should not be used with this purpose outside of research.[101]

The current literature of simulation-based assessments describes two main types of scoring, those for explicit process (i.e. based on marking each aspect of a performance) and those for implicit process (marking the process as a whole). Checklists are commonly used to assess explicit processes. Checklists denote the key actions that candidates should successfully accomplish in order to optimally manage the patient. These actions are predetermined by an experienced practitioner and are usually supported by recognized guidelines. Checklists have several limitations. Any single action might have the same weight in the final score, which may not take into account that certain actions are more important than others. Secondly, there is not usually a sequential order in which to achieve the different actions, and thus appropriate prioritization may not be rewarded. Finally, checklist scoring can prompt the candidate into quick-fire action in order to score as highly as possible.

Implicit process scoring is designed to grade the entire scenario in a holistic way, taking in to consideration many factors including non-technical skills. One of the advantages of this type of scoring is the freedom to make observations of overall performance and it is more appropriate for multidimensional complex scenarios.[102]

Studies comparing these two scoring modalities in simulation have found that they are equivalent in their ability to rank the ability of participants in simulation.[103] The main advantages of checklists are their simplicity to mark and their reproducibility. In practice, a combination of assessing implicit and explicit processes is used through a checklist of key actions, and global rating of non-technical skills in the different domains. This seems to be the strategy mostly used to assess participants in simulation.[104]

The use of assessment using simulation is developing rapidly. It is important that the assessment of a participant is reliable and reflects their capability in real clinical practice. Good candidates can be put off by simulation and perform below their abilities; some who are less able may actually do well in the simulation environment, especially as widespread use of simulation means candidates can be 'primed' from past experience during the same or similar scenarios. Before any summative assessment is put in place, rigorous quality assurance needs to be performed to ensure that its outcomes are valid.

### Assessing healthcare systems

Simulation-based assessment of healthcare systems is probably best done through *in situ* simulation. This can unmask latent errors within systems, and allow assessment of the interactions between different areas of the hospital such as laboratories and other support services in real time and place.[81]

More than half of the obstetric units in England and Wales conduct *in situ* simulation on a regular basis.[105] There is evidence that drill training improves readiness and reaction times during emergencies, and its frequent use can also improve the availability of equipment and drugs at the point of care.[101]

## Setting up a simulation programme

The construction of an effective and enduring simulation programme is rarely a simple and stress-free task. Frequently enthusiasm and good intentions are squandered, along with significant amounts of work, on programmes that either peter out soon after conception or indeed never get past the design stage. Unfortunately there is little empirical evidence to serve as a roadmap to a successful programme. However, testimony from experienced individuals involved in simulation around the world serves to outline the common pitfalls and obstacles encountered when putting a simulation programme together.

Firstly, be realistic with your aims. In a centre with no infrastructure, constructing a unique, self-funding, international programme of simulation may take decades or may even not be possible. On the other hand, a local programme, tailored to address specific issues within your unit could be achievable in a reasonable time frame. If targeted correctly, it could become invaluable and serve as a stepping-stone to future simulation development.

Avoid simulation for simulation's sake. Some individuals are simulation enthusiasts; some are not. Simulation is not the answer to all training needs. It is worthwhile remembering that a poorly constructed simulation can serve to worsen outcome. Expensive high-fidelity simulators are not always the best simulators to teach a specific task. Nevertheless, any type of simulation often necessitates a considerable investment in man-hours if nothing else.

Achieving and maintaining that man-hour investment can make the difference between a short-lived venture and a sustainable training tool, so the importance of involving and encouraging individuals who express enthusiasm for simulation cannot be overstated. If your institution has enthusiastic teachers and trainers, or if there is a local simulation centre, their involvement in the project can be invaluable. Conversely the inception of a simulation programme is not the time to convert sceptics to your cause; their cynicism is only likely to increase as the inevitable faults of a naïve programme are uncovered.

Once these initial considerations have taken place it is time to commit to a repetitive cycle of course or scenario development (Figure 53.8). Each individual stage helps to ensure a robust final product.

### Needs assessment

Your needs assessment might examine data from audit, critical incident reporting, feedback survey, or staff perceptions of inefficiency. There are many different models of systematic needs assessment; however, the key with regards to simulation is to be able to target resources with the aim of beneficially affecting outcome.

### Scenario/course design

The educational objectives will be determined by the needs assessment. The scenario/course design must draw on the educational theory in order to achieve these objectives. When constructing scenarios it is useful to use a scenario proforma. Not only does this aid in the construction of the scenario but it also enables

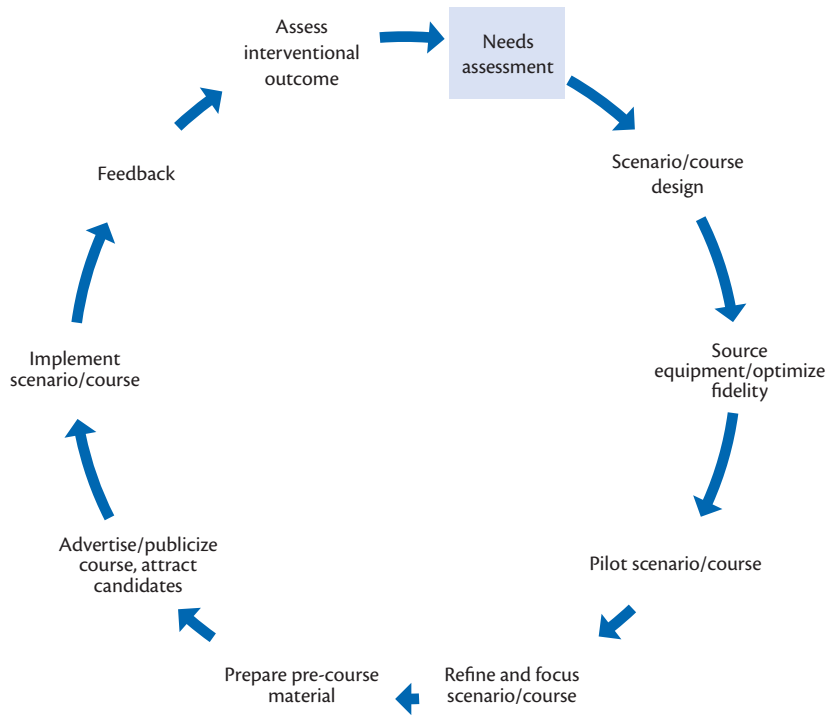

**Figure 53.8** The stages required to successfully set up a simulation programme.
Reproduced with permission from Dr. Peter Weinstock.

immediate quantification of the diversity of faculty and equipment required to run the scenario.

### Source equipment/optimize fidelity

Equipment may be available from local simulation or education centre. You may be able to borrow from other departments. You may also need to be creative to achieve the desired level of fidelity. Some caveats need to be remembered when sourcing equipment. If ward stock is used it must be documented and replaced so as not to leave clinical areas short of equipment. Similarly, particularly when using point-of-care simulation, a robust system must be in place to ensure simulation equipment is not confused with ward stock after the course has run, with potentially catastrophic consequences.

Attention must be paid to sources of danger in simulation as in real life. Sharps and drugs must be safely disposed of, defibrillators and other electrical devices must be managed appropriately. Also the use of cadaveric products should be carefully considered; cultural and religious objections should be borne in mind.

### Pilot the scenario/course

Test runs are important to iron out unanticipated glitches in the running of the course. These teething problems would otherwise have the ability to seriously detract from the course's educational value.

### Refine and focus the scenario/course

Following the pilot stage there may be areas that require redesign or elements that clearly need addressing. These should be implemented prior to launching the course.

### Prepare pre-course material

The type and scope of pre-course material will depend on various factors including the educational objectives of the course, time constraints for delivering the course, whether the scenarios are to form part of an assessment, and the ratios of human factors to skills and/or knowledge training involved in the course. Resuscitation courses now employ a large degree of online learning and formative assessment to be completed prior to attendance on their courses. This strategy has the advantage of allowing candidates to learn in their own time but crucially aims to ensure that candidates reach a baseline level of knowledge prior to participation. This sort of approach can be important for courses designed primarily to test knowledge and its application. Courses designed to test systems or involve a greater degree of human factors training might benefit from less detailed pre-course material.

### Advertise/publicize the course

Intrapartum update simulations have been shown to improve outcomes[106] but to achieve this they are run at least yearly and have 100% participation. If you wish to attract candidates from outside of your unit you will need to publicize your course. In order for that publicity to be successful your own needs assessment will have to be in line with the needs of the potential candidate.

### Implement the scenario/course

The faculty for early versions of the course is likely to comprise primarily of the development team. As the course evolves, it becomes increasingly important to develop flexible and motivated faculty members to help with the running and further development of the course. This faculty may be previous candidates on the course or staff with an interest in simulation and training. Either way, encouraging the involvement of new faculty will allow the course to be sustainable. Numerous 'Train the Trainers' courses are available to ensure that faculty is appropriately trained for the various simulation modalities that may be needed, and to ensure that they can deliver the sessions and the feedback in a standardized way.

### Feedback

Feedback from candidates and faculty is important to ascertain which parts of the course/scenarios are working and which need to be changed. This is also an appropriate stage to review which bits of simulation equipment require servicing or replacement.

### Assess the interventional outcome

There is precious little data on the ability of simulation training to change patient outcome. You should aim to demonstrate that the simulation course fulfils the original needs assessment. To facilitate this process establishing an audit trail alongside the training programme would be appropriate.

The process is cyclical. As the needs of training evolve, so does the course. As the course evolves, so does the course material and the faculty.

## The key elements of successful simulation

Whilst 'success' in simulation may be described in many ways, the intended outcome of most medical simulation is to improve patient outcomes. The other key component is a consistent demonstration of improved learning.

### Educational outcomes

Issenberg, McGaghie, and their colleagues have examined the outcomes of simulation-based medical education from 1969 onwards, through a systematic review of the published literature.[76,97] They have identified key features and best practices that are found in papers that given rise to effective learning. Those from their latest work, which covers 2003–2009, are summarized in Table 53.1.[107]

### Patient outcomes

Given that improving patients' outcomes is the primary aim of most medical simulation, it may seem surprising that there is a paucity of data to support the translation of simulation training into better clinical results.[14] Much of the published evidence demonstrates that simulation training improves performance in future simulations. Does this mean that clinical performance will also improve? And why are there so few data?

Part of the difficulty is that simulation is often geared to prepare for rare emergencies. Rare and unpredictable emergencies are challenging to monitor and capture, their outcomes are often hard to neatly encapsulate, and to ascribe a causal relationship between the clinical outcome and the training can be tenuous. Randomized controlled studies, the highest level of evidence, are difficult to perform in this setting and would likely require multicentre collaboration. Much of the evidence we do have comes from retrospective studies, and even here the discovery of improved patient outcomes has sometimes been fortuitous. However, there

**Table 53.1** Features and best practice for effective learning through simulation

| Feature | Relevance |
|---|---|
| Feedback given | The most valuable component for learning |
| Deliberate practice (expert-level learning) | Continuously challenges learners |
| Integrated into the whole curriculum | Complements other education |
| Outcomes measured | Required for valid research |
| Simulation fidelity appropriate | Technology should be matched to the learning objectives |
| Skill acquisition and maintenance | Repetition is needed to ensure the learning lasts |
| Mastery of learning | Accomplish *all* educational objectives |
| Transferable to clinical practice | Achieves a deeper level of learning[107] |
| Team training | In addition to clinical tasks |
| High-stakes testing | Simulation for summative assessment must be reliable |
| Instructor training | Ability to facilitate is not innate |
| Set in the learner's educational and professional context | Should be relevant to the leaner's needs |

Reproduced with permission from McGaghie WC, Issenberg SB, Petrusa ER, Scalese RJ, A critical review of simulation-based medical education research: 2003–2009, *Medical Education*, Volume 44, Issue 1, pp. 50–63, Copyright © 2010 John Wiley and Sons.

are a number of studies where simulation training has been shown to improve patient outcomes (Table 53.2).

With regard to obstetrics, eight key components are shared by all the hospitals in which obstetric training has yielded improved patient outcomes. These are summarized in Box 53.1.

It is challenging to identify the elements of training programmes that give rise to the best outcomes. This is especially true in simulation, where 'success' can be difficult to quantify, and the clinical denominator is often relatively low. No one can be certain precisely what is required in the ideal simulation recipe, nor in what quantities, nor how much 'cooking' is required, and how often. Using the above components is a good start, but more data needs to be collected about which training leads to improved outcomes in the real world.

Gaba has rightly argued that 'no industry in which human lives depend on the skilled performance of responsible operators has waited for unequivocal proof of the benefits of simulation before embracing it. In my opinion, neither should anesthesiology'.[111] However, unless more irrefutable evidence of real-world benefit is collected, there is a limit to how long we can continue to argue for the investments of manpower, time, and money that good quality simulation requires. Simulation in obstetrics and obstetric anaesthesia probably does save lives; those working in the specialty instinctively believe it, but there is also a need to produce high quality data in order to prove it.

**Box 53.1** The components shared by hospitals with obstetric simulation programmes that have led to improved patient outcomes

- Institution-level incentives to training
- Relevant, *in situ* training
- Non-threatening assessment
- 100% penetration: train the entire workforce
- Train in multiprofessional teams
- Clinical training and teamwork training combined
- Realistic tools (high fidelity rather than high technology)
- Self-directed infrastructural change: local solutions to national problems.

Data from Siassakos D *et al.*, The active components of effective training in obstetric emergencies, *BJOG: An International Journal of Obstetrics and Gynaecology*, Volume 116, Issue 8, pp. 1028–1032, Copyright © 2009 Jon Wiley & Sons

**Table 53.2** Examples of studies that have shown improved patient outcomes following simulation training

| Clinical improvement | Type of training |
|---|---|
| Improved Apgar scores in infants[15] | *In situ* multidisciplinary team training |
| Reduction in brachial plexus injury after shoulder dystocia[16] | *In situ* multidisciplinary team training |
| Reduction in hypoxic-ischaemic encephalopathy in infants[15] | *In situ* multidisciplinary team training |
| Safer insertion of central venous catheters[108] | Part-task training with screen-based teaching |
| Reduced catheter-related bloodstream infections from central venous catheters[109] | Part-task training with screen-based teaching |
| Reduction in complications during eye surgery[110] | Part-task training and structured curriculum |

Data from various sources (see references).

# CHAPTER 54

# Ultrasound

Sudhir Immani and John Loughrey

## Introduction

The use of ultrasound in medical practice was first reported in the 1950s with one of the first descriptions of its use in clinical anaesthesia practice dating back to the late 1970s.[1] A number of reviews have recommended its usefulness in anaesthesia.[2–4] The most obvious and current application for ultrasound for obstetric anaesthetists is in the improvement of the safety, quality, and success of neuraxial anaesthesia. The description of current technique comprises the main content of this chapter. Cork and Currie both published initial reports of ultrasound application for pre-neuraxial block landmark assessment in obstetric populations in the 1980s.[5,6] However, there remains a relative paucity of good data charting the developing utility of ultrasound in obstetric anaesthesia practice and many published studies are from a small number of enthusiasts (Table 54.1). In fact, to date there is only one meta-analysis on benefits of ultrasound-guided neuraxial procedures.[7]

There are other applications of ultrasound in obstetric anaesthesia practice including vascular access, cardiac assessment, and possibly even gastric volume assessment.

## Neuraxial blockade equipment

From the technical perspective, spinal ultrasound imaging is difficult, as the area of interest is protected by bone. As the ultrasound beam does not pass through bone very well, the acoustic window towards the area of interest is relatively narrow. Bony surfaces reflect most of the waves back so structures beyond bone are not 'seen' with ultrasound and a black/grey area is observed behind a thick white line on the image screen. High-frequency transducers produce high-resolution images but with poor tissue depth penetration as more sound is absorbed. Low-frequency transducers have greater tissue penetration but resolution is poorer. Most anaesthetists use a linear high-frequency ultrasound probe for superficial vascular access and brachial plexus anaesthesia. However, these probes are generally insufficient for neuraxial imaging. A curved or curvilinear array low-frequency (2–5 MHZ) probe provides depth penetration required for imaging the Ligamentum flavum(LF)–Dural (D)complex with some compromise on image quality. Linear probes can be programmed to utilize lower-frequency ultrasound, but usually down to a limit of 5–7 MHz.

## Basic vertebral anatomy

A review of the anatomy of the lumbar spine is worthwhile before highlighting the sonoanatomy of the spine.

A typical vertebra can be divided into two parts (Figure 54.1): the body and the arch. The vertebral arch is made up of the following elements: pedicles, laminae, transverse processes, spinous process, and the superior and inferior articular processes[8] (Figure 54.1).

The vertebrae articulate at the facet joints (zygapophyseal joints) between the superior and inferior articular processes and at the intervertebral discs between vertebral bodies. The posterior longitudinal ligament runs along the length of the anterior wall of the vertebral canal.

The LF is a dense connective tissue ligament that bridges the interlaminar spaces. It is arch-like in cross-section and is thickest in the midline. The LF attaches to the anterior surface of the lamina above but splits to attach to both the posterior surface (superficial component) and anterior surface (deep component) of the lamina below. The spinous processes are connected at their tips by the supraspinous ligament, which is a strong fibrous cord, and along their length by the interspinous ligament, which is thin and membranous.

Within the vertebral canal lie the thecal sac (formed by the dura mater and arachnoid mater) and its contents (spinal cord, cauda equina, and cerebrospinal fluid). The epidural space is the space within the vertebral canal but outside the thecal sac.

The anatomy of the epidural space is more complex than is frequently conceptually visualized by practitioners.[9] It is divided into anterior, lateral, and posterior epidural spaces with respect to the thecal sac, with the posterior epidural space being of most interest in neuraxial blockade.

The posterior epidural space is not continuous. Instead, it is segmented into a series of fat-filled compartments in the interlaminar areas. The lateral epidural spaces are located at the level of each intervertebral foramen and contain spinal nerves, radicular vessels, and fat. The primary structure of importance in the anterior epidural space is the internal vertebral venous plexus.

### The lumbar spine

The posterior surface of the laminae of the five lumbar vertebrae slopes in an anterosuperior direction (Figure 54.2). The spinous processes are broad and flat in the vertical dimension and project posteriorly, with only a slight inferior angulation.

**Table 54.1** Clinical studies assessing the utility of ultrasound relevant to the obstetric population

| | Study design | Methods | Findings |
|---|---|---|---|

Data from various sources (see references).

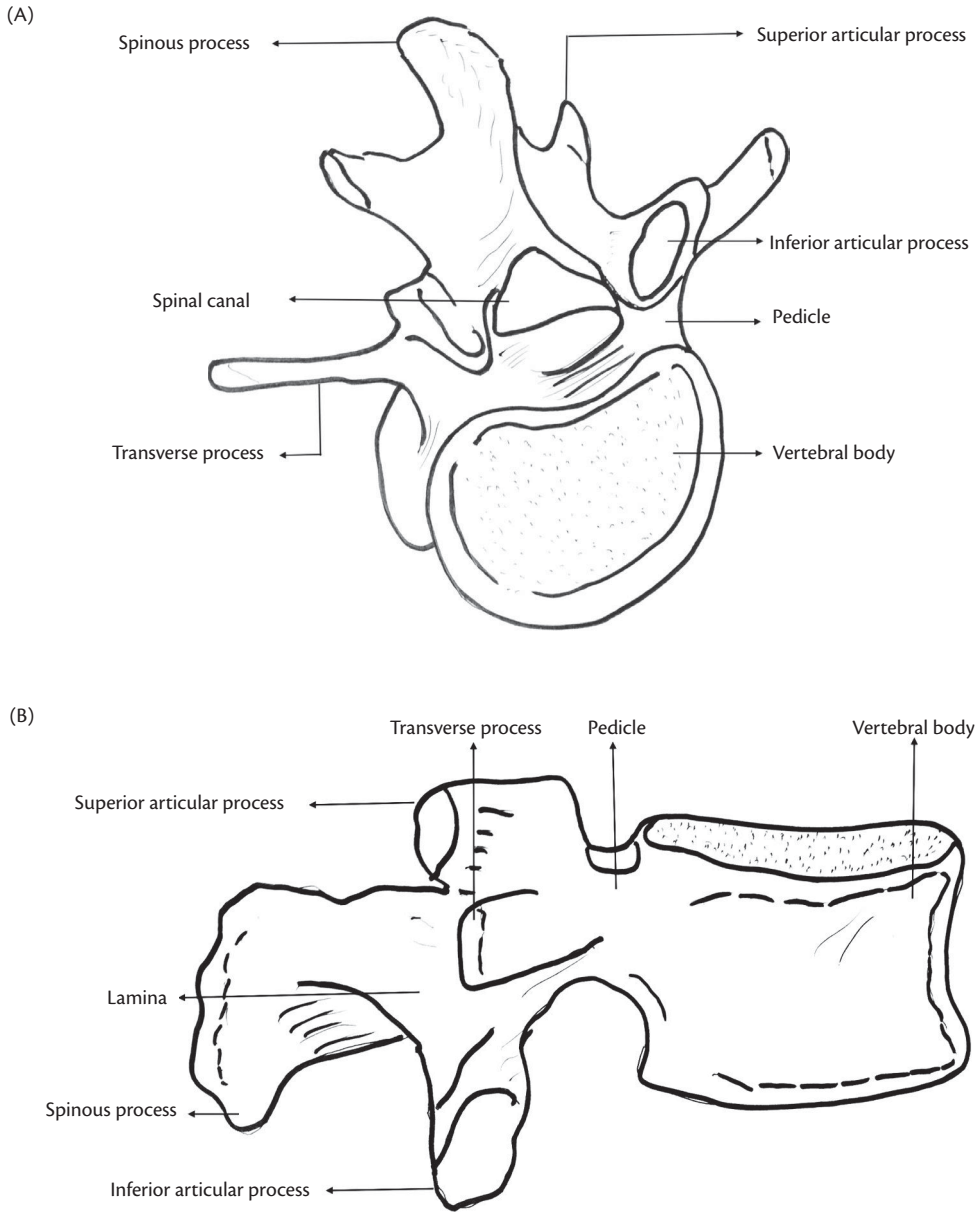

**Figure 54.1** Lumbar vertebra.

Thus, accessing the vertebral canal in the midline via the interspinous and interlaminar spaces is relatively easy, with the interlaminar (paramedian) aperture being the larger. These spaces are further enlarged by forward flexion.[10] The transverse processes arise anterior to the articular processes and project posterolaterally; the L3 transverse process is characteristically the longest.[8] The facet joints and transverse processes lie in approximately the same transverse plane as the interlaminar space, and the inferior edge of the spinous process overlies the widest part of the interlaminar space.

The LF arches over the interlaminar space; deep to it lies the fat-filled compartment of the posterior epidural space. The posterior epidural space has a triangular cross-section (typically 7 mm deep in the midline anteroposterior dimension) in the lumbar region and narrows away to a virtual space anterior to the laminae.[10.] Within the thecal sac, the conus medullaris in the adult is most often located at the level of the first lumbar (L1) vertebral body; however, its location in any individual patient follows a normal distribution and may range from the middle of the 12th thoracic (T12) vertebra to the upper third of L3.[11]

The conus medullaris gives rise to the cauda equina and filum terminale. The thecal sac typically ends at the midpoint of the second sacral vertebra (S2), although in the individual patient this can range from the upper border of S1 to the lower border of S4.[12]

## Sonographic assessment of the lumbar spine

Lumbar spine ultrasound scanning can be done either as a:

- 'pre-puncture' procedure to demarcate the landmarks or with
- 'real-time' scanning to provide dynamic images during epidural placement.

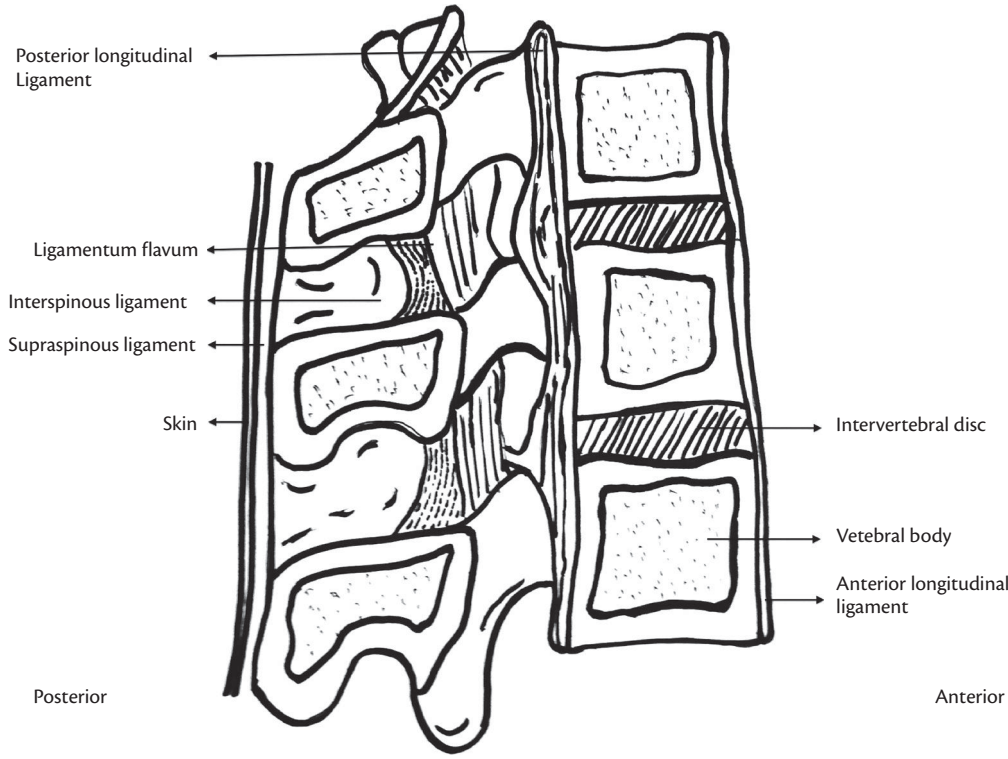

**Figure 54.2** Lumbar spine.

Currently, the 'pre-puncture' method is the most widely practised, as it is relatively simple and easy to perform and provides clinically reliable information.[13] It is important to ensure that the scanning is performed with the patient in the same position as for the needle placement. The following information can be obtained during pre-puncture ultrasound scanning:

- The correct level of the interlaminar space
- The midline of the bony spine
- The skin puncture point corresponding to a good starting approach point for a needle
- The angle for needle insertion
- The depth to the epidural space
- The potentially difficult or variant anatomy.

## Preparation for scanning

During pre-procedure scanning of the lumbar spine, patients should be placed in the position in which the block is to be performed. An initial screen depth setting of 7–8 cm for a normal size patient or 9–11 cm for patients with higher body mass should be set as appropriate. The depth, focus, and gain settings of the ultrasound machine should be adjusted as needed during the scanning process to produce an optimal image.

There are two basic orientations of the ultrasound probe and beam:

1. *Paramedian sagittal oblique (PSO) plane* , when the beam is oriented in the sagittal plane of the spine lateral to the median (midline) sagittal plane with a slight tilt towards the median plane (Figure 54.3)
2. *Transverse median (TM) plane*, when the beam is orientated parallel to the transverse or horizontal plane (Figure 54.4).

### Paramedian sagittal oblique views

#### Identifying the sacrum

There are two ways of reaching the desired interlaminar space: identifying the level by noting the thoracic level above (by finding the 12th rib) and then counting caudally to the desired level; alternately the sacrum can be identified from below. The horizontal white hyperechoic line found 2–3 cm lateral to the midline in the PSO plane is the upper border of sacrum (Figure 54.5).

#### Counting the interlaminar spaces

Once the upper border of sacrum is identified, the probe should be advanced in the cephalad direction in the same PSO plane. The first indentation or 'dip' of the hyperechoic white line usually is the L5–S1 interlaminar space.

This image is then followed by a 'saw-tooth' pattern (Figure 54.6) wherein the teeth of the saw represent the lamina interrupted by interspaces. Hence the next dip after the L5–S1 interlaminar space is the L4–5 interlaminar space and so on. If the probe is over the midline, the spinous processes are observed instead of laminae. These appear more superficial and rounded than laminae and are more difficult to use when assessing the correct interspace.

#### Selecting the ideal interlaminar space

Once the interlaminar space count is established, the preferred level below L2 is chosen based on the ease of

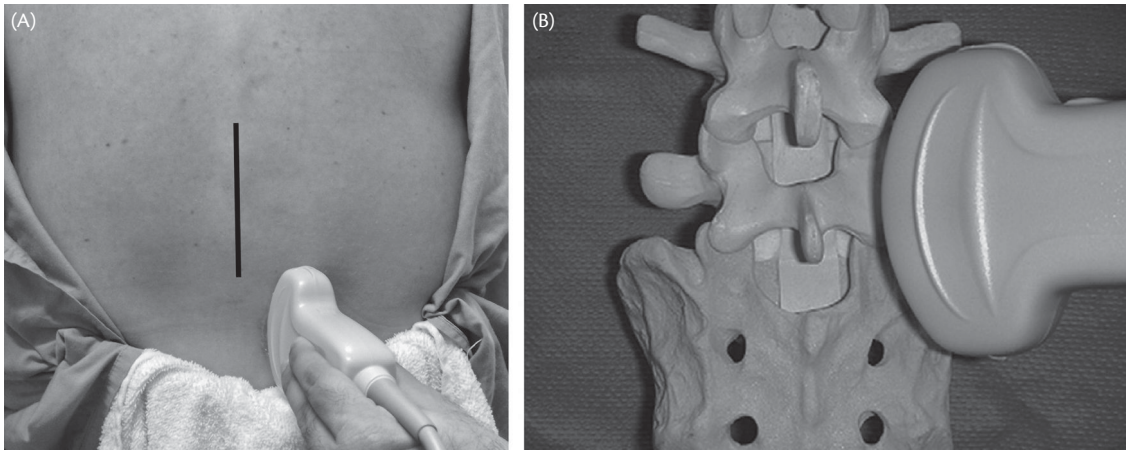

**Figure 54.3** (A) Ultrasound probe orientation in paramedian saggital oblique position (PSO plane) (B) Ultrasound probe orientation in PSO plane in relation to spine.
(B) This figure was published in *Anesthesiology Clinics*, Volume 26, Jose Carlos Almeida Carvalho, Ultrasound-Facilitated Epidurals and Spinals in Obstetrics, pp. 145–158, Copyright (2008).

visualization of certain structures. These structures are seen as two parallel (dorsal and ventral) hyperechoic lines (an 'equal' sign—Figure 54.7).

The dorsal line is of more significance to the anaesthetist and consists of the LF–dura mater (D) (posterior complex). These two structures are generally seen as one line but in certain patients with a better acoustic window, they can be seen split into two hyperechoic lines with the hypoechoic epidural space in between them.

The ventral line consists of three structures namely ventral dura, posterior longitudinal ligament, and vertebral body (anterior complex). Clear visibility of the anterior complex predicts an easy neuraxial placement compared with partial or no visibility, which is associated with difficult spinal or epidural anaesthesia.[14]

Ideally, the interlaminar space with both lines visualized should be considered for neuraxial anaesthesia, but even if only the ventral line is visible the chances of success are still high.[14] The depth of LF–D from skin can be measured here and should be noted, but it is also accurately measured in the TM view.

### Marking the selected interlaminar space

Once the interlaminar space is selected, it has to be carefully marked. The middle of the probe corresponds to the midpoint of the image on screen. Fixed markings on the probe help here and smaller probes in future would reduce inaccurate marking. Stabilize the probe with one hand and with the other hand mark the midpoint of the probe and draw a horizontal line lateral to it (Figure 54.8). This marking is essential because when the probe is shifted to the TM approach, it is very easy for it to drift over a space above or below.

## Transverse midline views

Once the interlaminar space is chosen and marked, the ultrasound probe is rotated by 90° to lie on the same interlaminar space horizontally.

### Pattern recognition in TM plane

In this plane we see the structures classically described as the 'flying bat'. This pattern recognition is of key importance as the point

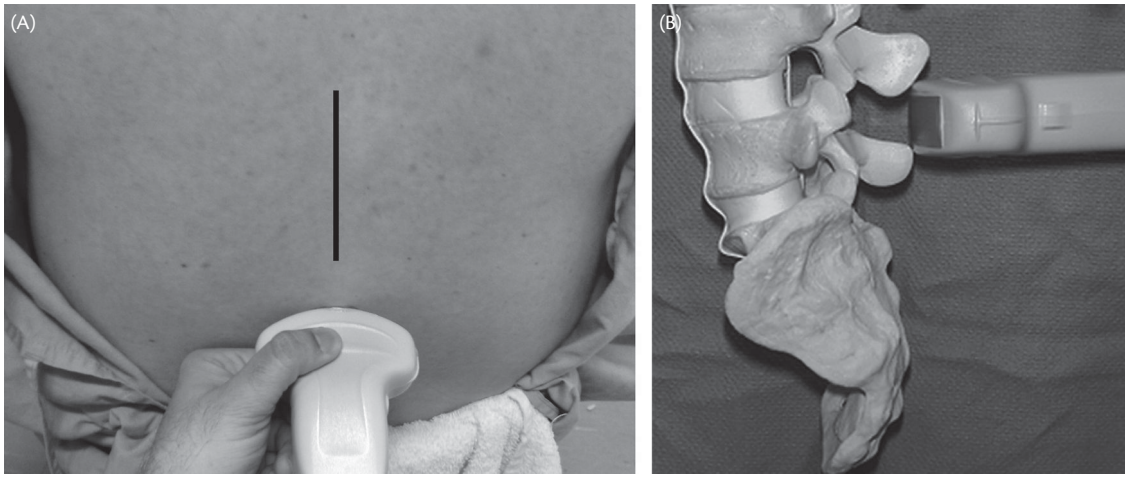

**Figure 54.4** (A) Ultrasound probe orientation in transverse median plane (TM PLANE) (B) Utrasound probe orientation in transverse median plane (TM PLANE )—Lateral view in relation to Spine.

of needle entry is based on this. The structures that can be visualized in this plane include the LF–D (posterior complex), the ventral dura/posterior longitudinal ligament/vertebral body (anterior complex), the articular processes comprising facet joints, and the transverse processes (Figure 54.9).

The posterior complex and the anterior complex can be visualized as midline structures, which also produce a hyperechoic 'equal' (=) sign in the middle of the interspace. The articular processes and transverse processes appear as the bilateral symmetric hyperechoic structures in a more lateral position.[15] The transverse processes appear as the lateral elongations of the LF–D unit reflections and are not seen well in thin patients where the curved probe loses contact with the skin.

## Marking the midline

In the TM plane, as the transducer is moved cephalad or caudad to the interspace, the upper or lower spinous processes can be visualized. Hence, the midline of the spine can be identified as corresponding to the spinous processes, which produces a hyperechoic signal below the skin with a hypoechoic triangular shadow underneath (Figure 54.10).

Thus, scanning in this plane can determine both the midline of the spine and the middle of the interspace. In obese parturients this may be the only discernible bony structure, which helps with identifying the true midline when this is not palpable.

## Estimating the depth of dura (skin to LF–D distance)

Once the best image of the interspace structures or the '=' sign is captured in the TM plane, the image is frozen on the screen. With the aid of a built-in caliper on the ultrasound machine, the depth to the epidural space can be measured as the distance from the skin to the ventral border of the LF–D complex (Figure 54.11). It is advisable to measure the depth in the TM plane and to confirm the measurement with scanning in the PSO plane. It should be noted that the depth to the epidural space continues to increase as we scan down

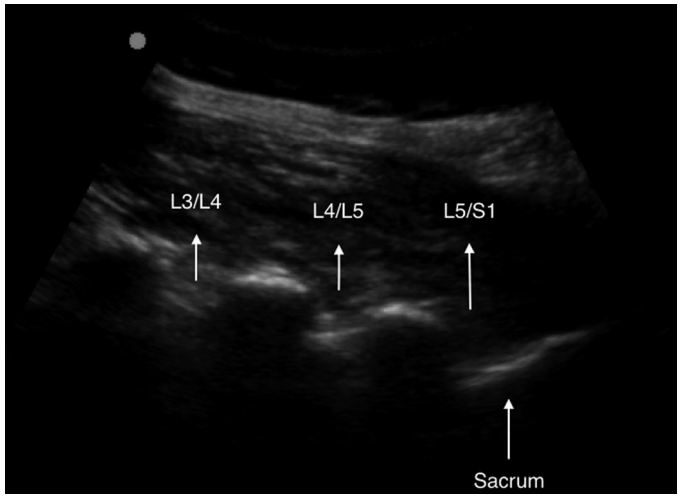

**Figure 54.6** Sawtooth pattern.

**Figure 54.8** Marking the interlaminar space.

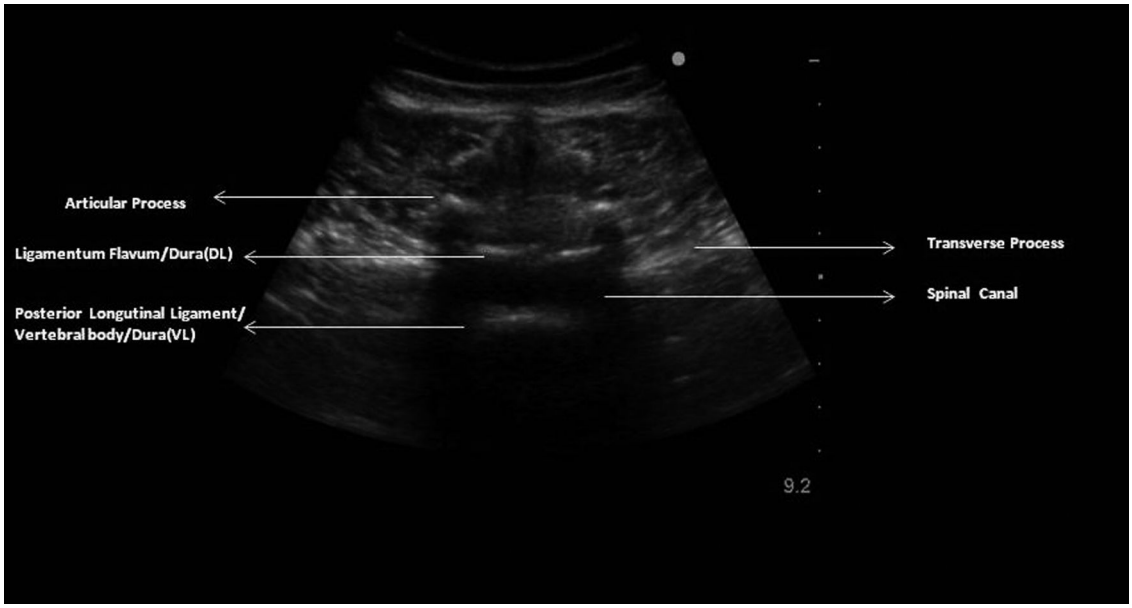

**Figure 54.9** Flying bat pattern. The ears of the 'bat' comprise the articular processes comprising facet joints and the 'head' of the bat comprises the ligamentum flavum/dura line.

the lumbar intervertebral spaces. The information obtained from both the PSO and TM planes can complement each other. It has been suggested that measuring the anteroposterior diameter of the dural sac may provide information regarding dose requirements.

The compression of the skin from ultrasound probe should be taken into account while measuring the depth, and generally in a normal pregnant patient would account for 0.5 cm,[16] but in obese patients depth measurement to the epidural space may be less accurate.

### *Noting the angle of ultrasound probe*

In addition to marking the insertion point, the angle of the transducer providing the best image of the interspace structures must be replicated by the needle trajectory. If the beam can pass through to the thecal sac, the needle will make its way through the same passage to the target if on the same trajectory and plane.

### *Marking the point of entry*

With the transducer kept still, and making sure that the hyperechoic '=' sign is visualized, the skin is marked at the centre of both the upper and the lateral aspects of the transducer. The transducer is then removed, and lines are drawn to connect these marks. The insertion point is determined by the intersection of these two lines (Figure 54.12).

In this manner, the insertion point for both the midline and the paramedian punctures can be determined by scanning in the transverse and the paramedian sagittal planes, respectively. The needle insertion point is marked by indenting the skin as antiseptics will erase the marker. Since midline punctures are commonly performed in the obstetric population, a transverse approach is preferred to determine the insertion point.

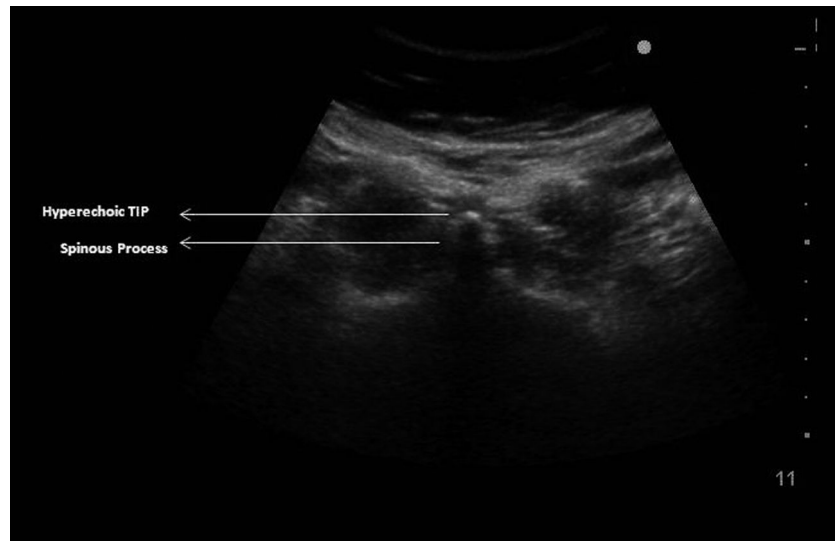

**Figure 54.10** Spinous process.

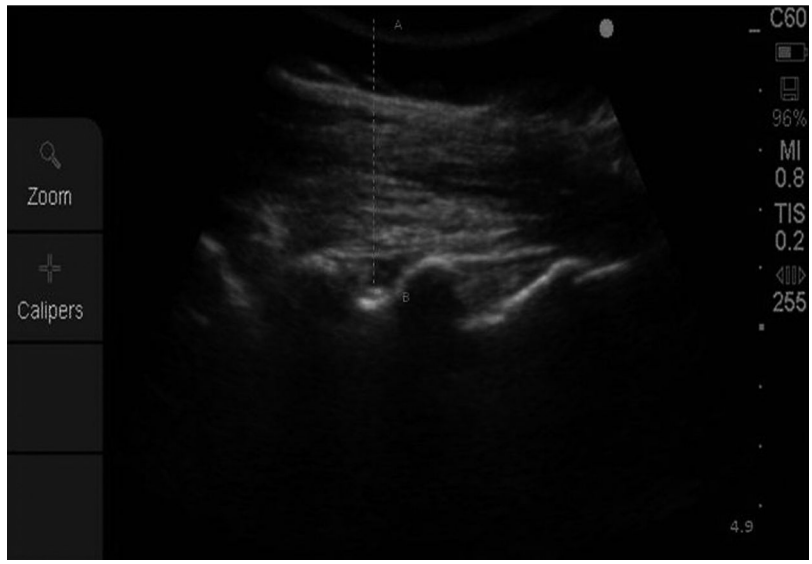

**Figure 54.11** (A) Depth, PSO plane. (B) Depth, TM plane.

## Variant sonoanatomy

Certain patients with abnormal sonoanatomy, patients with morbid obesity, scoliosis, and spinal instrumentation, may pose a considerable challenge for the placement of neuraxial anaesthesia. Pre-procedural ultrasound in these patients can help us to determine the presence of anatomy amenable to neuraxial anaesthesia and to choose the best intervertebral space or avoid a difficult intervertebral space.

In obese patients, subcutaneous fat makes it difficult to palpate the landmarks and hence ultrasound can be utilized to mark the midline of the intervertebral space and the appropriate intervertebral level is marked best in the PSO plane. Care should be taken not to compress the ultrasound probe too hard on to the skin as it can underestimate the depth to the LF–D complex. In most patients, the depth to the dura is less than 8 cm. If the ultrasound predicts a depth of more than 8 cm a long needle may be selected for these patients.[16]

In patients with scoliosis, there is variable degree of axial rotation of the vertebral bodies and angulation of spinous processes. The sonographic image in these patients can reveal the location of the spinous process lateral to the virtual midline of the patient, asymmetry of the articular and transverse processes, and discontinuous LF in the TM plane (Figure 54.13 and Figure 54.14).

In such situations, several interspaces should be scanned, and the interspace with normal sonoanatomy and continuous LF should be chosen for the neuraxial block.[17]

In patients with spinal instrumentation, ultrasound can help in determining the intervertebral space with preserved anatomy and thus neuraxial anaesthesia can still be contemplated in this group of patients.[18]

## Learning curve

A great deal of training is required before one can be efficient in ultrasound-guided spinal and epidural anaesthesia. Margarido et al.[19] have shown that even after attending lectures and workshops, novices requires more than 20 attempts to master critical tasks necessary for locating accurate ultrasound landmarks. Common flaws included missing the L5–S1 space, not marking the skin meticulously, and inadvertently sliding the transducer to a lower segment while marking the skin insertion point. Thus, ultrasound should not be reserved for technically difficult cases because it requires experience in routine cases with easily identified palpable landmarks before it can be used effectively in difficult cases.

## Real-time scanning

Real-time ultrasound scanning can be performed as an out-of-plane technique by scanning in the PSO approach and inserting the epidural needle in the midline or as part of an in-plane technique.[20,21] The obvious limitations of this technique include poor demarcation of individual structures, such as the LF and D, and the need for an assistant to perform scanning if an epidural with loss-of-resistance is used. An operator has to revert to standard blind loss-of-resistance using both hands when the needle is sent on a satisfactory path. However, the utilization of epidural syringes with an auto detect loss-of-resistance function may facilitate a single skilled operator in performing ultrasound-guided epidural placement.[22] A single operator combined spinal–epidural technique has been described in a case series which involves a modification of the ultrasound transducer with biopsy bracket and needle guide using geometrical principles.[23] A GPS needle tracking system is also described, which allows the operator to make adjustments to needle trajectory during advancement, which ensures greater precision in reaching the target.[24] At present, the role of neuraxial real-time ultrasonography is clinically restricted and advances in the transducer design and technology are required to establish its clinical relevance.

## Efficacy of ultrasound-guided procedures

A 2013 meta-analysis[7] has shown that ultrasound imaging can reduce the risk of failed lumbar punctures and epidural

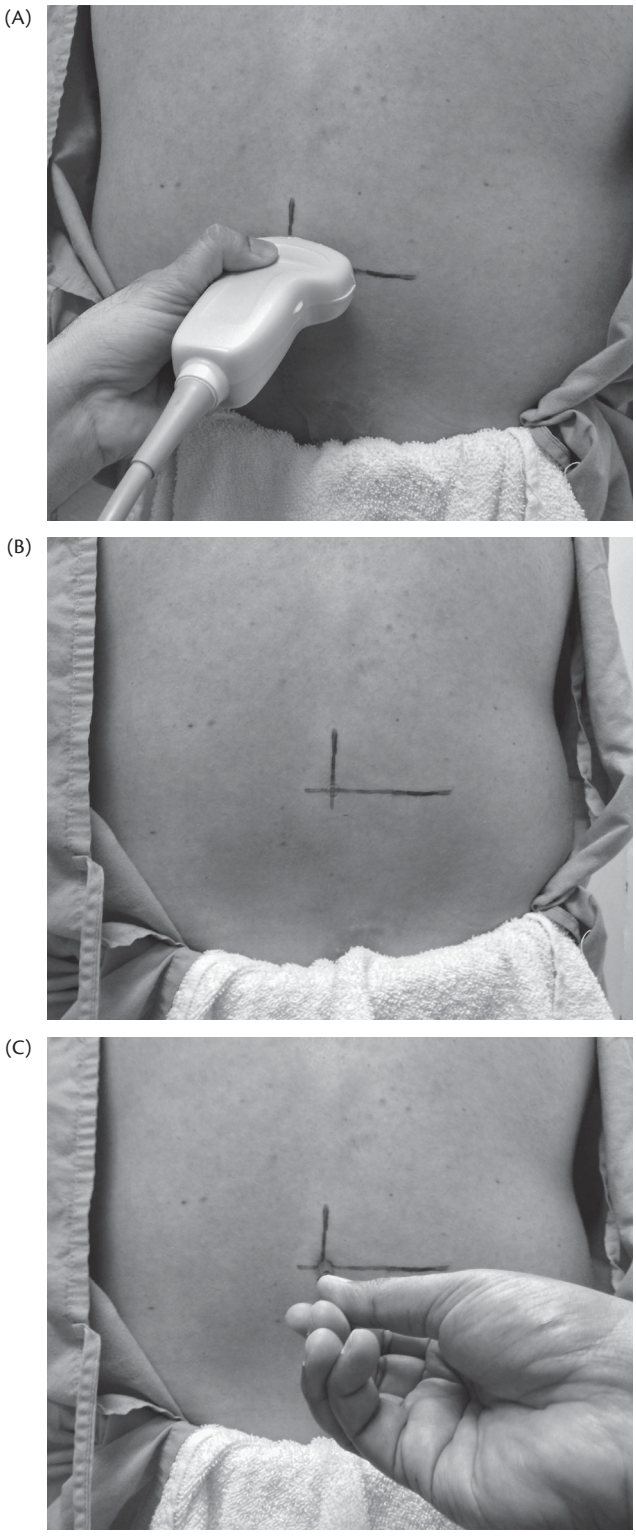

**Figure 54.12** Marking point of entry.

catheterizations as well as reduce the risk of traumatic procedures and the number of needle insertions and redirections.

Grau et al. demonstrated that ultrasound guidance improved the success of blocks, minimized the complication rate, and improved overall patient satisfaction when compared with the conventional palpationmethod.[20,25–27] Such benefits were also demonstrated in many other studies.[28–30]

The inaccuracy of clinical palpation to confirm an intervertebral level is well documented, as have the risks of an inadvertently high intervertebral space selection for spinal anaesthesia.[31] Ultrasound imaging has been shown to be superior to palpation in correctly identifying lumbar intervertebral level, with traditional landmark palpation techniques erring to select a higher level than was intended or recorded in up to 50% ofcases.[32,33] As ultrasound equipment becomes more widely available, documentation of its use may become the accepted standard of care.

Several studies involving obstetric patients have shown an excellent correlation between the ultrasound-estimated depth to the epidural space and the actual needle depth. The expected depth to the epidural space can be predicted within a range of ± 0.7 cm in non-obese parturients and ±1 cm in obese parturients with a 95% confidence interval.[16,28] In obese parturients, the quality of image capture in the TM plane is generally inferior to the PSO plane and this requires excessive pressure form the ultrasound transducer which, in turn, can measure a false low value. The depth to epidural space can reasonably be estimated in the PSO plane and this corresponds well with the depth estimated from the TM plane.[34]

Ultrasound guidance has also been used for placement of an epidural blood patch,[35–37] and Lee et al. have suggested that pre-puncture imaging may identify defects in LF predisposing some parturients to unintended dural puncture at that interspace.[38] In addition to reduced skin punctures and needle redirections, enhanced analgesic success of ultrasound-guided epidural placement has also been reported.[38] Thecal sac anteroposterior diameter can be measured using ultrasound although a correlation between this and predicted height of spinal anaesthesia has not been demonstrated.[39] The length of the lumbar spine determined by ultrasound, rather than the lumbar spine volume, combined with the weight or body mass index of the subject, is of particular value in predicting the intrathecal spread of local anaesthetic during combined spinal–epidural analgesia for labour.[40]

Concerns regarding the potential for increased time required to site an epidural where ultrasound is utilized are overstated as ultrasound leads to fewer attempts at epidural space localization and is likely to reduce overall procedure time in patients with difficult anatomic landmarks.[41]

## Clinical guidelines

On the basis of the available studies which included paediatric practice, in 2008 the UK National Institute for Clinical Excellence (now National Institute of Health and Care (NICE)) published a recommendation stating that ultrasound may be effective in achieving correct placement of epidural catheters.[42] Reduced needling time enhances safety and the patient experience and this appears to be the main benefit of incorporating ultrasound assessment into obstetric anaesthesia practice.

## Vascular access

Ultrasound-guided central venous cannulation gained significance following a meta-analysis by Randolph et al. in 1996.[43] This showed a reduction in placement failure, decreased incidence of multiple attempts, and decreased rate of complications with ultrasound-guided cannulation compared to standard

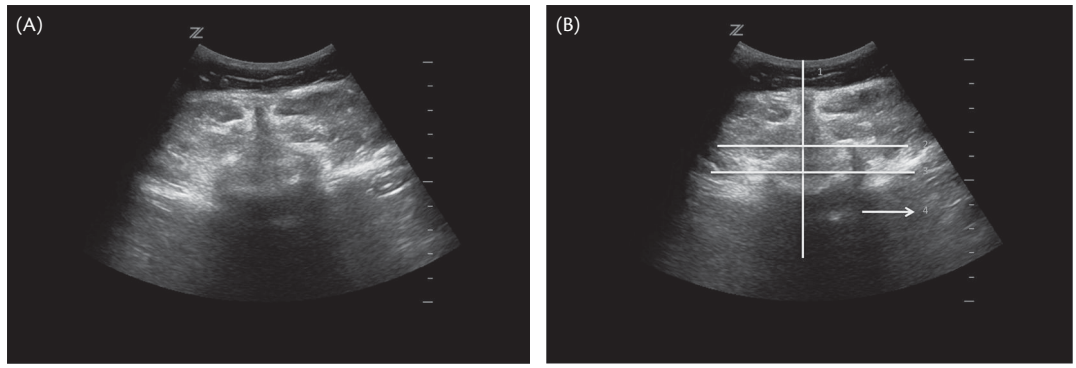

**Figure 54.13** (A) Scoliosis. (B) Scoliosis—note the planes:

1. Midline plane: the spinous process is at an angle to midline
2. Plane of right articular process
3. Plane of left articular process plane
4. PLL–VB: visible only on the right side.

landmark techniques. These results were confirmed by another meta-analysis in 2003 comparing the use of two-dimensional ultrasound guidance with an anatomical landmark technique.[44] Based on these and other studies, NICE recommended that two-dimensional ultrasound guidance should be considered in most clinical circumstances where central venous cannulation is indicated.[45] Ultrasound-guided placement facilitates accurate central vascular access with more limited patient positioning for comfort. Ultrasound for central venous cannulation has proven to be most valuable in complicated cases, such as patients with coagulopathy, obese or hypovolaemic patients, those who cannot tolerate recumbent position, or who have had multiple previous cannulations.[46] For central venous catheterization, it has been shown that real-time ultrasound guidance is better than the pre-puncture imaging of anatomy.[47] The common technique for ultrasound-assisted central vein cannulation is the short-axis out-of-plane view. In addition to central venous catheters, ultrasound guidance is increasingly used for peripheral venous cannulation in patients with difficult venous access,[48] and for insertion of arterial catheters for invasive blood pressure monitoring. This has obvious potential in obese parturients although central venous line insertion has become less common.

## General anaesthesia

O'Sullivan et al. have published on effects of labour and opioids on gastric emptying and residual gastric volumes in parturients. Ultrasound-based technology in many of these studies was used to assess gastric volumes.[49] Perlas et al. have shown that the gastric antral cross-sectional area, as measured by ultrasonography correlates well with gastric volume and also can provide accurate qualitative information regarding gastric content type. Bedside ultrasonography could potentially become a clinically useful non-invasive tool to stratify perioperative aspiration risk.[50] As skills among obstetric anaesthetists improve, the idea of using ultrasound technology to assess gastric volumes in a non-elective case outside a research setting is thought-provoking and may guide clinical decision-making with respect to anaesthesia technique.

Location of the cricoid cartilage for correct application of cricoid pressure during rapid sequence induction is traditionally performed by the landmark technique, but may also be identified using ultrasound. Ultrasound technology may useful to identify the cricothyroid membrane, which may lead to improved safety when considering percutaneous tracheal cannulation.[51]

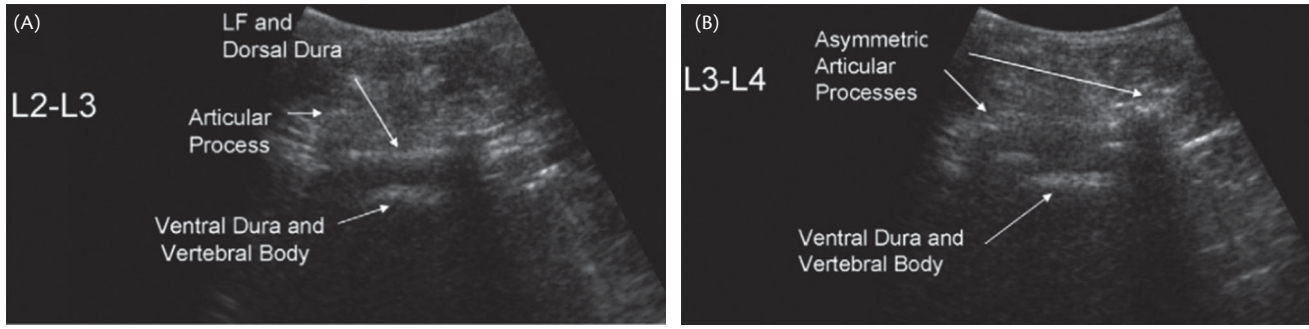

**Figure 54.14** (A) Normal vertebra. (B) Scoliosis.

This figure was published in *Anesthesiology Clinics*, Volume 26, Jose Carlos Almeida Carvalho, Ultrasound-Facilitated Epidurals and Spinals in Obstetrics, pp. 145–158, Copyright (2008).

### Cardiac evaluation

Transthoracic cardiac imaging is now feasible with the higher-resolution equipment now utilized in most centres for regional anaesthesia. Bedside ultrasound evaluation of the hypotensive parturient may help to differentiate non-invasively between hypovolaemia and other conditions such as cardiomyopathy or pulmonary embolism.[52]

### Acute and chronic pain control

There has been some interest in the literature in abdominal wall infiltration techniques for post-caesarean analgesia.[53] Field blocks such as the transversus abdominis plane (TAP) block, may be performed with enhanced accuracy using ultrasound. Although the block was originally described without ultrasound, using a landmark technique, complications such as peritoneal injection or haematoma are possible. The sonoanatomy of the muscle planes is more clearly defined in the area between the level of the anterior superior iliac crest, the subcostal margin and the umbilicus.[54] The TAP block as originally described uses clinical landmarks at the mid-axillary line, above the iliac crest, at the lumbar triangle of Petit.[55] However, the sonoanatomy, in terms of identifying muscle and fascial planes at this point are less clear. Performance of the block in a more anterior site with ultrasound may yield comparable efficacy and studies are awaited. Though McMorrow et al.[56] have shown that TAP block using a landmark technique does not provide comparable analgesia or additional benefit to spinal morphine for post-caesarean analgesia, they have concluded that lack of ultrasound for their block could have erroneous placement of the drug either too superficially or too deep (i.e. intraperitoneal) and further studies are warranted using ultrasound. Furthermore, it is likely that clinically useful catheter-based techniques may demonstrate the most benefit in postoperative analgesia, rather than single-shot techniques. Nevertheless, ultrasound will undoubtedly have a role in the evolution and development of abdominal field anaesthesia for post-caesarean analgesia as part of a multimodal balanced analgesic plan.

Pelvic girdle pain syndromes, which involve pubic symphysis, sacroiliac, and coccygeal-related pain, are a relatively rare but disabling constellation of syndromes which have been treated with local application of anaesthetic and steroid agents. Ultrasound may be used to avoid fluoroscopy and the risks of radiation to the fetus. Obturator nerve blockade, which has been described for chronic perineal pain syndromes, has been performed using ultrasound.[57]

## Cost

The cost of purchasing high-resolution equipment with at least two different probes and accessories can be substantial and in the region of EUR 50,000. More basic ultrasound technology sufficient for central venous catheterization is less expensive and justified on safety grounds. Access to devices commonly used by obstetricians may be readily available in patient areas and with appropriate specification, be sufficient to explore initial neuraxial assessment. Ultrasound has been suggested as one area with improvement potential on future reductions in anaesthesia-related maternal mortality.[58] A reduced potential for neuraxial injury from inadvertent high intervertebral space selection where spinal anaesthesia is planned may justify more widespread use. Until more data are available of the benefits to high-risk parturients, the cost of the equipment will be the main barrier to wider implementation in addition to limited technical expertise.

## Conclusion

Placement of epidural catheters or spinal needles is an area where widespread use of ultrasound will potentially become more commonplace. Ultrasound may become increasingly useful in other invasive procedures such as vascular access and field blocks. The pace of development in portable ultrasound technology brings new refinements to image quality and we can expect wider availability of ultrasound technology on our delivery suites and operating theatres and further innovations in clinical application.

# CHAPTER 55

# International outreach

Gordon Yuill and Simon Millar

## Maternal mortality and morbidity: a global problem

### Maternal mortality

The tenth and current revision of the International Classification of Diseases, Injuries and Causes of Death (ICD-10) defines maternal mortality as 'the death of a woman while pregnant or within 42 days of termination of pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from accidental or incidental causes'.[2] Both the World Health Organization (WHO) and the Centre for Child and Maternal Health Enquiries (CMACE) further divide deaths into those that are *directly* related to pregnancy and conditions that are unique to pregnancy, and those that are *indirectly* related to pregnancy where an existing or developing disease is exacerbated by the pregnancy.

The maternal mortality ratio (MMR), the number of direct and indirect maternal deaths per 100,000 live births, is an often used health indicator when discussing national and global progress and comparisons (Figure 55.1). When the WHO determined that its Millennium Development Goal 5 (MDG 5) was to improve maternal health, the headline target it chose was to reduce the MMR by three-quarters between 1990 and 2015. This may prove to be an ambitious objective, yet by 2010 there were an estimated 287,000 deaths worldwide representing a MMR of 240 and a decline of 47% from the 1990 levels (Figure 55.2).[3] The difference between developing and developed regions is highlighted by a MMR that is 15 times higher in the former (Figure 55.3). Even this is probably an underestimate in countries with poorly developed data collection and death registration systems.[4]

*Beyond the Numbers* is a WHO programme that encompasses a maternal mortality review tool kit.[5] It encourages countries to review their maternal mortalities and offers a number of ways to do this allowing for varied logistical and financial circumstances. The longest running example of such a review is the *Confidential Enquiries into Maternal Deaths in the United Kingdom*, coordinated by CMACE. The most recent of its eight triennial reports was published in 2011 reviewing the years 2006–2008,[6] and calculated the MMR in the United Kingdom as 11.39 (95% confidence interval (CI) 10.09–12.86)/100,000 maternities.

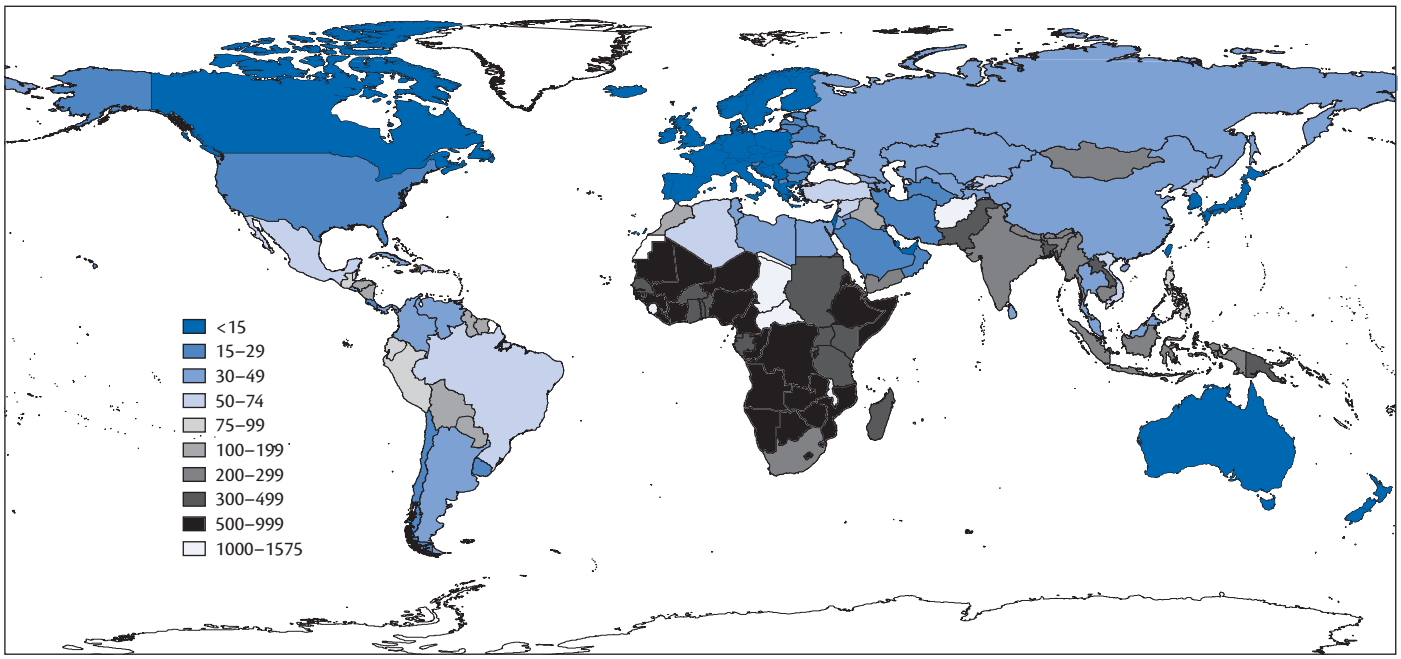

**Figure 55.1** (See colour figure section). Maternal mortality ratio per 100,000 live births, 2008.

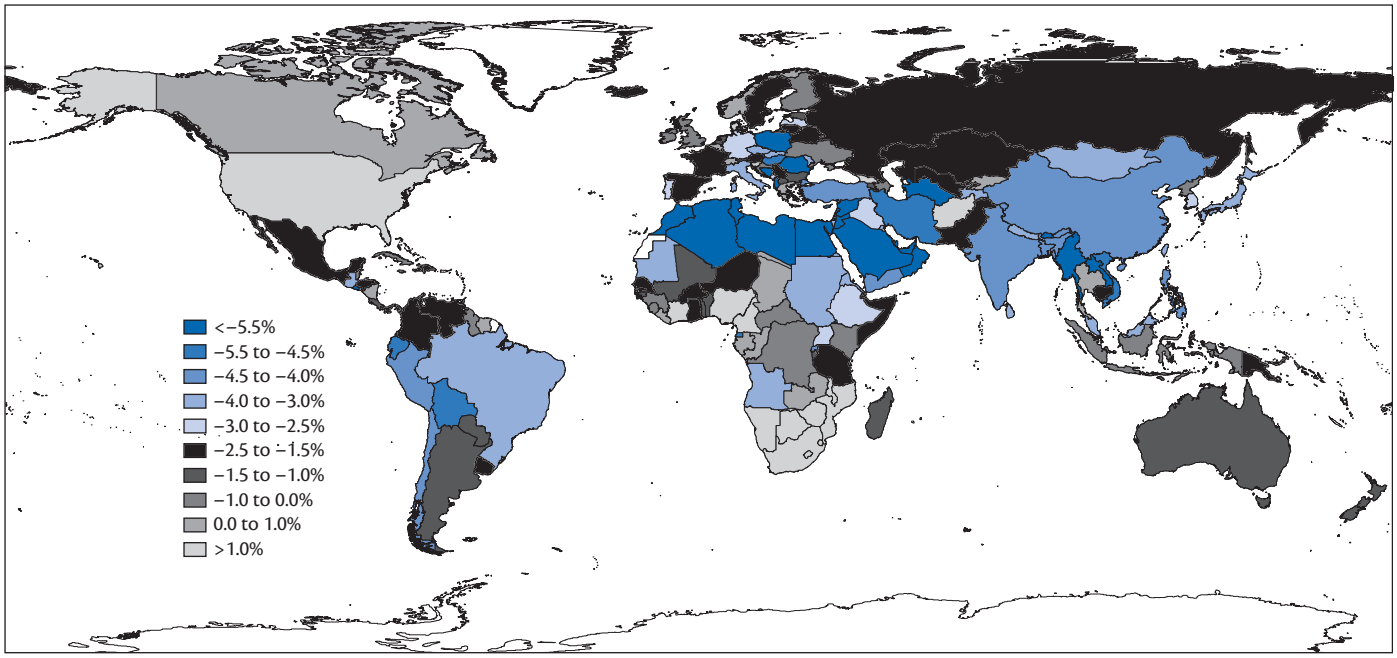

**Figure 55.2** (See colour figure section). Yearly rate of decline in maternal mortality ratio, 1990–2008.

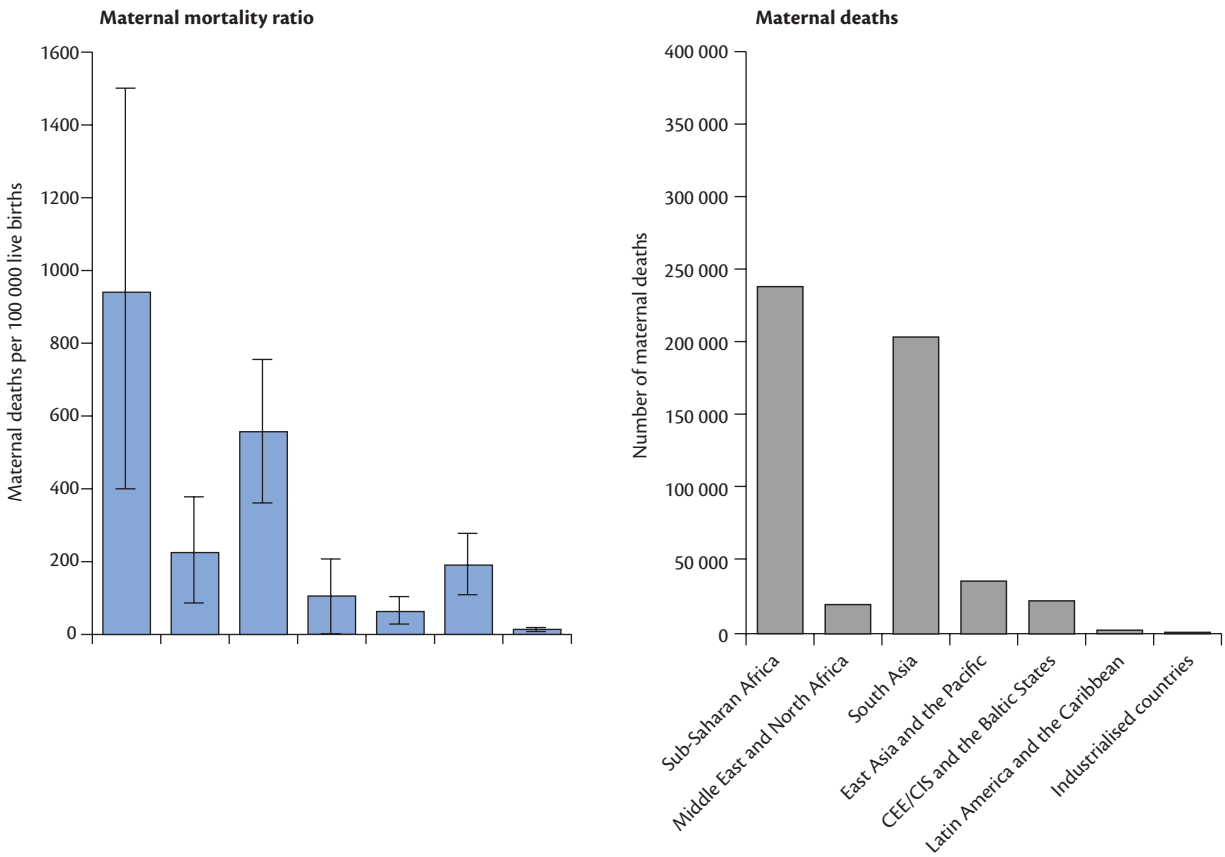

**Figure 55.3** Regional variation in maternal mortality ratio and number of maternal deaths.

This was a statistically significant decline from 13.95 (95% CI 12.45–15.64)/100,000 reported in the previous triennium. By contrast, the WHO reported in 2010 that the MMR in sub-Saharan Africa was 500/100,000 live births.

Another way to qualify the disparity between countries is to look at the *lifetime risk* of maternal death, which estimates the probability of maternal death during a women's reproductive life. In 2010, Save the Children quoted the lifetime risk in Afghanistan as 1/6, compared to 1/47,600 in Ireland.[7]

Such discrepancies between the developed and developing countries are alarming and have been cited as 'the largest discrepancy of all public-health statistics'.[8] It is substantially greater than that for child or neonatal mortality, and some of the reasons behind it will be explored later in this chapter.

## Causes of maternal death

The vast majority of maternal deaths occur around labour, delivery, and the immediate postpartum period, with a substantial number occurring in hospital.[9] Such data as demonstrated in Figure 55.4 confirms that professional and trained care should be focused on this period. In 2006, a WHO systematic review of causes of maternal death found that direct causes accounted for most of the deaths, with haemorrhage, hypertensive diseases, and infections being the main causes (Figure 55.5).[10] This is despite haemorrhage being described as the ' one major cause of maternal mortality in which women were dying needlessly for want of common skills that every midwife and practitioner should posses'.[11] Deaths due to unsafe abortion remain close to 13% of all maternal deaths, representing an actual number of 47,000.[12] The WHO estimates that 21.6 million unsafe abortions took place worldwide in 2008, with almost all of them in developing countries.

Human immunodeficiency virus (HIV), malaria, tuberculosis, and hepatitis undoubtedly contribute to the indirect causes of maternal mortality, especially in sub-Saharan Africa. The sheer prevalence of such diseases and the associated lack of available testing, under-diagnosing, and under-reporting make it difficult to assess their importance as a cause of death. However, 'in countries that are most severely affected by HIV the AIDS epidemic has thought to have reversed previous gains in maternal mortality'.[9] In Uganda, the overall MMR is around 900/100,000 but is reported as 1300/100,000 in HIV-infected mothers.[9]

Although deaths from accidents, murders, or suicides are classed as incidental and excluded from maternal mortality statistics, there is evidence from India and Bangladesh that the pregnancy may have played a role.[9]

## Where women die

Many of the worldwide maternal deaths occur in hospital and fall into one of three scenarios: they arrive in a moribund state too late to benefit from emergency care; they arrive with complications and could have been saved if they had received timely and effective interventions; and those that are admitted for normal delivery who subsequently develop serious complications (natural or iatrogenic) and die with or without receiving emergency care.[9] The latter two scenarios raise concerns regarding the quality of hospital care. Numerous studies have shown that delays in recognition and treatment of life-threatening complications, as well as substandard practices, contribute directly to maternal deaths.[13,14] In cases where women arrive in a moribund state, it is likely that problems exist with referrals between facilities, or there are community barriers to accessing care, such as physical, cultural, or financial.[9,15]

Time since pregnancy and mortality in women of reproductive age in Matlab, Bangladesh. Paper presented at the British Society for Population Studies; December 2002; London, UK.

## Maternal morbidity

For every maternal death in the developing world, it is estimated that 30 women suffer morbidity during childbirth, such as chronic anaemia, infertility, stress incontinence, vaginal fistulae, chronic pelvic pain, emotional depression, and physical exhaustion.[16]

## Reasons for differences between the developed and the developing world

The gap in the delivery of healthcare between the developed and developing nations is mainly caused by economic, geographical, sociobehavioural, cultural, and clinical factors.

### Economic factors

Health planners face formidable challenges in the poorest countries. There are limited material and human resources, low government spending on health (often less than US$10/person/year), weak administrative and managerial support and a huge burden of disease.[17] One of the main focuses of MDG 5 is to increase the number of deliveries that are attended by skilled health personnel. The regions with the highest maternal mortality, sub-Saharan Africa and Southern Asia, are also those with the lowest coverage of births by skilled health personnel. In developing regions over all, the proportion of deliveries attended by skilled health personnel rose from 55% in 1990 to 65% in 2010.[18]

Even if obstetric services are accessed they are severely limited. Most anaesthetics are provided by non-physicians, nurses, or unqualified personnel facing erratic electrical supplies, inconsistent oxygen delivery, paucity of drugs or equipment, and even lack of running water.[17] The inadequate public spending on health has led to a poor quality of care characterized by long waiting times, lack of medication, and inappropriately trained staff. There is often an erosion of ethical values and professional conscience and a general culture of impunity. There are major problems with procurement, storage, and management. Corruption is increasingly recognized as a consequence.[19] Workforce issues such as

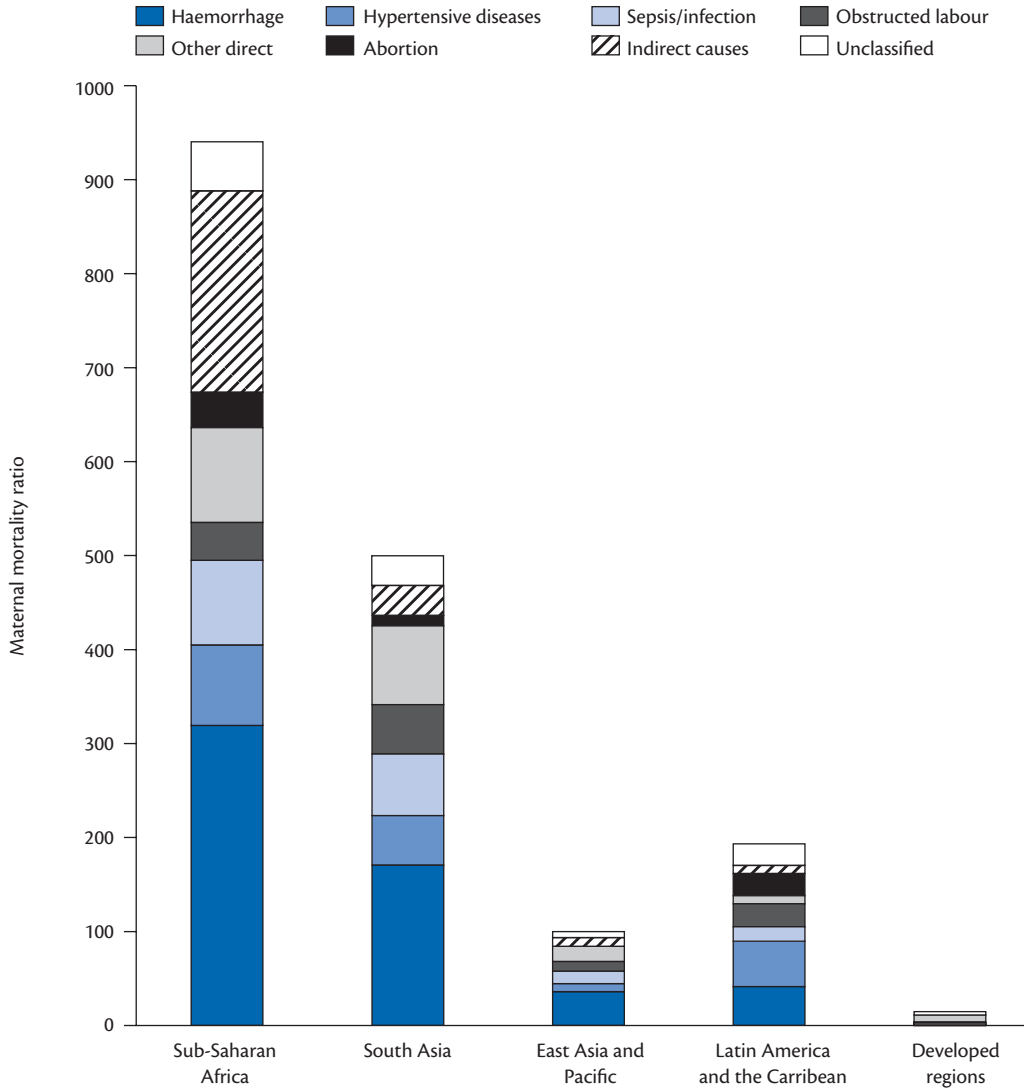

**Figure 55.5** (See colour figure section). Maternal mortality ratios for 2000 by medical cause and world region.

Reprinted from *The Lancet*, Volume 368, number 9542, Ronsmans C, Graham W, Maternal survival 1. Maternal mortality: who, when, where and why, pp. 1189–1200, Copyright (2006), with permission from Elsevier. Data from WHO, UN Children's Fund, UN Population Fund. Maternal mortality in 2000: estimates developed by WHO, UNICEF, UNFPA. Geneva: World Health Organization; 2004.

emigration of skilled workers, absenteeism through illness, and migration away from the health sector due to poor working conditions leads to a further burden on the healthcare system and economies of developing countries.[20]

### Geographical factors

Although one might expect that differences in maternal mortality between world regions may be explained by economic growth, it is not that simple. Despite similar gross national incomes per head, Vietnam and Sri Lanka have achieved much lower MMRs than Yemen and Ivory Coast.[9] Indeed, internal variations such as geographical, economic, and social factors, are not just confined to the developing world, and hence inequalities in the risk of maternal death are found everywhere.

Differences in maternal mortality between urban and rural areas within poor countries are also substantial. In Egypt, the MMR was more than twice as high in the nomadic Frontier region than in the Metropolitan region (120 vs 48 deaths/100,000).[21] In Afghanistan, the differences were even more striking, with mortality being 418/100,000 in the capital city of Kabul compared with 6507/100,000 in the remote district of Ragh.[22]

### Sociobehavioural and cultural factors

In addition to financial and physical access to obstetric services there are sociobehavioural and cultural factors. Such barriers include late recognition by women and families of the need to seek care that is either intentional or unintentional and transportation difficulties in reaching hospitals.[15] Most women labour in their houses for several days and go to hospital only as a last resort because delivery is considered 'natural', not as an 'illness' requiring hospitalization. Unfortunately, death during labour or delivery may also be accepted as normal and inevitable.[15] Additionally, a lack of health education and/or poor reputation of healthcare facilities leave many patients unconvinced or frankly afraid of the value of modern obstetric management.[15,23] A random questionnaire administered to a group of rural women in the Akosombo district of Ghana revealed that about 70% of women associated hospital confinement with severe discomfort, especially related to caesarean delivery.[23] Others have a natural disinclination towards caesarean delivery because their peer groups insult them openly if they have been unable to deliver vaginally, considered the 'natural' way.[23] A lack of support and privacy in the hospital is a factor keeping some away and women may associate surgery with mortality.[15] Furthermore, it is a status symbol to have large families and women believe that caesarean delivery will limit the number of children that they may bear.[23] In some cultures, a pregnant woman with complications or a woman in labour cannot be taken to the hospital without the husband's consent, further delaying care.[15,23] These social issues, along with the physical impediments of travel to referral centres, put the lives of the mother and the fetus at risk.

Figure 55.6 shows the barriers to uptake of professional birthing care faced by countries with marginal exclusion and those with massive deprivation. In both settings, all of these barriers play a part in coverage. The scarcity of providers, supportive infrastructure, and policies are the primary barriers for women in sites of massive deprivation; however, reluctance to use services and poor quality care detract from use where services are available.[24]

### Clinical factors

Anaesthetists are an integral part of the obstetric team in the United Kingdom, and participate in over 50% of parturients care.[25] Anaesthetists have knowledge of acute physiology and are skilled at fluid management, invasive monitoring, and the other aspects of critical care that are essential when dealing with a critically ill mother with obstetric haemorrhage, sepsis, and eclampsia. In the developing world, many women present with life-threatening complications and could be saved if the anaesthetic provider was skilled at recognizing the need for, and able to carry out, prompt and effective resuscitation.[16]

Most studies, however, identify the same issues—few medically qualified anaesthetists, lack of appropriate training and supervision for non-medical anaesthetists, limited monitoring of anaesthesia, and inadequate supplies of drugs and equipment, including blood for transfusion.[26] The lack of trained anaesthetic personnel also seems to have an impact on caesarean delivery rates. The WHO may recommend a caesarean delivery rate of between 5% and 10%, but in reality it is often below 1% for the poorest populations, often in sub-Saharan Africa.[27] In India, medical officers are discouraged from practising anaesthesia—there are few training positions, remuneration and working conditions are poor, and most doctors prefer to work in private practice in urban areas or migrate.[28] Medical migration is also rife in sub-Saharan Africa. Currently in Uganda, for example, there are 14 physician anaesthetists in a population of 30 million—approximately 1 anaesthetist per 2 million people.[29] By comparison, in the United States, the ratio is 1/4000 and in the United Kingdom, 1/5000. Most Ugandan anaesthesia providers work in cities, in conditions that would still be considered austere by Western standards. Postgraduate training programmes in Uganda remain unfilled because of difficulty recruiting and funding trainees. In 2010, there were only 12 anaesthesia residents in training although 47 positions were available.[30] The annual cost of training is approximately US$3500, nearly ten times the estimated mean annual household income in Uganda.[30] In neighbouring Kenya (population 32 million), there are 120 anaesthetists, but only 13 of these are employed in the public sector. The remainder work in private practice in the capital, Nairobi. There are several hundred surgeons at Kenyatta National Hospital, the national referral and teaching hospital, but only nine anaesthetists.[30] Thus the vast majority of anaesthetics are administered by non-physician anaesthetic providers working alone, unsupervised, and often with limited training. This should be considered when reading some reports of worryingly high perioperative mortality rates for caesarean deliveries in Africa in the region of 1–2%.[31–35] Most of these deaths were avoidable and one-third of deaths are directly attributable to anaesthesia, mainly due to airway problems. Another significant cause is the lack of access to blood transfusion.

As well as staffing concerns, health facilities are also woefully lacking. Two surveys in Uganda showed that few facilities had running water, electricity, a functional operating theatre, or midwives. Also that only 23% of anaesthetists had the facilities to deliver safe anaesthesia to an adult having major surgery, 13% to deliver safe anaesthesia to a child, and 6% had the facilities to deliver safe anaesthesia to a mother undergoing caesarean delivery (spinal needles, blood for transfusion, oxytocic agents, antihypertensive agents, or magnesium sulphate). Furthermore, ten anaesthetists were working without oxygen supplies.[29,36]

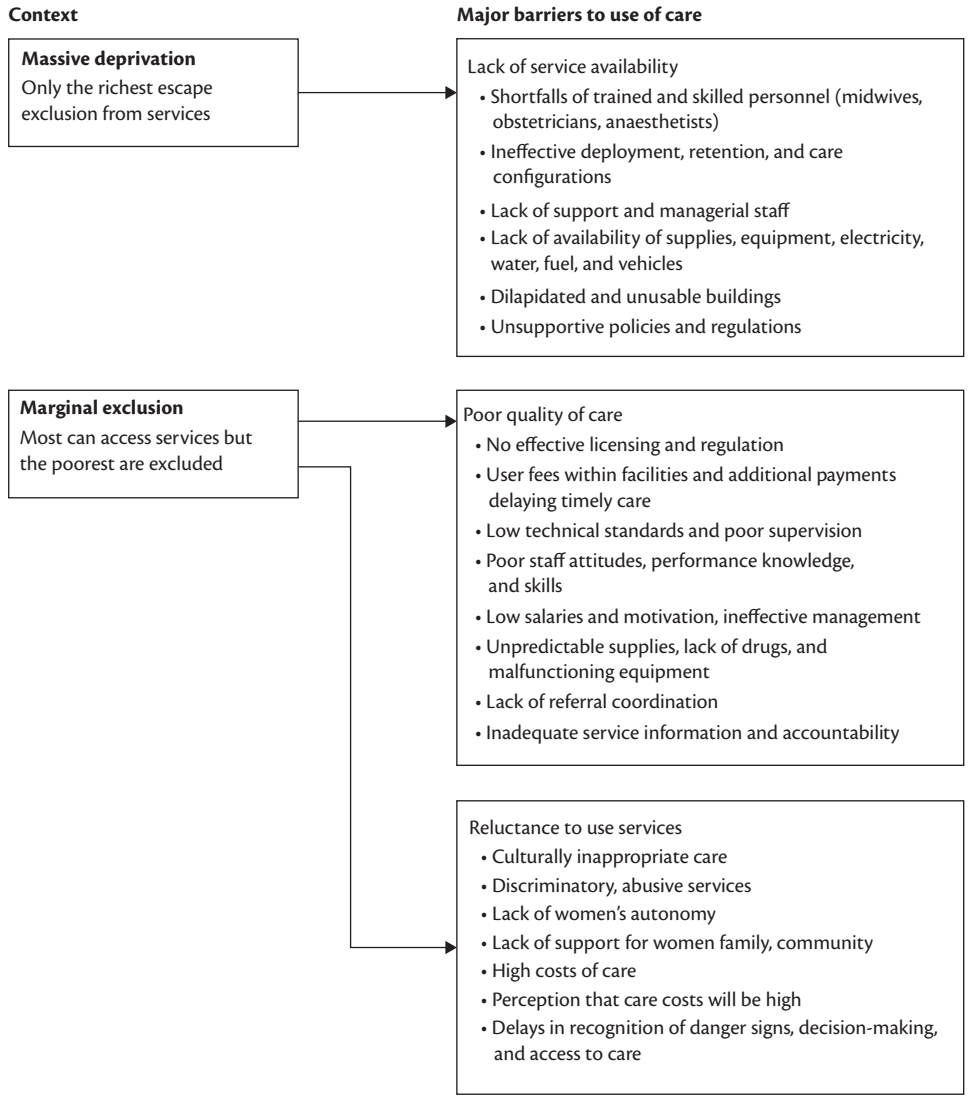

**Figure 55.6** Barriers to scaling up according to context.

Reprinted from *The Lancet*, Volume 368, number 9544, Koblinsky M, Matthews Z, Hussein J *et al.*, Maternal Survival 3: Going to scale with professional skilled care, pp. 1377–1386, Copyright (2006), with permission from Elsevier.

Outcome would be better if a few common needs were met: access to a suitable facility to receive care, a sufficient number of competently trained medical staff, and a sustainable source of supplies and equipment.

## International outreach: a global response

A concern for human welfare means that the developed world cannot be passive and inactive whilst such a global disparity exists. Thus aid, humanitarian and outreach organizations, and programmes have developed allowing nations and individuals to help. Some examples of an exhaustive list are discussed below.

### National governmental aid

As long ago as 1970, the General Assembly of the United Nations agreed that 'each economically advanced country will progressively increase its official development assistance (ODA) to the developing countries and will exert its best efforts to reach a minimum net amount of 0.7% of its gross national product at market prices by the middle of the decade'.[37] However, in economic crises, aid to foreign countries is often the first victim of cutbacks. In 2014, only five countries (Sweden, Luxembourg, Norway, Denmark, and the United Kingdom) had met this target (see Figure 55.7).

The Department for International Development (DFID) is the UK department with responsibility for managing Britain's aid to poor countries.[38] ODA is the internationally agreed standard definition of aid, with the UK ODA in 2011 being £8,570 million or 0.56% of UK gross national income (GNI).[39] The UK government is committed to raising ODA to 0.7% of GNI by 2013.[39] However, in the current economic crisis, aid to foreign countries is often the first victim of cutbacks. The DFID contributes to the running costs of United Nations Agencies such as the WHO. It also supports the World Bank and Regional Development Banks, and the European Commission. It further supported a number of global health

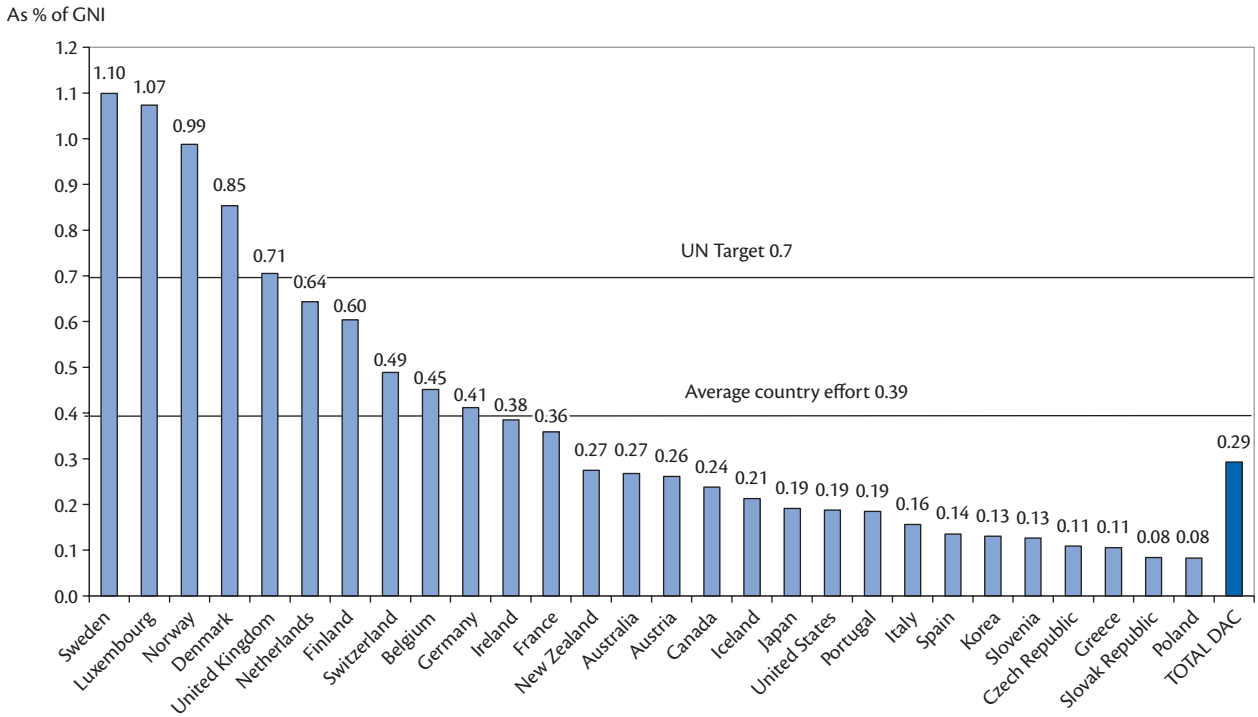

**Figure 55.7** Official development assistance as per cent of gross national income (GNI) 2014.
Data taken from http://www.oecd.org/dac/stats/development-aid-stable-in-2014-but-flows-to-poorest-countries-still-falling.htm June 2015.

initiatives, and allocations directly to countries are based on need, historical relationships, the governance and policy environment, and their strategic importance for regional development.[38] The DFID works with national governments in countries where the annual health budget is nearer to £5–10 per person rather than the £1500 in the United Kingdom, to address the challenges already mentioned in this chapter and to help strengthen the systems that underpin delivery of basic health services—the trained staff, infrastructure, drug and commodity supply, and management and information systems. Where possible this is done by directly funding the national budget to support countries to implement their own health plans that reflect national priorities.[38]

## World Health Organization

The WHO has been promoting safety and quality in healthcare since its inception.[40] In response to mounting attention that iatrogenic harm represented a public health problem comparable with deaths and injuries from road traffic accidents, the WHO established a programme for action called the *Global Patient Safety Challenge*. The first challenge, *Clean Care is Safer Care*, made a major impact in improving hand washing and thereby preventing the spread of infection. The aim of the second challenge, *Safe Surgery Saves Lives*, is to reduce errors in surgical care to avoid injury.

### Safe surgery saves lives

The goal of the Safe Surgery Saves Lives challenge is to improve the safety of surgical care around the world by ensuring adherence to proven standards of care in all countries.[41] In 2007 and 2008, a WHO pilot study involving hospitals in eight cities around the globe demonstrated that the use of a simple surgical checklist, developed by the WHO, can lower the incidence of surgery-related deaths and complications by one-third during major operations. This has since been reproduced in the Netherlands showing that with the use of the checklist, surgery complications were reduced by more than one-third and deaths were reduced by almost half.[42] Since the release of the WHO Surgical Safety Checklist globally more than 3900 hospitals representing more than 122 countries have registered as Safe Surgery Saves Lives participating hospitals.[41] If there are an estimated 234 million operations performed globally each year then at least half a million deaths per year would be preventable with effective implementation of the WHO Surgical Safety Checklist worldwide.[41]

### Safe childbirth checklist

Following the success of the Surgical Safety Checklist the WHO has developed a pilot edition of the Safe Childbirth Checklist, to support the delivery of essential maternal and perinatal care practices. It contains 29 items addressing the major causes of maternal death (haemorrhage, infection, obstructed labour and hypertensive disorders), intrapartum-related stillbirths (inadequate intrapartum care), and neonatal deaths (birth asphyxia, infection, and complications related to prematurity) in low-income countries. It was developed following a rigorous methodology and tested for usability in ten countries across Africa and Asia.[43] A collaboration was launched in November 2012 inviting organizations to study the implementation and usefulness of the checklist in diverse health-care settings. It is hoped to have as much of an impact, if not more, than that seen by the implementation of the Surgical Safety Checklist.

## Anaesthesia societies

### The World Federation of Societies of Anaesthesiologists

The World Federation of Societies of Anaesthesiologists (WFSA) was formed in 1955. It's objectives are 'exclusively educational, scientific, and charitable in nature and are to make available the highest standards of anaesthesia, pain medicine, trauma management, resuscitation, and preoperative/critical care medicine to all peoples of the world and to disseminate the same amongst them'.[44] This is achieved by dissemination of scientific information, recommending standards of training, encouraging research into all aspects of anaesthesia, establishing safety measures including standardization of equipment, and by providing information regarding opportunities for postgraduate training and research.[45] The WFSA is a federation of 126 national societies of anaesthesia and is part funded by an annual subscription from each national society (US$2 per member), 50% of any profit from the World Congress, and charitable funds collected by the WFSA Foundation.[45]

The 'Global Oximetry project' *Lifebox* of the Safety & Quality of Practice Committee will be discussed later in this chapter.

#### *International Standards for the Safe Practice of Anaesthesia*

In 1992, the WFSA adopted the *International Standards for the Safe Practice of Anaesthesia*, revisions of which have been ratified in 2008 and 2010.[46] These standards are recommended for anaesthesia professionals throughout the world. They are intended to provide guidance and assistance to anaesthesia professionals, their professional societies, hospital and facility administrators, and governments for improving and maintaining the quality and safety of anaesthesia care. For some, these standards will represent a future goal, while for others they may have already been implemented and be regarded as mandatory. In settings where the standards regarded as mandatory are not met, the WFSA recommend that the provision of anaesthesia should be restricted to procedures which are absolutely essential for the urgent or emergency saving of life or limb. In addition, provision of anaesthesia care at standards lower than those outlined as mandatory for elective surgical procedures cannot be construed as safe acceptable practice.[46] Table 55.1 gives a detailed outline of the integration of the practice standards with the levels of facilities/infrastructure, the goal being that all providers meet the 'Highly Recommended' standards and striving to meet as many of the 'Recommended' and 'Suggested' standards as well.[46]

The Publication Committee of the WFSA has a number of activities, including *Update in Anaesthesia*—a twice-yearly journal produced in English, French, Spanish, Chinese, and Russian distributed free of charge; and *Anaesthesia Tutorial of the Week*—an electronic peer-reviewed tutorial which is emailed out, free of charge, around the world. They have also encouraged the donation of books and journals from anaesthetists to colleagues without access to them.[45]

The Obstetric Committee of the WFSA has formed strong links with the Obstetric Anaesthetists' Association (OAA) and the Association of Anaesthetists of Great Britain and Ireland (AAGBI), successfully delivering projects such as the *Obstetric Anaesthesia for Developing Countries* textbook—specifically targeted at anaesthetic providers in resource-poor areas; *Obstetric Anaesthesia Resource Discs*—including a webcast of the 2008 OAA 3-day course with slides and abstract book, video of how spinals work, back copies of the *International Journal of Obstetric Anaesthesia* (IJOA), *Update in Anaesthesia*, and *Anaesthesia Tutorial of the Week*; and the *Safer Anaesthesia From Education (SAFE) Obstetric Anaesthesia* training course (see below).

### Association of Anaesthetists of Great Britain and Ireland

The Association of Anaesthetists of Great Britain and Ireland (AAGBI) was a founder member of the WFSA in 1955 and has long assisted its members and colleagues working elsewhere in more challenging circumstances.[47]

The International Relations Committee of the AAGBI promotes education, research, and safety in international anaesthesia. Its aims are to support anaesthetists who train, work, or undertake research in low- and middle-income countries, distribute educational materials and develop high-quality anaesthesia training courses, and to promote access to safe surgery and anaesthesia as a public health priority.[48] Their many activities include offering funding for projects, individual travel grants, and long-term voluntary work. They administer the *Overseas Anaesthesia Fund* to support a book donation project, anaesthesia fellows in Uganda, the *SAFE Obstetric Anaesthesia* course and the global pulse oximetry project, *Lifebox*. The *SAFE Obstetric Anaesthesia* course is a 3-day refresher course in obstetric anaesthesia that has been developed in consultation with the WFSA. It is aimed at non-physician anaesthetists in developing countries and consists of short lectures, interactive sessions, and workshops that focus on recognition and management of the leading causes of maternal death in resource poor settings, and includes the principles of the WHO Safe Surgery Saves Lives project. It was successfully piloted in Uganda in June 2011 and with grants from the British Council and the WFSA, in conjunction with the WHO and the Director General of Maternal and Child Health, further training in Uganda, Bangladesh, and Liberia is to be rolled out.[48,49]

Many collaborations exist with government bodies, other organizations, and charities to establish educational programmes in Liberia, Zambia, and Kenya.[48]

### Obstetric Anaesthetists' Association

The OAA was formed in 1969 to promote the highest standards of anaesthetic practice in the care of the mother and baby and has an international membership of over 2450. The OAA provides both education and training for anaesthetists in the United Kingdom and overseas and a resource for women seeking information about pain relief in labour and anaesthesia for caesarean delivery, translated into up to 37 languages.[50] The OAA and its membership have a long history of supporting obstetric anaesthesia around the world including nations with under-resourced healthcare systems where maternal mortality and the provision of safe obstetric anaesthesia remain challenging problems. As well as offering grants and bursaries, the OAA targets obstetric issues specifically—aiming to provide more focused educational outreach and support, mainly by running short lecture-based refresher courses.[51]

## The Global Oximetry project

The Global Oximetry project is a great example of various organizations, bodies, networks and industry working together for the greater good.

Pulse oximetry is accepted as an essential part of modern anaesthesia practice and use of a pulse oximeter has been regarded as standard for many years.[52,53] Unfortunately it is either unavailable

**Table 55.1** Guide to infrastructure, supplies and anaesthesia standards at three levels of healthcare facility, infrastructure, and supplies

| **Level 1 (Should meet at least *HIGHLY RECOMMENDED* anesthesia standards) Small hospital/health centre** | **Level 2 (Should meet at least *HIGHLY RECOMMENDED* and *RECOMMENDED* anesthesia standards) District/provincial hospital** | **Level 3 (Should meet at least *HIGHLY RECOMMENDED, RECOMMENDED* and *SUGGESTED* anesthesia standards) Referral hospital** |
|---|---|---|

Note: drug concentrations and quantities are indicative only. All equipment should be appropriate for patients' age and size

or is only patchily available in many low- and middle-income countries, with an estimated 77,700 operating theatres worldwide currently working without pulse oximeters.[54] The Global Oximetry initiative was launched in 2004, as a partnership between AAGBI, WFSA, and GE Healthcare, promoting oximetry in low-resource countries.[53] Since then, WHO patient safety has worked with the Harvard School of Public Health, WFSA, AAGBI, and many other partners around the world to facilitate the development of pulse oximetry technical standards that led to the development of a high-standard, low-cost pulse oximeter. This had led to the development of a charity project, *Lifebox*, that addressed the pulse oximeter gap by making pulse oximeters available to low- and middle-income countries. The *Lifebox* statement of purpose is 'to preserve and protect the health of patients worldwide by providing and assisting in the provision of equipment and support services in low-resource and lower–middle-income countries at no or reduced cost; and to advance the education in healthcare of the general public and especially those in the medical or similar professions by the provision of education and training worldwide'.[55]

## Anaesthesia outreach and educational mission

There is no doubt that there is a hunger for advancement in obstetric anaesthesia amongst practitioners in the developing world. This is matched by a considerable interest from individuals in the developed world in helping support a change for the better.[56] In the earlier sections in this chapter, some of the ways that governments and large global and national organizations can support, help, and influence change on a wider and more general scale have been discussed. However, significant work and change can be achieved by more focused educational outreach and support. Howell describes four key components to making a project really effective, worthwhile, sustainable, and successful:[56]

1. Local champions. The local practitioners must be enthusiastic, keen to listen, learn, and drive change forward themselves. Identifying these key people is crucial, requiring a good deal of planning, often including a reconnaissance trip or a fact-finding mission.
2. Teaching and supporting appropriate concepts, in an appropriate way. This needs intuition, sensitivity, and an ability to listen and to grasp the local needs and possibilities. It is unwise to assume to know what local practitioners need without establishing the local circumstances.
3. Team members must be flexible, able to engage with the local practitioners well, and quickly adapt to an unaccustomed environment, which may be a considerable culture shock.
4. Ongoing support and follow-up are needed to cement relationships between organizations and to provide continual reinforcement and encouragement for the local practitioners.

*Kybele, Mothers of Africa*, and the *Tropical Health and Education Trust (THET)* are successful examples of such focused educational outreach in obstetric anaesthesia.

### Kybele

Kybele is a non-profit humanitarian organization dedicated to improving childbirth safety worldwide through educational partnerships. The role of Kybele is to bring professional medical teams into host countries, to work alongside doctors and nurses in their home hospitals, to improve healthcare standards.[57] Since 2004, Kybele has conducted medical training in Turkey, Croatia, Ghana, Georgia, Armenia, Romania, Egypt, Mongolia, and Brazil. Kybele has sponsored 16 major in-country medical conferences and has trained hundreds of doctors and nurses. It has developed an educational model to quickly implement sustainable interventions at a minimal cost, whilst being culturally sensitive and country specific.

A programme is initiated by an invitation submitted by a physician from a prospective country. A site visit is then arranged and a small team and the host observe conditions and practices within several hospitals. As already mentioned, the enthusiasm and friendship that develops between the host and the team is crucial in the development of a successful and sustainable programme. Then a project is designed with the host physician to fit the specific needs of the country for return with a full multidisciplinary team about 12 months later. A full trip generally lasts 10–14 days, comprising of a national conference and on-site training, working alongside doctors and nurses within their home hospitals. Kybele maintains collaboration with host countries and repeat visits are encouraged to sustain development, growth and change. Following this format, Kybele has shown a significant increase in the uptake of regional anaesthesia in Croatia, Armenia, and Georgia.[58–60] Kybele has also seen a reduction in the MMR of a large regional hospital in Ghana from 496/100,000 live births in 2007 to 328/100,000 in 2009, a period of sustained visits from their multidisciplinary team.[61]

### Mothers of Africa

Mothers of Africa is a medical educational charity that trains medical staff in sub-Saharan Africa to care for mothers during pregnancy and childbirth. It was initially established as a link between the academic departments in Togo and Benin and the academic and NHS departments of the University Hospital of Wales in 2005. Since then educational visits to Togo, Benin, Liberia, Zambia, Ethiopia, and Tanzania have been completed, providing a mixture of seminars, lectures, workshops, and in-theatre teaching.[62,63]

### Tropical Health and Educational Trust

THET is a specialist global health organization that educates, trains, and supports health workers through global health partnerships, strengthening health systems and enabling people in low- and middle-income countries to access essential healthcare. It encourages and supports links between hospitals and healthcare training institutions in the countries of the southern hemisphere and their counterparts in the United Kingdom, or indeed any economically developed country. These links can be used to equip staff with essential skills, including anaesthetic skills, to improve morale, to increase their motivation, and thus to contribute to a strengthened infrastructure.[64,65] Throughout the dialogue between the northern and southern partners it remains essential that the southern partner defines the needs of their hospital or training school, and that the northern partner remains sensitive to the southern partner's superior knowledge of the local context. Both partners have to be innovative, adaptable, and ready to adopt methods that are new and that may not yet have been tested in the context of a developing country.[65] Advantages of a link are that it can be flexible, adapt to changing needs, and provide for a wide range of healthcare workers and service development. They do have to be long-term if they are to contribute to international development, short-term interventions do not work.[65]

## Anaesthesia in developing countries: the experience

This chapter has already discussed some of the problems in developing countries due to a critical shortage of staff and resources, and how stretched healthcare services are by diseases such as malaria and HIV, the loss of trained staff to developed countries, and the insecurities and economic effects of long-term conflict.[29] These factors ensure that a visiting anaesthetist from the developed world will experience a very different anaesthetic environment in the developing world.

Hodges et al. conducted a survey of Ugandan anaesthetists in 2006 to demonstrate the reality of anaesthesia in developing countries.[29] They found that only 6% of anaesthetists were able to provide a safe anaesthesia service for caesarean delivery by both general and spinal anaesthesia. The hospitals unable to provide safe anaesthesia for caesarean delivery had a total estimated caseload of 32,784 cases. Seventy-eight per cent of anaesthetists worked in hospitals where magnesium sulphate was unavailable for at least some of the time. Thirteen per cent worked without oxytocin or ergometrine for some of the time.[29] With regards to spinal anaesthesia, 59% of anaesthetists had no spinal anaesthetic solution at least some of the time, and comments included 'the surgeons do not like the technique' and 'there is no spinal anaesthesia performed since there are no spinal needles. The district cannot afford to buy such needles'.[29] Table 55.2 and Table 55.3 illustrate what drugs are available, showing that anaesthesia is largely ketamine based, with ether as the main volatile agent. Supplies of suxamethonium were unreliable and non-depolarizing neuromuscular blocking drugs were not commonly used. Very worryingly, blood for transfusion was only available to 23% of anaesthetists, and 10% of anaesthetists always worked without oxygen.[29]

**Table 55.2** Availability of anaesthetic drugs. Values are number (%) of anaesthetists

| *n* = 91 | Always available | Sometimes available | Never available | Don't know |
|---|---|---|---|---|
| Ketamine | 84 (92%) | 3 (3%) | 4 (4%) | 0 |
| Thiopental | 54 (59%) | 22 (24%) | 14 (15%) | 1 |
| Suxamethonium | 50 (54%) | 21 (23%) | 18 (19%) | 2 |
| Non-depolarizing relaxant | 14 (15%) | 11 (12%) | 63 (69%) | 3 |

| Nitrous oxide | 0 (0%) | 3 (3%) | 84 (92%) | 4 |
| Blood for transfusion | 21 (23%) | 54 (59%) | 15 (16%) | 1 |

## Equipment

The design of anaesthesia equipment for use in hospitals in the developing world must take into account the local conditions, particularly whether reliable supplies of compressed oxygen and electricity are available.[66]

### Equipment for delivery of inhalational anaesthesia

The developing world often has to cope with extremes of temperature, humidity, and dust, and thus an anaesthetic machine must be physically robust, easy to understand and operate, require minimal servicing and have affordable, readily available spare parts. It should also be capable of functioning without compressed gases or electricity. In the developed world, a continuous flow plenum machine is favoured for many reasons: its accurate delivery of volatile agents, presence of a reservoir bag acting as a respiratory indicator, the use of a T-piece, nitrous oxide, and circle circuit systems. However, there are many drawbacks when considering the developing world, especially the requirement of compressed gas supplies that may well be scarce. In addition, nitrous oxide and soda lime supplies are problematic and expensive. Thus it is not unusual to come across an 'anaesthetic machine graveyard' within many hospitals in Africa.[66]

One solution to these problems is draw-over anaesthesia, consisting of a low-resistance breathing circuit with one-way valves to prevent re-breathing, a self-inflating bag or bellows to ventilate the patient, and a draw-over vaporizer such as the EMO (Epstein, Macintosh, Oxford) or the OMV (Oxford Miniature Vaporiser) vaporizers seen in Figure 55.8. This system is usually robust, portable, easy to assemble, and requires minimal maintenance.[67,68]

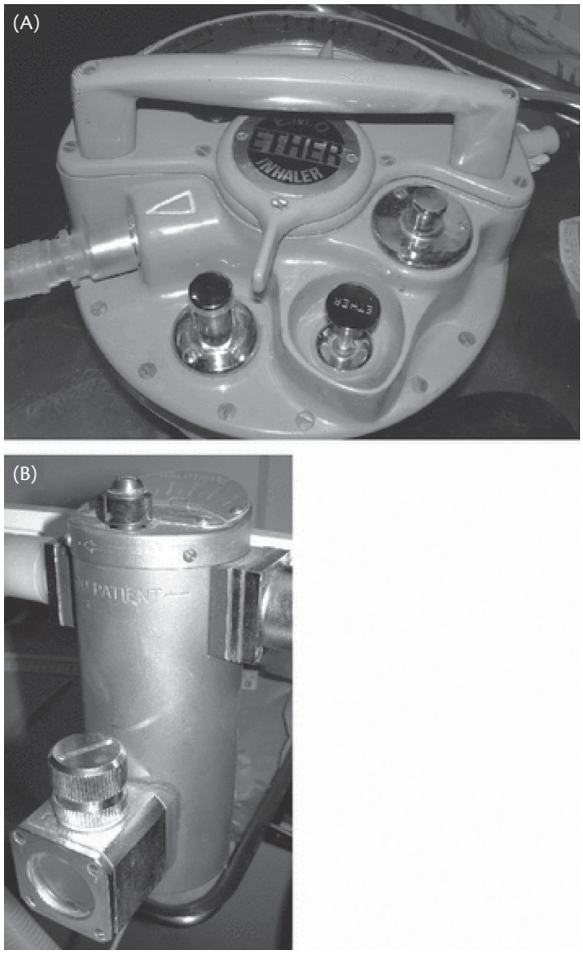

**Figure 55.8** (A) An Epstein, Macintosh, Oxford (EMO) ether vaporizer. (B) An Oxford Miniature Vaporiser (OMV).

## Oxygen concentrators

An oxygen concentrator will produce oxygen at 95% concentration by passing atmospheric air through zeolite to adsorb nitrogen, thus reducing dependence on cylinder supplies. If excessive flows are demanded, the delivered concentration is reduced. Small concentrators, which meet WHO's standards can deliver 4 L/min of oxygen (>90%) consuming approximately 350 watts (thus electricity or an AC generator are required). Concentrators are usually the cheapest source of oxygen at roughly 30–50% the cost of cylinders.[69]

## The Glostavent®

The Glostavent® (Diamedica, Barnstaple, Devon, UK) is the first anaesthetic machine that meets the WFSA performance standard for anaesthetic equipment for low- and low–middle-income countries.[70] It combines an oxygen concentrator, gas-driven ventilator, low-resistance vaporizer, modified draw-over breathing circuit, uninterruptible power supply (UPS), and a reserve oxygen cylinder (see Figure 55.9).[66] It is robust, able to withstand extremes of temperature and humidity, does not require nitrous oxide or soda lime, and accidental delivery of a hypoxic mixture is impossible.[69] It can be used in either draw-over or continuous flow mode, with any breathing circuit, on any size patient using most of the commonly used inhalational agents.

## Ketamine

Ketamine is a very versatile inexpensive drug and plays an invaluable role in the developing world. In regions where access and funding for a wider range of drugs is problematic, its broad range of clinical applications is ideal. Its good safety profile and ease of storage makes it ideal for use in areas where refrigerators, complex monitoring, electricity, and oxygen may all be in short supply or unreliable.[71]

Ketamine is a phencyclidine derivative that has an antagonistic action at *N*-methyl-D-aspartate receptors throughout the central nervous system. Being both water- and lipid-soluble, ketamine may be administered by a number of routes, and indeed intravenous (IV), intramuscular (IM), oral, rectal, subcutaneous, epidural, and transnasal routes have all been described.[71]

Typical doses for ketamine are induction of anaesthesia: 0.5–1.5 mg/kg IV or 4–10 mg/kg IM; maintenance of anaesthesia: 10–30 mcg/kg/min via IV infusion; sedation and

analgesia: 0.2–0.75 mg/kg IV or 2–4 mg/kg IM followed continuous infusion of 5–20 mcg/kg/min with or without supplemental oxygen.[72]

Ketamine anaesthesia usually maintains the airway with some preservation of pharyngeal and laryngeal reflexes. As this is not guaranteed, airway protection must still be a priority in circumstances where aspiration is a risk, such as induction of general anaesthesia for caesarean delivery. Partial airway obstruction may be overcome by simple airway manoeuvres, and apnoea after a rapid IV bolus may require a brief period of bag–mask ventilation. Bronchodilation is a useful effect that is used in the management of moderate to severe asthma, most likely mediated by a central effect inducing catecholamine release and secondly via inhibition of vagal pathways to produce an anticholinergic effect acting directly on bronchial smooth muscle.[71]

Ketamine produces an increase in blood pressure, stroke volume, and heart rate whilst maintaining systemic vascular resistance, making it an ideal agent for the shocked patient but less appropriate for patients with severe ischaemic heart disease.[71]

It produces a dissociative anaesthesia, characterized by the patient often having their eyes open and making reflex movements during anaesthesia and surgery. Hallucinations occur during recovery in up to 30% of patients, particularly in females and after large and or rapid IV boluses. These can be reduced by premedication with benzodiazepines.

Its potent analgesic qualities mean it can be used as the sole analgesic agent intraoperatively, although a balanced technique will reduce the amount of ketamine required. Some studies have shown that its intraoperative use has led to a decreased opiate requirement postoperatively, and it is extremely useful itself as a postoperative, acute pain, and chronic pain agent.

### Neuraxial anaesthesia

In modern anaesthesia practice, neuraxial techniques are preferred to general anaesthesia for many types of surgery, particularly in obstetric care. Improved outcomes have been recorded in the United Kingdom, but the techniques remain underutilized in many parts of the world. With encouragement, training, and a regular supply of appropriate needles and local anaesthetic agents, the advantages of regional techniques in the developing world could be realized.[73]

Drugs are in short supply in the developing world, funding can be erratic, and storage and stock-keeping inadequate.[73] As already discussed, Hodges et al. found that 30% of Ugandan anaesthetists stated that they never had, and 28% stated that they only sometimes had, local anaesthetic solution for spinal anaesthesia in their hospitals.[29] Unfortunately, that can lead to practitioners using multidose vials of local anaesthesia putting the patient at risk of infection. A series of 27 patients over 18 years with iatrogenic meningitis in a referral hospital in India has been reported. All cases followed spinal anaesthesia, often caesarean delivery. The mortality rate was 36%.[74]

The prevailing hot and humid climate of much of the developing world can also cause a problem with storage of drugs and equipment. This was noticed to devastating effect in Sri Lanka after the 2004 tsunami when five women contracted *Aspergillus fumigatus* meningitis following spinal anaesthesia for caesarean delivery. Unfortunately three of these women died. Subsequent examination of supplies confirmed that 43 syringes from three different manufacturers were contaminated with *Aspergillus fumigatus*. The Ministry of Health stores were found to be full of post-tsunami donations and the regular procurements were being kept in a poorly maintained humid warehouse.[75]

Lack of equipment, or inadequate or inappropriate equipment, for neuraxial anaesthesia is an ongoing problem. The most commonly used needle in Zambia is the 22 G Quincke needle, for cost reasons.[73] A study in Ghana using the same needle found an incidence of 33% postdural puncture headache in women having caesarean delivery, and the headaches were generally rated as mild to moderate.[76]

There is also a lack of training in neuraxial anaesthesia, exacerbated by the lack of access to textbooks. This is demonstrated by the poor understanding of physiological changes that occur during spinal anaesthesia for caesarean delivery. It is not uncommon for a woman to undergo this operation without any form of left lateral tilt applied.[73] It can only be hoped that this can be overcome with increased Internet access and other teaching.

What about epidural analgesia? It is argued that analgesia in labour is a fundamental human right and that an epidural may also be a medical necessity in some parturients. Once again, however, lack of equipment, drugs, and monitoring prevent the establishment of many epidural programmes. There is also resistance from many obstetricians who are unfamiliar with these techniques and are impatient to wait for onset of analgesia and anaesthesia. These challenges can be overcome, especially with the ambition, drive, and support of key team players of the health institution.[77]

### Critical care

The provision of obstetric critical care in developing nations is a huge task for medical professionals and health administrators. The gap in delivery of obstetric critical care between developing and developed nations is similarly caused by economic, sociobehavioural, clinical, and cultural factors.[78] However, the value of allocating increased nurse/patient ratios, appropriate monitoring and greater medical supervision to a percentage of hospital beds is equally valid in the resource limited location as any other.[79] Eighty per cent of perioperative caesarean delivery deaths occur in the postoperative period on the general world, so it is appropriate to consider how to identify and observe these vulnerable patients at this critical time.[33] Some isolated studies from the developing world have shown very high mortality (16.8–68.4%) among obstetric patients admitted to the intensive care unit.[78] The disparity in the quality of care within developing countries is very wide though, with the practice in some private urban institutions rivalling those in the developed world.[79]

## Conclusion

As we have entered the twenty-first century, the rate of globalization, technical development, and interdependence between countries and economies has increased at an incredible pace, and yet we are still faced with 'the largest discrepancy of all public-health statistics'; the lifetime risk of maternal death for some women in this world is as high as 1 in 6. This is an unacceptable scar on the world's conscience that demands a humanitarian response from us all, not just as nations but as individuals as well.

# APPENDIX 1

# Guidelines

Wint Mon, York-Mui Liu, Ioanna Mavridou, and Roshan Fernando

## Anaesthesia

### Association of Anaesthetists of Great Britain and Ireland. *Consent for Anaesthesia*. Revised Edition, 2006

http://www.aagbi.org/sites/default/files/consent06.pdf

This guideline from the Association of Anaesthetists of Great Britain and Ireland (AAGBI) aims to address the conduct of obtaining consent for anaesthesia and the amount of information which is necessary to ensure that a patient can give fully informed consent prior to an anaesthetic intervention.

#### Key points

- Patients for elective surgery should be given information about their anaesthetic prior to meeting the anaesthetist on the day of surgery. The anaesthetic room is not an appropriate place to provide such information.
- Information given to a patient should be tailor made to each patient's individual needs and preferences.
- Issues discussed should be clearly document by the anaesthetist. There is presently no requirement for formal signed consent before anaesthesia.
- If a patient lacks capacity, then anaesthetists should act in accordance with the Mental Capacity Act 2005 (http://www.legislation.gov.uk/ukpga/2005/9/contents).
- Every effort should be made to minimize harm and maximize benefit to the patient, especially if a trainee is to perform a practical procedure on the patient.

### The Mental Capacity Act 2005

http://www.legislation.gov.uk/ukpga/2005/9/contents

- Capacity can be defined as the ability to understand and retain any information which is given, use the information to make an informed decision, and communicate any decision made following such consideration of information.
- A person may lack capacity on either a temporary or permanent basis.
- Any decision made or performed under this act must be in the best interests of the patient. When determining what may be in the patient's best interests, it may be necessary to take into consideration any prior wishes expressed, any legal documentation signed by the patient (e.g. Lasting Power of Attorney), or carry out a consultation with the patient's friends, family, or carers.
- All efforts must be made to help the patient communicate with the medical team.
- A patient must not be deemed to lack capacity simply because they make an unwise decision. Likewise, a patient must not be considered to lack capacity simply based on their age or appearance.

### AAGBI Guideline: *Pre-Operative Assessment and Patient Preparation—The Role of the Anaesthetist*, January 2010

http://www.aagbi.org/sites/default/files/preop2010.pdf

This guideline describes the role of anaesthetists in preoperative services.

#### Key points

- Anaesthetists should lead the preoperative assessment service to ensure that the patients are pre-assessed and optimized appropriately for their operations.
- In addition, high-risk patients should be identified at this stage and counselled about their risks for the surgery. The level of care required at the postoperative phase must also be identified at this stage.
- Skilled nurse practitioners can provide a cost-effective pre-assessment service. They should communicate effectively with anaesthetists and the rest of the perioperative team in order to prepare the patients appropriately for their surgery.
- Children and their families must be provided with suitable preoperative information. They should be admitted to the designated children ward for the perioperative period.
- Preoperative tests should be requested according to national and local guidelines.
- Anaesthetic departments should arrange one consultant whole-time equivalent to run high-risk pre-assessment clinics on a daily basis.
- High standards of perioperative care should be maintained for the patients who are admitted for emergency surgery.
- All departments should have a lead consultant for the pre-assessment service.

## AAGBI Guideline: *Recommendations for Standards of Monitoring During Anaesthesia and Recovery,* March 2007

http://www.aagbi.org/sites/default/files/standardsofmonitoring07.pdf

### Key Points

- The patient must be monitored and cared for continuously by an appropriately trained anaesthetist throughout the conduct of anaesthesia.
- Standard monitoring equipment and the alarm limits must be checked by the anaesthetist before use.
- The anaesthetist must document the monitoring devices used and the information they provided on the anaesthetic record.
- The following monitoring devices are essential for the safe conduct of anaesthesia:
  - Minimum monitoring for neuraxial anaesthesia or sedation for an operative procedure: electrocardiogram (ECG), pulse oximetry, and non-invasive blood pressure monitoring.
  - Minimum monitoring for induction and maintenance of general anaesthesia: ECG, pulse oximetry, non-invasive blood pressure monitoring, airway gases ($O_2$, $CO_2$ and anaesthetic volatile agent), and airway pressures.
  - Devices that should be immediately available: a nerve stimulator if a muscle relaxant is used, a device to check the temperature, capnograph, and ECG.
  - Minimum monitoring for recovery from anaesthesia: pulse oximetry and non-invasive blood pressure monitoring.

## Difficult Airway Society Guideline: *Unanticipated Difficult Intubation During Rapid Sequence Induction,* 2004

http://www.das.uk.com/files/rsi-Jul04-A4.pdf

The Difficult Airway Society (DAS) has produced algorithms for the management of the difficult airway during intubation and extubation. The algorithm for the management of unanticipated difficult intubation during rapid sequence induction can be found via the above-mentioned link.

## DAS Guideline: *Rescue Techniques for 'Can't Intubate, Can't Ventilate' Situation,* 2004

http://www.das.uk.com/files/cvci-Jul04-A4.pdf

DAS has produced algorithms for the management of the difficult airway during intubation and extubation. Rescue techniques for 'can't intubate, can't ventilate' situation can be found via the above link.

## National Institute for Health and Care Excellence. *Inadvertent Perioperative Hypothermia: The Management of Perioperative Hypothermia in Adults.* Clinical Guideline 65, April 2008

http://guidance.nice.org.uk/cg65

The National Institute for Health and Care Excellence (NICE) has issued this guideline to prevent and manage inadvertent hypothermia in surgical patients.

### Perioperative care

Patients and their carers should be informed that:

- keeping warm during the perioperative period will reduce the risk of surgical complications such as bleeding.
- they should bring additional warm clothing.

When measuring patient temperature, healthcare professionals should:

- remember that they may need to make some adjustments in certain devices to estimate core temperature.

### Preoperative phase

- Patients are regarded as high risk for developing perioperative hypothermia if they have any two of the following factors:
  - ASA grade higher than II.
  - Temperature before the surgery is lower than 36.0°C.
  - Require both general and neuraxial anaesthesia.
  - Having major surgery.
  - Risk factors to develop cardiovascular complications during the perioperative period.
- If the patient's temperature is below 36.0°C, they should be actively warmed preoperatively and intraoperatively.

### Intraoperative phase

- The patient's temperature should be measured preoperatively and every 30 minutes intraoperatively.
- If the patient requires intravenous fluid (500 mL or more) or blood products, a fluid warming device must be used and set at 37°C.
- If the anaesthesia and surgery is longer than 30 minutes, the patient must be actively warmed during the procedure.

### Postoperative phase

- Temperature monitoring must be continued in the recovery. It should be measured every 15 minutes.
- Patients should not be discharged from the recovery if their temperature is below 36.0°C.

## AAGBI Guideline: *Infection Control in Anaesthesia,* October 2008

http://www.aagbi.org/sites/default/files/infection_control_08.pdf

Also published as Association of Anaesthetists of Great Britain and Ireland. Infection control in anaesthesia. *Anaesthesia* 2008; 63:1027–36.

### Key points

- Every anaesthetic department should have a named consultant to liaise with the hospital infection control team.
- Standard precautions must be applied to prevent the transmission of infection between patients and staff or between patients.
- Effective hand washing must take place immediately before every episode of direct patient contact.
- Every anaesthetist must follow the hospital infection control policy. All sharps must be discarded into an approved sharps container.

- Single-use disposable equipment should be used wherever appropriate. All reusable anaesthetic equipment must be decontaminated as per national standards.
- Anaesthetic facemasks, oral and nasal airways, and endotracheal tubes should be single use. A new, effective bacterial/viral breathing circuit filter must be placed between the anaesthetic machine and the patient. Breathing circuits should be changed on a daily basis.
- Anaesthetists must use maximum barrier precautions for certain invasive procedures. These include insertion of central venous catheters, spinals, epidurals, and caudals. Chlorhexidine or iodine-based preparations can be used to clean the procedure site.

### Glahn KP, Ellis FR, Halsall PJ, *et al*. Recognizing and managing a malignant hyperthermia crisis: guidelines from the European malignant hyperthermia group. *Br J Anaesth* 2010; 105:417–20

http://bja.oxfordjournals.org/content/105/4/417.full.pdf

The authors of this article have produced consensus guidelines for the recognition and the management of malignant hyperthermia (MH). This is of particular use in countries which do not have their own guideline. The AAGBI have produced their own MH flowchart (see http://www.aagbi.org/sites/default/files/mh_guideline_for_website.pdf).

### Popat M, Mitchell V, Dravid R, *et al*. Difficult airway society guidelines for the management of tracheal extubation. *Anaesthesia* 2012; 67:318–40

http://www.das.uk.com/content/das-extubation-guidelines

DAS has produced algorithms for the management of the difficult airway during intubation and extubation. The algorithm for the management of tracheal extubation can be found via the above-mentioned link.

### AAGBI Safety Guideline: *Immediate Post-Anaesthesia Recovery 2013*, March 2013

http://www.aagbi.org/sites/default/files/immediate_post-anaesthesia_recovery_2013.pdf

Also published as Association of Anaesthetists of Great Britain and Ireland. Immediate post-anaesthesia recovery 2013. *Anaesthesia* 2013; 68:288–97.

#### Key points

- After general or neuraxial anaesthesia, patients should be transferred to a designated recovery area, compliant with national standards.
- There must be a formal handover from the anaesthetist to an appropriately trained and registered practitioner.
- All departments must have agreed, written criteria that patients should fulfil before being discharged to the ward.
- All recovery areas must have an emergency call system, which is tested on a regular basis.
- If a patient, who does not fulfil the discharge criteria, is in the recovery area, there must be at least two staff present. One of them must be a trained, registered practitioner.
- All recovery practitioners should have appropriate training to the standard set by the UK National Core Competencies for Post-Anaesthesia Care.
- An anaesthetist or a registered recovery practitioner should give one-to-one care to the patient until he or she regains control of the airway, the cardiovascular and respiratory parameters are stable, and he/she is able to communicate.
- It is the anaesthetist's responsibility to remove an endotracheal tube. Capnography must be applied if an endotracheal tube is still *in situ*.
- Recovery areas for children must be appropriately equipped and staffed.
- All the above-mentioned standards should be applied to all post-anaesthetic care areas including those in obstetric units, endoscopy, radiology, cardiology, dental units, and psychiatric units. Only registered post-anaesthesia care unit practitioners should recover the patients in those areas.
- Patient safety should be a primary concern. Patient privacy and dignity should be respected.
- If a critically ill patient is managed in the recovery area due to intensive care bed shortage, the critical care team should take the primary responsibility of that patient's care.
- There must be regular audits and incident reporting systems in all recovery units.

### Royal College of Anaesthetists: *Raising the Standard: A Compendium of Audit Recipes* (Section 8.8 Technique of Anaesthesia for Caesarean Section), 2012

http://www.rcoa.ac.uk/system/files/CSQ-ARB-section8.pdf

In this audit recipe book, the Royal College of Anaesthetists recommends the proposed standard for quality improvement audits that should be carried out in individual hospitals.

#### Proposed standards for the technique of anaesthesia for caesarean delivery

- Greater than 95% of elective caesarean deliveries should be performed under neuraxial anaesthesia.
- Greater than 85% of emergency caesarean deliveries should be performed under neuraxial anaesthesia.
- The conversion rate from neuraxial to general anaesthesia in elective caesarean deliveries should be less than 1%.
- The conversion rate from neuraxial to general anaesthesia in emergency caesarean deliveries should be less than 3%.

### The American Society of Anesthesiologists task force on obstetric anesthesia. Practice guidelines for obstetric anesthesia. *Anesthesiology* 2007; 106:843–863

http://anesthesiology.pubs.asahq.org/article.aspx?articleid=1923100

#### Summary of recommendations

- *Peri-anaesthetic evaluation*
  - History—maternal health, anaesthetic and obstetric history.

- Examination—airway, cardiovascular, respiratory, and examination of the back.
- A system of communication must be in place to encourage early referral to the anaesthetist from other members of the multidisciplinary team.
- A routine intrapartum platelet count is not required in a healthy parturient.
- A group and screen or cross-match must be requested, based on the maternal history and risk factors for bleeding.
- Fetal heart rate should be monitored before and after neuraxial analgesia.

◆ *Aspiration prophylaxis*

- Uncomplicated labouring women are allowed to drink clear liquids. Solid foods should be avoided in labouring patients.
- For those undergoing an elective caesarean delivery, modest amount of clear liquids can be allowed up to 2 hours before the induction of anaesthesia, and solid food is allowed up to 6–8 hours before the induction.
- Non-particulate antacids and $H_2$ receptor antagonists for aspiration prophylaxis are recommended before surgical procedures.

◆ *Anaesthetic care for labour and delivery*

- Resources must be available to treat complications resulting from local anaesthetic and opioid drugs.
- Intravenous fluid should be started before the neuraxial analgesia or anaesthesia and continued throughout the duration of the neuraxial block.
- Early neuraxial analgesia should be considered in the following women if there is no contraindication:
- Women who are attempting vaginal birth after previous caesarean delivery.
- Women with twin pregnancies or pre-eclampsia.
- Women with anticipated airway problems or obese women.
- When continuous infusion of epidural analgesia (CIE) is used, the lowest concentration of local anaesthetic that provides adequate analgesia should be used. An opioid may be added to improve the analgesic quality, reduce local anaesthetic concentration, and minimize motor block.
- Single injection of spinal opioid with or without local anaesthetic or combined spinal epidural (CSE) can be used for labour analgesia.
- Patient-controlled epidural analgesia (PCEA) is preferable to CIE as it is effective and flexible and causes less motor blockade.

◆ *Manual removal of retained placenta (MRP)*

- There is no preferred anaesthetic technique for the MRP. The woman should be haemodynamically stable before receiving neuraxial anaesthesia.
- Nitroglycerine may be used to relax the uterus for the removal of retained placenta.

◆ *Anaesthetic choices for caesarean delivery*

- The delivery suite should have equipment and support personnel comparable to main operating theatres.
- Neuraxial anaesthesia is preferable to general anaesthesia for most caesarean deliveries. However, in situations such as persistent fetal bradycardia, suspected ruptured uterus, severe haemorrhage, and placental abruption, general anaesthesia may be the most suitable choice.
- Left lateral tilt position should be applied in all caesarean deliveries to achieve uterine displacement.
- Both phenylephrine and ephedrine can be used to treat hypotension related to neuraxial blockade.
- Neuraxial opioids are preferred over parenteral opioids.

◆ *Postpartum tubal ligation*

- Patients should follow routine fasting guidelines prior to surgery and aspiration prophylaxis should be considered.
- Neuraxial anaesthesia is preferred to general anaesthesia.

◆ *Management of obstetric and anaesthetic emergencies*

- All institutions offering obstetric care should have facilities to manage major haemorrhage. In emergencies, O-negative or type-specific blood can be used. When blood is not available or a patient refuses blood products, cell salvage should be considered.
- The anaesthetist should be familiar with the difficult intubation drill. If an intubation attempt fails, one should continue ventilating with a face mask and cricoid pressure or with a laryngeal mask airway. If ventilation is not possible, a surgical airway should be instituted.
- Delivery suites should also have basic and advanced life support facilities. Uterine displacement should be applied during cardiopulmonary resuscitation. If spontaneous circulation is not achieved within 4 minutes, perimortem caesarean delivery should be performed.

## Working Party on Obstetric Anesthesia of the Belgian Association for Regional Anaesthesia (BARA). Belgian guidelines and recommendations for safe practice in obstetric anesthesia. *Acta Anaesthesiol Belg* 2003; 54:119–125

http://www.bara2001.be/guidelines/belgian-guidelines-and-recommendations-for-safe-practice-in-obstetric-anesthesia.aspx

### Guideline 1: Pre-anaesthetic evaluation

- The entire parturient file should be available to the attending anaesthetist.
- If a parturient has significant medical problems (ASA III or above), her obstetrician should inform the anaesthetic team as soon as feasible.
- A repeat platelet count is not necessary in women with uncomplicated pregnancies if the platelet counts were normal in the third trimester.
- If a woman is booked for caesarean delivery or if she has any risk factor for bleeding, group and screen should be performed.

### Guideline 2: Equipment

- An operating theatre should be available 24/7 for caesarean deliveries and obstetric emergencies.
- All labour and delivery rooms should have the following facilities: oxygen supply, suction, emergency call buzzer, adequate lighting, electric power points, electronic fetal heart rate monitoring, non-invasive blood pressure and maternal heart rate monitoring. and continuous pulse oximetry.
- An operating theatre should have all standard anaesthetic equipment including those required to deal with difficult intubation.
- A well-equipped resuscitation cart and uterine displacement equipment should be available on all delivery suites.

### Guideline 3: Sterile technique

- Before the neuraxial block, the parturient's back should be cleaned with an antiseptic solution and allowed to dry for 2 minutes. All injectable solutions should be aspirated from the original ampoule in a sterile manner. The anaesthetist should wear a facemask, a cap, and sterile gloves.

### Guideline 4: Anaesthetic staffing and availability

- An anaesthetist must ensure maternal observations and fetal heart rate are normal, and they must be available for at least 30 minutes after the initiation of neuraxial analgesia.
- The level of the blockade and quality of the analgesia should be documented on the observation chart at least every hour.
- An anaesthetist and other appropriate staff must be readily available for an urgent caesarean delivery.

### Guideline 5: Midwifery tasks

- There should be a written hospital policy for the maintenance of neuraxial analgesia.
- Midwives are responsible for the continuous care and monitoring of the mother and the fetus during the period of epidural blockade.
- Midwives should be trained to assist anaesthetists with administering neuraxial and general anaesthesia in theatre, and to care for parturients in the immediate postoperative period.

### Guideline 6: Monitoring of mother and fetus during neuraxial labour analgesia

- Before the start of the neuraxial block:
- Fetal heart rate, maternal blood pressure and pulse
- After the initiation of neuraxial block:
- Maternal blood pressure and heart rate pulse every 5 minutes for 30 minutes and until the parameters are stable• Fetal heart rate continuously for at least 30 minutes

### Guideline 7: Monitoring during anaesthesia for caesarean delivery

- Anaesthetists should use standard monitoring for caesarean delivery as for any surgical procedure.
- Parturients must be positioned with 30° left lateral tilt.

### Guideline 8: Ambulation

- Parturients are allowed to ambulate after neuraxial analgesia if there is no contraindication. However, a parturient's ability to mobilize need to be assessed by a midwife or an anaesthetist.
- The parturient must be accompanied by a responsible adult when she ambulates.

### Guideline 9: Fluid intake, nil per oral-policy and aspiration prophylaxis

- Uncomplicated parturients are allowed to drink clear fluid in labour.
- Women on the elective caesarean delivery list are allowed to eat solid food up to 6 hours before the operation and clear liquid up to 2 hours before the procedure.
- All caesarean delivery patients must have aspiration prophylaxis.

### Guideline 10: Caesarean delivery

- Neuraxial anaesthesia is the recommended technique for elective caesarean delivery.
- General anaesthesia should not be started until the surgeon is scrubbed and ready to perform the procedure.
- Prophylactic antibiotics should be given as per hospital policy.
- Anaesthetic trained staff must be available throughout the procedure.

### Guideline 11: Maternal and neonatal resuscitation

- The anaesthetist should direct maternal resuscitation in a shared effort with the obstetricians.
- The anaesthetist may assist in neonatal resuscitation after having considered the benefit for the newborn against the risk to the mother under his or her care.

### Guideline 12: High-risk pregnancies

- Any high-risk parturient must be referred to the anaesthetist as soon as possible. An anaesthetic plan should be documented in advance of the delivery.
- Invasive monitoring facilities should be available in the delivery suites.

## ACOG Practice Bulletin 36: *Obstetric Analgesia and Anaesthesia*, July 2002

http://www.acog.org/~/media/List of Titles/PBListOfTitles.pdf?dmc=1&ts=20140222T1342330971 (ACOG practice bulletins may be viewed by ACOG members or with a valid ATHENS password)

This guideline is produced to give obstetricians a better understanding of available methods of analgesia and anaesthesia.

### Available methods of anaesthesia and analgesia

*Parenteral*

- Opioid drugs can be given as intermittent doses or as patient-controlled analgesia.
- When compared with neuraxial analgesia, parenteral agents result in higher pain scores on a visual analogue scale.

- Patients should be aware of the risks of aspiration and maternal and fetal respiratory depression.
- All parenteral drugs have significant transplacental passage.
- Norpethidine, an active metabolite of pethidine has a long neonatal half-life, and can cause prolonged neonatal sedation.

*Epidural*

- Indications for epidural analgesia include maternal request and medical indications.
- Medical indications are anticipated airway difficulty, malignant hyperthermia, selected forms of respiratory and cardiovascular disease, and prevention of autonomic hyperreflexia in patients with high spinal cord lesion.
- Epidural preparations usually consist of low-dose local anaesthetic with an opioid drug to decrease the risk of motor blockade and increase the chance of spontaneous vaginal delivery.
- Prospective cohort studies (see Practice Bulletin for details) have found no significant association between epidural analgesia and chronic back pain.
- The mechanism of epidural-related fever is unclear. Intrapartum fever results in a significant risk of maternal and neonatal antibiotic treatment.
- Epidural analgesia can prolong the labour by 40–90 minutes. It can also increase the need for oxytocin to augment labour.
- There is also a higher risk of prolongation of the second stage of labour. The rate of operative vaginal delivery is increased in women who use epidural analgesia.
- Most anaesthetists will perform an epidural block if platelet counts are higher than 100,000/μL.
- If patients are on a once-daily regimen of low-molecular-weight heparin (LMWH), neuraxial analgesia or anaesthesia should not be offered within 12 hours of the last dose.
- If patients are on twice-daily LMWH, a neuraxial procedure should not be performed within 24 hours of the last dose.
- Routine platelet count is, however, not necessary in uncomplicated women in labour.
- Neuraxial analgesia and anaesthesia are preferred in patients with pre-eclampsia if there is no contraindication.
- Breastfeeding success is not affected by intrapartum epidural analgesia.

*Spinal*

- Single-shot spinals can be used for pain relief in the second stage of labour and for procedures such as caesarean delivery and tubal ligation.

*Combined spinal–epidural*

- This method provides rapid-onset analgesia and ability to insert an epidural catheter to continue the analgesia. It can also be used for caesarean delivery and post-caesarean pain relief.

*General anaesthesia*

- Induction to delivery time should be reduced when using general anaesthesia.
- All inhaled anaesthetic agents can cause neonatal depression, uterine relaxation, and increase the risk of haemorrhage.

*Local anaesthesia*

- Various local anaesthetics are used for infiltration for perineal and vaginal repairs.
- Obstetricians also use local anaesthetics in pudendal nerve blocks for operative vaginal deliveries.

*Maternal mortality*

- Failed intubation rate in the obstetric population is tenfold higher than that of the non-obstetric population.
- In patients with a higher risk of requiring caesarean delivery, neuraxial analgesia should be recommended early during labour.

*Postoperative analgesia*

- Opioids are administered with local anaesthetic intrathecally or epidurally at the time of caesarean delivery. They can provide analgesia for 12–24 hours after delivery.
- Non-steroidal anti-inflammatory drugs (NSAIDs) should also be given if there is no contraindication.

## Obstetric Anaesthetists' Association Clinical Guideline: *Inadequate Regional Block*, 2011

http://www.oaa-anaes.ac.uk/ui/content/content.aspx?id=173

- Inadequate neuraxial block has clinical and medicolegal consequences.
- The Obstetric Anaesthetists' Association (OAA) clinical guideline page has example guidelines on inadequate neuraxial block from three UK National Health Service (NHS) hospitals.
- In order to prevent inadequate block in the operating theatre, it is advised that the duty anaesthetist ensures labour epidurals are working effectively at the beginning of the shift and replaces any ineffective epidurals early.
- Upper block levels vary among different guidelines, ranging from 'T4 cold' to 'T4 cold and T5 touch'.
- The anaesthetist must ask the obstetrician to stop the surgery once the patient complains of pain.
- Choice of pain-relieving strategies depends on the stage of the operation. Options include Entonox®, intravenous opioids such as alfentanil, other analgesics such as ketamine, local infiltration by the obstetrician, and general anaesthesia.
- All guidelines emphasize the importance of accurate documentation.
- It is good practice to visit the mother after surgery to explain the events that occurred in theatre.

## Royal College of Anaesthetists. *Report and Findings of the Third National Audit Project* (Chapter 16: Complications after Obstetric CNB), January 2009

http://www.rcoa.ac.uk/nap3

Summarized under 'Neurology'.

### *Fourth National Audit Project. Major Complications of Airway Management in the UK: Results of the Fourth National Audit Project of the Royal College of Anaesthetists and the Difficult Airway Society.* London: Royal College of Anaesthetists, 2011

http://www.rcoa.ac.uk/nap4

Learning points and recommendations for obstetric cases are summarized.

#### Learning points

1. Physiological changes in pregnancy, active labour, and isolated location increase the complexity of management of airway complications when they occur.
2. All theatre personnel (obstetricians, midwives, and operating department practitioners) should be aware of the considerable difficulty in managing airway complications in obstetric patients.
3. Three out of four parturients were obese and had complex obstetric, medical, and anaesthetic issues.
4. While preparing failed intubation strategies, it should be recognized that it is not always possible to wake the patient up.
5. Decisions regarding management of complex patients require multidisciplinary collaboration when forming initial and backup plans.

#### Recommendations

1. Obstetric anaesthetists should maintain airway skills which include the management of difficult and failed tracheal intubation and 'can't intubate, can't ventilate' scenario.
2. Obstetric anaesthetists should be competent in the use of second-generation supraglottic airway devices, which give better protection against aspiration and facilitate ventilation and/or intubation.
3. Anaesthetic departments should ensure airway skills and equipment are available whenever awake fibreoptic intubation is indicated.
4. Recovery staff including midwives should be trained and be competent to recover patients following an anaesthetic.

### AAGBI Safety Guideline: *Management of Severe Local Anaesthetic Toxicity*, December 2010

http://www.aagbi.org/sites/default/files/la_toxicity_2010_0.pdf

Summarized under 'Critical Care and Resuscitation'.

## Analgesia

### Committee of Origin: Obstetrical Anaesthesia (Approved by the ASA House of Delegates). *Statement on Pain Relief During Labour*, last amended in October 2010

http://www.asahq.org/~/media/legacy/for%20members/documents/standards%20guidelines%20stmts/statement%20pain%20relief%20labor.pdf

This is a joint statement from the American Society of Anesthesiologists (ASA) and the American College of Obstetricians and Gynecologists (ACOG).

#### Summary of the statement

- Labour causes severe pain for many women. Maternal request should be a sufficient indication for the provision of pain relief in labour provided there is no contraindication. Pain relief should also be offered when clinically indicated.
- Neuraxial analgesia is the most effective method of analgesia and it is also the least depressing to the central nervous system.
- The American Society of Anesthesiologists (ASA) and the American College of Obstetricians and Gynecologists (ACOG) believe that women should not be deprived of labour analgesia and anaesthesia services due to the lack of health insurance or inadequate nursing participation.
- Labour nursing personnel should be able to manage epidural infusions, adjust dosage and discontinue infusions under the supervision of a physician.

### NICE. *Intrapartum Care: Care of Healthy Women and their Babies During Childbirth* (Section 8: Coping with Pain in Labour: Non-Epidural). Clinical Guideline 190, December 2014

http://www.nice.org.uk/guidance/cg190/evidence/cg190-intrapartum-care-full-guideline3

#### Pain-relieving strategies

- Women who wish to use breathing and relaxation techniques and massage therapy in labour should be supported.
- Use of birthing pool is recommended for pain relief. Maternal and water temperatures need to be monitored hourly. The water temperature should not rise above 37.5°C. The bath or birthing pool should be cleaned as outlined in a protocol agreed with the microbiology department.
- Acupuncture, acupressure, and hypnosis should not be provided but if women wish to use them, they should not be prevented from doing so.

#### Non-pharmacological analgesia

- Transcutaneous electrical nerve stimulation (TENS) is not an effective analgesic technique in established labour.

#### Inhalational analgesia

- Entonox® should be accessible in all birthing areas. However, women should be informed about the side effects of Entonox®, which include nausea and dizziness.

#### Intravenous and intramuscular opioids

- All birthing units should have commonly used opioids such as diamorphine and pethidine as options for pain relief. However, women should be made aware about possible side effects associated with these drugs and that these side effects may affect both her and her unborn child. (See section 8.6.4.1.4 on page 347 of NICE guidance for a full list of side effects.)
- Women should be made aware that if they have received an opioid analgesic, they should avoid using a birthing pool within 2 hours of administration or if they feel drowsy.

## American Society of Anesthesiologists task force on neuraxial opioids. practice guidelines for the prevention, detection, and management of respiratory depression associated with neuraxial opioid administration. *Anesthesiology* 2009; 110(2):218–30

http://www.guideline.gov/content.aspx?id=15133 [currently being updated] http://www.asahq.org/~/media/Sites/ASAHQ/Files/Public/Resources/standards-guidelines/practice-guidelines-for-the-prevention-detection-and-management-of-respiratory-depression.pdf

This guideline was produced to prevent and manage respiratory depression after the administration of neuraxial opioids.

### Identification of patients at increased risk of respiratory depression

- Anaesthetists should carry out a focused history and examination before giving neuraxial opioids. Anaesthetists should enquire about symptoms of sleep apnoea and current medication history, including preoperative opioid use.

### Prevention of respiratory depression after neuraxial opioids

- Patients with sleep apnoea, on non-invasive positive airway pressure ventilation treatment, should bring their own equipment to the hospital.
- Epidural opioids have a lower risk of respiratory depression compared to parenteral opioids.
- Neuraxial morphine should not be given to outpatient surgical patients.
- The lowest effective dose of neuraxial opioids should be given, in order to reduce the risk of respiratory depression.
- In patients who have had neuraxial opioids, parenteral opioids should be used cautiously, if necessary.

### Detection of respiratory depression

- All patients receiving neuraxial opioids should be monitored for the adequacy of ventilation, oxygenation, and sedation (Table A1.1).

### Management and treatment

- Oxygen should be given if patients have reduced consciousness, respiratory depression, or hypoxaemia.
- Reversal agents should be available.
- If severe airway obstruction or hypoxia occurs, non-invasive positive-pressure ventilation should be commenced.

**Table A1.1** Monitoring required for neuraxial opioids

| Type of neuraxial opioid administration | Monitoring |
|---|---|
| Single-injection neuraxial lipophilic opioids (e.g. fentanyl) | Monitoring for a minimum of 2 h<br>Continuous monitoring for first 20 min, then once per hour until 2 h have passed<br>After 2 h, monitoring should depend on the clinical condition |
| Continuous infusion or patient-controlled epidural analgesia (PCEA) with neuraxial lipophilic opioids | Monitoring during the entire time of infusion<br>Continuous monitoring for the first 20 min, then once per hour until 12 h has passed<br>From 12 to 24 h, monitor once every 2 h<br>After 24 h, monitor at least once every 4 h |
| Continuous infusion or PCEA with neuraxial hydrophilic opioids (e.g. morphine) | Monitoring during the entire time of infusion<br>Monitoring once per hour for the first 12 h after initiation<br>From 12 to 24 h, monitor once every 2 h<br>After 24 h, monitor at least once every 4 h |

## OAA clinical guideline: *Remifentanil*

http://www.oaa-anaes.ac.uk/ui/content/content.aspx?id=191

Remifentanil PCA guidelines from five NHS trusts were described on the OAA website.

- Some hospitals offer remifentanil PCA as one of the routine analgesic options while others offer it if women have any contraindications to neuraxial analgesia.
- Remifentanil PCA should be set up by an anaesthetist.
- Typical remifentanil PCA protocols consist of doses ranging from 20 mcg to 40 mcg delivered stat with a lockout of 2 minutes. Background infusions should not be used. A dedicated cannula must be used for the PCA.
- A midwife must be present in the room to provide constant one-to-one care.
- Continuous pulse oximetry should be applied. Observations including heart rate, blood pressure, respiratory rate, sedation, and pain scores should be monitored and documented every 30 minutes.
- The midwife should start oxygen supplementation if the oxygen saturation is less than 93% or the woman becomes drowsy. Criteria that warrant an anaesthetist's presence include oxygen saturation of less than 90% despite oxygen therapy, sedation score more than 2, and respiratory rate of less than 8 breaths per minute.
- *Sedation score:*
  1: Fully awake
  2: Drowsy
  3: Eyes closed but rousable by voice
  4: Eyes closed but rousable by physical stimulus
  5: Eyes closed and not rousable.
- Contraindications to remifentanil PCA include opioid allergy, opioid analgesia administration in the last 4 hours, premature labour, and ASA III and above.
- Remifentanil PCA use should be regularly audited.

## Royal College of Anaesthetists: *Raising the Standard: A Compendium of Audit Recipes* (Section 8.9: Pain Relief after Caesarean Section), 2012

http://www.rcoa.ac.uk/system/files/CSQ-ARB-section8.pdf

- It is vital to provide adequate pain relief after caesarean delivery (CD) so that the mother can start mobilizing and look after the baby.
- Patients after surgery should have a pain score of 3 cm or less on a visual analogue scale (VAS) of 0–10 cm.

- Proposed standards by the Royal College of Anaesthesia are:
  - Nine out of ten women should have a pain score of 3 or less when assessed with a 10 cm VAS.
  - Regular NSAIDs should be given to all postoperative women if there is no contraindication.
  - Opioids should be given epidurally or intrathecally in all women who undergo CD under neuraxial anaesthesia.
  - The following observations should be performed every hour after an administration of opioids.
    - Respiratory rate
    - Sedation score
    - Pain score.
  - There should be adequate perioperative pain relief in over 90% of women undergoing CD.

### MotherToBaby: a service of the organization of teratology information specialists

http://www.otispregnancy.org/

- The Organization of Teratology Information Specialists provides evidence-based information about drug and substance exposures in pregnancy.
- Teratology information of the drugs related to the anaesthetic practice is described as follows:
  - *Acetaminophen (paracetamol)*. It is safe to take during pregnancy and during breastfeeding. There is no evidence to cause miscarriage or birth defects.
  - *Ibuprofen and other NSAIDs*. There is some evidence that NSAIDs may have a negative effect on the implantation of the early fetus. If NSAIDs are taken in the first and second trimesters, there is a possible association with certain birth defects, such as gastroschisis. During the third trimester, NSAIDs can cause premature closure of ductus arteriosus. NSAIDs are safe to use in breastfeeding mothers. NB Use of aspirin in pregnancy is not discussed in their factsheet.
  - *Opioids*. There is no strong evidence of causing miscarriage or birth defects. If a mother has been on prescription opioids, signs of withdrawal should be monitored in the baby. When opioids are used for a short period in recommended doses during breastfeeding, they are unlikely to cause harm to the baby.
  - *Benzodiazepines*. They do not significantly increase the risk of birth defects. There is some evidence that benzodiazepines can increase the risk of preterm birth and low birth weight in infants when the mother takes them during pregnancy. Signs of withdrawals should also be monitored in the neonates. During breastfeeding, long acting benzodiazepines should be avoided.

### Crews KR, Gaedigk A, Dunnenberger HN, *et al*. Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines for codeine therapy in the context of cytochrome P450 2D6 (CYP2D6) genotype. *Clin Pharmacol Ther* 2012; 91:321–6

http://onlinelibrary.wiley.com/doi/10.1038/clpt.2011.287/epdf

This evidence-based guideline aims to look at the effect that individuals with different variations of the cytochrome P450 2D6 genotype have on codeine metabolism. It makes recommendations regarding the use of codeine in these individuals.

#### Key points

- *Ultrametabolizer phenotype*: 1–2% of the population. These individuals are more likely to produce morphine after codeine administration, so increasing their risk of toxicity. It is advisable that codeine and perhaps tramadol should be avoided in these individuals.
- *Extensive metabolizer phenotype*: 77–92% of the population. These individuals have normal codeine metabolism and can safely be given codeine according to the manufacturer's recommendations (15–60 mg every 4 hours).
- *Intermediate metabolizer phenotype*: 2–11% of the population. These individuals have reduced morphine formation after codeine. In such patients, the analgesic effect should be monitored after administration of 15–60 mg of codeine every 4 hours. If there is no benefit, then consider changing to morphine or another analgesic. Tramadol metabolism may be similarly affected.
- *Poor metabolizer phenotype*: 5–10% of the population. These individuals have severely reduced morphine formation after codeine and thus derive no analgesic benefit from codeine. Tramadol should also be avoided in these individuals.

### Rigg JR, Jamrozik K, Myles PS, *et al*.; MASTER anaesthesia trial study group. epidural anaesthesia and analgesia and outcome of major surgery: a randomised trial. *Lancet* 2002; 359(9314):1276–82

http://www.thelancet.com/journals/lancet/article/PIIS0140-6736(02)08266-1/fulltext

- In this multicentre trial, 915 high-risk patients undergoing major abdominal surgery were randomized to epidural and control (alternative analgesic regimen) groups.
- Most adverse outcomes were not reduced by the use of general anaesthesia combined with an epidural or by postoperative epidural analgesia.
- However, lower pain scores and a reduction in respiratory failure were seen in the epidural group.

## Cardiovascular

### NICE. *Hypertension in Pregnancy: The Management of Hypertensive Disorders During Pregnancy*. Clinical Guideline 107, August 2010

http://www.nice.org.uk/guidance/cg107

Primary or secondary hypertension may present in women of childbearing age. Hypertensive disease in pregnancy is associated with significant maternal morbidity, as it increases the lifetime cardiovascular risk. Hypertensive disorders in pregnancy may also have a significant impact on neonatal outcomes: 5% of all stillbirths result from pre-eclampsia, whereas hypertension in pregnancy accounts for 8–10% of all preterm births. This guideline covers the diagnosis and management of hypertension during conception, pregnancy, labour, and the postpartum period.

### Key points

- Women at high risk of pre-eclampsia should be advised to take aspirin 75 mg from 12 weeks' gestation until delivery.
- Proteinuria in pregnancy should be monitored using an automated reading-strip or a spot urea:creatinine ratio, especially if in secondary care setting.
- Women who are taking angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) should be advised of the risk of teratogenicity with these drugs and efforts should be made to substitute them with safer alternatives.
- Women with uncomplicated chronic hypertension should aim to keep their blood pressure below 150/100 mmHg.
- Patients with gestational hypertension and pre-eclampsia should be offered an integrated care package, which covers monitoring and management in the community, admission to hospital for inpatient treatment, and plans for labour and delivery.
- Following consultation with an obstetric consultant, biochemical and clinical parameters to expedite delivery before 34 weeks' gestation should be documented in the notes of all women with pre-eclampsia.
- All women with pre-eclampsia should be offered a follow-up appointment 6–8 weeks postpartum.
- Women need to be warned of the risks of recurrence of gestational hypertension (13–53%) and pre-eclampsia (16–55%) in future pregnancies.

## Action on Pre-eclampsia. *PRECOG: The Pre-Eclampsia Community Guideline*, 2004

http://action-on-pre-eclampsia.org.uk/wp-content/uploads/2012/07/PRECOG-Community-Guideline.pdf

This guideline has been written to assist healthcare providers in the community with the surveillance, diagnosis, and management of pregnant women, who may be at risk of or have been diagnosed with hypertensive disease of pregnancy and possible pre-eclampsia. The guideline was developed in collaboration with the Royal College of Midwives, the Royal College of General Practitioners, and the National Childbirth Trust.

### Key points

- Pre-eclampsia is a major cause of maternal and fetal morbidity and mortality.
- According to the Magpie collaborative group, pre-eclampsia is associated with stillbirth, fetal growth restriction, and preterm birth.
- Most deaths associated with pre-eclampsia are secondary to substandard care, a failure to identify and act on risk factors at booking, and a failure to recognize and treat the signs and symptoms of pre-eclampsia after 20 weeks' gestation.
- *Recommendation 1*: Identifiable risk factors for pre-eclampsia at booking include primiparity, maternal age greater than 40, multiple pregnancy, maternal obesity, previous history of pre-eclampsia, family history of pre-eclampsia, or proteinuria at booking.
- *Recommendation 2*: Early referral to a centre which manages pre-eclampsia should be made for women with a multiple pregnancy, pre-existing medical conditions which predispose to pre-eclampsia, a history of pre-eclampsia, or two of the risk factors mentioned in recommendation 1.
- *Recommendation 3*: women with a higher risk of developing pre-eclampsia should be reviewed more frequently (e.g. every 3 weeks) than those with a low risk. Women should be made aware that pre-eclampsia can develop at any time after 20 weeks and that they can self-refer.
- *Recommendation 4*: At every assessment, the following five factors should be looked for: new hypertension (diastolic blood pressure (BP) > 90 mmHg), new or significant proteinuria, maternal headache or visual disturbance, epigastric pain or vomiting, and reduced fetal movements or small growth.
- *Recommendation 5*: the subsequent management of proteinuria detected on screening will depend on the presence of hypertension and other symptoms. Women with new proteinuria after 20 weeks with a diastolic BP greater than 90 mmHg or a systolic BP greater than 170 mmHg associated with visual disturbances or headaches require immediate admission for further assessment.
- *Recommendation 6*: an appropriate sized BP cuff needs to be used, with the patient in a semi-recumbent position with the arm at the level of the heart. Korotkoff sound V should be used to determine the diastolic BP and palpation to estimate the systolic BP.
- *Recommendation 7*: all staff measuring proteinuria need to be suitably trained to use and interpret a dipstick result. Using an automated dipstick reader may reduce error. Twenty-four-hour urine collection should be used to quantify the amount of excreted urine.
- *Recommendation 8*: fetal growth needs to be assessed in the community but there is no evidence to suggest which method of assessment is superior.

## The task force on the management of cardiovascular diseases during pregnancy of the European Society of Cardiology (ESC). ESC guidelines on the management of cardiovascular diseases during pregnancy. *Eur Heart J* 2011; 32:3147–97.

http://www.escardio.org/static_file/Escardio/Guidelines/publications/PREGN Guidelines-Pregnancy-FT.pdf

This guidance was developed by the European Society of Cardiology and is endorsed by the European Society of Gynaecology, the Association for European Paediatric Cardiology, and the German Society for Gender Medicine.

### Key points

- *Surveillance*: offer pre-pregnancy counselling in all women with known or suspected cardiovascular system disease. Echocardiography, exercise testing, and magnetic resonance imaging (MRI) without contrast may be used to assess cardiac function in pregnant women. Echocardiography to assess for fetal cardiac abnormalities should be undertaken from week 13 of gestation. Where possible, radiation, catheter techniques and surgical interventions should be avoided.

- *Congenital heart disease*: care should be individualized and the risks of pregnancy depend on the underlying disease itself. A vaginal delivery remains possible. Pregnancy should be avoided in patients with pulmonary hypertension and Eisenmenger syndrome due to the high risk of maternal mortality. Maternal cyanosis ($SpO_2$ < 85%) is associated with a low probability of fetal survival (<12%). Fontan circulation remains a moderate to high risk to pregnancy.
- *Aortic disease*: when aortic dissection occurs in high-risk individuals, it is more likely to occur in the last trimester (50%) or early postpartum (33%). Pregnancy should be discouraged in patients with Marfan syndrome, who have an aortic root diameter of greater than 45 mm. About 50% of patients with a bicuspid aortic valve and aortic stenosis have dilatation of the ascending aorta and remain at risk of dissection. A caesarean delivery should be considered when the aortic root diameter is greater than 45 mm.
- *Valvular heart disease*: moderate to severe mitral stenosis will need treatment prior to conception. Treatment for aortic stenosis before pregnancy is dependent on symptoms and cardiac function. Regurgitant lesions are better tolerated in pregnancy than stenotic lesions. Patients with metallic heart valves will need their oral anticoagulation modified to reduce fetal teratogenicity and to minimize the risk of bleeding.
- *Coronary artery disease*: primary percutaneous coronary intervention (PCI) with a bare metal stent is the treatment of choice in pregnant women, presenting with an acute coronary syndrome (ACS) or ST elevation myocardial infarction (STEMI). Women with coronary artery disease may consider pregnancy if there is no ongoing ischaemia and left ventricular ejection fraction (LVEF) greater than 40%.
- *Cardiomyopathies*: peripartum cardiomyopathy may develop in the last trimester or immediately postpartum. If the ejection fraction has not normalized after delivery, then a subsequent pregnancy should be discouraged due to a recurrence risk of 30–50% and the chance that left ventricular (LV) function may deteriorate by up to 50% during pregnancy. Patients with dilated cardiomyopathy have a high risk of deterioration, whilst those with hypertrophic cardiomyopathy tolerate pregnancy well.
- *Arrhythmias*: these may occur in pregnant women, though the incidence of life-threatening arrhythmias is rare. Direct cardioversion should be considered in unstable patients and pacemaker insertion is recommended in the presence of complete heart block.
- *Hypertension*: drug treatment in severe gestational hypertension is beneficial. Alpha-methyldopa is the agent of choice during pregnancy. Labetalol has comparable efficacy to alpha-methyldopa and may be used in severe hypertension. Calcium channel blockers are second choice agents.
- *Venous thromboembolism*: all pregnant women should undergo a risk assessment in pregnancy. High-risk patients should receive antenatal prophylaxis with LMWH, which should continue for 6 weeks postpartum.
- *Drug therapy during pregnancy*: no specific recommendations. In the case of an emergency, drugs which are not recommended in pregnancy and breastfeeding should not be withheld from the mother.

**Table A1.2** Definition of different grades of hypertension

| Grade of hypertension | Measured clinic readings | Average ambulatory or home BP readings |
|---|---|---|
| Stage 1 | 140/90 mmHg or higher | 135/85 mmHg or higher |
| Stage 2 | 160/100 mmHg or higher | 150/95 mmHg or higher |
| Severe | Systolic BP reading 180 mmHg or higher *or* diastolic BP reading 110 mmHg or higher | |

### NICE. *Hypertension: Clinical Management of Primary Hypertension in Adults*. Clinical Guideline 127, August 2011

http://www.nice.org.uk/guidance/cg127

This link to the updated quick reference guide replaces NICE Clinical Guideline 34 from 2006.

#### Key points

- Definitions (see Table A1.2):
- Patients with stage 1 hypertension should be considered for referral to specialist services for further investigation if:
  - Less than 40 years of age
  - No evidence of end-organ damage
  - No cardiovascular disease
  - No renal disease
  - No diabetes.
- Antihypertensive agents should be started in patients with stage 2 hypertension or above.
- The choice of antihypertensive agent will depend on age, race, and response to treatment.
- Lifestyle changes such as exercise and alcohol consumption should be addressed in the management of hypertension.

## Chronic maternal infections

### Royal College of Obstetricians and Gynaecologists. *The Prevention of Malaria in Pregnancy*. Green-Top Guideline No. 54A, April 2010

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg54apreventionmalariapregnancy0410.pdf

This guideline is designed to provide evidence-based medicine for the treatment of women living in the United Kingdom who may travel to malarial regions whilst pregnant.

#### Key points

- Malaria infection in pregnancy may be harmful to both the mother and the fetus. Where there is low immunity to malaria

(e.g. in the UK), infection is associated with maternal mortality, miscarriage, stillbirth, and premature labour. In regions where malaria is endemic, the infection may lead to babies with low birth weights and the concomitant health problems associated with it.

- It is advisable that where possible, a trip to a region where malaria is endemic should be postponed or avoided for a woman who is planning to become pregnant or who is pregnant. If travel is unavoidable, the woman should be encouraged to seek advice from a centre experienced in treating malaria regarding risks and avoidance strategies.
- Pregnant women returning from an malaria-endemic region should be advised that a fever or flu-like illness after travelling or up to a year after return may be suggestive of malaria infection.
- Malaria prevention may be divided into for components using the 'ABCD' formula:
  - **A**wareness of risk—women should be made aware of the signs and symptoms of malaria and be warned that even despite prophylaxis, they may still develop malaria.
  - **B**ite prevention—the use of 20% DEET repellent in pregnant women has not been associated with any adverse effects, even though DEET may be found in the cord blood of 8% of fetuses. Given that the consequences to the fetus may be devastating in malaria, 50% DEET should be used. Pyrethroid sprays quickly kill mosquitoes whereas permethrin sprays repel and kill mosquitoes and both may be used when pregnant. Bed nets impregnated with long-lasting pyrethroids have been recommended for use by the WHO (Level 1++ evidence). After sunset, long-sleeved clothing and long trousers should be worn. Presently, there is not enough evidence to recommend the use of any herbal remedies in the prevention of mosquito bites.
  - **C**hemoprophylaxis—there is no one drug which offers 100% protection against malaria. It is advisable to avoid travel to a malaria-endemic region whilst pregnant and not to become pregnant whilst taking chemoprophylaxis. However, chemoprophylaxis appears to be associated with a low risk of teratogenicity. In the second and third trimesters and whilst breastfeeding, mefloquine 5 mg/kg once a week is the recommended chemoprophylaxis. It may also be used in the first trimester, but specialist opinion should be sought before starting it. All other available drugs for chemoprophylaxis are not recommended for use during pregnancy.
  - **D**iagnosis and treatment—malaria should be suspected if a woman complains of a flu like illness or has a temperature of 38°C or above. Suspected malaria is a medical emergency and should be treated as soon as possible is with quinine 600 mg three times a day for 7 days and clindamycin 450 mg three times a day for 5–7 days. Once this course has been completed, mefloquine should be started 1 week after the last treatment dose of clindamycin and quinine.

## Royal College of Obstetricians and Gynaecologists. *The Diagnosis and Treatment of Malaria in Pregnancy.* Green-Top Guideline No. 54B, April 2010

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg-54bdiagnosistreatmentmalariapregnancy0810.pdf

This guideline offers advice regarding the drug treatment of malaria in pregnant women.

### Key points

- Diagnosis of malaria may be difficult due to the lack of specific signs and symptoms. A travel history to a malaria-endemic region should be sought in all women presenting with a pyrexia of unknown origin.
- A blood film should be performed in all suspected cases to confirm the diagnosis. Rapid diagnostic tests which detect malarial antigen or enzyme in the blood may be used but are less specific than a blood film.
- A delay in diagnosis or treatment are common reasons for deaths in Europe and the United States due to malaria.
- If a patient who is febrile has had three negative malarial blood films more than 12–24 hours apart may have malaria excluded as a possible diagnosis.
- Women with uncomplicated malaria should be admitted to hospital whereas those with severe and complicated malaria should be admitted to the intensive care unit.
- The drug treatment for the different types of malaria are summarized in Table A1.3, which is from the guideline:
- Complications of malaria in pregnancy include the following:
  - Hypoglycaemia less than 2.2 mmol/L: may be profound and persistent and be a result of treatment with quinine.
  - Pulmonary oedema or acute respiratory distress syndrome (ARDS): regularly monitor jugular venous pressure or central venous pressure, and aim to keep right atrial pressure below 10 $cmH_2O$.
  - Severe anaemia less than 8 g/100 mL: slowly transfuse 1 unit of packed red cells with frusemide or consider exchange transfusion.
  - Secondary bacterial infection: this should be suspected especially if the patient becomes hypotensive.
- Cases of severe malaria should be managed by a multidisciplinary team which includes an obstetrician, anaesthetist, and intensive care physician to ensure the best care is provided to both the mother and the baby.
- Uncomplicated malaria is not an indication for induction of labour.
- The woman should be made aware of the possibility of vertical transmission to the baby and blood films should be performed on the placenta, cord, and baby's blood as well as sending the placenta off for histological examination.
- The risks of thromboprophylaxis should be considered in such cases and should be withheld if the platelet count is falling or below 100, which is suggestive of thrombocytopaenia.
- Babies born to mothers with a confirmed diagnosis of malaria in pregnancy should be screened with standard blood films at birth and every week for 28 days.

## Guidelines for the Management of Syphilis. In James D, Steer P, Weiner C, et al. (eds) *High Risk Pregnancy: Management Options* (2nd ed). Philadelphia, PA: WB Saunders; 2003

Guidelines for treatment of syphilis are shown in Table A1.4.

**Table A1.3** UK treatment guidelines for malaria in pregnancy

| Severity | Indication | Drug and dosage |
|---|---|---|
| Severe or complicated malaria | Any species | Artesunate IV 2.4 mg/kg at 0, 12, and 24 hours, then daily thereafter. When the patient is well enough to take oral medication she can be switched to oral artesunate 2 mg/kg (or IM artesunate 2.4 mg/kg) once daily, plus clindamycin. If oral artesunate is not available, use a 3-day course of Riamet® or Malarone® or a 7-day course of quinine and clindamycin at 450 mg 3 times a day for 7 days |
| | | **Alternative:**<br>Quinine IV 20 mg/kg loading dose (no loading dose if patient already taking quinine or mefloquine) in 5% dextrose over 4 hours and then 10 mg/kg IV over 4 hours every 8 hours plus clindamycin IV 450 mg every 8 hours (maximum dose quinine 1.4 g). When the patient is well enough to take oral medication she can be switched to oral quinine 600 mg 3 times a day to complete 5–7 days and oral clindamycin 450 mg 3 times a day for 7 days (an alternative rapid quinine-loading regimen is 7 mg/kg quinine dihydrochloride IV over 30 minutes using an infusion pump followed by 10 mg/kg over 4 hours)<br>**Note**: quinine dosing should be reduced to 12-hourly dosing if IV therapy extends more than 48 hours or if the patient has renal or hepatic dysfunction. Quinine is associated with severe and recurrent hypoglycaemia in late pregnancy |
| Uncomplicated malaria | *Plasmodium falciparum* | Oral quinine 600 mg 8-hourly and oral clindamycin 450 mg 8-hourly for 7 days<br>**or** Riamet® 4 tablets/dose for weight > 35 kg, twice daily for 3 days<br>**or** Malarone® 4 standard tablets daily for 3 days |
| | Vomiting but no signs of severe or complicated malaria | Quinine 10 mg/kg dose IV in 5% dextrose over 4 hours every 8 hours plus IV clindamycin 450 mg every 8 hours. When the patient is well enough to take oral medication she can be switched to oral quinine 600 mg 3 times a day to complete 5–7 days and oral clindamycin can if needed be switched to 450 mg 3 times a day 7 days |
| Non-falciparum malaria | *P. vivax, P. ovale, P. malariae* | Oral chloroquine (base) 600 mg followed by 300 mg 68 hours later. Then 300 mg on day 2 and again on day 3 |
| | Resistant *P. vivax* | As for uncomplicated malaria *P. falciparum* |
| | Preventing relapse during pregnancy | Chloroquine oral 300 mg weekly until delivery |
| | Preventing relapse after delivery | Postpone until 3 months after delivery and G6PD testing |
| | *P. ovale* | Oral primaquine 15 mg single daily dose for 14 days |
| | *P. vivax* | Oral primaquine 30 mg single daily dose for 14 days |
| | G6PD (mild) for *P. vivax* or *P. ovale* | Primaquine oral 45–60 mg once a week for 8 weeks |

**Table A1.4** Recommended treatment for drug treatment of different stages of syphilis

| Stage of disease | Recommended treatment |
|---|---|
| Early syphilis (primary, secondary, or latent syphilis of <1 year duration) | Benzathine penicillin G 2.4 million units IM in a single dose<br>*Alternatives*:<br>◆ Tetracycline 500 mg orally 4 times daily for 2 weeks<br>◆ Erythromycin 500 mg orally 4 times daily for 2 weeks<br>◆ Ceftriaxone 1 g IM daily for 10 days |
| Late latent syphilis (> 1 year duration and cardiovascular syphilis) | Benzathine penicillin G 2.4 million units IM weekly for 3 consecutive weeks<br>*Alternative*:<br>◆ Tetracycline 500 mg orally 4 times daily for 4 weeks |
| Neurosyphilis | Aqueous crystalline penicillin G, 3–4 million units IV every 4 h for 10–14 days, followed by benzathine penicillin G 2.4 million units IM weekly for 3 consecutive weeks<br>*Alternative*:<br>◆ Aqueous procaine penicillin G 2.4 million units IM daily and probenecid 500 mg orally 4 times daily, both for 10–14 days |

# Complications or problems in reproductive medicine

## Royal College of Obstetricians and Gynaecologists. *The Management of Ovarian Hyperstimulation Syndrome*. Green-Top Guideline No. 5, 2006

https://www.rcog.org.uk/en/guidelines-research-services/guidelines/gtg5/

This guideline aims to provide an evidence-based approach to managing ovarian hyperstimulation syndrome (OHSS). Healthcare workers may be unfamiliar with the presentation of OHSS as it is a disease associated with assisted conception, which may take place at sites separate to acute hospitals. This guideline includes outpatient management, admission criteria, and basic inpatient management of OHSS.

### Key points

- OHSS is a systemic disease, which results from increased capillary permeability leading to leakage of fluid from the vascular compartment and accumulation in third spaces. In severe cases, the condition can lead to organ dysfunction, thrombosis, and ARDS.
- OHSS may occur in up to 33% of pregnancies in a mild form.
- Diagnosis of OHSS is usually clinical, associated with a history of taking gonadotrophins or antioestrogens.
- Any death resulting from OHSS must be reported to the Confidential Enquiries into Maternal Deaths (now MBRRACE).
- There are four grades of OHSS: mild, moderate, severe, and critical.
- Mild and moderate OHSS may be managed in the outpatient setting. Advice, antiemetics, and analgesia should be offered to these patients.
- Severe and critical OHSS require inpatient admission and management by a multidisciplinary team, which may include intensive care. Daily assessment should include measuring abdominal girth and assessing hydration state.
- Intravenous fluid replacement may be indicated if there is evidence of haemoconcentration (Hb > 14g/dL, haematocrit > 45%).
- Ultrasound-guided drainage of ascites may need to be performed if there is abdominal distension and oliguria despite adequate volume replacement.
- Thromboprophylaxis should be started on all women admitted with OHSS and may need to be continued after discharge, depending on other risk factors.

## NICE. *Ectopic Pregnancy and Miscarriage*. Clinical Guideline 154, 2012

https://www.nice.org.uk/guidance/cg154/resources/guidance-ectopic-pregnancy-and-miscarriage-pdf

Fetal loss in early pregnancy accounts for over 50,000 admissions each year in the United Kingdom. The rate of ectopic pregnancy in the United Kingdom is about 11/1000 pregnancies, with a mortality rate of about 0.2/1000 pregnancies. This guideline addresses the pastoral, medical, and surgical management of ectopic pregnancy and miscarriage.

### Key points

- These women must be treated sympathetically, with care and dignity. Throughout the management process, the patient and her partner must be given the opportunity to ask questions and seek advice regarding their care.
- Where an early pregnancy assessment unit exists, the woman should be able to self-refer and access the facility 7 days a week. Staff working in these units should be appropriately trained in communication with and management of such patients.
- Staff should be aware that clinical presentation in these cases may be varied. There should be access to pregnancy tests in all units.
- If ultrasound scanning is required, then a transvaginal scan should be offered. If this scan is unacceptable, then a transabdominal scan may be performed and the patient must be made aware of the limitations of the scan.
- Serum human chorionic gonadotropin (hCG) measurement should not be used to determine the viability of the pregnancy. Rather, it should be used to guide subsequent management.
- Management of miscarriage may be expectant (where no treatment is given and the patient is observed to see if the condition resolves), medical or surgical.
- Misoprostol, not mifepristone, should be offered for incomplete or missed miscarriage. This ideally should be given vaginally, but oral is an acceptable alternative. Analgesics and antiemetics should be offered concurrently.
- Surgical management of miscarriage includes manual vacuum aspiration under local anaesthetic or general anaesthetic.
- Systemic methotrexate should be offered as first-line treatment of ectopic pregnancy where appropriate.
- Surgical treatment should be first-line treatment of ectopic pregnancy in certain circumstances including the presence of severe pain and a fetal heart beat on ultrasound. The surgery should be performed laparoscopically where possible and this may include salpingectomy or salpingotomy.
- Anti-D should be offered to all Rhesus-negative women undergoing surgical management of miscarriage or ectopic pregnancy.
- A pregnancy of unknown location (PUL) is one where there is a positive serum hCG test but no embryo can be seen on ultrasound scanning. An ectopic pregnancy cannot be ruled out in these cases. Serial serum hCG testing should be taken 48 hours apart and must be used to guide subsequent management rather than try to determine the position of the embryo. If there is an increase of 63% in serum hCG after 48 hours, a viable intrauterine pregnancy is possible. A decrease of serum hCG by more than 50% after 48 hours is suggestive of a miscarriage.

## Royal College of Obstetricians and Gynaecologists. *The Investigation and Treatment of Couples with Recurrent First-trimester and Second-trimester Miscarriage*. Green-Top Guideline No. 17, 2011

https://www.rcog.org.uk/en/guidelines-research-services/guidelines/gtg17/

Miscarriage is defined as 'the spontaneous loss of pregnancy before the fetus reaches viability'. Recurrent miscarriage is defined as 'the loss of three or more consecutive pregnancies' and affects 1% of couples trying to conceive.

### Key points

- Increasing parental age is associated with an increased risk of miscarriage. The association with other epidemiological risk factors like caffeine intake, smoking, and anaesthetic gases is equivocal.
- Lupus anticoagulant, anticardiolipin antibodies, and anti-$B_2$ glycoprotein I antibodies are collectively known as antiphospholipid antibodies and are detected in 15% of women with recurrent miscarriage.
- Genetic factors include parental chromosomal rearrangements and chromosomal abnormalities of the embryo.
- Uterine malformations and cervical weakness may also cause miscarriage but the true incidence is unknown.
- Bacteraemia or viraemia resulting from a severe infection can lead to miscarriage. The organisms screened for in TORCH (toxoplasmosis, rubella, cytomegalovirus, herpes simplex, HIV) do not fulfil this criteria and such screening should be abandoned.
- Both inherited and acquired thrombophilias (e.g. factor V Leiden, deficiencies in protein C/S) have been associated with recurrent miscarriage as a result of promoting thrombosis.
- Investigations for recurrent miscarriage:
  - Test the woman for antiphospholipid antibodies and screen for thrombophilias.
  - Perform cytogenetic analysis on products of conception of the third and subsequent miscarriage.
  - Perform a pelvic ultrasound scan to assess uterine anatomy.
- Treatment options for recurrent miscarriage:
  - Refer patient to a specialist clinic.
  - Consider treatment with low-dose aspirin and heparin in women with antiphospholipid syndrome. There is no benefit from the use of corticosteroids in these patients.
  - Refer for genetic counselling should abnormal karyotyping be found.
  - Serial cervical ultrasonography to assess cervical weakness. Cerclage should only be performed if it is deemed to benefit the woman.
  - Presently, there is insufficient evidence to support the use of hormonal or metformin supplementation.

## Royal College of Obstetricians and Gynaecologists. *The Management of Early Pregnancy Loss*. Green-Top Guideline No. 25, 2006

This guideline has now been superseded by NICE Clinical Guideline 154 as referenced earlier in this section.

## Royal College of Obstetricians and Gynaecologists. *The Management of Tubal Pregnancy*. Green-Top Guideline No. 21, 2010

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg21_230611.pdf

The annual rate of ectopic pregnancies is about 11.1/1000 pregnancies. During the triennium of 1997–1999, there were 13 maternal deaths from a tubal pregnancy. Management of such pregnancies must be provided on an individual basis, taking into account the clinical presentation and the future fertility requirements of the woman.

### Key points

- Management may be surgical (laparotomy or laparoscopy), medical, or, occasionally, by observation alone.
- In the stable patient, laparoscopic surgery is preferable to the open approach.
- In the unstable patient, surgical management must be by the most expedient method. Usually this is the open approach.
- In suitable cases (serum hCG < 3000 IU/L and minimal symptoms), methotrexate may be offered as medical management of an ectopic pregnancy in an outpatient setting.
- Expectant management (observation alone) is suitable for women who are stable, with minimal symptoms and the location of the pregnancy is unknown or is identified on ultrasound and is associated with a falling serum hCG which was less than 1000 IU/L to start with.
- All Rhesus-negative women who have a suspected or confirmed ectopic pregnancy should be given anti-D immunoglobulin.

## Royal College of Obstetricians and Gynaecologists. *The Management of Gestational Trophoblastic Disease*. Green-Top Guideline No. 38, 2010

https://www.rcog.org.uk/globalassets/documents/guidelines/gt38managementgestational0210.pdf

Gestational trophoblastic disease (GTD) refers to a group of conditions encompassing complete and partial molar pregnancies, as well as malignant conditions of invasive mole, choriocarcinoma, and placental site trophoblastic tumour. The incidence of GTD in the UK is 1/714 live births.

### Key points

- Complete moles are diploid and are formed solely from paternal genetic tissue and usually arise when a single sperm duplicates after fertilizing an 'empty' ovum. Partial moles, on the other hand, are triploid in origin and are formed from both paternal and maternal genes.
- A molar pregnancy typically presents with erratic vaginal bleeding, severe vomiting, disproportionate uterine enlargement, and early miscarriage. Although ultrasound is useful, histological examination of the tissues of conception is required to confirm the diagnosis.
- Medical evacuation of a molar pregnancy should be avoided, as there is a theoretical risk of trophoblastic tissue embolization, and dissemination from the use of oxytocic drugs. Suction evacuation is the treatment of choice and anti-D should be given where appropriate.
- Should a woman develop persistent vaginal bleeding following a pregnancy, they should be investigated for gestational trophoblastic neoplasia (GTN).
- All women diagnosed with GTD should be given written information regarding their condition and referred to a trophoblastic

screening centre for follow-up. They should be advised not to try to conceive until their follow-up is complete.

- Women who receive chemotherapy as treatment for GTN should not try to conceive for at least a year after completion of treatment. These women are also at risk of early menopause and of developing secondary tumours.

## Royal College of Obstetricians and Gynaecologists. *Cervical Cerclage*. Green-Top Guideline No. 60, 2011

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg_60.pdf

Cervical cerclage is used to manage women who are at high risk of mid-trimester loss. Preterm birth is defined as delivery before 37 weeks' gestation and is the leading cause of perinatal death and disability, especially in those born before 33 weeks. The rate of preterm births continues to rise globally despite interventions aimed at preventing it.

### Key points

- There are several different indications for the insertion of a cervical cerclage:
  - History-indicated cerclage—inserted at 12–14 weeks' gestation in women who have had three or more previous preterm births and/or second trimester losses.
  - Ultrasound-indicated cerclage—sonographic assessment of the cervix occurs between 14–24 weeks' gestation. A cerclage may be indicated in cases of shortened cervical length without exposed fetal membranes, associated with a previous history of preterm birth or spontaneous mid-trimester miscarriage.
  - Rescue cerclage—this is used as a salvage procedure when there is premature cervical dilatation with exposed fetal membranes in the vagina. The decision to insert one must be made by a senior obstetrician and once inserted, it may delay delivery by up to 5 weeks.
  - Transvaginal cerclage (McDonald)—a purse-string suture is placed where the cervix meets the vaginal without mobilizing the bladder.
  - High transvaginal cerclage (Shirodkar)—a transvaginal purse-string suture placed following bladder mobilization, to allow insertion above the level of the cardinal ligaments.
  - Transabdominal cerclage—a suture is performed at laparotomy or laparoscopy and is placed it at the junction of the cervix and isthmus. This method is associated with increased maternal morbidity. It needs to be inserted preconceptually or in early pregnancy and may be considered when vaginal cerclage has failed.
  - Occlusion cerclage—a continuous non-absorbable suture is placed to occlude the external os so that the mucus plug may be retained.
- There is no evidence to support the use of history or ultrasound-indicated cervical cerclage in women with multiple pregnancies, as the cerclage itself is associated with an increased risk of preterm delivery and pregnancy loss.
- There is insufficient evidence to support the routine use of a cervical cerclage to prevent preterm delivery in women with uterine anomalies.
- The use of preoperative antibiotics and the type of anaesthetic used to insert a cerclage should be made at the discretion of the theatre team.
- Routine bed rest, abstinence from sexual intercourse, and ultrasound surveillance is not recommended. Post-procedural care should be decided on an individual basis.
- A cerclage should be removed before labour, typically between 36 and 37 weeks, unless delivery is by caesarean delivery, where the suture may be removed after delivery.
- In cases of preterm premature rupture of membranes between 24 and 34 weeks' gestation where there is no evidence of infection, removal of the suture may be delayed by 48 hours.

## NICE. *Fertility: Assessment and Treatment for People with Fertility Problems*. Clinical Guideline 156, February 2013

https://www.nice.org.uk/guidance/cg156/resources/guidance-fertility-pdf

### Key priorities for implementation

- A woman of reproductive age who fails to conceive after unprotected sex for a year, in the absence of any cause of infertility, should be assessed along with her partner.
- Early specialist referral is recommended for those women who are over 36 years of age or those who have a known cause of (or known risk factor) for infertility.
- Oral ovarian stimulation agents should not be offered to those with unexplained infertility.
- *In vitro* fertilization (IVF) treatment should be offered to women with unexplained infertility, who have not conceived after 2 years of regular unprotected sex.
- People with unexplained infertility, mild endometriosis, or mild male factor infertility should be advised to try to conceive for a total of 2 years before IVF is offered.
- A full cycle of IVF treatment should include one episode of ovarian stimulation and the transfer of any fresh and frozen embryo(s).
- Criteria for referral for IVF are shown in Table A1.5.
- The recommended number of fresh or frozen embryos to be transferred are described in Table A1.6.

**Table A1.5** Referral criteria for IVF

| Age | Previous history and treatment | Recommended treatment |
|---|---|---|
| <40 years | 2 years of regular unprotected sex or<br>12 cycles of artificial insemination | 3 full cycles of IVF |
| 40–42 years | 2 years of regular unprotected sex or<br>12 cycles of artificial insemination<br>No previous IVF<br>No history of low ovarian reserve | 1 full cycle of IVF |

**Table A1.6** Recommended number of embryos to be transferred

| Age | First cycle | Second cycle | Third cycle |
|---|---|---|---|
| <37 years | Single | Single if top quality embryos are available<br>Double if there is no top quality embryo | No more than 2 embryos |
| 37–39 years | Single if top quality embryos are available<br>Double if there is no top quality embryo | Single if top quality embryos are available<br>Double if there is no top quality embryo | No more than 2 embryos |
| 40–42 years | Double | | |

# Critical care and resuscitation

## AAGBI Safety Guideline: *Blood Transfusion and the Anaesthetist: Management of Massive Haemorrhage*, November 2010

http://www.aagbi.org/sites/default/files/massive_haemorrhage_2010_0.pdf

This guideline by the AAGBI covers massive haemorrhage from a variety of causes, and is not limited to just the obstetric population. The guideline was designed to address the fact that at the time of initial writing, only 16% of emergency departments had a massive haemorrhage protocol in place.

### Key points

- Emphasis is made on good clinical leadership, good teamwork, and clear communication with various departments in the hospital, including the telephone operator, blood bank, and porters, in order to provide coordinated care for the critically ill patient.
- The main treatment points are to:
  - stop the bleeding
  - assess the patient
  - alert other team members of the massive haemorrhage incident
  - transfer the patient to an appropriate place for ongoing care.
- Resuscitation of the patient involves inserting wide-bore cannulae, taking baseline bloods including a cross-match sample and infusing intravenous fluids. Near-patient testing of bloods (e.g. TEG®/ROTEM®/Hemocue®) may be used if available.
- Once control of the bleeding has been achieved, resuscitation should continue to normalize blood pressure, acid–base balance, and temperature. The use of vasopressors should be avoided where possible and active warming should be started as soon as convenient.
- Patients with a massive haemorrhage almost certainly develop a coagulopathy and this must be anticipated during resuscitation. A fibrinogen less than 1 g/L or prothrombin time and activated partial thromboplastin time greater than 1.5 times normal are suggestive of coagulation problems and are predictive of microvascular bleeding. Early use of 15 mL/kg fresh frozen plasma (FFP) may address these issues. Established coagulopathy may need more than 15 mL/kg of FFP. Fibrinogen concentrate is an alternative and if fibrinogen is unavailable, cryoprecipitate may be used.
- A platelet count below $50 \times 10^9$/L is suggestive of microvascular bleeding and platelets should be kept above $75 \times 10^9$/L where possible.
- The military regimen of 1:1:1 red cell:FFP:platelet is not routinely recommended in the management of massive haemorrhage in a hospital setting, unless the patient has had coincidental severe trauma.
- Tranexamic acid, correction of hypocalcaemia and hypomagnesaemia, and recombinant factor VIIa may be considered for use in the management of massive haemorrhage.
- Venous thromboprophylaxis should be started as soon as possible after the haemorrhage has been controlled due to the fact that these patients develop a procoagulant state afterwards.
- A system for collecting blood, checking blood, and tracing transfused blood products must be in place in each hospital.

## European resuscitation council. european resuscitation guidelines. *Resuscitation* 2005; 6751:51–2

The Resuscitation Council UK advocates (https://www.resus.org.uk/pages/GL2010.pdf, p. 73), that intraosseous access is now an acceptable route of drug administration and should be performed should there be two unsuccessful attempts at intravenous cannulation during resuscitation. Both the tibial and humeral routes are acceptable.

## Royal College of Obstetricians and Gynaecologists. *Maternal Collapse in Pregnancy and the Puerperium*. Green-Top Guideline No. 56, January 2011

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg56.pdf

This publication from the Royal College of Obstetricians and Gynaecologists provides a succinct account of the aetiology of maternal collapse and the physiological changes which occur in pregnancy. It offers practical information regarding the initial resuscitation, as well as the subsequent management and investigation of such patients, including the need for a perimortem caesarean delivery.

### Key points

- Early modified warning scores should be used for all patients on the delivery suite to help early identification of the ill patient.
- There are many causes of maternal collapse. The following are discussed in the guideline:
  - Haemorrhage
  - Thromboembolism
  - Amniotic fluid embolism
  - Cardiac disease
  - Sepsis

- Drug toxicity or overdose
- Eclampsia
- Intracranial haemorrhage
- Anaphylaxis.

- All staff who may be responsible for looking after a pregnant patient should be aware of the physiological changes of pregnancy and the impact these have on resuscitation.
- Maternal resuscitation should follow the resuscitation algorithms provided by the Resuscitation Council (UK), with some modification.
- A perimortem caesarean delivery should be performed within 5 minutes of the collapse. This should not be delayed by moving the woman to theatre. The obstetrician should use the caesarean technique which they are most familiar with to deliver the baby.
- Clear documentation of the events, with timings, should be undertaken. All maternal deaths should be reported to MBRRACE-UK.
- A debriefing session should occur with the patient and their family as well as the staff involved in the management of the incident.

## AAGBI Safety Guideline: *Management of Severe Local Anaesthetic Toxicity*, December 2010

http://www.aagbi.org/sites/default/files/la_toxicity_2010_0.pdf

### Key points

- Recognize signs of local anaesthetic toxicity. These are usually neurological and cardiovascular.
- Immediate management: stop local anaesthetic injection and provide supportive treatment.
- Control seizures with benzodiazepines, thiopental, or propofol in incremental doses.
- In circulatory arrest, start cardiopulmonary resuscitation, treat arrhythmia as per standard advanced life support protocol, and commence lipid emulsion therapy.
- In the absence of circulatory arrest, use conventional therapies to treat hypotension and arrhythmia, and consider lipid emulsion therapy.
- Lipid emulsion therapy:
  - Give an initial intravenous bolus of 20% lipid emulsion (1.5 mL/kg over 1 minute).
  - Start an intravenous infusion of 20% lipid emulsion at 15 mL/kg/h.
  - After 5 minutes, give a maximum of two further boluses (same dose) and double the rate of infusion to 30 mL/kg/h if cardiovascular stability has not been restored or an adequate circulation deteriorates. Leave 5 minutes between boluses.
  - A cumulative dose should not exceed 12 mL/kg.
  - Continue the infusion until an adequate circulation is restored or maximum dose of lipid emulsion is given.
- Patient should be transferred to a clinical area with appropriate equipment and suitably trained staff.
- Exclude pancreatitis by regular review, including daily amylase or lipase assays for 2 days.
- Report cases in the United Kingdom to the appropriate regulatory authority.

## OAA Clinical Guidelines: *Modified Early Obstetric Warning Score (MEOWS)*, 2009

http://www.oaa-anaes.ac.uk/ui/content/content.aspx?id=186

### Key points

- The early warning score was introduced in order to recognize deteriorating patients early and to instigate treatment at the earliest opportunity.
- Examples of MEOWS from four NHS hospitals are described on the OAA website.
- Physiological parameters measured are pulse, blood pressure, oxygen saturation, respiratory rate, conscious level, temperature, and urine output. Some units also incorporate pain scores and partograms into the MEOWS charts.
- Colour triggers are usually used at the upper and lower limits to alert midwives to take action. (Red colour as an alert to take urgent action and amber to suggest that the patient's condition is worsening, and an escalation of treatment is required.)
- A clear algorithm of the action plan required for different levels of triggers needs to be available.
- The algorithm should include whom to call for help, how to escalate if help is not immediately available, and frequency of observations required if a patient's condition deteriorates.
- Regular audit is required to check staff compliance with the MEOWS.

## Centre for Maternal and Child Enquiries (CMACE). Saving mothers' lives: reviewing maternal deaths to make motherhood safer: 2006–2008. The eighth report of the confidential enquiries into maternal deaths in the United Kingdom. *BJOG* 2011; 118(Suppl 1):1–203.

http://www.hqip.org.uk/assets/NCAPOP-Library/CMACE-Reports/6.-March-2011-Saving-Mothers-Lives-reviewing-maternal-deaths-to-make-motherhood-safer-2006-2008.pdf

The top ten overall recommendations are summarized here:

1. Women of childbearing age with a pre-existing medical condition should be made aware throughout their pregnancy that their condition may worsen and require a change in medication which may affect their unborn child. Such counselling services should be an integral part of the commissioning of community care of the pregnant woman.
2. All pregnant women who do not speak English should have access to professional interpretation services.
3. All referrals made to other specialties for a pregnant patient should be regarded as urgent and it should be clearly documented on the referral that the patient is pregnant. Such

referrals should be made following consultation with senior clinicians.

4. All women whose pregnancies are likely to be complicated by serious medical or mental health conditions, regardless of whether the condition existed prior to pregnancy, should be referred to specialist centres for expert care in a timely fashion. Those providing care of the parturient in the community should be allowed to make such referrals without prior approval from an obstetrician. However, the obstetrician should be kept informed if any such referrals are made.
5. All clinical staff must complete regular training for the identification and initial management of serious obstetric conditions or other medical emergencies, such as sepsis. Clinical staff must also take regular training for basic, intermediate, and advanced life support skills appropriate for their positions.
6. There should be a routine use of a national modified early obstetric warning score (MEOWS) chart in all pregnant or postpartum women who become unwell. MEOWS was introduced to recognize deteriorating patients early and to instigate treatments at the earliest opportunity. The management of pregnant or postpartum women with an acute severe illness requires a multidisciplinary team approach. Obstetric trainees should seek help early from senior medical, anaesthetic and critical care staff.
7. All pregnant women with pre-eclampsia and a systolic blood pressure of 150–160 mmHg or higher require urgent antihypertensive treatment in line with the guidelines from NICE. Antihypertensive treatment may be considered in women who do not fulfil the BP criteria but are otherwise high risk of becoming seriously unwell from hypertensive disease in pregnancy.
8. All pregnant and recently delivered women should be informed of the risks and signs of genital tract infection and how to prevent its transmission. All clinical staff should follow local infection control policy, and be aware of the signs and symptoms of sepsis. High-dose intravenous broad-spectrum antibiotics should be given within the first hour of recognition of septic shock or severe sepsis.
9. A high-quality local review must take place when there is a maternal death. The results of the review must be discussed with all maternity staff. The recommendations from the review process must be implemented and audited at regular intervals.
10. Specialist pathologists who perform maternal autopsies should have this agreed in their job plans. Furthermore, the provision of such services should be streamlined so fewer centres are able to perform high quality autopsies.

### Key points

- All anaesthetic practitioners should have regular drills in the management of failed intubation to maintain this core skill.
- The multidisciplinary team should be involved in the management of the acutely unwell parturient with early anaesthetic and critical care involvement.
- If a woman has had a fully working epidural during labour and the decision is made for an operative delivery, then her epidural should be topped up as soon as is possible to provide surgical anaesthesia. If this is established outside the theatre environment, then appropriate monitoring and necessary precautions should be implemented.
- If a serious untoward incident occurs, all the drugs and equipment used should be kept for review until the cause of the incident has been determined.
- A woman should be fully awake before extubation if she has been given a general anaesthetic with a potentially full stomach. The insertion of an 'in and out' nasogastric tube to decompress the stomach prior to extubation may be considered in such cases.
- Parturients with severe pre-eclampsia should have BP control instigated early with regular monitoring in a high dependency unit environment. Anaesthetic and where necessary critical care input should be instituted early on.
- A parturient with sepsis should be managed with broad-spectrum antibiotics, cardiovascular support including inotropes, and appropriate fluid resuscitation to prevent circulatory collapse. Transfer to critical care and surgery should be considered in management of severe sepsis.
- Women with known risk factors for major haemorrhage should be managed in specialist maternity units. Management of major haemorrhage may require the use of cell salvage and specialist services such as interventional radiology or critical care.
- The acute anaphylaxis management algorithm should be immediately available in all clinical areas.
- There must be a clear escalation pathway to provide additional skilled assistance, if the medical staff on the delivery suite are busy and a woman with an acute, severe illness requires high-dependency care.

## Confidential Enquiry into Maternal and Child Health. *Why Mothers Die 2000–2002: The Sixth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom* (Chapter 17: Trends in Intensive Care), 2004

http://www.hqip.org.uk/assets/NCAPOP-Library/CMACE-Reports/33.-2004-Why-Mothers-Die-2000-2002-The-Sixth-Report-of-the-Confidential-Enquiries-into-Maternal-Deaths-in-the-UK.pdf

This chapter discusses the importance of early recognition of the sick parturient. It also stresses the significance of the early involvement of senior help, to assist in the resuscitation and management of the acutely unwell parturient.

### Key points

- As with other surgery, elective cases requiring intensive care postoperatively should be pre-arranged with the intensive care unit. This may require the cancellation of other planned surgery if bed capacity is reached.
- Aggressive resuscitation and treatment for the sick parturient should begin on the ward prior to arriving in intensive care.

Appropriate lines and invasive monitoring should be instituted on the ward where possible.

- A blood gas should be performed as soon as possible and a metabolic acidosis must be treated seriously.
- Early communication with the intensive care consultant should occur when there is a sick patient on the delivery suite.
- Appropriately modified early warning scores should be used on labour ward. Tachypnoea is an early sign of a deteriorating patient and should always be investigated.
- It is possible to provide a higher level of care in obstetric theatres if there is a delay in admission to the intensive care unit.
- Where available, intensive care outreach teams must be utilized to assist with maternal resuscitation.
- In the management of major obstetric haemorrhage, the priorities are to stop the bleeding, correct the haemoglobin and clotting, and to call for senior anaesthetic help as soon as possible.

This theme continues to be important in the global care of the sick parturient and is reiterated in Chapter 16 'Critical Care', pp.173–180 of the *Eighth Report of the Confidential Enquiries into Maternal Deaths in the UK* (http://www.oaa-anaes.ac.uk/assets/_managed/editor/File/Reports/2006-2008%20CEMD.pdf):

- Severe sepsis remains an important cause of significant morbidity and mortality and should be managed with early protocol-driven care based on the Sepsis Care Bundles prior to transfer to intensive care (see following 'Surviving Sepsis Campaign' section).
- The use of modified early warning scores for pregnant women can assist in the detection of the deteriorating parturient.
- Where available, the early involvement of critical care outreach teams would assist in maternal resuscitation.
- Maternal resuscitation in major obstetric haemorrhage should include early use of clotting factors and blood products to reduce the volume of crystalloids infused. A coordinated response from the wider multidisciplinary team ensures that appropriate products are given in a timely fashion. More information can be found from reading the Royal College of Obstetricians and Gynaecologists Green-Top Guideline No. 52 (May 2009): *Prevention and Management of Postpartum Haemorrhage* (http://www.rcog.org.uk/files/rcog-corp/GT52PostpartumHaemorrhage0411.pdf), which is summarized in Chapter 35 of this book.
- Simulation scenarios should be used to help train staff and maintain their skills in managing obstetric emergencies.

### Surviving Sepsis Campaign. *Sepsis Six Care Bundle*

http://www.survivingsepsis.org/SiteCollectionDocuments/SSC_Bundle.pdf

This two-page care bundle outlines the goals, investigations, and treatment strategies that need to be established within the first hour of presentation, when managing the acutely unwell septic patient.

#### Key points

- Give high-flow oxygen via facemask
- Obtain blood cultures (ideally before giving antibiotics)
- Prescribe and administer broad-spectrum antibiotics
- Give intravenous fluid boluses as needed
- Take bloods including haemoglobin and serum lactate
- Measure hourly urine output.

## Endocrine

### Scottish Intercollegiate Guidelines Network. *Management of Diabetes: A National Clinical Guideline.* SIGN 116, March 2010

http://www.sign.ac.uk/pdf/sign116.pdf

This guideline by the Scottish Intercollegiate Guidelines Network (SIGN) encompasses the management of type 1 and type 2 diabetes in pregnant and non-pregnant patients. Good glycaemic control before conception and during pregnancy can lead to good maternal and fetal outcomes. Diabetes is associated with miscarriage, pre-eclampsia, maternal infection, fetal congenital malformation, and late intrauterine death. The following points summarize the management of diabetes in pregnancy.

#### Key points

- The care of a pregnant woman with diabetes should involve a multidisciplinary team, which includes an obstetrician and a physician with an interest in diabetes. There should be good communication between team members.
- The choice of contraception should be decided on an individual basis. The oral contraceptive pill (OCP) may not be suitable for all women due to the presence of diabetic vascular complications. Intrauterine devices and hormonal implants are effective alternatives.
- Pre-pregnancy care with a multidisciplinary team leads to improved maternal and fetal outcomes. Pre-pregnancy glycaemic control should aim for an HbA1c of less than 7%. The higher the HbA1c, the higher the risk of fetal malformations.
- High-dose folic acid 5 mg should be given to diabetic women prepregnancy and continued up to 12 weeks' gestation.
- The use of metformin and glibenclamide in early pregnancy is not associated with any additional risk of teratogenesis or pregnancy loss. The use of other types of sulphonylureas should be avoided due to their ability to cross the placenta.
- The use of statins and ACEIs should be avoided due to the increased risk of fetal malformations.
- Dietetic advice should be available to women pre- and during pregnancy to ensure optimum glycaemic control. Postprandial glucose monitoring should be advised in women with gestational diabetes (GDM) and may be considered in women with type 1 or 2 diabetes.
- The choice of insulin therapy should be made on an individual basis. Human insulins are licensed for use during pregnancy but oral hypoglycaemic agents are not.
- Pregnancy-induced hypertension and thromboembolism should be screened for and managed accordingly.

- Women and their partners should be educated in recognizing the signs of hypoglycaemia and ketoacidosis, as these may be associated with fetal death. Appropriate treatment advice including self-referral to hospital should be given.
- Retinopathy may deteriorate during pregnancy and monitoring is advocated prepregnancy and in each trimester in women with type 1 and 2 diabetes. Early referral to an ophthalmologist is recommended.
- Pre-existing diabetic nephropathy is associated with poorer pregnancy outcomes. Close attention should be given to monitoring and managing blood pressure in these patients.
- Both macrosomia and intrauterine growth restriction (IUGR) are more likely in women with diabetes. In cases of suspected IUGR, fetal monitoring with growth scans and umbilical artery Doppler should be carried out.
- Once diagnosed with GDM, dietary advice to lower blood glucose should be offered. Treatment with oral hypoglycaemic agents and/or insulin may be needed.
- In women with diabetes, delivery should occur within 40 weeks. These women have a higher rate of caesarean delivery compared with the normal population. An agreed plan should be made in advance regarding insulin management in labour and intravenous insulin and dextrose may be necessary to maintain blood glucose between 4 and 7 mmol/L in labour.
- There is no need to routinely admit babies born to mothers with diabetes to the neonatal unit, but they should be monitored closely for neonatal hypoglycaemia. This is defined as a blood sugar below 2.6 mmol/L and is associated with neurodevelopmental problems. In the postpartum period, women with type 1 and 2 diabetes will need to be followed up and their doses of insulin may need to be adjusted. Dietary advice, weight loss, and lifestyle changes need to be given to women with GDM postpartum as they are at risk of developing type 2 diabetes in later life. They will also need to be given good preconception counselling in subsequent pregnancies.

## NICE. *Diabetes in Pregnancy*. Clinical Guideline 63, March 2008

http://www.nice.org.uk/guidance/CG063

In England and Wales, 2–5% of all pregnancies are complicated with diabetes, 87.5% of which are due to GDM. This guideline contains best practice advice regarding women with diabetes who are either planning to become pregnant, who are pregnant, or who have recently delivered. Poorly managed diabetes of any type during pregnancy can have serious implications for both the mother and fetus.

### Key points

- Preconception advice needs to be offered to all diabetic women of childbearing age, with emphasis on good glycaemic control in order to minimize effects on the developing fetus. Women with diabetes should be encouraged to take folic acid 5 mg a day before conception and up to 12 weeks' gestation to minimize the risk of neural tube defects.
- Women should be encouraged to keep and maintain their HbA1c below 6.1% to minimize the likelihood of congenital malformations. . Women with an HbA1c more than 10% need to be strongly discouraged from getting pregnant.
- Metformin and fast-acting insulins (aspart and lispro) are safe to use in early pregnancy. All other oral hypoglycaemics should be stopped and substituted with insulin. Statins and ACEIs should also be discontinued before conception.
- Digital retinal assessment with tropicamide should be offered to women either preconception or at their first appointment after conception.
- An assessment of renal function should also be made early in pregnancy and referral to a nephrologist where proteinuria is greater than 2 g/day.
- Risk factors for GDM include previous history of GDM, family history of GDM, and body mass index (BMI) greater than 30 kg/m$^2$. Diet and exercise may reduce the likelihood of developing GDM.
- Ten to 20% of women with GDM will require treatment with metformin or insulin during pregnancy.
- Screening for GDM should be in the form of a 2-hour oral glucose tolerance test at 24–28 weeks' gestation.
- Any woman with suspected diabetic ketoacidosis should be admitted to a level 2 facility, with both medical and obstetric input.
- All women with diabetes should be offered ultrasound scanning with a four-chamber view of the fetal heart and outflow tracts between 18 and 20 weeks' gestation.
- Fetal well-being should be assessed using ultrasound to determine the rate of growth and volume of amniotic fluid every 4 weeks between 28 and 36 weeks' gestation.
- During pregnancy, the diabetic team should aim to contact the woman every 1–2 weeks to assess maternal well-being.
- Beta-mimetic drugs should not be used for tocolysis in this group.
- Delivery should be offered after 38 weeks' gestation where possible, by elective caesarean delivery or induction of labour.
- Anaesthetic assessment of women with diabetes should occur in the third trimester.
- During labour and delivery, blood glucose should be maintained between 4 and 7 mmol/L. In women treated with insulin, an intravenous insulin and dextrose infusion may be required.
- If a general anaesthetic has been given, the maternal blood glucose should be checked every 30 minutes from induction until she is fully conscious.
- Fetal blood glucose should be measured 2–4 hours after delivery. Women should be encouraged to start early feeding and at 2–3-hourly intervals until the pre-feed neonatal blood glucose is greater than 2 mmol/L.
- The baby may be looked after by the mother after birth, unless there is an indication for neonatal intensive care admission.
- Women with type 1 diabetes should reduce their insulin postpartum and be aware that they are at risk of hypoglycaemia, particularly if they are breastfeeding.

- Women with GDM should be given exercise, dietary, and lifestyle advice in the postpartum period, a fasting blood glucose check 6 weeks after delivery, and annually thereafter.

### CMACE/Royal College of Obstetricians and Gynaecologists Joint Guideline: *Management of Women with Obesity in Pregnancy*, March 2010

http://www.hqip.org.uk/assets/NCAPOP-Library/CMACE-Reports/15.-March-2010-Management-of-Women-with-Obesity-in-Pregnancy-Guidance.pdf

Maternal obesity is defined as a BMI of greater than 30 kg/m$^2$ at the first antenatal appointment. Obesity in pregnancy is associated with serious adverse outcomes including miscarriage, GDM, pre-eclampsia, postpartum haemorrhage, and neonatal death. It is also associated with a higher caesarean delivery and lower breastfeeding rate when compared with women with a normal BMI.

#### Key points

- Advice on weight loss, exercise, and diet should be given in primary care to all women of childbearing age. They should also be made aware of the risks and complications associated with obesity in pregnancy.
- Women should be encouraged to take 5 mg of folic acid a day during preconception and the first trimester and 10 mcg of vitamin D daily during pregnancy and breastfeeding.
- All antenatal clinics should have provision to manage obese patients.
- Women with a BMI greater than 40 kg/m$^2$ should have an antenatal appointment with an obstetric anaesthetist to discuss the potential plan and anticipate any difficulties during labour and delivery.
- Antenatal thromboprophylaxis should only be given if there is a specific indication following appropriate assessment. Postpartum, these women should be encouraged to mobilize as soon as possible. All women with a BMI greater than 40 kg/m$^2$ should be offered thromboprophylaxis for a week postpartum, regardless of the mode of delivery.
- During antenatal assessment of blood pressure, an appropriately sized cuff needs to be used and the size of the cuff should be documented in the notes. Surveillance for pre-eclampsia should be in accordance with the PRECOG (Pre-eclampsia Community Guideline) guidelines (see earlier in the 'Cardiovascular' section).
- All women with a booking BMI of greater than 30 kg/m$^2$ should be screened for gestational diabetes as per NICE guidelines (see NICE Clinical Guideline 63, summarized earlier in this section).
- Women with obesity should have an antenatal appointment to discuss plans for labour and delivery and the potential complications which may occur. An individual plan should be made in each case. Delivery should occur in a consultant-led unit where there are appropriate neonatal support services.
- When admitted in labour, it is important to inform the duty anaesthetist and an experienced obstetrician early, so that they are able to assess the patient and make the necessary plans for labour and delivery.
- Midwifery care should continue throughout labour. These patients should have an intravenous line inserted early and have active management of the third stage of labour.
- The theatre team should be informed if the woman weighs more than 120 kg and is due to have an operative procedure in theatre.
- Antibiotic prophylaxis should be given before caesarean delivery due to the higher risk of poor wound healing.
- Where there is more than 2 cm of subcutaneous fat, suturing of the subcutaneous space should occur to minimize the risk of wound infection and separation.
- Postpartum, women should be encouraged to breastfeed and advice offered regarding lifestyle, weight management, and diet.

### NICE. *Obesity: The Prevention, Identification, Assessment and Management of Overweight and Obesity in Adults and Children*. Clinical Guideline 43, December 2006

http://www.nice.org.uk/guidance/CG43

This guideline offers advice on the prevention, identification, assessment, and management of overweight and obesity in adults and children.

#### Key points

- Local authorities, schools, and nurseries should endeavour to provide facilities and activities, which promote a more healthy and less sedentary lifestyle.
- Health practitioners should be able to offer advice and support to overweight adults and children regarding diet, lifestyle changes, and weight management programmes. Referral to specialists may be needed in individuals with complex care needs.
- Drug treatment to assist with weight loss should only be started in adults following a full discussion of the risks and benefits.
- Bariatric surgery is recommended as a treatment option in the following circumstances:
  - A BMI of 40 kg/m$^2$ or more or a BMI between 35 and 40 kg/m$^2$ with other significant disease (e.g. hypertension or diabetes) which would be improved with weight loss.
  - All other appropriate weight loss measures have been tried and failed to produce or maintain weight loss for at least 6 months.
  - The person has been or will be managed by a specialist obesity service.
  - The person is generally fit for anaesthesia and surgery.
  - The person is motivated and will commit to long term follow-up.
  - Surgery may be offered as a first-line treatment in patients with a BMI of 50 kg/m$^2$ in whom surgery would be appropriate.

## Fetal

### Royal College of Obstetricians and Gynaecologists. *Management of Monochorionic Twin Pregnancy*. Green-Top Guideline No. 51, 2008

https://www.rcog.org.uk/globalassets/documents/guidelines/t51managementmonochorionictwinpregnancy2008a.pdf

This is summarized under 'Intrapartum Care'.

## Royal College of Obstetricians and Gynaecologists. *The Management of Breech Presentation*. Green-Top Guideline No. 20b, 2006

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg-no-20b-breech-presentation.pdf

This is summarized under 'Intrapartum Care'.

## NICE. *Antenatal Care: Routine Care for Healthy Pregnant Women*. Clinical Guideline 62, March 2008

http://www.nice.org.uk/guidance/cg62

### Key points on antenatal fetal assessments

- For a woman who is nulliparous with an uncomplicated pregnancy, ten antenatal appointments should be offered.
- For a woman who is multiparous with an uncomplicated pregnancy, seven appointments should be adequate.
- An early ultrasound scan should be carried out to determine the gestational age and to detect multiple pregnancies.
- An ultrasound scan to screen for structural anomalies should be offered ideally between 18 and 20 weeks' gestation. This should be done by an appropriately trained sonographer and with equipment of an appropriate standard.
- By April 2007, pregnant women should be offered screening for Down's syndrome with a test, which provides a detection rate of above 75% and a false-positive rate of less than 3%.
- Pregnant women should be offered an estimation of fetal size by measuring the symphysis–fundal distance at each antenatal appointment.
- Fetal presentation should be examined by abdominal palpation at 36 weeks or later, when presentation is likely to influence the birth plan. Suspected fetal malpresentation should be confirmed by an ultrasound.
- Routine formal fetal-movement counting is not recommended.
- Routine auscultation of the fetal heart is not recommended. However, when requested by the mother, an auscultation of the fetal heart may give reassurance.
- Routine use of antenatal electronic fetal heart rate monitoring (cardiotocography) should not be offered to women with an uncomplicated pregnancy.

## NICE. *Intrapartum Care: Care of Healthy Women and their Babies During Childbirth*. Clinical Guideline 190, December 2014

http://www.nice.org.uk/guidance/CG190

### Key points on intrapartum fetal monitoring

*First stage of uncomplicated labour in low-risk women*

- Intermittent auscultation of the fetal heart after a contraction should be carried out for at least 1 minute, at least every 15 minutes.
- Fetal heart rate (FHR) should be recorded as an average.
- Maternal pulse should be monitored hourly to differentiate the two heart rates.

*Second stage of labour in low-risk women*

- Intermittent auscultation of the fetal heart should be done after a contraction for at least 1 minute, at least every 5 minutes.
- The maternal pulse should be palpated if fetal bradycardia or any other FHR anomaly is suspected.

*Low-risk women should be monitored using continuous electronic fetal monitoring (EFM) for the following circumstances:*

- Significant meconium-stained liquor (should also be considered for light meconium-stained liquor)
- Abnormal FHR (<110 bpm, >160 bpm or any decelerations after a contraction)
- Maternal pyrexia
- Fresh bleeding in labour
- Augmentation of labour with oxytocin
- Maternal request.

*Complicated labour*

- Continuous EFM should be done in complicated labour.
- A systematic assessment of EFM should be undertaken every hour.
- In cases of suspected or confirmed acute fetal compromise, delivery should be done within a time appropriate for the condition.
- If fetal death is suspected, fetal viability should be confirmed with a real-time ultrasound assessment.
- Fetal blood sampling is advised in the presence of a pathological trace, unless there is acute compromise.

*Fetal monitoring after epidural analgesia*

- Continuous EFM should be carried out for at least 30 minutes during the establishment of neuraxial analgesia and after each bolus of 10 mL or more of a 0.1% bupivacaine solution (10 mg).

## ACOG Practice Bulletin No. 88, December 2007. Invasive prenatal testing for aneuploidy. *Obstet Gynecol* 2007; 110(6):1459–67

http://www.acog.org/~/media/List of Titles/PBListOfTitles.pdf?dmc=1&ts=20140223T0705285265

### Summary of recommendations

- Amniocentesis is not recommended before 15 weeks of gestation due to the high risk of miscarriage and complications.
- Pregnancy loss rate after mid-trimester amniocentesis is less than 1/300–500.
- In experienced centres, pregnancy loss rate after chorionic villus sampling is the same as that of amniocentesis.
- Risk factors for fetal aneuploidy include:
  - One major or at least two minor structural defects on the fetal ultrasound scan

- previous fetus or child with an autosomal trisomy or sex chromosome abnormality
- parental aneuploidy, chromosomal translocation, or chromosomal inversion.

- Invasive diagnostic testing to detect aneuploidy should be available to all women.

## International Society of Ultrasound in Obstetrics and Gynecology (ISUOG) Practice Guidelines: *Performance of First-Trimester Fetal Ultrasound Scan*, January 2013

http://www.isuog.org/NR/rdonlyres/9225E408-C904-4A7F-84AE-812E456FBDDD/0/ISUOG1stTguidelines2013.pdf

### Key points

- First-trimester fetal ultrasound scan is performed for the following reasons:
  - To confirm viability
  - To establish an accurate gestation age
  - To determine the number of fetuses
  - To assess chorionicity and amnionicity if it is a multiple pregnancy
- At the end of first trimester, an ultrasound scan can be used to detect gross fetal abnormalities and to measure nuchal translucency as part of aneuploidy screening.
- Many malformations may, however, develop later in pregnancy.
- The scan is offered between 11 and $13^{+6}$ weeks' gestation.
- The sonographer should have specialized training that is suitable for the practice of diagnostic ultrasound scans for pregnant women.
- B and M mode ultrasound scans are safe for all stages of pregnancy.
- The following assessments should be performed during first-trimester ultrasound scans:
  - Viability—confirm the presence of an embryo with cardiac activity and the presence of an intrauterine gestational sac.
  - Early pregnancy measurements—crown–rump length (CRL) provides a more accurate assessment of gestational age when compared with mean gestational sac diameter.
  - First trimester measurements—CRL, biparietal diameter and head circumference are usually measured.
  - Fetal anatomy assessments for first trimester are described in the appendices.
  - Chromosomal anomaly assessment—Nuchal translucency measurement should be done between 11 and $13^{+6}$ weeks.

## International Society of Ultrasound in Obstetrics and Gynecology (ISUOG) Practice Guidelines: *Performance of Routine Mid-Trimester Fetal Ultrasound Scan*, 2010.

http://www.isuog.org/NR/rdonlyres/EA865840-6CA3-45AC-9E99-FBAF775119A9/0/ISUOGGuidelinesmidtriscan20101210.pdf

### Key points

- Mid-trimester ultrasound is performed to give accurate diagnostic information to optimize the antenatal care for the mother and fetus.
- The following assessments should be made during mid-trimester ultrasound scan:
  - Cardiac activity
  - Fetal size/age
  - Number of fetuses
  - Basic fetal anatomy
  - Placental appearance and location.
- A mid-trimester ultrasound is usually performed between 18 and 22 weeks' gestation.
- The sonographer should have specialized training that is suitable for the practice of diagnostic ultrasound scans for pregnant women.
- Prenatal ultrasound scans are safe for mothers and fetuses.
- Biparietal diameter, head circumference, abdominal circumference, and femur diaphysis length are used to assess gestational age and fetal size.
- Amniotic fluid volume can be assessed subjectively or objectively using ultrasonographic measurements.
- In the case of multiple pregnancy, the following additional evaluations should be carried out.
  - Visualization of placental cord insertion
  - Chorionicity
  - Distinguishing features (gender, unique markers, and position in uterus).
- Recommended minimum requirements for basic mid-trimester fetal anatomical survey are described in the appendices of the guidelines.

## Advice from the Health Protection Agency, the Royal College of Radiologists and the College of Radiographers: *Protection of Pregnant Patients During Diagnostic Medical Exposures* to *Ionizing Radiation*, 2009

http://www.rcr.ac.uk/docs/radiology/pdf/HPA_Diagnostic_Pregnancy.pdf

### Key points

- The radiation dose from any diagnostic procedure does not pose any significant risk to the mental and physical development of the fetus or death.
- Exposure of the fetus to radiation up to 1 milligray gives a childhood cancer risk of less than 1 in 10,000. This is considered to be an acceptable risk.
- The risk of childhood cancer is doubled with increasing levels of radiation exposure greater than a few milligrays. As a result, all investigations involving radiation should be avoided in pregnancy. However, if they are necessary or performed inadvertently, the childhood cancer risk remains below 1 in 200.

- Examples of high-dose procedures are barium enema, lumbar spine X-ray and computed tomography (CT), 99mTc bone scan, abdominal CT, and pelvis CT.
- There is a negligible risk of radiation-induced hereditary conditions in the offspring of an unborn child.

### ACOG Practice Bulletin 106: *Intrapartum Fetal Heart Rate Monitoring: Nomenclature, Interpretation, and General Management Principles*, July 2009

http://www.acog.org/~/media/List of Titles/PBListOfTitles.pdf?dmc=1&ts=20140228T0623236788

The American College of Obstetricians and Gynecologists has published this guideline to describe the role of intrapartum fetal heart rate monitoring in the decision-making process of obstetric and gynaecology care.

#### Summary of recommendations

- The use of electronic fetal monitoring (EFM) is associated with an increased rate of instrumental and caesarean delivery.
- EFM has a high false-positive rate for predicting cerebral palsy (>99%) The use of EFM does not reduce the incidence of cerebral palsy.
- When EFM tracing shows recurrent variable decelerations, amnioinfusion should be performed to relieve umbilical cord compression. (Amnioinfusion is a procedure in which a needle is introduced into the uterine cavity under ultrasound guidance and saline is infused to increase the volume of amniotic fluid.)
- Pulse oximetry is not clinically useful for evaluating fetal status.
- Reinterpretation of the FHR tracing, especially if the neonatal outcome is known, may not be reliable.
- A three-tiered system for the categorization of fetal heart rate patterns is recommended. (See 'A Three-Tiered System for the Categorization of Fetal Heart Rate Patterns' in Appendix 2 in this book.)
- High-risk labouring women should be monitored with continuous EFM.

## Gastrointestinal

### Royal College of Obstetrician and Gynaecologists. *Obstetric Cholestasis*. Green-Top Guideline No. 43, April 2011

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg_43.pdf

Obstetric cholestasis may complicate up to 1.5% of pregnancies, with an increased risk in parturients of Indian and Pakistani-Asian origin. This guideline summarizes the evidence for the fetal risks associated with obstetric cholestasis, which include preterm birth and fetal death.

#### Key points

- Unexplained pruritus, especially of the palms and soles of the feet, with deranged liver function tests (LFTs), which resolve after delivery, suggests obstetric cholestasis. In suspected cases, LFTs should be repeated every 1–2 weeks in pregnancy and resolution of LFTs confirmed 10 days after delivery.
- Compared with uncomplicated pregnancies, there is an increased risk of neonatal death associated with obstetric cholestasis, though this risk has not been quantified.
- A woman with obstetric cholestasis should be considered 'high risk' and her care and delivery of the baby should be conducted in a hospital by a consultant-led specialist team. Those providing intrapartum care should be aware of the risks of premature delivery, increased risks of passage of meconium, caesarean delivery, and postpartum haemorrhage.
- Continuous fetal monitoring during labour should be used. There is no one specific test or imaging modality, which can reliably predict fetal outcome.
- Regarding delivery, a discussion with the woman about both the maternal and fetal risks associated with induction of labour at $37^{+0}$ weeks' gestation should take place. In those with severe derangement of LFTs, there may be a stronger case in favour of an early expedited delivery.
- Women should be informed that there is no one test which is able to predict the incidence of stillbirth should the pregnancy continue beyond $37^{+0}$ weeks.
- There is no evidence that any one specific treatment may affect outcome. Emollient creams and chlorpheniramine may provide maternal symptomatic relief, but are not proven to improve outcome. There is insufficient evidence to recommend the use of S-adenosyl methionine (SAMe); however, ursodeoxycholic acid (UDCA) does appear to improve pruritus and LFTs in women with obstetric cholestasis, but again the maternal and fetal safety data concerning its use is lacking.
- Women with obstetric cholestasis may become deficient in vitamin K so a discussion regarding the use of oral vitamin K supplementation should take place, especially where there is a prolongation of the prothrombin time.
- Follow-up of women postnatally should take place with a liver specialist and the LFTs should be repeated.

### NICE. *Antenatal Care: Routine Care for Healthy Pregnant Women*. Clinical Guideline 62, 2008

https://www.nice.org.uk/guidance/cg62/chapter/1-Guidance#management-of-common-symptoms-of-pregnancy

Section 1.4.1 in this guidance covers the symptomatic management of nausea and vomiting in pregnancy.

#### Key points

- Nausea and vomiting usually resolves spontaneously between 16 and 20 weeks' gestation and is not associated with poor pregnancy outcomes.
- Ginger and the acupuncture pressure point P6 on the wrist are recommended non-pharmacological symptomatic treatments.
- Antihistamines are the recommended pharmacological treatment.

### Wegrzyiak LJ, Repke J, Ural SH. Treatment of hyperemesis gravidarum. *Rev Obstet Gynecol* 2012; 5(2):78–84

http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3410506/pdf/RIOG005002_0078.pdf

Hyperemesis is defined as 'uncontrolled vomiting requiring hospitalization, severe dehydration, muscle wasting, electrolyte imbalance, ketonuria, and weight loss of more than 5% of body weight' and complicates between 0.3% and 2.3% of pregnancies. The symptoms are at their worst between 9 and 20 weeks of gestation and 5% of women may require hospital admission for management of hyperemesis and dehydration. Women who suffer from hyperemesis in their first pregnancy have a high risk of suffering from hyperemesis in subsequent pregnancies.

#### Key points

- Infants born to mothers with hyperemesis are at risk of preterm delivery, small for gestational age, low birth weights, and a 5-minute Apgar score of less than 7.
- The pathogenesis of hyperemesis is not fully understood but may be due to effects of hormones, gastrointestinal dysfunction, thyrotoxicosis, autonomic dysfunction, liver abnormalities, *Helicobacter pylori* infection, or psychosomatic reasons.
- Dietary changes to manage symptoms include reducing meal sizes, increasing protein and carbohydrate intake, drinking electrolyte beverages, and avoiding any known food triggers.
- Affected women should be advised to avoid stress and rest as much as possible. Psychological support may be necessary as the condition may be very debilitating.
- Intravenous fluids may be necessary to treat dehydration. Electrolytes should be monitored and replaced as necessary.
- Thiamine 1.5 mg/day should be given routinely to all women with prolonged vomiting.
- Antiemetics should not be used before 12–14 weeks' gestation due to the possible risk of teratogenicity. First-line treatment, as recommended by the 2004 guidelines produced by the American Congress of Obstetricians and Gynecologists, should be intravenous dimenhydrinate, metoclopramide, or promethazine.
- Droperidol, ondansetron, and methylprednisolone have also been used in the research literature.
- Ginger has also been shown to reduce nausea and vomiting, most likely by increasing gastric motility and decreasing stimuli to the chemoreceptor trigger zone.
- Supplementary feeding via a nasogastric tube or total parental nutrition may need to be considered in severe cases.
- The use of acupuncture at the pressure point P6, which is 5 cm proximal to the wrist crease, has been shown to reduce the incidence of nausea and vomiting, by presumably blocking nociceptive transmission and autonomic reflexes.
- Hypnosis to control autonomic responses has been studied to assess its possible use to manage the symptoms of nausea and vomiting in pregnancy.

### NICE. *Hepatitis B (Chronic) Diagnosis and Management of Chronic Hepatitis B in Children, Young People and Adults*. Clinical Guideline 165, 2013

http://www.nice.org.uk/guidance/cg165

Chronic hepatitis B infection is characterized by detection of hepatitis B surface antigen (HBsAg) in the serum for 6 months or longer. It is a condition, which may have a variable clinical presentation which range from no symptoms to the development of liver fibrosis, cirrhosis, and hepatocellular carcinoma. Treatment with antivirals is aimed at preventing these serious complications of chronic hepatitis B infection by reducing the amount of hepatitis B virus (HBV) DNA present in the blood.

With regards to pregnancy and breastfeeding, the guideline advises that tenofovir disoproxil should be offered to women who have HBV DNA levels greater than $10^7$ IU/mL in the third trimester to reduce the likelihood of HBV transmission to the fetus.

### British Liver Trust Factsheet: *Acute Fatty Liver of Pregnancy*, 2012

http://www.britishlivertrust.org.uk/liver-information/liver-conditions/acute-fatty-liver-of-pregnancy/

Acute fatty liver of pregnancy (AFLP) affects 1/20,000 pregnancies and usually occurs in the third trimester. Risk factors include primiparity, male fetuses, and multiple births. The exact cause of the condition is unknown. Some experts believe it is related to pre-eclampsia whereas others have noted an association with fetal long-chain acyl-CoA dehydrogenase (LCHAD). LCHAD is a rare autosomal recessive condition where unmetabolized fetal free fatty acids are returned via the placenta to the maternal circulation and deposit in the liver.

#### Key points

- Symptoms of AFLP include nausea and vomiting, abdominal pain, general malaise, jaundice, and excessive thirst.
- The differential diagnosis of AFLP includes acute viral hepatitis, pre-eclampsia, HELLP syndrome, and obstetric cholestasis.
- Blood tests to investigate AFLP include taking LFTs and in particular looking for raised levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). In some cases there may also be raised levels of alkaline phosphatase (ALP) and gamma-glutamyl transferase (GGT). Full blood count, urea and electrolytes, clotting screen, glucose, uric acid and lactate dehydrogenase should also be checked.
- Investigations include liver ultrasound, MRI, or CT scan.
- Once diagnosed, the patient should be admitted and the condition monitored with regular blood tests. The mode of delivery will need to be discussed with the patient and may include caesarean delivery.
- After delivery, the woman should continue to be monitored and this may require transfer to a high dependency unit. Complications of AFLP include infection, pancreatitis, liver failure, and death. In severe cases, a liver transplant may be necessary.
- There is a risk that AFLP may recur in future pregnancies, but again this is poorly understood.

## Ko HH, Yoshida E. Acute fatty liver of pregnancy. *Can J Gastroenterol* 2006; 20(1):25–30.

http://www.ncbi.nlm.nih.gov/pmc/articles/PMC2538964/

AFLP is a condition with an incidence of 1/10,000 to 1/15,000 pregnancies and is characterized by microvesicular fatty infiltration of hepatocytes without any evidence of inflammation or necrosis. It has a maternal mortality rate of 75% and fetal mortality rate of 85%. With prompt diagnosis and treatment, these rates may be reduced to 18% and 23% respectively. The mainstay of treatment is supportive with expedited delivery of the fetus.

### Key points

- The condition may present between 28 and 40 weeks of gestation, typically occurring at 35–36 weeks.
- Patients may present with a variety of vague symptoms such as anorexia, malaise, nausea, headache, and abdominal pain, which makes the diagnosis of AFLP difficult. Consistent clinical findings suggestive of the condition include fever and jaundice. In severe cases, patients may present with signs of multiorgan involvement including renal failure, pancreatitis, encephalopathy, and gastrointestinal bleeding. Women may also have concomitant pre-eclampsia and HELLP syndrome. Due to the vague symptoms, AFLP is sometimes a diagnosis of exclusion.
- A maternal metabolic acidosis may develop as a result of AFLP, which in turn could adversely affect the fetus. Correction of this acidosis will help fetal well-being but early delivery may be indicated.
- Laboratory findings of AFLP include the following:
  - Raised white blood cell count greater than $15 \times 10^9$/L
  - Normal haematocrit except in the presence of haemorrhage
  - Haemolysis
  - Thrombocytopaenia
  - Prolonged prothrombin time and partial thromboplastic time
  - Low fibrinogen level
  - Disseminated intravascular coagulation
  - Raised serum aminotransferases (ALT and AST)
  - Raised ammonia, amino acid level, lactic acidosis, uric acid, bilirubin as a sign of liver failure
  - Hypoglycaemia
  - Raised ALP—however, this may normally occur in women in the third trimester
  - Raised urea and creatinine levels as a sign of renal failure.
- Investigation of the condition using liver ultrasound and CT scanning to identify fatty infiltration of the liver has low sensitivity and specificity. However, wider availability of laboratory testing for viral hepatitis and other serum markers of AFLP have made the need for liver biopsy less critical for the diagnosis to be made.
- Once the diagnosis of AFLP has been made, the mother should be admitted and resuscitated accordingly. This may require admission to intensive care. Fetal assessment during resuscitation and correction of coagulation abnormalities needs to also take place.
- Once the mother has been stabilized, delivery of the fetus needs to be arranged. Vaginal delivery may be considered in uncomplicated cases but caesarean delivery may be needed in the more serious cases.
- Postpartum, the woman should be closely monitored as coagulation defects and haemorrhage remains a risk, as does hypoglycaemia.
- Pancreatitis may complicate AFLP, especially after hepatic and renal dysfunction.
- Liver transplantation may be needed in cases of fulminant liver failure which has failed to respond to resuscitation and delivery of the fetus.

## Riely CA. Liver disease in the pregnant patient. *Am J Gastroenterol* 1999; 94(7):1728–32

http://s3.gi.org/physicians/guidelines/LiverDiseaseinPregnantPatient.pdf

These clinical guidelines have been developed in association with the American College of Gastroenterology. ALP usually rises in the third trimester, however the rest of the LFTs remain unchanged by pregnancy. Therefore any changes in LFTs other than ALP warrant further investigation.

### Key points

- Liver diseases which may occur in pregnancy depend on the gestation:
  - *First trimester*—hyperemesis gravidarum which in extreme cases require intravenous fluids and resuscitation. Peptic ulcer disease and acute viral hepatitis needs to be excluded
  - *Second trimester*—pre-eclampsia, variceal bleeding in associated with portal hypertension, acute viral hepatitis, obstetric cholestasis
  - *Third trimester*—pre-eclampsia, acute viral hepatitis which tends to be worse in the third trimester, AFLP, HELLP
- Other disorders which affect the liver may occur coincidentally with pregnancy:
  - Viral or drug-induced hepatitis
  - Gallstones
  - Malignancy with metastases to the liver
  - Thrombosis of outflow tracts of the liver (e.g. Budd–Chiari syndrome)
  - Chronic hepatitis B or C—there is no increased risk to the mother, however transmission to the fetus may occur.

## Alcohol intake in pregnancy

NICE guidance to the consumption of alcohol during pregnancy is contained in the NICE antenatal care guideline CG62 (https://www.nice.org.uk/guidance/cg62).

### Key points

- Women who are planning to become pregnant or who may be pregnant should avoid alcohol in the first trimester due to the increased risk of miscarriage.
- Although there is uncertainty regarding the amount of alcohol which may be safely consumed during pregnancy, women who choose to continue to drink alcohol should limit the amount to 1–2 units per week.
- Pregnant women should avoid getting drunk or binge drinking (consumption of >7.5 units in one sitting) to avoid harm to the fetus.
- 1 small glass of wine = 1.5 units.
- 5 small glasses of wine = 7.5 units.

## Food intake in labour

### NICE. *Intrapartum Care: Care of Healthy Women and their Babies During Childbirth* (Section 4.4: Eating and Drinking in Labour). Clinical Guidance 190, December 2014

http://www.nice.org.uk/guidance/cg190/resources/guidance-intrapartum-care-care-of-healthy-women-and-their-babies-during-childbirth-pdf

- Women in established labour are allowed to drink as long as there are no complications.
- Isotonic drinks may be consumed instead of water in labour.
- If no opioids have been offered and there are no risk factors suggesting a likely operative delivery, a low-risk woman may be allowed to eat in labour.

### OAA Clinical Guideline: *Oral Intake in Labour*, 2014

http://www.oaa-anaes.ac.uk/ui/content/content.aspx?id=187

- Selected guideline examples from two NHS trusts are shared on the OAA website.
- Low-risk women may take clear fluids and eat a light diet during labour.
- High-risk women may drink clear fluid in labour, but they should not eat solid food.
- Factors, which constitute high-risk pregnancy, vary marginally in the different trust (hospital) guidelines.
- Examples of high-risk factors are morbid obesity, multiple pregnancy, previous caesarean delivery or uterine scar, pre-eclampsia, diabetes mellitus, breech presentation, slow progress, oxytocin infusion, and signs of fetal distress.

### American Society of Anesthesiologists task force on obstetric anesthesia. practice guidelines for obstetric anaesthesia. *Anesthesiology* 2007; 106:843–63

- Low-risk labouring women are allowed to drink clear liquids. For those undergoing an elective caesarean delivery, modest amounts of clear liquids can be allowed up to 2 hours before the induction of anaesthesia.
- Solid foods should be avoided in labouring patients. For elective surgical patients, solid food is allowed up to 6–8 hours before the induction of anaesthesia.

## Aspiration prophylaxis

### NICE. *Intrapartum Care: Care of Healthy Women and their Babies During Childbirth* (Section 4.4: Eating and Drinking in Labour). Clinical Guidance 190, December 2014

http://www.nice.org.uk/guidance/cg190/resources/guidance-intrapartum-care-care-of-healthy-women-and-their-babies-during-childbirth-pdf

- $H_2$ antagonists and antacids should only be offered to parturients who have received opioid analgesia in labour or have developed risk factors which make a general anaesthetic more likely. They should not be offered as routine to otherwise low-risk parturients.

### OAA Clinical Guideline: *Antacid Prophylaxis*, 2010

http://www.oaa-anaes.ac.uk/ui/content/content.aspx?id=168

- Selected guideline examples from two NHS trusts are shared on the OAA website.
- $H_2$ receptor antagonists (e.g. ranitidine 150 mg to 300 mg orally or 50 mg intravenously) should be given to all elective surgery patients, emergency surgery patients and high-risk women in labour.
- Sodium citrate 30 mL 0.3M should be given orally, before induction of general anaesthesia for emergency surgery.

American Society of Anesthesiologists task force on obstetric anesthesia. practice guidelines for obstetric anaesthesia. *Anesthesiology* 2007; 106:843–63

- Administration of non-particulate antacids, $H_2$ receptor antagonists, and/or metoclopramide for aspiration prophylaxis is recommended before surgical procedures.

# Haematological

### Royal College of Obstetricians and Gynaecologists. *Antepartum Haemorrhage*. Green-Top Guideline No. 63, November 2011

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg_63.pdf

Antepartum haemorrhage (APH) is one which occurs between 24 weeks of pregnancy and delivery. The most important causes of APH are placenta praevia and placental abruption. Management of APH is important, as it is responsible for 50% of maternal deaths worldwide as well as being a cause of preterm labour in 20% of cases with subsequent neonatal morbidity. This guideline is restricted to the management of antepartum haemorrhage.

### Key points

- Due to multifactorial causes, APH itself cannot be reliably predicted.
- If a woman has had a placental abruption in a previous pregnancy, she is at increased risk of further abruption in subsequent pregnancies. Other risk factors for placental abruption include pre-eclampsia, increasing maternal age, intrauterine infections, multiple pregnancy, and fetal growth restriction. A comprehensive list of risk factors is included in the document.
- There is an increased risk of bleeding later in pregnancy if it has occurred in the first trimester.

- Evidence suggests that the causes of placental abruption are related to conditions, which develop during pregnancy whereas factors which lead to placenta praevia tend to exist prior to pregnancy.
- Risk factors for placenta praevia are strongly related to the number of previous caesarean deliveries and also include advanced maternal age and smoking.
- Women should report all episodes of vaginal bleeding in pregnancy to their antenatal care providers.
- APH should be suspected if the woman complains of continuous abdominal pain and the uterus feels tense on palpation. If the pain is intermittent in nature, then labour should be suspected.
- In cases of suspected placenta praevia, an ultrasound scan should be performed first to rule out the diagnosis before performing a digital examination of the vagina.
- Investigations to assess APH include Kleihauer blood test, coagulation screen, full blood count, cross match of 4 units, ultrasound scan to determine placental location and cardiotocograph monitoring of the fetus.
- Women with bleeding heavier than spotting or streaking should be admitted to hospital for observation and further management.
- If a woman presents with APH after 24 weeks of gestation and before 35 weeks, a course of antenatal steroids should be given.
- Tocolytics are not advised for use in patients who present with a major APH and are clinically unstable or there is evidence of fetal distress.
- If fetal death occurs following an APH, where possible, vaginal delivery is recommended.
- A caesarean delivery is recommended if there is evidence of fetal distress.
- Where possible, a neuraxial anaesthetic technique should be performed to facilitate operative delivery. A consultant anaesthetist should be present in the management of unstable patients. A general anaesthetic may be considered in very unstable patients for caesarean delivery.
- A woman who has suffered an APH is at risk of postpartum haemorrhage. Provisions should be made to manage and observe the woman after delivery.
- Coagulopathy needs to be managed with the replacement of clotting factors and by seeking advice from haematologists.

## Royal College of Obstetricians and Gynaecologists. *Prevention and Management of Postpartum Haemorrhage*. Green-Top Guideline No. 52, April 2011

https://www.rcog.org.uk/globalassets/documents/guidelines/gt52postpartumhaemorrhage0411.pdf

Primary postpartum haemorrhage (PPH) is defined as 'the loss of 500 mL of blood or more from the genital tract within 24 hours of delivery' and is the most common form of major obstetric haemorrhage. It remains one of the major causes of maternal deaths globally. This guideline is limited to the management of PPH.

### Key points

- Minor PPH—blood loss of 500–1000 mL.
- Major PPH—blood loss of greater than 1000 mL and can be further subdivided into:
  - moderate—blood loss of 1000–2000 mL
  - severe—blood loss of greater than 2000 mL.
- Once a PPH has been identified, the patient must be monitored and assessed for signs of haemodynamic instability and ongoing bleeding and appropriate protocol-driven management must begin.
- Most women suffering a PPH do not have any identifiable risk factors.
- Active management of the third stage of labour and the use of prophylactic oxytocics (e.g. oxytocin 5 or 10 IU IM), can reduce the risk of PPH.
- A multidisciplinary team including a senior obstetrician, anaesthetist, haematologist, and senior midwife will need to be involved in the management of a PPH.
- Once identified, there are four components to the management of PPH, which need to occur simultaneously: communication, resuscitation, monitoring and investigation, and arresting the bleeding. If large amounts of fluids have been used in resuscitation, a coagulopathy is likely to develop. Replacement of clotting factors and fibrinogen will need to be considered. Recombinant factor VIIa, although not widely advocated, could be considered as a potential treatment following discussion with a haematologist—there is a risk of thrombosis associated with its use.
- If anaesthesia is required, the anaesthetist will need to assess the woman for haemodynamic instability and provide the most appropriate anaesthetic as necessary. Haemodynamic instability is a relative contraindication to neuraxial anaesthesia.
- Uterine atony is the most common cause of PPH. Other causes include coagulation abnormalities, retained tissues, and trauma to the genital tract.
- Uterine atony may be managed by a variety of pharmacological methods using oxytocin, ergometrine, carboprost, and misoprostol. See guideline for full dosing regimen.
- Surgical methods to manage uterine atony include balloon tamponade, brace suturing, bilateral ligation of uterine or internal iliac arteries, and selective arterial embolization.
- Hysterectomy must be considered early on in the management of PPH and a second consultant obstetrician or gynaecologist should be consulted in the decision to proceed with one.
- Secondary PPH is usually associated with endometritis. Antibiotics (ampicillin and metronidazole with gentamicin in certain circumstances) and surgical removal of retained products of conception need to be considered in the management of secondary PPH.

## Royal College of Obstetricians and Gynaecologists. *Placenta Praevia, Placenta Accreta and Vasa Praevia: Diagnosis and Management*. Green-Top Guideline No. 27, January 2011

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg_27.pdf

Placenta praevia and accreta are significant causes of maternal and fetal morbidity and mortality. The rising rate of caesarean deliveries, in combination with increasing maternal age, means that the incidence of these conditions is going to increase. This guideline covers the diagnosis as well as the antepartum and peripartum management of these conditions.

### Key points

- Placenta praevia is the condition where the placenta has implanted wholly or in part in the lower segment of the uterus.
- Placenta accreta, increta, and percreta are types of morbidly adherent placenta and describe the extent of the invasion of the myometrium by the placenta.
- Vasa praevia describes the condition where fetal blood vessels penetrate through the membranes and appear below the presenting part of the fetus. These vessels are fully exposed, and not protected by any placental tissue or umbilical cord. It has an incidence of about 1/2000 to 1/6000 pregnancies. The main risks are to the fetus, as these vessels are at risk of rupture and catastrophic haemorrhage following fetal membrane rupture, with a mortality rate of about 60%.
- Placenta praevia should be suspected in women presenting with vaginal bleeding after 20 weeks' gestation. This can then be confirmed with ultrasound scanning to determine the placental location. A transvaginal scan is more accurate than a transabdominal scan.
- Should the placenta be found to cover or overlap the cervical os at the 20-week scan, the patient should be followed up to determine the final location of the placenta closer to the time of delivery.
- In women who have had a previous caesarean delivery, the placental location should be determined to assess the risk of a morbidly adherent placenta developing.
- Any antenatal anaemia should be treated and women should be counselled about the risks of preterm delivery and major obstetric haemorrhage. Outpatient care may be suitable for women with minor placenta praevia or who are otherwise asymptomatic.
- If the placenta is more than 2 cm from the cervical os, then a vaginal delivery may be considered. Elective caesarean delivery may be considered after 38 weeks for placenta praevia and between 36 and 37 weeks for a suspected morbidly adherent placenta.
- Thorough preparation involving both consultant obstetric and anaesthetic care along with availability of blood products must be in place prior to delivery. The use of cell salvage may also be considered.
- The choice of anaesthetic is determined by the anaesthetist managing the case. There is insufficient evidence to recommend either anaesthetic technique (i.e. neuraxial block or general anaesthesia).
- When performing the caesarean delivery, it is worth considering making the uterine incision at a site away from the placenta to reduce the risk of bleeding and to allow further assessment of the placenta to then guide further management.
- Women must be warned of the risk of a hysterectomy following delivery of the baby.
- Should the placenta not separate after the delivery of the baby, one strategy would be to leave the placenta *in situ*. In these cases, women must be warned of the risks of infection and bleeding. Prophylactic antibiotics may be given to minimize the risk.
- At present, there are no recommendations to screen routinely for vasa praevia.
- Colour transvaginal Doppler ultrasound may be used to confirm the diagnosis in suspected cases of vasa praevia.
- A caesarean delivery should be performed to deliver the baby if bleeding occurs in a woman with known vasa praevia.

## Royal College of Obstetricians and Gynaecologists. *Blood Transfusion in Obstetrics*. Green-Top Guideline No. 47, May 2015

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg-47.pdf

There are many conditions in obstetrics which may require the need for a blood transfusion. Inappropriate management of haemorrhage may be associated with maternal morbidity and mortality. It is accepted that a blood transfusion itself is not without risks, therefore strict procedures and checking policies should be followed, even in an emergency.

### Key points

- During antenatal screening, a haemoglobin (Hb) level less than 10.5 g/dL must be investigated and treated. Oral iron supplementation is the first-line treatment, with parenteral iron use in those patients unable to tolerate or comply with oral therapy.
- Blood loss at delivery must be minimized. One way of achieving this is to actively manage the third stage.
- Women who are at high risk of a peripartum haemorrhage, must be encouraged to deliver in hospital.
- All women should have their blood group and antibodies checked routinely at booking and at 28 weeks' gestation.
- Ensure that a parturient has a valid cross-match sample on the day of delivery.
- Elective use of cell salvage may be considered in cases where blood loss is expected to be greater than 1500 mL.
- The decision to transfuse blood must be made on both clinical and haematological grounds. Patients with Hb greater than 10 g/dL should not be transfused, whereas those with Hb less than 6 g/dL almost always require transfusion.
- FFP, platelets, and cryoprecipitate may be needed in the management of coagulopathy and their use should be given on

clinical grounds rather than waiting for formal coagulation screen results.

- Platelets should not be allowed to fall below $50 \times 10^9$/L, so it is advisable to transfuse a pool of platelets when levels fall to $75 \times 10^9$/L.
- Anti-D immunoglobulin will need to be given to a Rhesus-negative woman if the platelets are Rhesus positive.
- There is no evidence to support the prophylactic use of recombinant factor VIIa in caesarean delivery, but its use may be considered when managing major haemorrhage.
- Transfusion should be considered in the peripartum period if the Hb is about 7–8 g/dL. The decision to transfuse should be based on symptoms and clinical examination.
- In women who object to receiving a blood transfusion, their Hb must be optimized as much as possible in the antepartum period and appropriate planning for delivery should be made.

### AAGBI Safety Guideline: *Blood Transfusion and the Anaesthetist: Management of Massive Haemorrhage*, November 2010

http://www.aagbi.org/sites/default/files/massive_haemorrhage_2010_0.pdf

This guideline is described under 'Critical Care and Resuscitation'.

### Lee CA, Chi C, Pavord SR. The obstetric and gynaecological management of women with inherited bleeding disorders—review with guidelines produced by a taskforce of UK haemophilia centre doctors' Organisation. *Haemophilia* 2006; 12:301–36

http://onlinelibrary.wiley.com/doi/10.1111/j.1365-2516.2006.01314.x/full

This article summarizes the evidence around the obstetric and anaesthetic management of women with coagulation disorders who become pregnant. The main conditions of haemophilia, von Willebrand's disease (vWD), and factor XI deficiency are covered.

#### Haemophilia

- All carriers of haemophilia should be offered prepregnancy counselling in order to discuss the options regarding conception methods and prenatal diagnosis (grade C evidence, level IV).
- Chorionic villus sampling should be used to test for haemophilia in the fetus antenatally. Maternal clotting should be tested before the procedure is carried out (grade C evidence, level IV).
- It is important to determine the fetal gender as early as possible: if the fetus is female, the need for further invasive testing is avoided. If the fetus is male, then invasive fetal monitoring, forceps, and vacuum extraction should be avoided, unless the coagulation status of the fetus is known to be normal. The parents need to be informed of the need to determine fetal gender early in pregnancy (grade C evidence, level IV).
- Known carriers of haemophilia should have their clotting factors (VIII and IX) checked at booking, and 28 and 34 weeks' gestation to help determine the most appropriate mode of delivery and to anticipate any treatment which may be needed (grade C evidence, level IV).
- Recombinant factor VIII and IX is the treatment of choice in pregnant carriers of haemophilia A and B (grade C evidence, level IV).
- Neuraxial blocks for labour and delivery are permitted if the coagulation screen is normal and the relevant factor level is above 50 IU/dL. The procedure should be performed by an experienced anaesthetist and the density and duration of the anaesthetic block should be monitored. Any abnormal prolongation in anaesthetic blockade must be investigated by MRI to exclude an epidural haematoma.
- The use of NSAIDs should be avoided if the clotting factors are below normal (grade C evidence, level IV).
- The use of a fetal scalp electrode should be avoided in male fetuses known to be affected or who have an unknown coagulation status (grade C evidence, level IV).
- Factor levels should be monitored and kept above 50 IU/dL for 3 days after vaginal delivery and for 5 days after caesarean delivery.
- In neonates with known haemophilia or unknown coagulation status, IM injections and venepuncture should be avoided. Vitamin K may be given orally, with routine immunizations given subcutaneously or intradermally. Circumcision should be delayed until the coagulation status of the neonate is known and any treatment reviewed by the haematologist (grade C evidence, level IV).
- The risk of intracranial haemorrhage is estimated to be about 1–4% and is associated with significant morbidity. A cranial ultrasound or CT scan should be arranged in all neonates where labour has been premature, traumatic, or if there is any evidence of bleeding. Treatment should be given to raise plasma clotting levels to 100 IU/dL (grade C evidence, level IV).

#### Von Willebrand disease

- Prenatal diagnosis should be offered to and discussed with women with vWD, where there is an identifiable genetic mutation (grade C evidence, level IV).
- Patients with vWD should have the following factors checked at booking, and 28 and 32 weeks' gestation: vWF:Ag, vWF:AC and FVIII:C and the levels should be kept above 50 IU/dL for any invasive procedures or delivery (grade C evidence, level IV).
- Desmopressin increases FVIII and vWF levels and may be used in pregnancy. However repeated doses and its use in pre-eclampsia should be avoided. Women need to be monitored for the possibility of fluid retention after its administration (grade C evidence, level IV).
- Patients with vWD type 1 do not require any prophylactic treatment for delivery. Those with vWD type 2 only need treatment for operative delivery or in cases of perineal trauma. Only patients with vWD type 3 need treatment for all modes of delivery (grade C evidence, level IV).

- An epidural may be sited in patients with vWD type 1 whose vWF activity is above 50 IU/dL. It is not recommended in women with vWD types 2 and 3 (grade C evidence, level IV).
- Women with a vWF activity level below 50 IU/dL should receive prophylactic treatment before the onset of labour and planned caesarean delivery (grade C evidence, level IV).
- VWF activity and FVIII levels should be maintained above 50 IU/dL and monitored for 3 days after vaginal delivery and for 5 days after caesarean delivery. Tranexamic acid may be considered in the management of any prolonged or intermittent postpartum haemorrhage (grade C evidence, level IV).
- Invasive monitoring, vacuum extraction, and the use of rotational or mid-cavity forceps should be avoided in all fetuses at risk of vWD, except in those with mild disease. The cord blood should be sent off for analysis (grade C evidence, level IV).

### Factor XI deficiency

- Factor XI deficiency is inherited in an autosomal fashion and exhibits a more variable bleeding tendency compared with haemophilia A and B. Efforts should be made to identify the individual's bleeding tendency and the existence of any confounding factors (grade C evidence, level IV).
- Factor XI levels should be checked at booking, and 28 and 32 weeks' gestation. Management may be expectant ('watch and wait'). Only patients with very low levels or a positive bleeding history should be given prophylactic treatment with FXI concentrate or virally inactivated FFP to cover any invasive procedures (grade C evidence, level IV).
- To minimize the risk of a haematoma, an epidural may be sited following consultation with a haematologist who may advocate the administration of FXI concentrate. An epidural should be avoided in women with severe disease or a significant bleeding history.
- Where given, prophylactic treatment should be continued for 3 days after vaginal delivery and for 5 days after caesarean delivery (grade C evidence, level IV).

## NICE. *Sickle Cell Acute Painful Episode: Management of an Acute Painful Sickle Cell Episode in Hospital.* Clinical Guideline 143, June 2012

https://www.nice.org.uk/guidance/cg143

Sickle cell disease affects about 12,500 to 15,000 people in the United Kingdom. Acute painful sickle cell episodes (or painful crises) may be unpredictable in nature and vary in duration. They result from the blockage of small blood vessels by sickle-shaped red blood cells. The management of these painful crises are a source of complaints in hospitals, as patients may experience long delays in analgesia, inadequate analgesia, and accusations of drug-seeking behaviour. This guideline aims to detail the principles of management in hospital.

### Key points

- An acute, painful sickle cell episode should be regarded as a medical emergency and analgesia should be offered within 30 minutes of arrival in hospital. The patient and their family should be involved in the management of the crisis from the outset.
- Simple analgesics such as paracetamol and NSAIDs should be offered in addition to opioids. Discussion with the patient regarding previous analgesic management should occur to help guide management. Pethidine should not be given in an acute episode.
- Other causes of acute pain should be looked for and excluded when assessing a patient presenting with an acute crisis.
- The patient should have basic observations recorded and the effectiveness of pain relief documented. A patient-controlled analgesia may be needed, especially if the patient is requiring frequent doses of strong opioids.
- Antiemetics, laxatives, and antipruritics should be offered to those patients on opioids.
- As the crisis resolves, the analgesia regimen may need to be reduced and each hospital should have local protocols to guide how this may be done.
- Corticosteroids should not be used in the treatment of uncomplicated acute painful sickle cell episodes.
- On discharge, patients and carers should be given information about how to manage the current episode, where to seek help and support, when to return to hospital, and any side effects or possible complications that may develop from any treatment they have received.

## NICE. *Venous Thromboembolism in Adults Admitted to Hospital: Reducing the Risks.* Clinical Guidance 92, January 2010

https://www.nice.org.uk/guidance/cg92

### Assessing the risk of venous thromboembolism and bleeding

- A venous thromboembolism (VTE) assessment must be done for all patients on admission.
- Medical patients who have reduced mobility for more than 3 days and have risk factors are at increased risk of VTE.
- Surgical and trauma patients have an increased of VTE if they have prolonged surgery, reduced mobility, intra-abdominal pathology, or risk factors.
- Risk factors for VTE include age of patient, dehydration, and medical comorbidities. See the guidelines for a full comprehensive list.
- The bleeding risk must be evaluated before the patient is offered pharmacological thromboprophylaxis.
- The bleeding and VTE risks must be reassessed within 24 hours of admission and whenever the clinical condition changes.
- The risk of VTE may be reduced through the use of pharmacological prophylaxis until the patient is no longer at risk and by encouraging mobilization when it is safe to do so.
- Patient and carer education regarding prevention and treatment of VTE should begin before discharge planning.
- Pregnant women or women who have delivered in the preceding 6 weeks should be offered VTE prophylaxis if they are at

increased risk of developing VTE. See guidelines for maternal risk factors for VTE.

### AAGBI, OAA, Regional Anaesthesia UK Guidance Document: *Regional Anaesthesia and Patients with Abnormalities of Coagulation* (RAPAC), 2011

http://www.aagbi.org/sites/default/files/rapac_2013_web.pdf

This consensus document offers guidance regarding the performance of neuraxial blocks in patients who are taking medication to alter their coagulation and their recommendations are summarized in four tables within the document.

#### Key points

- The time needed to wait before performing a block is dependent on the anticoagulant used (see tables in guideline for further details).
- In a patient with altered coagulation, central neuraxial blocks pose a higher risk compared to a superficial nerve block.
- The more abnormal the coagulation, the higher the risk of post-procedure complications. It is advisable that an anaesthetist who has experience in performing the block undertakes the procedure in these high-risk patients.
- Coagulation may be abnormal in trauma, sepsis, uraemia, liver failure, massive transfusion, and disseminated intravascular coagulopathy. Further assessment is needed before performing a block in such situations.

### Gogarten W, Vandermeulen E, Van Ake H, *et al*. Regional anaesthesia and antithrombotic agents: recommendations of the European Society of Anaesthesiology. *Eur J Anaesthesiol* 2010; 27:999–1015

http://www.csen.com/guidelines.pdf

This guideline was produced to minimize the risk of bleeding complications associated with neuraxial anaesthesia techniques.

Recommended minimum time intervals between antithrombotic drugs and neuraxial procedures are the same as the RAPAC guideline for commonly used drugs such as prophylactic unfractionated heparin (UFH), prophylactic and treatment doses of LMWH, and aspirin.

### Horlocker T, Wedel DJ, Rowlingson JC, *et al*. Regional anesthesia in the patient receiving antithrombotic or thrombolytic therapy: American Society of Regional Anesthesia and Pain Medicine Evidence-Based Guidelines (Third Edition). *Reg Anesth Pain Med* 2010; 35(1):64–101

http://journals.lww.com/rapm/Fulltext/2010/01000/Regional_Anesthesia_in_the_Patient_Receiving.13.aspx

This guideline describes the neuraxial anaesthetic management of surgical patients who are receiving common antithrombotic drugs and herbal medicines such as garlic, ginkgo, and ginseng.

#### Key points

- In obstetric patients, oral anticoagulants should be changed to LMWH or UFH of similar dosing before 36 weeks' gestation.
- LMWH should be stopped 36 hours before the planned induction of labour or caesarean delivery. Intravenous or subcutaneous UFH can be used as a bridging therapy if necessary. UFH must be stopped 4–6 hours before the planned delivery.
- If a pregnant woman on LMWH goes into labour, she should be instructed to stop the drug until she has been assessed by the obstetric team.
- A plan must be made for restarting anticoagulation in the postpartum period when planning neuraxial analgesia or anaesthesia.
- Re-initiation of thromboprophylaxis should be withheld for 12 hours after abdominal delivery or removal of the epidural catheter, whichever is later. If the patient requires therapeutic anticoagulation, it must be started 24 hours after delivery. (NB These timings differ from THE AAGBI and OAA RAPAC guidelines discussed earlier.)

### Royal College of Obstetricians and Gynaecologists. *Reducing the Risk of Venous Thromboembolism During Pregnancy and the Puerperium*. Green-Top Guideline No. 37a, April 2015

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg-37a.pdf

VTE is a preventable cause of morbidity and mortality in the parturient. Effective thromboprophylaxis can markedly reduce the risk of developing VTE in this population. VTE may occur at any stage during pregnancy, but the highest risk remains in the postpartum period.

#### Key points

- VTE is more likely to occur following a caesarean delivery compared with a vaginal delivery, but the risk of VTE remains regardless of the mode of delivery.
- Once risk assessed, VTE prophylaxis should be started as early in the pregnancy as is practical.
- Women who are considered at very high risk of VTE will usually be on long-term oral anticoagulation prior to conception. They should be counselled about the teratogenic risks to the fetus from oral anticoagulants, such as warfarin. They require treatment with higher-dose LMWH (usually divided into two 12-hourly doses) during pregnancy and 6 weeks postpartum or until they are converted back to their oral regimen. They will also need specialized care provided by haematologists and obstetricians throughout pregnancy and delivery. In certain situations, such as mechanical heart valves, it may be necessary to continue with oral anticoagulants throughout pregnancy.
- Women at high risk of VTE require treatment with LMWH during pregnancy and for 6 weeks postpartum. This includes women who have had previous VTE (excluding VTE as a result from major surgery).
- Women with inherited thrombophilia which have resulted in the development of a VTE should be managed by specialists with knowledge of haemostasis in pregnancy, who may consider monitoring anti-Xa levels and consider antithrombin replacement prior to delivery.

- The guideline contains more details regarding management of specific inherited and acquired thrombophilias.
- Thrombophilia screening should be offered to women who have had a non-oestrogen-provoked VTE in the presence of a minor risk factor, as this will determine further antenatal management and treatment.
- Women with an asymptomatic inherited thrombophilia and no other risk factors may be monitored for VTE during pregnancy and be offered LMWH for at least 7 days postpartum.
- A neuraxial anaesthetic technique should not be performed within 12 hours of a prophylactic dose of LMWH or within 24 hours of a treatment dose of LMWH. Suitable analgesic alternatives should be offered to these women in labour.
- A prophylactic dose of LMWH may be given at least 4 hours after a central neuraxial block or removal of an epidural catheter.
- The first prophylactic dose of LMWH should be given as soon as possible after delivery as long as there is no haemorrhage and no neuraxial anaesthetic technique was used.
- LMWHs are as safe and effective as UFH. Danaparoid and fondaparinux may be considered as alternatives in women who are intolerant of LMWHs, following consultation with a haematologist.
- Low-dose aspirin may be used safely in pregnancy to manage antiphospholipid syndrome but it is not advised for use as thromboprophylaxis in pregnancy.
- Graduated compression stockings may be considered for use in women as thromboprophylaxis where treatment with LMWH or an alternative is contraindicated, after a caesarean delivery, or if they are at high risk of developing VTE.
- Each woman should be risk assessed for VTE in the postpartum period. The duration of treatment may range from 10 days to 6 weeks after delivery depending on the number of risk factors present.
- Women with a BMI greater than 40 kg/m$^2$ should be offered prophylactic LMWH at an appropriate dose for their weight for 10 days after delivery.
- Following caesarean delivery, all women should be risk assessed to identify those who will require prophylactic LMWH for 10 days postpartum.

## Royal College of Obstetricians and Gynaecologists. *Thromboembolic Disease in Pregnancy and the Puerperium: Acute Management*. Green-Top Guideline No. 37b, April 2015

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg-37b.pdf

Venous thromboembolism (VTE) continues to be the main cause of direct maternal deaths during the latest Confidential Enquiries review (2009–2012). Although it is known that pregnant women are at particularly high risk of developing VTE, especially in the puerperium, the subjective clinical assessment of these patients can be unreliable. This guideline offers an evidence-based approach to the investigation and management of women where VTE is suspected.

### Key points

- If VTE is clinically suspected, all women should have investigations arranged promptly and LMWH started until the diagnosis has been excluded.
- Leg elevation and compression stockings should be advised in addition to LMWH for the treatment of VTE.
- Compression duplex ultrasound is the first-choice investigation for VTE in the lower leg. Should the scan be negative and clinical suspicion is low, then LMWH may be discontinued. If the scan is inconclusive, it should be repeated on days 3 and 7 and LMWH continued until the diagnosis has been excluded.
- If iliac vein thrombosis is suspected, magnetic resonance venography or contrast venography may be considered instead of duplex ultrasound.
- Where an acute pulmonary embolus (PE) is suspected, a chest X-ray should be performed in the first instance. Where this is normal, a duplex scan should be performed. Should both these tests be negative and the patient still has clinical signs suggestive of a PE, either a ventilation-perfusion (V/Q) scan or a computed tomography pulmonary angiography (CTPA) scan should be performed. LMWH should be continued until the diagnosis has been excluded.
- Compared with CTPA, there is a slightly increased risk of childhood cancer with V/Q scanning but a reduced maternal risk of developing breast cancer.
- Should a patient have symptoms of both PE and deep vein thrombosis, then duplex scan should initially be performed. If this scan is positive, then no further tests are necessary and appropriate treatment should be started.
- Due to physiological changes in coagulation during pregnancy, especially in the later stages and the immediate postpartum period, performing a D-dimer test to exclude a VTE is not advisable as it is likely to be raised.
- Prior to starting anticoagulation therapy, baseline bloods should be taken, including full blood count, urea and electrolytes, liver function tests, and coagulation screen. It is not necessary to perform a thrombophilia screen.
- If treatment with LMWH is required, the daily dose should be based on either the booking or the most recent body weight. LMWH does not cross the placenta nor does it increase the risk of severe bleeding in the peripartum period.
- Anti-Xa levels to monitor the effect of LMWH should only be performed in women at the extremes of weight (<50 kg or >90 kg).
- A multidisciplinary approach must be taken when managing a life-threatening PE. Treatment with intravenous UFH should be started with consideration given to thrombolysis, thoracotomy, or surgical embolectomy.
- An inferior vena cava filter should be considered for women who have either an iliac VTE, are at risk of a PE or who continue to develop a PE despite adequate anticoagulation.
- Once the diagnosis of VTE has been confirmed, treatment with LMWH should continue for the duration of pregnancy.

Presently it is not certain whether the daily dose should be given as a single dose or divided into two doses. Women should have their platelet count monitored for 14 days after starting therapeutic LMWH to monitor for thrombocytopaenia. Due to adverse effects on the fetus, it is not advisable to use oral anticoagulants in pregnancy.

- Newer agents (e.g. fondaparinux) may be considered in patients who have an adverse reaction to all forms of heparin or danaparoid.
- Once a woman is in established labour, no further doses of LMWH should be given. For planned deliveries, LMWH should be stopped 24 hours prior to delivery and neuraxial anaesthesia.
- After a caesarean delivery, LMWH should be restarted 3 hours later or more than 4 hours of epidural catheter removal. The epidural catheter should only be removed more than 12 hours after the last injection of LMWH.
- Should the activated partial thromboplastin time be prolonged close to the time of delivery following treatment with LMWH, protamine sulphate can be given to correct this.
- Due to the increased risk of bleeding, consideration should be given to leaving a wound drain *in situ* or using clips or intermittent sutures to close the skin to allow drainage of a potential haematoma. Intravenous UFH should be continued postoperatively if there is increased risk of bleeding.
- LMWH should be continued for at least 6 weeks postpartum and until 3 months of treatment in total has been given. Oral anticoagulants may be used in this period. Neither LMWH nor warfarin is contraindicated in breastfeeding.
- Oral warfarin should be restarted on day 5 postpartum. It may be necessary to delay re starting warfarin longer than 5 days in patients who are at high risk of postpartum haemorrhage.
- Using LMWH for more than 12 weeks postpartum helps prevent post-thrombotic syndrome. The evidence for prolonged postpartum use of compression stockings in preventing post-thrombotic syndrome is inconclusive.
- Women require follow-up and counselling on the need for further anticoagulation treatment in subsequent pregnancies, ideally in a joint obstetric haematology clinic.

Further advice regarding the management of the pregnant or recently pregnant patient with thromboembolic disease may be found in NICE Clinical Guideline 92 'Venous Thromboembolism: Reducing the Risk' (pp.31–33), published in January 2010 (http://www.nice.org.uk/nicemedia/pdf/CG92NICEGuidelinePDF.pdf).

## Sibai BM. Diagnosis, controversies and management of the syndrome of hemolysis, elevated liver enzymes and low platelet count. *Obstet Gynecol* 2004; 103(5 Pt 1):981–91

http://www.utilis.net/Morning%20Topics/Obstetrics/HELLP,%20Sibai.pdf

This review article collates information from various expert sources to provide guidance for clinicians in the diagnosis and management options available to parturients with HELLP.

### Key points

- HELLP is an acronym which stands for H = haemolysis, EL = elevated liver enzymes, LP = low platelets. It is a condition which comprises of these abnormal laboratory results and is a separate condition to pre-eclampsia.
- Haemolysis is defined as 'the presence of microangiopathic haemolysis' and is the hallmark of HELLP syndrome. Haemolysis may be detected using laboratory tests by an abnormal peripheral smear, raised serum bilirubin, raised lactate dehydrogenase or a significant fall in serum haemoglobin levels.
- Liver enzymes used to assess the severity of HELLP include serum AST, ALT, and bilirubin. However, there is no consensus regarding which liver enzymes should be used or how elevated the enzymes need to be in the diagnosis of HELLP.
- Again, there is no consensus in the literature regarding how low the platelets need to be in order to diagnosis HELLP. Low values in studies range from 75,000/mm$^3$ to 279,000/mm$^3$.
- The lack of consensus of laboratory values is partly due to the wide range of different assays available which test for liver enzymes and thrombocytopaenia. The author advises that individuals should be familiar with the normal values for these laboratory tests in their own institution.
- HELLP may be diagnosed during the expectant management of pre-eclampsia, in labour or postpartum. The maternal and fetal outcomes vary depending on when HELLP is diagnosed and how frequent blood tests are performed.
- Clinical presentation is variable and women may complain of non-specific symptoms such as malaise, a recent viral-like illness, nausea, and vomiting. More specific symptoms may include right upper quadrant or epigastric pain, headaches, visual disturbances, hypertension, and proteinuria. Some may even present with symptoms of thrombocytopaenia. There is no one symptom which has been consistently found to be present in every woman diagnosed with pre-eclampsia or HELLP.
- Acute fatty liver of pregnancy, antiphospholipid syndrome, and acute pancreatitis are some of the differential diagnoses of HELLP syndrome.
- The presence of HELLP is associated with a maternal mortality rate of 1%. It is also associated with increased maternal morbidity including pulmonary oedema (8%), acute kidney injury (3%), disseminated intravascular coagulation (15%), placental abruption (9%), and adult respiratory distress syndrome (< 1%). Pregnancies complicated by HELLP lead to an increased risk of wound haematoma and blood transfusion.
- There is an increase in perinatal mortality rates associated with HELLP, with values ranging from 7.4% to 20.4%. The higher mortality rates tend to be in pregnancies where HELLP develops at an earlier gestational age (e.g. 28 weeks or less).
- Once diagnosed, HELLP syndrome is a progressive condition with associated deterioration in the maternal condition. Experts agree that if the condition is diagnosed after 34 weeks' gestation, then prompt delivery is indicated. There is also agreement that delivery is indicated if HELLP develops before

34 weeks and there is associated multiorgan dysfunction or evidence of fetal distress.

- There is disagreement in the management of women who develop HELLP before 34 weeks' gestation, who are otherwise stable and there is no evidence of fetal distress. Some experts advocate the use of corticosteroids to assist with fetal lung maturation and delivery within 24 hours. Others advocate a more expectant approach with close monitoring of the woman and only expedite delivery when there is a deterioration in the condition or fetal distress develops. Regardless of the management, there remains an increased fetal mortality rate despite expedited delivery.
- It is accepted that corticosteroid use improves fetal outcomes in women who develop HELLP before 34 weeks' gestation. Some studies have reported improvement in platelet numbers following corticosteroid administration, allowing women to have epidural anaesthesia for delivery. However, there is good evidence to suggest that the use of corticosteroids results in a reduction in maternal morbidity.
- In all patients where HELLP is suspected, immediate admission to hospital for observation on the delivery suite is advised. Magnesium sulphate should be given as a seizure prophylaxis and hypertension treated to maintain a systolic BP below 160 mmHg or a diastolic BP below 105 mmHg. Hydralazine, labetalol, or nifedipine may be used to treat hypertension. Laboratory tests should then be taken and sent to confirm or exclude the diagnosis of HELLP.
- Regarding when to delivery, if the diagnosis is confirmed before 35 weeks' gestation, then transfer to a tertiary centre is recommended if the maternal condition is stable. The decision of when to deliver is made by determining if the maternal condition has been stabilized, fetal well-being has been assessed, and whether there is a need to delay delivery whilst corticosteroids are given to aid fetal lung maturation.
- The presence of HELLP syndrome is not an indication for immediate caesarean delivery. The decision to delivery by caesarean should be based on gestational age, presence or absence of labour, fetal well-being, and cervical Bishop score. Vaginal delivery may be indicated if the patient is in labour or there has been rupture of membranes and there are no obstetric contraindications to vaginal delivery.
- Pain relief for vaginal delivery may be provided by intermittent boluses of systemic opioids. Pudendal block is contraindicated due to the risk of haematoma formation and bleeding. Epidural analgesia is contraindicated if the platelet count is below 75,000/mm$^3$. For caesarean delivery, general anaesthesia may be indicated in the presence of a platelet count below 75,000/mm$^3$.
- Platelet transfusion is indicated either before or after delivery if there is significant bleeding or the platelet count is below 20,000/mm$^3$.
- After delivery, close monitoring of vital signs, fluid status, laboratory tests, and pulse oximetry should be continued for 48 hours. The majority of patients show resolution of the condition within 48 hours of delivery.
- HELLP may develop in the postpartum period within a few hours of delivery up to 7 days after birth, with the majority occurring within 48 hours. Management remains the same: the use of magnesium sulphate prophylaxis, BP management, and the use of laboratory tests to monitor the disease progression.
- The rate of recurrence of pre-eclampsia in subsequent pregnancies is 20%, whereas the rates of HELLP range between 2% and 19%. Women should be counselled about the need for close monitoring in any future pregnancies. There is presently no preventative treatment against the development of HELLP in subsequent pregnancies.

## Imaging

### NICE. *Ultrasound-Guided Catheterisation of the Epidural Space*. Interventional Procedure Guidance 249, 2008

https://www.nice.org.uk/guidance/ipg249

This guidance acknowledges that there is limited evidence on the use of ultrasound to assist epidural catheter placement. It does support, however, that it is a safe technique and may be a helpful way of achieving successful localization of the epidural space. This guideline covers epidural catheter placement in the obstetric and non-obstetric populations.

#### Key points

- Ultrasound may be used to guide the epidural needle towards the epidural space in real time. The conventional loss of resistance technique is still used as a safeguard.
- Ultrasound may also be used in a pre-puncture technique whereby the depth of the epidural space is located using the ultrasound and the ideal puncture site is marked on the back. The epidural catheter is then inserted using the conventional loss of resistance technique.
- Studies suggest that the use of both pre-puncture and real-time ultrasound-guided techniques to assist epidural catheter placement is associated with fewer attempts to locate the epidural space and with higher patient satisfaction.
- Studies in children showed that the use of ultrasound was associated with faster epidural catheter placement and with a higher success rate in terms of epidural effectiveness.
- With regards to safety, the use of the ultrasound was associated with a lower rate of dural puncture, aspiration of blood in the catheter and lower number of patients reporting 'severe' headache after an epidural.

### NICE. *Guidance on the Use of Ultrasound Locating Devices for Placing Central Venous Catheters*. Technology Appraisal Guidance 49, 2002

https://www.nice.org.uk/guidance/ta49/resources/guidance-guidance-on-the-use-of-ultrasound-locating-devices-for-placing-central-venous-catheters-pdf

Central venous catheters (CVCs) are inserted by a range of medical personnel for a variety of indications. When using the landmark technique, the failure rate for the insertion of CVCs may be as high as 35%. The complications associated with the insertion of CVCs include arterial puncture, pneumothorax, arteriovenous fistula, and multiple attempts. This guidance offers advice

regarding the use of ultrasound to assist the insertion of CVCs, with a view to minimizing complications.

### Key points

- Ultrasound guidance should be used to assist in the insertion of CVCs in both elective and emergency situations. All those involved in inserting CVCs should undergo appropriate training in the use of ultrasound.
- The use of ultrasound allows identification of the target vein, detection of any anatomical abnormalities, and can rule out vessel thrombosis.
- Compared with the landmark technique, ultrasound-guided CVC insertion in the internal jugular vein has been associated with:
  - reduced risk of failed catheter placement
  - reduced risk of catheter placement complications
  - reduced failure on first attempt at catheter placement
  - fewer number of attempts to successfully place the catheter.
- Similar findings were found when ultrasound was used to assist CVC insertion in infants.
- Similar results were also found when ultrasound was used to assist CVC placement in the subclavian vein. However, the operators in this study were relatively inexperienced in inserting CVCs into the subclavian vein using the landmark technique.
- Ultrasound guidance significantly reduced the number of attempts needed to successfully insert a CVC into a femoral vein compared with the landmark technique.
- The use of audio-guided ultrasound technique is not recommended.

## Intrapartum care

### *Safer Childbirth: Minimum Standards for the Organisation and Delivery of Care in Labour*, October 2007

http://www.rcoa.ac.uk/system/files/PUB-Safer_Childbirth.pdf

Joint publication from the Royal College of Obstetricians and Gynaecologists, Royal College of Midwives, Royal College of Anaesthetists and Royal College of Paediatrics and Child Health.

This publication provides the minimum essential standards for staffing, training, and equipment required for providing a safe environment for the parturient and neonate.

### Key points

- CMACE, along with the Confidential Enquiry into Stillbirths and Deaths in Infancy (CESDI) and the Confidential Enquiry into Maternal Deaths (CEMD) have recommended a review into the organization and provision of maternity care services.
- Through good teamwork, it is possible to provide safe and effective patient-centred care. The importance of the individual roles of the midwife, obstetrician, anaesthetist, paediatrician, and other support staff involved in the care of the pregnant patient is highlighted.
- Changes in shift patterns and recruitment shortages have resulted in inadequate numbers of midwives to provide the appropriate care to labouring women. Appropriately trained maternity care assistants can assist but not substitute midwifery care.
- 'Modernising Medical Careers' and changes to working times have reduced the availability and experience of junior medical staff on labour ward, thus requiring consultant obstetricians to be more present on labour ward.
- Maternity services are associated with higher litigation costs than other services.
- Better organization and provision of services requires good communication and strong leadership to maintain and boost staff morale.
- Clear, concise documentation should be maintained at all times. This is especially important should an incident arise.
- Due to the changing role of the anaesthetist on labour ward, a suitably trained anaesthetist should be available to manage labour analgesia and provide appropriate anaesthesia for operative delivery.
- Paediatric staff on labour ward must be competent in neonatal life support.
- Every attempt should be made to keep the mother and baby together after birth.

### Royal College of Obstetricians and Gynaecologists. *Placenta Praevia, Placenta Accreta and Vasa Praevia: Diagnosis and Management*. Green-Top Guideline No. 27, January 2011

http://www.rcog.org.uk/files/rcog-corp/GTG27PlacentaPraeviaJanuary2011.pdf

This guideline is summarized under 'Haematological'.

### Royal College of Obstetricians and Gynaecologists. *Preterm Premature Rupture of Membranes*. Green-Top Guideline No. 44, 2006 (Minor Amendment 2010)

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg_44.pdf

This revised guideline makes recommendations regarding the diagnosis, investigation, and management of preterm premature rupture of membranes (PPROM). PPROM occurs in about 2% of pregnancies but is associated with 40% of preterm deliveries, which in turn is associated with significant neonatal morbidity and mortality.

### Key points

- PPROM is known to be associated with preterm birth, neonatal sepsis, and pulmonary hypoplasia, which can lead to neonatal death.
- Women with intrauterine infections have earlier deliveries and neonates born with sepsis have a mortality rate four times higher than neonates born without sepsis.
- PPROM is best diagnosed through history and a sterile speculum examination. An ultrasound scan can be used to assist diagnosis in some cases.

- Once diagnosed, women should be observed for signs of chorioamnionitis, which include maternal pyrexia, offensive vaginal discharge, and fetal tachycardia. There is no need to carry out weekly high vaginal swabs or blood tests. Cardiotography (CTG) may be useful in assessing fetal tachycardia.
- Presently there is not enough evidence to support the use of routine amniocentesis to detect subclinical infection in women with PPROM.
- Erythromycin should be given for 10 days once PPROM has been diagnosed as this has been shown to reduce the number of deliveries occurring 48 hours after PPROM. Co-amoxiclav should be avoided as studies showed an increase in neonates born with necrotizing enterocolitis following maternal treatment with co-amoxiclav. Penicillin or clindamycin should be given if group B *Streptococcus* is isolated in PPROM.
- Corticosteroids should be given in cases of PPROM occurring between 24 and 34 weeks' gestation to reduce the incidence of neonatal respiratory distress syndrome.
- Ritodrine has been shown to delay delivery for 24 hours after PPROM but this effect does not persist beyond 24 hours. Other studies involving tocolytics did not show any benefit and their routine use is not recommended.
- Delivery of the baby should be considered after 34 weeks. If delivery is to be delayed, the woman should be warned of the increased risk of chorioamnionitis and the reduced risk of neonatal respiratory problems.
- It is advisable to admit women with PPROM for monitoring and treatment.
- Amnioinfusion during labour is not recommended in PPROM as it does not prevent umbilical cord compression. (Amnioinfusion is a procedure in which a needle is introduced into the uterine cavity under ultrasound guidance and saline is infused to increase the volume of amniotic fluid.)

## Royal College of Obstetricians and Gynaecologists. *Antenatal Corticosteroids to Reduce Neonatal Morbidity and Mortality*. Green-Top Guideline No. 7, 2010

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg_7.pdf

Antenatal corticosteroids have been previously shown to reduce the incidence of respiratory distress syndrome and are also beneficial in preventing other complications of prematurity, such as intraventricular haemorrhage. This guideline aims to provide up-to-date information regarding the most appropriate use of corticosteroids antenatally and in neonates. The use of corticosteroids shows no benefit for the mother.

### Key points

- A single course of corticosteroids should be offered to women between $24^{+0}$ and $34^{+6}$ weeks' gestation, who are at risk of preterm delivery. Corticosteroids may be considered in women less than 24 weeks' gestation but the decision must be made by a senior clinician.
- Antenatal corticosteroids have the best chance of reducing neonatal mortality from respiratory distress syndrome between 24 hours and up to 7 days after the second dose has been given.
- A single course of antenatal corticosteroids does not appear to have any immediate or long-term adverse effects on the mother or fetus. There remains insufficient evidence regarding the adverse effects following multiple courses of antenatal corticosteroids.
- Antenatal corticosteroids should be used with caution in women with a systemic infection. Senior review should be sought when considering a delay in delivery for steroid prophylaxis in women with overt chorioamnionitis.
- Antenatal corticosteroids should be given to all women who are at risk of preterm delivery before $34^{+6}$ weeks' gestation and in all elective caesarean deliveries before $38^{+6}$ weeks' gestation.
- Diabetes mellitus is not a contraindication to giving antenatal corticosteroids. However, these patients need to be closely monitored and additional insulin may need to be given.
- The corticosteroid agent of choice to enhance lung maturation is betamethasone 12 mg in two doses or dexamethasone 6 mg in four doses. Both are given intramuscularly.

## Royal College of Obstetricians and Gynaecologists. *Tocolysis for Women in Preterm Labour*. Green-Top Guideline No. 1B, 2011

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg1b26072011.pdf

Preterm birth is defined as delivery before $37^{+0}$ weeks' gestation. Infant mortality in this age group was 42/1000 live births compared with 5/1000 live births overall. The mortality rate in the first year of infants born before $32^{+0}$ weeks is 144/1000 compared with 1.8/1000 live births of those born at term. Very preterm birth is defined as delivery before 32 weeks and is responsible for 51% of infant deaths. Commonly used tocolytic agents in the United Kingdom include beta-agonists, calcium channel blockers, oxytocin receptor antagonists, prostaglandin synthetase inhibitors, nitric oxide donors, and magnesium sulphate.

### Key points

- The use of a tocolytic drug may prolong a pregnancy by up to 7 days. However, there is no evidence that these drugs improve neonatal outcomes. Nonetheless, it is worth considering using them if the delay in delivery facilitates care, for example, completing a course of steroids, allowing an *in utero* transfer.
- Both nifedipine and atosiban are effective in delaying delivery by up to 7 days.
- Nifedipine is associated with an improvement in neonatal outcome, when compared to beta-agonists, though the long-term effects are unknown.
- Beta-agonists can delay birth by up to 48 hours compared to placebo, but there is no evidence to suggest they are superior to other tocolytic agents. However, they have a high frequency of adverse effects.
- Nifedipine, atosiban, and cyclooxygenase inhibitors have fewer adverse effects compared to beta-agonists but it is unclear how these agents compare with each other.
- Although there is no strong evidence to support the use of magnesium sulphate to reduce the risk of preterm birth, studies have shown it to decrease the risk of cerebral palsy following

preterm delivery. For this reason, magnesium sulphate should be given to those at risk of preterm delivery.

- It is not recommended to administer more than one tocolytic agent at one time due to an increased risk of adverse side effects.

## Royal College of Obstetricians and Gynaecologists. *Management of Monochorionic Twin Pregnancy*. Green-Top Guideline No. 51, 2008

https://www.rcog.org.uk/globalassets/documents/guidelines/t51managementmonochorionictwinpregnancy2008a.pdf
*(Reference 45 in chapter 33)*

A monochorionic (MC) twin pregnancy is one where both twins share a single placenta. About 1/3 of twin pregnancies are monochorionic. A major risk in MC pregnancies is the development of vascular placental anastomoses between the two umbilical circulations, resulting in twin-to-twin transfusion syndrome (TTTS).

### Key points

- TTTS occurs in about 10–15% of MC pregnancies and is more likely due to unidirectional flow in an artery–vein anastomosis rather than a bidirectional artery–artery anastomosis. TTTS can occur in both monochorionic, monoamniotic (MCMA) and monochorionic, diamniotic (MCDA) twin pregnancies, though it is more common in MCDA due to a high number of protective artery–artery anastomoses in MCMA.
- All women with a twin pregnancy should be offered an ultrasound examination at 10–13 weeks' gestation. Chorionicity is best assessed before 14 weeks, with a sensitivity and specificity of 89.9% and 99.5% respectively.
- The diagnosis of TTTS is made on specific ultrasound criteria: single placenta, concordant gender, oligohydramnios.
- Evidence of abnormal bladder size and haemodynamic and cardiac compromise suggest severe TTTS.
- MC twin pregnancies have a higher rate of fetal loss than dichorionic (DC) twin pregnancies.
- There is not enough evidence to suggest nuchal translucency measurements should be used routinely to predict TTTS.
- All MC twin pregnancies should have a detailed ultrasound scan assessment, which includes views of the heart. Fetal echocardiography should be considered in cases of suspected severe TTTS.
- In uncomplicated MC twin pregnancies, routine ultrasound scanning should be performed every 2–3 weeks after 16 weeks.
- The Quintero classification system can be used to grade the severity of TTTS (see Appendix 2 of this book).
- Severe TTTS should be treated with laser ablation if diagnosed before 26 weeks' gestation. Some anastomoses may be missed and TTTS can recur later in the pregnancy in up to 14% of cases treated with laser ablation.
- In severe TTTS, selective termination of one twin or complete termination of pregnancy are alternative options which need to be discussed.
- Aim to deliver uncomplicated MC pregnancy at 36–37 weeks' gestation. It is appropriate to aim for a vaginal delivery unless there are indications for a caesarean delivery.
- Should one twin die *in utero*, the surviving twin has a 12% chance of death and 18% chance of neurological abnormalities. Such women should be referred to a specialist fetal medicine centre.
- There is a high chance of cord entanglement in MCMA twin pregnancies and these are best delivered at 32 weeks by caesarean delivery following a course of antenatal corticosteroids.

## Royal College of Obstetricians and Gynaecologists. *The Management of Breech Presentation*. Green-Top Guideline No. 20b, 2006

https://www.rcog.org.uk/en/guidelines-research-services/guidelines/gtg20b/

This guideline provides information regarding the route of delivery and the choice of various techniques, which may be used during delivery of a breech presentation. Breech presentation occurs in about 3–4% of term pregnancies.

### Key points

- A planned caesarean delivery for a breech presentation carries a reduced perinatal mortality and early neonatal morbidity compared with planned vaginal delivery. However, there is no evidence to suggest that the long-term health of the baby is affected by the mode of delivery.
- Compared with vaginal delivery, caesarean delivery carries a small increase in serious immediate complications.
- Women should be assessed for suitability for a vaginal breech delivery. If there are any unfavourable features, then caesarean delivery should be considered.
- A vaginal breech delivery should occur in a place where there are facilities to perform an emergency caesarean delivery. If favourable, an induction of labour may take place but the labour should not be augmented.
- An epidural is not routinely advocated. The woman should have a choice regarding labour analgesia.
- Continuous CTG monitoring during labour should still occur. However, fetal blood sampling from the buttocks is not recommended.
- If there is a delayed second stage, a caesarean delivery should be considered.
- The maternal position advocated to facilitate a breech delivery is the dorsal or lithotomy position.
- There are various manoeuvres which may be performed to facilitate breech delivery: Lovset, Mauriceau–Smellie–Veit, and Burns–Marshall. (see Appendix 2 of this book).
- Routine breech extraction is not recommended.
- Routine caesarean delivery should not be performed for a preterm breech fetus or a twin pregnancy where the second twin is breech.

## Royal College of Obstetricians and Gynaecologists. *Birth after Previous Caesarean Birth*. Green-Top Guideline No. 45, February 2007

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg4511022011.pdf

- Women with a previous history of caesarean birth should have antenatal counselling regarding the options of a planned vaginal birth after caesarean (VBAC) and a repeat elective caesarean delivery, if they fulfil the following criteria:
  - Previous operation was an uncomplicated lower segment transverse caesarean delivery
  - There is no complication in the current pregnancy at term
  - There is no reason to suggest vaginal delivery would be unsuccessful.
- The final decision for the mode of delivery should be made ideally by 36 weeks' gestation. The management plan should be clearly documented, in case labour starts prior to the scheduled date.
- The chances of successful planned VBAC are between 72% and 76%.
- If a woman has had a classical caesarean delivery, elective repeat caesarean delivery (ERCD) should be recommended.
- Women with a previous uterine incision other than a low transverse caesarean delivery or two previous uncomplicated lower transverse caesarean deliveries should be counselled by a consultant obstetrician regarding the potential risks, if they wish to consider VBAC.
- Women considering the birth options after a previous caesarean delivery, should be aware of the risks detailed in Table A1.7.
- Planned VBAC should take place in an appropriately staffed and equipped delivery suite. Facilities for immediate caesarean delivery and advanced neonatal resuscitation must be available. Continuous electronic fetal monitoring should be applied. Continuous intrapartum care must be given so that uterine scar rupture can be promptly identified.
- It is safe to use epidural analgesia in planned VBAC.
- If labour is induced and/or augmented, there is two- to threefold increased risk of uterine rupture and 1.5-fold increased risk of caesarean delivery when compared with spontaneous labour.

**Table A1.7** Possible birth risks after a previous caesarean delivery

| Complication | Planned VBAC | ERCD |
|---|---|---|
| Uterine rupture | 22–74/10,000 | No risk |
| Blood transfusion | 1% additional risk compared to ERCD | |
| Birth related perinatal death | 2–3/10,000 additional risk compared to ERCD | |
| Neonatal hypoxic ischaemic encephalopathy | 8/10,000 risk | |
| Neonatal respiratory problems | 2–3% | 3–4% |
| Anaesthetic risk | Extremely low for both | |
| Serious complications for future pregnancies | | Elevate the risks |

- Serial cervical assessments should be performed preferably by the same person to assess if there is adequate progress.
- A consultant obstetrician should discuss with the woman the parameters of progress that would necessitate discontinuing VBAC.

## Royal College of Obstetricians and Gynaecologists. *Operative Vaginal Delivery*. Green-Top Guideline No. 26, January 2011

https://www.rcog.org.uk/globalassets/documents/guidelines/gtg26.pdf

### Key points

- The following factors have been shown to reduce the need for operative vaginal delivery:
  - Continuous support during labour
  - Upright or lateral positions
  - Avoiding the use of an epidural for pain relief.
- Delayed pushing should be allowed in primiparous women with an epidural in order to reduce the need for rotational and midcavity deliveries.
- A standard classification of operative vaginal delivery should be used. (outlet, low, mid and high; see Appendix 2 in this book).
- For gestations of less than 34 weeks, vacuum extraction should not be used.
- For gestations between 34 weeks and 36 weeks, vacuum extraction should be used with caution.
- All women should be given information about operative vaginal delivery during the antenatal period. A written consent should be signed before a trial of operative vaginal delivery in the operating theatre.
- An experienced obstetrician, who is competent at mid-cavity deliveries, must be present from the outset for all rotational or mid-cavity operative vaginal delivery.
- Operative vaginal deliveries, which have a higher chance of failure, should be performed in a place where a caesarean delivery can be performed immediately.
- The options for rotational delivery are Kielland forceps, manual rotation followed by direct traction forceps or rotational vacuum extraction. An experienced obstetrician should perform the rotational delivery.
- When there is no progressive descent with moderate traction during each contraction or where delivery is not imminent following three contractions of a correctly applied instrument by an experienced operator, operative vaginal delivery should be abandoned.
- An incident form must be submitted for any adverse outcomes, including unsuccessful instrumental delivery.
- Paired cord blood samples should be taken after all attempts at operative vaginal delivery.
- There is an increased neonatal morbidity with failed operative vaginal delivery. The neonatologist should be informed when this occurs to ensure appropriate management of the baby.

- There is inadequate evidence to support the routine use of prophylactic antibiotics in operative vaginal delivery.
- Venous thromboembolism risk needs to be reassessed after delivery.
- Regular paracetamol and diclofenac should be prescribed if not contraindicated.
- Women should be offered physiotherapy to prevent urinary incontinence following operative vaginal delivery.
- Individualized care should be given to all women who have sustained a third- or fourth-degree perineal tear.

### NICE. *Induction of Labour.* Clinical Guideline 70, July 2008

http://www.nice.org.uk/guidance/cg70/resources/guidance-induction-of-labour-pdf

#### Key recommendations

- At the 38-week antenatal visit, all women should be informed of the risks associated with pregnancies that last longer than 42 weeks (e.g. placental insufficiency, meconium aspiration syndrome, fetal macrosomia, and birth injury).
- Women should be informed about membrane sweep, induction of labour between 41 and 42 weeks, and expectant management.
- Women offered an induction of labour, should be informed about:
  - the reasons for induction
  - time, place, and method of induction
  - pain relief options
  - alternative options if the woman does not choose to have an induction of labour or if an induction is not successful
  - the risks and benefits of each induction method.
- Induction of labour should be offered to the women with uncomplicated pregnancies between 41 and 42 weeks to avoid the risks associated with prolonged pregnancy.
- If a woman presents with PPROM after 34 weeks, she should be made aware of the risks to her and the baby as well as the availability of neonatal facilities, prior to a decision of induction of labour. Vaginal prostaglandin $E_2$ is the method of choice for induction. It is given as a gel, tablet, or controlled release pessary. Women should be informed about the risks of uterine hyperstimulation.
- If the induction fails, the woman's condition should be fully assessed, and electronic fetal monitoring should be instituted. Subsequent treatment options include a repeat attempt at induction or a caesarean delivery.

### Royal College of Obstetricians and Gynaecologists. *Shoulder Dystocia*. Green-Top Guideline No. 42, March 2012

http://www.rcog.org.uk/files/rcog-corp/GTG42_25112013.pdf

#### Key points

- Risk assessment tools for shoulder dystocia are insufficiently predictive to prevent the majority of cases.
- Risk of shoulder dystocia can be reduced by an induction of labour at term in women with GDM. However, the induction does not prevent shoulder dystocia in non-diabetic women with a suspected fetal microsomia.
- Elective caesarean delivery should be considered in diabetic women with an estimated fetal weight of more than 4.5 kg.
- In women with previous history of should dystocia, a caesarean or vaginal delivery may be appropriate. The management decision ought to be made jointly by the woman and her medical team.
- All maternity staff should be aware of the methods for diagnosing shoulder dystocia and the manoeuvers used to facilitate delivery. The birth attendant should routinely observe for the following signs:
  - Difficulty with delivery of the face and chin
  - The head remaining tightly applied to the vulva or even retracting (turtle-neck sign)
  - Failure of restitution of the fetal head
  - Failure of the shoulders to descend.
- Routine traction in an axial direction can be applied in order to diagnose shoulder dystocia. Once shoulder dystocia is recognized, help should be called immediately.
- McRoberts' manoeuvre should be the first intervention. Suprapubic pressure can be applied to facilitate the McRoberts' manoeuvre.
- Internal manoeuvres or 'all-fours' position are both second-line manoeuvres.
- Third-line manoeuvres should be considered cautiously to avoid unnecessary morbidity and mortality.
- The team should prepare for possible postpartum haemorrhage and severe perineal tears.
- A neonatal clinician should examine the baby to rule out any injury.
- All maternity staff should take part in the shoulder dystocia training every year. High-fidelity equipment should be used in the training.

## Neonatal

### Nuffield Council of Bioethics and the British Association of Perinatal Medicine. *Guidelines on Giving Intensive Care to Extremely Premature Babies*, 2006

http://nuffieldbioethics.org/report/neonatal-medicine-2/guidelines-intensive-care-extremely-premature-babies/

- At 25 weeks or more of gestation: intensive care should be started unless the baby suffers from a severe abnormality which is not conducive with any meaningful duration of life.
- Between $24^{+0}$ and $24^{+6}$ weeks' gestation: intensive care treatment should be initiated apart from in circumstances where the clinicians and parents concur that such treatment in view of the neonate's current clinical condition would not be beneficial to the neonate.

- Between $23^{+0}$ and $23^{+6}$ weeks' gestation: parents should be consulted for their wishes regarding intensive care therapy. However, the clinicians should not feel duty bound to commence treatment if they feel that such treatment would cause more harm to the neonate and would not be of any further benefit.
- Between $22^{+0}$ and $22^{+6}$ weeks' gestation: due to the likelihood of a poor outcome, resuscitation of the neonate should not be attempted unless the parents repeatedly request such course of action after thorough discussion with doctors regarding the likely outcome of such actions and the doctors agree that it ought to be attempted.
- Before 22 weeks: resuscitation should only be attempted in clinical research settings.

### Resuscitation Council (UK) Guideline: *Newborn Life Support*, 2010

Details of the algorithm may be found using the following link: http://www.resus.org.uk/pages/resuscitation-guidelines/

## Neurological

### OAA Clinical Guideline: *Postdural Puncture Headache: PDPH – Diagnosis and Management*, March 2014

http://www.oaa-anaes.ac.uk/ui/content/content.aspx?id=176

#### Key points

- PDPH is an important cause of morbidity following obstetric anaesthesia.
- The PDPH guidelines from three NHS hospitals in the United Kingdom can be found on the OAA clinical guideline page.
- PDPH is typically fronto-occipital. It is usually associated with neck stiffness and gets worse on sitting or standing up.
- When reviewing a patient with postpartum headache, the anaesthetist should consider differential diagnoses such as meningitis, intracranial haemorrhage, migraine, and cerebral vein thrombosis.
- Conservative treatment includes hydration, simple analgesia, and occasionally caffeine.
- If the headache is severe or if it does not improve with conservative management, an epidural blood patch (EBP) should be offered.
- An EBP should be performed under full aseptic precautions.
- Most hospitals advise women to lie flat for 2 hours after the blood patch.
- All women who have received a blood patch should be offered aftercare instructions prior to discharge.
- Patients should be informed to contact the hospital or the duty anaesthetist or attend the emergency department if their symptoms get worse or if there is any change in neurology.
- All patients with PDPH should be followed up by the anaesthetist by telephone or outpatient appointment after discharge from hospital.

### Royal College of Anaesthetists. *Report and Findings of the Third National Audit Project* (Chapter 16: Complications after Obstetric CNB), January 2009

http://www.rcoa.ac.uk/nap3

- The initial census phase of this project identified that 45% of all central neuraxial blocks (CNBs) are performed for obstetric indications.
- Out of 12 cases correctly reported after obstetric CNBs, five patients made a full and rapid recovery. The remaining seven patients were considered to have a potentially disabling complication.
- There were no cases of paraplegia or death after obstetric CNB.

#### Key points

- Obstetric CNB is associated with fewer major complications compared to CNBs for other indications (most notably perioperatively).
- Obstetric causes should also be considered when neurological deficits occur. A neurologist's opinion and electrophysiological studies may add considerable information.
- Multiple attempts at performing neuraxial blockade, which is associated with significant bleeding, may increase the risk of neuraxial infection despite full aseptic precautions.
- Although a headache after delivery is a common occurrence and is usually benign, it is important to exclude dural puncture, meningitis, and subdural haematoma as possible causes.
- The final height of a spinal block may be difficult to predict following a recent effective epidural for labour analgesia. In such cases, a CSE may be advisable as it allows the possibility for block height adjustment.
- Clinicians should be aware that giving drugs via the wrong route is more common in obstetric practice than in other clinical areas.

## Psychiatric

### Oates MR, Cantwell R. Deaths from Psychiatric Causes. In Centre for Maternal and Child Enquiries (CMACE). Saving mothers' lives: reviewing maternal deaths to make motherhood safer: 2006–2008. The eighth report on confidential enquiries into maternal deaths in the United Kingdom. *BJOG* 2011; 118(Suppl. 1):132–42

http://www.oaa-anaes.ac.uk/assets/_managed/editor/File/Reports/2006-2008%20CEMD.pdf

This chapter discusses the maternal deaths resulting from suicide or accidental substance overdose and makes recommendations for their management.

#### Key points

- All women should have a full history taken including any previous psychiatric illnesses. Their current mental state should also be assessed. All women with a previous history of psychiatric illness should be referred to a psychiatrist, even if they are

currently well. These women should be followed up for a minimum of 3 months after delivery.

- Pregnant and recently delivered women should be able to easily access psychiatric services where they may be assessed, admitted, and treated. Where possible, the same mental health team should be involved to maintain continuity of care.
- There should be specialist teams in the community who are able to treat at-risk women in the peripartum period. Facilities should be made available to admit women either late in pregnancy or early in the postpartum period where mother and baby are able to be cared for together by such teams.
- Good communication is necessary, especially when English is not the main language, when a diagnosis of a psychiatric disorder is made of physical symptoms, distress, or agitation.
- Suicides in recently delivered women were more common in white, affluent women over the age of 30. It is important not to stereotype those from lower socioeconomic backgrounds as being high risk of suicide.
- Women with a previous history of a serious affective disorder such as bipolar disease or severe depression are at increased risk of suicide. Such women should be closely followed up and monitored for signs of recurrence.
- Puerperal psychosis remains rare. Healthcare providers must remain vigilant to this condition as the clinical symptoms may have a sudden onset and deteriorate rapidly, thus endangering the life of the mother and baby.
- The welfare and safeguarding needs of the child must be considered when managing a woman with a mental illness.
- Women may conceal or hide the nature or extent of their substance abuse. Community teams should provide support including regular monitoring and prescription of relevant substitutes. Such women should be referred to specialists for management of their on-going obstetric care.

## NICE. *Antenatal and Postnatal Mental Health: Clinical Management and Service Guidance*. Clinical Guideline 192, June 2015

http://www.nice.org.uk/guidance/cg192/resources/guidance-antenatal-and-postnatal-mental-health-clinical-management-and-service-guidance-pdf

This evidence-based guideline covers the management of both new and pre-existing mental health disorders in women of childbearing age. It also covers the teratogenic risk of psychotropic medication and the risks if used while breastfeeding. Individual diseases including depression, generalized anxiety disorders, panic disorder, and obsessive–compulsive disorder are discussed in more detail within the guidance.

### Key points

- A woman may need to be referred for preconception counselling. In particular, the effects of any current psychotropic medication on the fetus, possible drug substitutions during pregnancy, and impact of the drugs on the ability to breastfeed should be discussed before conception. The woman should be counselled about the consequences of stopping such medication before or during pregnancy.
- Women should be asked about any current or past mental health problems they or their families have encountered. This should be asked at the booking visit and also during the postpartum review at 4–6 weeks and 3–4 months.
- If a woman is assessed to require psychological treatment, this should be arranged to occur within a month of the initial assessment.
- When starting treatment, the risks of the treatment should be clearly explained to the patient. This is particularly important when deciding which antidepressant to use, as the safety profile in pregnancy varies with each class of drug. An individualized treatment plan made in agreement with the patient should be implemented. Healthcare providers should be aware that the needs of the patient may change throughout the pregnancy and in the postpartum period and treatment should be adjusted as necessary.
- There should be a network of specialist services to provide support and advice to women with mental health problems in the perinatal period.
- Where possible, involve the patient and partner in decisions about her care and that of the baby.

## Scottish Intercollegiate Guidelines Network. *Management of Perinatal Mood Disorders*. SIGN 127, March 2012

http://www.sign.ac.uk/pdf/sign127.pdf

This guideline from SIGN is an updated version of SIGN guideline 60 'Postnatal depression and puerperal psychosis'. It offers advice regarding the prevention, assessment, diagnosis, and treatment for perinatal mood disorders. The quick reference guide may be accessed by this link: http://www.sign.ac.uk/pdf/qrg127.pdf. The guideline offers advice on using various psychotropic drugs including antidepressants, lithium, antiepileptic drugs, and antipsychotics.

### Key points

- Mood disorders, depression, antenatal anxiety, and postpartum psychosis are covered in this guideline.
- All women should be asked about personal and family history of postpartum psychosis and any other affective disorders. Women who are at high risk of developing a postpartum affective disorder, should have a detailed plan regarding management in late pregnancy and regarding psychiatric follow-up in the early postpartum period. There should be a multidisciplinary team input in the support and management of such patients.
- As a minimum, women should be asked about depressive symptoms at booking and during postpartum follow up at 4–6 weeks and 3–4 months.
- For the treatment of mild to moderate depression, cognitive behavioural therapy may be an option (level B evidence).
- Contraception should be discussed with women of childbearing age who are on psychotropic medication. Valproate should not be routinely prescribed to women of childbearing age due to the risk of teratogenicity and neurobehavioural toxicity.

- Electroconvulsive therapy administered during pregnancy is effective and is of low risk to the mother and fetus.

## Renal

### EBPG Expert Group on Renal Transplantation. European best practice guidelines for renal transplantation. Long term management of the transplant patient. Section IV: Pregnancy in renal transplant patients. *Nephrol Dial Transplant* 2002; 17(Suppl 4):50–55

http://ndt.oxfordjournals.org/content/17/suppl_4/50.full.pdf+html

This article offers evidence-based guidelines for the management of renal transplant recipients who become pregnant.

#### Key points

- Fertility is usually restored following a successful renal transplantation. If the kidney is functioning well prior to conception, then pregnancy has no adverse effect on kidney function or the graft survival in the long term (level B evidence).
- It is advisable to consider pregnancy 2 years after successful transplantation as long as the graft is functioning well and there are no adverse symptoms such as proteinuria or evidence of rejection (level B evidence).
- A woman who has had a renal transplant and becomes pregnant, should be treated as a high-risk patient and managed jointly by a renal physician and an obstetrician. Once the pregnancy has been confirmed, the function of the graft should be closely monitored as well as continuing to monitor for signs of infection or rejection. Such women are at risk of premature delivery. Fetal well-being should be closely monitored as there is a risk of associated low birth weight.
- Urine cultures should be performed every month throughout pregnancy to monitor for bacterial infections. If detected, then these infections should be treated to prevent further complications. There should also be monitoring for possible viral infections (level B evidence).
- There is a risk of acute graft rejection following delivery. This should be closely monitored for and immunosuppressive drugs should be adjusted accordingly to prevent this (level C evidence).
- Women with a renal transplant are at increased risk of developing pre-eclampsia, especially if they have previously suffered with arterial hypertension. Blood pressure along with markers of end-organ dysfunction must be closely monitored for every 2–4 weeks with adjustment in any antihypertensive drugs as necessary (level B evidence).
- Current evidence suggests that ciclosporin and tacrolimus, either with or without steroids, may continue to be used safely during pregnancy. However, it is not advisable to breastfeed while on these drugs due to the transfer of drugs in breast milk. There is insufficient evidence presently to safely recommend the use of other immunosuppressive agents in pregnancy (level C evidence).
- A vaginal delivery is recommended where possible but in about 50% of cases, a caesarean delivery is advised. These women should deliver in a specialist centre where both renal and obstetric teams are present. After delivery, monitoring of blood pressure, fluid balance, and graft function should continue (level C evidence).

## Respiratory

### Edenborough FP, Borgo G, Knoop C, *et al*. Guidelines for the management of pregnancy in women with cystic fibrosis. *J Cyst Fibros* 2008; 7 Suppl 1:S2–S32

http://www.sciencedirect.com/science/article/pii/S1569199307001294

As more women with cystic fibrosis (CF) are surviving to childbearing age, these consensus guidelines have been developed to help provide evidenced-based care for this population. The maternal outcome following pregnancy is variable and emphasis is placed on maintaining optimal CF treatment in the preconception period and maintaining it throughout pregnancy.

#### Key points

- Where possible, preconception counselling, including genetic testing of one or both partners, should be undertaken to fully prepare the couple for the realities of pregnancy and having a child.
- Drug treatment needs to be rationalized to minimize the potential teratogenic effects.
- Where possible, preconception lung function should be optimized and stabilized, as both maternal and fetal outcomes are related to this. Optimization may include the use of antibiotics to suppress chronic infection, physiotherapy techniques, and mucolytics. In the event of an acute lung infection, additional contraception may be required to prevent a pregnancy occurring whilst using potentially teratogenic drugs.
- Where possible, preconception assessment of the adequacy of dietary intake with a dietician needs to take place. If suboptimal, then vitamin supplementation or supplementary enteral feeding may be needed.
- Pregnant women with all forms of diabetes have been shown to have poorer outcomes than those without diabetes. In such cases, diabetes needs to be carefully controlled through diet and insulin.
- Absolute contraindications to pregnancy are pre-existing pulmonary hypertension and cor pulmonale. A forced expiratory volume in 1 second ($FEV_1$) greater than 60% is recommended for pregnancy, whereas $FEV_1$ less than 50% is an indication for termination of pregnancy.
- Termination of pregnancy in CF patients may be medical or surgical. The choice of anaesthetic for surgical termination will need to be considered on an individual case basis, but general anaesthesia is generally avoided to minimize adverse effects on the lungs.
- A coordinated, multidisciplinary approach is required to provide support for CF patients who are pregnant.

- The majority of pregnancies end with spontaneous vaginal deliveries. A caesarean delivery may be considered in women with severe CF or in those who would not tolerate a prolonged Valsalva manoeuvre.
- Labour analgesia may be effectively provided by an epidural. The use of opioids and nitrous oxide needs to be carefully considered depending on the lung function of the individual.
- A neuraxial anaesthetic technique is recommended for caesarean delivery, followed by recovery in a high dependency setting, with early physiotherapy.
- A pregnancy occurring in a patient who has received a heart–lung transplant should be considered high risk, as the babies are at risk of intrauterine growth restriction and premature delivery. Such pregnancies have typically occurred 2 years after transplant.
- Support, both physical and psychological, should be maintained for women with CF after delivery to help them cope with managing their condition and the needs of a newborn baby.
- The outcomes of mothers following delivery are variable, but appear closely related to the severity of the CF.

## Service provision

### AAGBI and OAA Guidelines: *OAA/AAGBI Guidelines for Obstetric Anaesthetic Services 2013*, 2013

http://www.aagbi.org/sites/default/files/obstetric_anaesthetic_services_2013.pdf

This is an updated joint guideline from the AAGBI and OAA which is designed to ensure that obstetric patients receive the same standards of care as those recommended for the general surgical population.

#### Key points

- A suitably trained 'duty anaesthetist' should be immediately available to look after patients on the delivery suite at all times. There must be a designated consultant in charge of the care of the patients on the delivery suite, who should be easily contactable by the duty anaesthetist at any time.
- There should be separate teams to manage elective and emergency work on the delivery suite to avoid delays in both the elective and emergency work.
- There must be an increase in the presence of a consultant anaesthetist on the delivery suite to match the increasing workload of the obstetric anaesthetist. Elective obstetric anaesthetic services must also be consultant led. This needs to be in addition to the consultant sessions required to cover emergency work on the delivery suite.
- There may need to be restructuring in the provision of maternity services, with the merger of smaller units who may not be able to meet the demands and financial implications for a consultant-led service.
- There should be planned outpatient antenatal review of high-risk parturients and anaesthetists on the delivery suite must be given adequate notice when a high-risk patient is admitted to the delivery suite.
- In units that offer a 24-hour epidural service, the waiting time for an epidural should not exceed 30 minutes. There should be local guidelines in place regarding the appropriate levels of staffing to provide care for women with neuraxial analgesia in labour.
- All women undergoing a caesarean delivery should be reviewed by an anaesthetist preoperatively.
- There should be a suitably staffed recovery area to manage postpartum women.
- Maternal critical care is a developing area and staff should be trained to recognize the sick parturient and know who to contact should the situation arise.
- There should be good communication between all members of the multidisciplinary team to promote effective team working and improve patient safety.
- There should be suitable resuscitation facilities for parturients and neonates on the delivery suite.

### *Safer Childbirth: Minimum Standards for the Organisation and Delivery of Care in Labour*, October 2007

http://www.rcoa.ac.uk/system/files/PUB-Safer_Childbirth.pdf

This guideline is summarized under 'Intrapartum Care'.

### General Medical Council. *Consent: Patients and Doctors Making Decisions Together*, 2008

http://www.gmc-uk.org/guidance/ethical_guidance/consent_guidance_contents.asp

This 2008 guideline replaces *Seeking Patients' Consent: The Ethical Considerations* (1998). The guidance is an extension of the guidance, which is issued in *Good Medical Practice (2013)* (http://www.gmc-uk.org/guidance/good_medical_practice.asp), which requires doctors to be certain to have obtained consent from the patient or an appropriate authority before performing any examination, investigation, or treatment on the patient.

#### Key points

- Doctors and patients must develop a partnership based on trust where all aspects of treatment, no matter how minor, may be discussed in an informed way. If the patient has capacity, the doctor must respect the decision made by the patient.
- A doctor should be able to assess whether a patient has capacity. If the patient is deemed to lack capacity, then healthcare professionals must act according to the Mental Capacity Act 2005. Further guidance may be found at: http://www.legislation.gov.uk/ukpga/2005/9/contents and http://www.justice.gov.uk/downloads/protecting-the-vulnerable/mca/mca-code-practice-0509.pdf.
- If a patient requests a treatment which the doctor believes will not benefit the patient, the reasons for this request should be explored and discussed. A doctor is not obliged to provide the patient with treatment which will not benefit them. The doctor must explain their reasons for this decision and discuss other treatment options with the patient including seeking a second opinion.

- Throughout the consultation process, patients must be given the opportunity to ask questions and seek advice regarding their treatment. At all stages, comprehension must be checked to ensure that the patient fully understands what they may or may not be agreeing to.
- Reasons for withholding information from a patient must be clearly recorded. Furthermore, if a patient does not wish to be given information about their condition or their treatment, it must be made clear to them that their consent may not be valid as a result.
- Before taking consent from a patient for a procedure, the person taking consent must be suitably trained and act in accordance with this guidance.
- A patient's consent may be implied, oral, or written. The doctor must ensure that the patient is giving their consent voluntarily and that they have been adequately informed.
- A young person's ability to give consent is based more on their ability to understand and consider options rather than their actual age. Further guidance may be found at: http://www.gmc-uk.org/guidance/ethical_guidance/consent_guidance_involving_children_and_young_people.asp.
- In an emergency situation, where it is not possible to obtain a patient's consent, treatment may be given if it is necessary to save their life or to prevent further serious deterioration in their condition. Once the patient regains capacity, they should be informed about the treatment they have received and understand it.

## General Medical Council. *0–18 years – Guidance for All Doctors*, 2007

http://www.gmc-uk.org/guidance/ethical_guidance/children_guidance_index.asp

### Key points

- Children and young adults should be treated as individuals who are owed a right to confidentiality and be given respect for any decisions they make.
- It is the clinician's responsibility to act in the child's or young person's best interests as well a safeguard them against all forms of harm.
- The law surrounding the provision of care for children and young adults may be complex, so help from senior colleagues should be sought where necessary.
- During discussions of treatment and care for a young patient, it is necessary to listen not only to the patient's opinions, but also to those of the parents or carers.
- A doctor must be prepared that, in some instances, a young patient may request to be seen alone, without their parents or carers present.
- A young person may be considered as having capacity to consent to a procedure if they fulfil the criteria outlined in the Mental Capacity Act 2005 outlined in the following points.
- A young person aged 16 or over may be presumed to have consent, whereas a child under 16 needs to be assessed for competency.
- The law in the United Kingdom regarding the consent to treatment in young persons aged between 16 and 17 varies according to which country you are in.
- Parents cannot override the decision of a competent young person who refuses treatment. Legal advice should be sought if a competent young person refuses a treatment which may be life-saving to them.

### Parental responsibility

Parental responsibility is held by all mothers. A father may also have parental responsibility if he was married to the mother at the time of the child's birth, if they jointly registered the birth with the mother (from 1 December 2003 onwards), or if he attained parental responsibility through agreement with the child's mother or through a court order. Parental responsibility may also be held by a legally appointed guardian, the local authority in whose care a child is or a person with an emergency protection order for the child (https://www.gov.uk/parental-rights-responsibilities/who-has-parental-responsibility).

## Royal College of Anaesthetists Website: *The Risks of Anaesthesia*

http://www.rcoa.ac.uk/patients-and-relatives/risks

This website provides a link to a series of articles written by anaesthetists addressing various concerns patients and their relatives may have regarding to anaesthesia. The topics listed on the website are:

- 'Feeling sick' http://www.rcoa.ac.uk/system/files/PI-Risk1_3.pdf
- 'Sore throat' http://www.rcoa.ac.uk/system/files/PI-Risk2_1.pdf
- 'Shivering' http://www.rcoa.ac.uk/system/files/PI-Risk3_1.pdf
- 'Damage to lips, teeth and tongue' http://www.rcoa.ac.uk/system/files/PI-Risk4_3.pdf
- 'Damage to the eye during general anaesthesia' http://www.rcoa.ac.uk/system/files/PI-Risk5_0.pdf
- 'Post-operative chest infection' http://www.rcoa.ac.uk/system/files/PI-Risk6_2.pdf
- 'Becoming confused after an operation' http://www.rcoa.ac.uk/system/files/PI-Risk7_1.pdf
- 'Awareness during general anaesthesia' http://www.rcoa.ac.uk/system/files/PI-Risk8_1.pdf
- 'Serious allergy during an anaesthetic (anaphylaxis)' http://www.rcoa.ac.uk/system/files/PI-Risk9_1.pdf
- Headache after a spinal or epidural injection
- 'Nerve damage associated with an operation during a general anaesthetic' http://www.rcoa.ac.uk/system/files/PI-Risk10_2.pdf
- 'Nerve damage associated with a spinal or epidural injection' http://www.rcoa.ac.uk/system/files/PI-Risk11_1.pdf
- 'Nerve damage associated with peripheral nerve block' http://www.rcoa.ac.uk/system/files/PI-Risk12_1.pdf
- 'Equipment failure' http://www.rcoa.ac.uk/system/files/PI-Risk13_1.pdf

- 'Death or brain damage' http://www.rcoa.ac.uk/system/files/PI-Risk14_2.pdf

### Obstetric Anaesthetists' Association Website

http://www.oaa-anaes.ac.uk/content.asp?ContentID=221

This website has information leaflets in a variety of different languages. These may be printed out and given to the parturient and their families to help facilitate understanding and aid consent during labour and delivery. The different information leaflets are:

- 'Pain relief in labour'
- 'Caesarean section'
- 'Epidural information card'
- 'Phrase cards'
- 'High body mass index (BMI)'
- 'Headache after epidural'
- 'Regional anaesthesia for unplanned CS (caesarean section)'
- 'General anaesthesia for unplanned CS (caesarean section).'

### General Medical Council Guidance for Doctors: *Confidentiality*, 2009

http://www.gmc-uk.org/guidance/ethical_guidance/confidentiality.asp

This guidance is designed to aid and assist doctors in how they may maintain respect and confidentiality when caring for patients.

#### Key points

- Although confidentiality is crucial to developing trust between a patient and a doctor, sometimes it may be necessary to share patient information with appropriate individuals to provide safe, effective care for both the individual patient and others in their community.
- Confidentiality is an important duty but not an absolute one. A doctor may disclose information if there is a legal requirement to do so, if the patient consents, or if it is in the public interest to do so.
- Patients have a legal right to know how their information will be used and to have access to or copies of their health records when requested. They should also be informed of any requests from external parties for disclosure of information, even if their consent is not required.
- For research purposes, unidentifiable, codified data may be disclosed without patient consent.
- When considering to disclose patient information in the public interest, it may be necessary to consult with a Caldicott Guardian or other similar advisor, who is impartial and not immediately connected with the use of the information to be disclosed. The Privacy Advisory Committee in Northern Ireland can advise on this matter. The Privacy Advisory Committee in Scotland, however, performs a different role, so the Caldicott Guardian should be consulted.
- It should be established with the patient with whom they would like their information to be shared with (e.g. parents, carers, and other family members). Although it is not a breach of confidentiality to listen to concerns from other family members regarding a patient's condition, a doctor should make it clear that they may not be able to discuss the patient's treatment or condition with that relative if the patient does not wish so.

### British Medical Association Guidance: *Confidentiality and Disclosure of Information Toolkit*

http://www.bma.org.uk/practical-support-at-work/ethics/confidentiality-tool-kit

This website is made up of 16 readily downloadable cards, which cover specific areas relating to confidentiality including children, adults who lack capacity, and the deceased. The cards are designed to help assist the doctor regarding making decisions about patient confidentiality.

## Surgical

### Chen MM, Coakley FV, Kaimal A, *et al*. Guidelines for computed tomography and magnetic resonance imaging use during pregnancy and lactation. *Obstet Gynecol* 2008; 112(2 Pt 1):333–40

#### Key points

- This article describes evidence-based guidelines for the use of CT, MRI, and contrast media during pregnancy for selected indications including suspected acute appendicitis, pulmonary embolism, renal colic, trauma, and cephalopelvic disproportion.
- Risks and benefits of all imaging modalities should be discussed with patients.
- Suspected appendicitis—ultrasound is the investigation of choice. If it is negative, MRI or CT can be obtained.
- Suspected pulmonary embolism—CT is the initial diagnostic investigation.
- Suspected renal colic—ultrasound should be the initial imaging of choice.
- Trauma—ultrasound is the initial imaging evaluation for trauma. If serious injury is suspected, CT should be performed.
- Suspected cephalopelvic disproportion—pelvimetry is rarely required, but if necessary, low-dose CT pelvimetry can be performed.
- Contrast scans—iodinated contrast seems safe to use in pregnancy. Intravenous gadolinium is contraindicated, and should be used only if it is absolutely essential. It is safe to continue breastfeeding after receiving iodinated contrast or gadolinium.

### Society of American Gastrointestinal and Endoscopic Surgeons. *Guidelines for Diagnosis, Treatment, and Use of Laparoscopy for Surgical Problems During Pregnancy*, 2011

http://www.sages.org/publications/guidelines/guidelines-for-diagnosis-treatment-and-use-of-laparoscopy-for-surgical-problems-during-pregnancy/

### Key points on the surgical techniques

- Laparoscopy can be performed safely in any trimester of pregnancy.
- Pregnant patients should be positioned with left lateral tilt to avoid vena cava compression.
- Initial abdominal access can be performed with an open technique (Hasson), Veress needle, or an optical trocar. The location should be adjusted according to the uterine fundal height and previous incisions.
- $CO_2$ insufflation pressure should be maintained between 10 and 15 mmHg.
- Intraoperative and postoperative venous thromboprophylactic measures should be performed. LMWH should be given in patients undergoing extended major operations.
- Fetal heart rate monitoring should be carried out preoperatively and postoperatively in patients undergoing emergency procedures.
- The obstetric team should be consulted.
- Tocolytics should not be given routinely. However, it should be considered when there are signs of preterm labour.

## NICE. *Surgical Site Infection: Prevention and Treatment of Surgical Site Infection*. Clinical Guideline 74, October 2008

http://www.nice.org.uk/guidance/CG74

### Key points

- Surgical site infection is an infection which occurs in a wound after an invasive operation.
- All surgical patients and their carers should receive clear information on the risks of surgical site infections and methods of prevention and treatment.

*Preoperative phase*

- Routine hair removal is not recommended for clean non-prosthetic uncomplicated surgery.
- An electric clipper with a disposable head should be used on the day of surgery if hair removal is essential.
- Antibiotic prophylaxis is required for the following types of surgery:
  - Clean surgery which involves an insertion of a prosthesis or an implant
  - Clean surgery where there is a risk of contamination from other sites
  - Contaminated surgery.
- Local antibiotic guidelines should be used for the surgical prophylaxis.
- When the prophylaxis is required, a single shot of intravenous antibiotic is given at the induction of anaesthesia, or earlier if the surgery involves the use of tourniquet.

*Intraoperative phase*

- The surgical site should be cleaned immediately before incision using an antiseptic solution, such as povidone-iodine or chlorhexidine.

*Postoperative phase*

- A non-touch technique must be employed when changing surgical dressings. If the wound is left open to heal without surgical intervention, advice from a tissue viability nurse should be sought in order to choose a suitable dressing.

## World Health Organization. *WHO Guidelines for Safe Surgery 2009: Safe Surgery Saves Lives*, 2009

http://whqlibdoc.who.int/publications/2009/9789241598552_eng.pdf

### Ten essential objectives and recommendations

1. The theatre team should confirm the patient's identity and correct site of operation.
2. A professionally trained anaesthesia provider must be present throughout the case, and monitor the patient appropriately.
3. The team must be prepared for life-threatening loss of airway or respiratory function.
4. Risk of high blood loss should be assessed. Appropriate monitoring, adequate intravenous access, and blood products must be available if the risk of bleeding is high.
5. Allergies must be identified preoperatively.
6. The team should minimize the risk of surgical site infection by administering appropriate prophylactic antibiotics and antiseptic skin preparation.
7. A full count of swabs, instruments, and other items should be carried out by the team.
8. All surgical specimens must be correctly labelled with the patient's details, the specimen name, and the site and side from which the specimen was taken.
9. The surgeon should inform all team members of the critical steps of the operation; nursing staff and the anaesthetist should communicate any concerns clearly.
10. Regular audits of surgical capacity, and outcomes should be carried out.

## NICE. *Caesarean Section*. Clinical Guideline 132, November 2011

http://publications.nice.org.uk/caesarean-section-cg132

This guideline gives evidence-based recommendations for the management of women who may require a caesarean delivery.

### Woman-centred care

- Pregnant women should receive evidence-based information about caesarean delivery (CD) during the antenatal period. The information should include the indications for CD, the risks, benefits, and implications of CD on future births.

### Planned CD is offered for the following indications

- Breech presentation—if external cephalic version is contraindicated or unsuccessful
- Multiple pregnancy—if the first twin is not cephalic
- Placenta praevia—both minor and major
- Morbidly adherent placenta

- Women with HIV who are not receiving antiretroviral drugs or who have a viral load of 400 copies/mL on antiretroviral drugs
- Women who are co-infected with HIV and hepatitis
- Women with primary herpes simplex infection in the third trimester of pregnancy
- Maternal request—after explaining the risks and benefits of CD and offering support including mental health support.

### Factors reducing the likelihood of CD during intrapartum care

- Continuous support during labour
- A partogram with 4-hour action line to monitor labour progress
- Induction of labour beyond 41 weeks' gestation in uncomplicated pregnancies.

### Eating during labour

- Isotonic drinks during labour can prevent ketosis.

### Procedural aspects of CD

- Planned CD should not routinely take place before 39 weeks' gestation.
- Classification of urgency:
  1. Immediate threat to the life of woman or fetus (decision to delivery interval (DDI) 30 minutes)
  2. Maternal or fetal compromise, which is not immediately life-threatening (DDI 75 minutes in most cases)
  3. No maternal or fetal compromise but needs early delivery
  4. Delivery timed to suit woman or staff
- All women should have haemoglobin assessment before the CD. If they are at risk of blood loss of more than 1000 mL, the CD should take place at a hospital where there is an on-site blood transfusion service.
- Women should be offered neuraxial anaesthesia for CD if they do not have any contraindications. When general anaesthesia is required, it should include preoxygenation, cricoid pressure, and rapid sequence induction. Each maternity unit should have regular failed intubation drills. Antacids should be given before the CD and antiemetics should be offered during the CD. The operating table should be tilted 15°.

### Surgical techniques

- Antibiotics should be given before skin incision.
- The Joel Cohen transverse incision should be used.
- After delivery, 5 units of oxytocin should be given as a slow intravenous injection. The placenta is removed by controlled umbilical cord traction. Exteriorization of the uterus is not generally recommended.
- Umbilical artery pH should be measured after all CDs with suspected fetal compromise.
- Thromboprophylaxis should be offered to all women who have had CD.

### Care of the baby born by CD

- A practitioner skilled in newborn resuscitation should be present at CD if performed under general anaesthesia or if there is evidence of fetal compromise.

### Care of the woman undergoing CD

**Table A1.8** Monitoring requirements for women undergoing a CD

| | |
|---|---|
| After CD | One-to-one care (until women regain airway control and cardiorespiratory stability) |
| After recovery from anaesthesia | Observations every half hour for 2 hours and hourly afterwards (if stable) |
| For women who have had intrathecal opioids | A minimum of hourly observations for 12 hours (after diamorphine), 24 hours (after morphine) |
| For women who have had epidural opioids or those who have patient-controlled analgesia with opioids | Hourly monitoring throughout the treatment and at least 2 hours after cessation of treatment |

- Women should be offered intrathecal opioids for intra- and postoperative analgesia. NSAIDs should be offered as an adjunct provided there is no contraindication.
- If women are recovering well, they can eat and drink after the procedure. Urinary catheters should be removed 12 hours after the last neuraxial bolus.
- Monitoring requirements for women undergoing CD are described in Table A1.8.

### Recovery following CD

- Women should be given appropriate wound care.
- Healthcare practitioners should be also aware of the signs and symptoms for urinary problems, endometritis, and thromboembolic disease.
- Women should be given an opportunity to discuss the indication for CD and birth options for future pregnancies.

### Pregnancy and childbirth after CD

- When discussing future birth options, the following factors should be considered: maternal preferences, risks and benefits of repeat CD, and risks and benefits of planned vaginal birth after CD.

## Royal College of Obstetricians and Gynaecologists and Royal College of Anaesthetists. *Classification of Urgency of Caesarean Section – A Continuum of risk*. Good Practice No. 11, April 2010

http://www.oaa-anaes.ac.uk/assets/_managed/editor/File/RCoA/Good%20Practice%2011%20CS%20FINAL.pdf

This guideline reinforces the practice of using a nationally agreed classification system for grading the urgency of caesarean delivery and formalizes the idea that the urgency of caesarean delivery represents a continuum of risk.

### Summary of recommendations

- Delivery suites are encouraged to use the modified Lucas classification (see Appendix 2 in this book) of urgency of caesarean

delivery. Use of the colour spectrum from green to red signifies the spectrum of risk associated with caesarean deliveries.

- There must be effective communication among the members of the multidisciplinary team in emergency cases. The team should reassess the category of urgency when the patient arrives to the theatre.
- Delivery suites should organize a formal drill for 'emergency caesarean delivery' on a regular basis.

# APPENDIX 2

# Scores and scales

Wint Mon, York-Mui Liu, Ioanna Mavridou, and Roshan Fernando

## Analgesia

### Bromage scoring system for motor block

(Chapter 1)
The Bromage scoring system is used to measure the degree of lower limb motor block (see Table A2.1).

### Visual Analogue Scale (VAS)

(Chapters 14, 15, and 18)

No pain — Severe pain

**Figure A2.1** Visual Analogue Scale.

- VAS is usually described as a horizontal line, 100 mm in length. (See Figure A2.1)
- Word descriptors of pain severity are placed at each end.
- The patient is asked to mark on the line where they feel represents their perception of pain.
- The VAS score is obtained by measuring from the left hand of the scale to the point that the patient marked in millimetres.

### Verbal rating scale (VRS)

(Chapters 14, 15, and 18)

1. No pain
2. Mild pain
3. Moderate pain
4. Severe pain.

**Table A2.1** Bromage scoring system for lower limb motor block

| Grade | Criteria |
|---|---|
| I | Free movement of legs and feet |
| II | Just able to flex knees with free movement of feet |
| III | Unable to flex knees, but with free movement of feet |
| IV | Unable to move legs or feet |

Reproduced from Bromage PR. A comparison of the hydrochloride and carbon dioxide salts of lidocaine and prilocaine in epidural analgesia. *Acta Anaesthesiologica Scandinavica*, volume 9, Suppl. XVI: 55–69, Copyright © 1965 John Wiley & Sons.

- The VRS consists of a list of adjectives to describe increasing pain intensity.
- The most common words used are no pain, mild, moderate, and severe pain.
- Numbers are usually assigned to these adjectives to make the documentation easier.

### Numerical rating scale (NRS)

(Chapters 14, 15, and 18)

| 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| No pain | | | | | | | | | | Severe pain |

**Figure A2.2** Numerical Rating Scale.

- 0 on NRS scale represents no pain and 10 is for severe pain (see Figure A2.2).
- Patient is asked to choose a number from 0 to 10 which best describes the intensity of his/her pain.

## Antenatal care

(Chapter 6)
NICE guideline: *Routine Antenatal Care for Healthy Pregnant Women*, March 2008. http://www.nice.org.uk/guidance/cg62

For a summary of what should happen at antenatal appointments, see Table A2.2.

## Assisted conception

(Chapter 9)
NICE Guideline: *Fertility: Assessment and Treatment for People with Fertility Problems*, February 2013. http://www.nice.org.uk/guidance/CG156

See Table A2.3 for a glossary of terms used in *in vitro* fertilization (IVF).

## Critical care and resuscitation

### SPOILT acronym for intrauterine resuscitation

- **S**yntocinon off
- **P**osition—full left lateral

## Adult Advanced Life Support Algorithm Resuscitation Council UK, 2010

(Chapter 22)
The algorithm and an explanation of how it should be applied in clinical practice is detailed in the following link: https://www.resus.org.uk/pages/als.pdf.

## Clinical features of local anaesthetic toxicity

(Chapter 1)

**Table A2.4** Neurological and cardiovascular features of local anaesthetic toxicity

| Neurological features | Cardiovascular features |
|---|---|
| Sudden change in mental status | Sinus bradycardia |
| Loss of consciousness | Asystole |
| Agitation | Conduction abnormalities |
| Seizures—tonic clonic convulsion | Ventricular tachyarrhythmia |

Data from http://www.aagbi.org/sites/default/files/la_toxicity_2010_0.pdf.

AAGBI safety guideline: *Management of Severe Local Anaesthetic Toxicity*, December 2010. http://www.aagbi.org/sites/default/files/la_toxicity_2010_0.pdf

See Table A2.4 for clinical features of local anaesthetic toxicity.

## APACHE—Acute Physiology and Chronic Health Evaluation

- A scoring system applied within 24 hours of admission to intensive care to generate a morbidity score
- APACHE I contained 34 physiological variables. APACHE II and III scoring systems have further refined the data collected.

## SAPS—Simplified Acute Physiology Score

- 12-point physiological scoring system applied 24 hours after admission
- Integer score generated between 0 and 163 which predicts mortality between 0% and 100%
- SAPS II now superseded by SAPS III
- Compared with APACHE II, it is much better at comparing patients with different diseases.

## MPM—Mortality Prediction Model

- Scoring system to assess risk of death in intensive care
- Patients scored at 24, 48, and 72 hours after admission.

## Classification of shock

See Table A2.5 for different classes of shock.

## Protocol for management of minor postpartum haemorrhage

See Figure A2.3 for the protocol for management of minor postpartum haemorrhage.

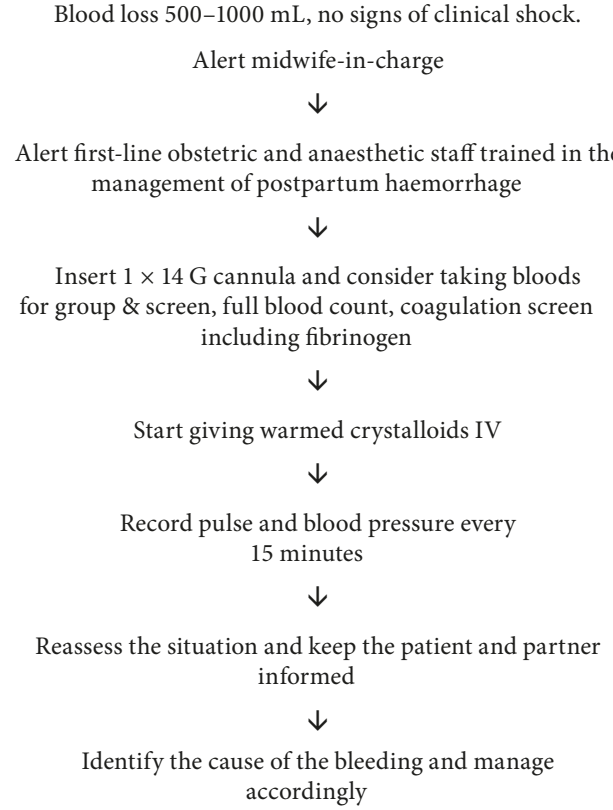

**Figure A2.3** Protocol for management of minor postpartum haemorrhage. Reproduced from: Royal College of Obstetricians and Gynaecologists. *Prevention and management of postpartum haemorrhage*. Green-top Guideline No. 52. London: RCOG; 2009, with the permission of the Royal College of Obstetricians and Gynaecologists.

**Table A2.5** Classification of shock

| | Class I | Class II | Class III | Class IV |
|---|---|---|---|---|
| Blood loss (mL) | Up to 750 | 750–1500 | 1500–2000 | 2000 or more |
| Blood loss (% blood volume) | Up to 15% | 15–30% | 30–40% | 40% or more |
| Pulse rate (bpm) | <100 | >100 | >120 | 140 or higher |
| Blood pressure | Normal | Normal | Decreased | Decreased |
| Pulse pressure | Normal/increased | Decreased | Decreased | Decreased |
| Capillary refill | Normal | Decreased | Decreased | Decreased |
| Respiratory rate | 14–20 | 20–30 | 30–40 | >35 |
| Urine output (mL/hour) | 30 or more | 20–30 | 5–15 | Negligible |
| Central nervous system—mental status | Slightly anxious | Anxious | Anxious—confused | Confused—lethargic |
| Fluid replacement | Crystalloid | Crystalloid | Crystalloid and blood | Crystalloid and blood |

Estimated Blood Loss Based on Patient's Initial Presentation (table 3.1) page 69 of the Ninth Edition Advance Trauma Life Support Student Manual. Reproduced with permission of American College of Surgeons.

## Protocol for management of major postpartum haemorrhage

See Figure A2.4 for the protocol for management of major postpartum haemorrhage

Blood loss more than 1000 mL and continuing to bleed or clinical shock.

Alert midwife-in charge AND an experienced midwife

↓

Call obstetric middle grade and alert the consultant

Call anaesthetic middle grade and alert the consultant

Alert consultant clinical haematologist on call

Alert blood transfusion laboratory

Call porters to enable delivery to specimens and blood

Alert one team member to document all events, timings, drugs given, etc.

↓

Assess patient using 'ABC' and administer oxygen via face-mask at 10–15 L/min

↓

Insert 2 × cannulae (14 G) and take bloods for cross-match (4 units minimum), full blood count, coagulation screen including fibrinogen, renal and liver function to check baseline

↓

Lie patient flat and try to keep them warm

Monitor temperature every 15 minutes. Continuously monitor pulse, blood pressure, and respiratory rate

Insert a Foley catheter to measure urine output

Consider inserting an arterial line

↓

Start giving warmed crystalloids rapidly until blood is available. Blood filters should not be used as they slow the rate of fluid administration

↓

Blood products given include red cells, fresh frozen plasma, platelets, and cryoprecipitate. Recombinant factor VIIa should only be used based on coagulation results

↓

Identify and treat the cause of the bleeding as appropriate

↓

Reassess the situation and consider transfer and admission to high dependency or intensive care units when stable

**Figure A2.4** Protocol for management of major postpartum haemorrhage
Reproduced from: Royal College of Obstetricians and Gynaecologists. *Prevention and management of postpartum haemorrhage*. Green-top Guideline No. 52. London: RCOG; 2009, with the permission of the Royal College of Obstetricians and Gynaecologists.

**Table A2.6** Apgar score

| | Score 0 | Score 1 | Score 2 |
|---|---|---|---|
| Activity (tone) | Limp | Some flexion | Active motion |
| Pulse | Absent | <100/min | >100/min |
| Grimace (reflex irritability) | No response | Grimace | Cry or active withdrawal |
| Appearance (skin colour) | Blue | Peripherally blue and centrally pink | Pink |
| Respiration | Absent | Weak cry or irregular respiration | Good cry |

Reproduced with permission from Virginia Apgar, A Proposal for a New Method of Evaluation of the Newborn Infant, *Survey of Anesthesiology*, Volume 19, Issue 4, Copyright © 1975 Wolters Kluwer Health, Inc.

# Fetal medicine and neonates

## Apgar score

(Chapter 1)
The score is assessed at 1-minute and 5-minute intervals. Initial resuscitation measures should not be delayed to assess the Apgar score at 1 minute. A score of 3 is critically low; a score of 7–9 at 5 minutes is normal. See Table A2.6.

## Fetal blood sampling results

(Chapter 4)
NICE guideline: *Fetal Blood Sampling*, November 2013. http://www.nice.org.uk/nicemedia/pdf/efmguidelinenice.pdf

- pH of 7.25 or more = normal
- pH of 7.21–7.24 = borderline
- pH of 7.20 or less = abnormal.

National Institute for Health and Clinical Excellence (2014) CG 190 *Intrapartum care: care of healthy women and their babies during childbirth*. London: NICE. Available from www.nice.org.uk/CG190 Reproduced with permission. NICE disclaimer: information accurate at time of press.

## Normal umbilical cord gases

(Chapter 4)
See Table A2.7 for normal umbilical cord gas values. Data presented are mean values ± standard deviation.

## Cardiotocography—electronic fetal monitoring

(Chapter 6)
NICE guideline: *Intrapartum Care*, September 2007. http://guidance.nice.org.uk/CG55/NICEGuidance/pdf/English

**Table A2.7** Normal umbilical cord gas values

| | Venous blood | Arterial blood |
|---|---|---|
| pH | 7.35 ± 0.05 | 7.28 ± 0.05 |
| $pCO_2$ (mmHg) | 38 ± 5.6 | 49 ± 8.4 |
| $pO_2$ (mmHg) | 29 ± 5.9 | 18 ± 6.2 |
| Base excess | −4 ± 2 | −4 ± 2 |
| Bicarbonate | 20 ± 2.1 | 22 ± 2.5 |

Reprinted from *American Journal of Obstetrics and Gynecology*, Volume 151, issue 6, Edward R. Yeomans, John C. Hauth, Larry C. Gilstrap, Daniel M. Strickland, Umbilical cord pH, Pco2, and bicarbonate following uncomplicated term vaginal deliveries, pp. 798–800, Copyright © 1985 with permission from Elsevier.

**Table A2.8** Description of cardiotocograph (CTG) features

| Description | Baseline (beats/min) | Variability (beats/min) | Decelerations |
|---|---|---|---|
| Normal/Reassuring | 100–160 | ≥5 | None or early |
| Non-reassuring | 161–180 | <5 for 30–90 minutes | Variable decelerations<br>◆ dropping from baseline by ≤60 beats/min and taking ≤60 seconds to recover<br>◆ present for >90 minutes<br>◆ occurring with >50% of contractions<br>Or<br>Variable decelerations<br>◆ dropping from baseline by >60 beats/min or taking >60 seconds to recover<br>◆ present for up to 30 minutes<br>◆ occurring with >50% of contractions<br>Or<br>Late decelerations<br>◆ present for up to 30 minutes<br>◆ occurring with >50% of contractions |
| Abnormal | >180 or <100 | <5 for >90 minutes | Non-reassuring variable decelerations<br>◆ still occurring 30 minutes after commencing conservative management<br>◆ occurring with >50% of contractions<br>Or<br>Late decelerations<br>◆ present for >30 minutes<br>◆ not improving with conservation management<br>◆ occurring with >50% of contractions<br>Or<br>Bradycardia or a single prolonged deceleration lasting ≥3 minutes |

## Typical fetal doses and risks of childhood cancer for some common imaging procedures

(Chapter 10)

Advice from the Health Protection Agency, The Royal College of Radiologists and the College of Radiographers: *Protection of Pregnant Patients during Diagnostic Medical Exposures to Ionizing Radiation*, 2009.
http://www.hpa.org.uk/webc/HPAwebFile/HPAweb_C/1238230848746

Table A2.10 shows a number of common diagnostic X-ray examinations with their typical fetal doses and associated cancer risks.

## WHO: *Breastfeeding and Maternal Medications*, 2002

(Chapter 11)

World Health Organization. *Breastfeeding and Maternal Medication. Recommendations for Drugs in the Eleventh WHO Model List of Essential Drugs*. 2002. http://whqlibdoc.who.int/hq/2002/55732.pdf

See Table A2.11 for WHO recommendations for maternal medication during breastfeeding.

## STAN analysis

(Chapter 12)

Amer-Wahlin I, Arulkumaran S, Hagberg H, *et al*. Fetal electrocardiogram: ST waveform analysis in intrapartum surveillance. *BJOG* 2007; 114:1191–3.

ST waveform analysis of fetal electrocardiogram (ECG) for intrapartum surveillance (STAN) is a new method of fetal monitoring, and is used in conjunction with cardiotocography (CTG) during labour. It has been used in the expert centres in Scandinavia. STAN simplified clinical guidelines recommend that if STAN events occur with suspicious or abnormal CTG (Table A2.12), an appropriate intervention should be performed within 20 minutes. During the first stage of labour, the interventions should include intrauterine resuscitation and the treatment for maternal low blood pressure. Caesarean section is recommended if there is no improvement. For the second stage of labour with active pushing, an appropriate intervention is an operative delivery, unless spontaneous vaginal delivery is imminent.

## A three-tiered system for the categorization of fetal heart rate patterns

(Chapter 20)

ACOG Practice Bulletin 106: *Intrapartum Fetal Heart Rate Monitoring: Nomenclature, Interpretation, and General Management Principles*, July 2009. http://www.acog.org/~/media/List of Titles/PBListOfTitles.pdf?dmc=1&ts=20140228T0623236788 (ACOG practice bulletin may be viewed by ACOG members or with a valid ATHENS password).

The three categories of the fetal heart rate (FHR) interpretation system are shown in Table A2.13.

# Gastrointestinal system

## Liver function tests in pregnancy

(Chapter 2)

**Table A2.9** Management for different CTG categories

| Category | Definition | Interpretation | Management |
|---|---|---|---|
| Normal/reassuring | All 3 features are normal/reassuring | ◆ normal CTG<br>◆ no non-reassuring or abnormal features<br>◆ healthy fetus | ◆ Continue CTG and normal care<br>◆ If CTG was commenced due to concerns arising from intermittent auscultation, remove CTG after 20 minutes if there are no non-reassuring or abnormal features and no ongoing risk factors |
| Non-reassuring and CTG suggests need for conservative management | 1 non-reassuring feature<br>AND<br>2 normal/reassuring features | May be associated with increased risk of fetal acidosis<br>(If accelerations are present, fetal acidosis is unlikely) | ◆ Consider possible underlying causes<br>◆ If baseline rate is >160 beats per minute, check maternal temperature and heart rate. If either is raised, give paracetamol and fluid<br>◆ Start ≥ 1 conservative measures<br>• Encourage the woman to mobilise or adopt a left lateral position and avoid being supine<br>• Give oral or intravenous fluid<br>• Stop oxytocin if being used and/or offer tocolysis<br>◆ Inform co-ordinating midwife and obstetrician |
| CTG is abnormal and indicates need for conservative measures and further testing | 1 abnormal feature<br>OR<br>2 non-reassuring features | More likely to be associated with fetal acidosis | ◆ Consider possible underlying causes<br>◆ If baseline rate is > 180 beats per minute, check maternal temperature and heart rate. If either is raised, give paracetamol and fluid<br>◆ Start ≥ 1 conservative measures<br>◆ Inform co-ordinating midwife and obstetrician<br>◆ Offer to take an FBS after starting conservative measures. Or expedite birth if an FBS cannot be taken and no accelerations are seen from scalp stimulation<br>◆ Take action sooner than 30 minutes if late decelerations are seen with tachycardia and/or reduced variability<br>◆ Inform consultant obstetrician if any FBS result is abnormal<br>◆ Discuss with consultant obstetrician if an FBS cannot be obtained or a third FBS is thought to be necessary |
| CTG is abnormal and indicates need for urgent intervention | Bradycardia or a single prolonged deceleration with baseline < 100 beats per minute lasting ≥3 minutes | Very likely to be associated with current fetal acidosis or imminent rapid development of fetal acidosis | ◆ Start ≥ 1 conservative measures<br>◆ Inform co-ordinating midwife<br>◆ Urgent ask for obstetric help<br>◆ Prepare for urgent birth<br>◆ Expedite birth if persists for 9 minutes<br>◆ If fetal heart rate recovers before 9 minutes, reassess decision to expedite birth in discussion with the woman |

**Table A2.10** Typical fetal doses and risks of childhood cancer for some common diagnostic medical exposures

| Procedure | Fetal dose range (mGy) | Childhood cancer risk |
|---|---|---|
| X-ray chest | 0.001–0.01 | <1/1,000,000 |
| X-ray CT pulmonary angiogram | 0.01–0.1 | 1/1,000,000 to 1/100,000 |
| X-ray CT chest and liver | 0.1 to 1.0 | 1/100,000 to 1/10,000 |
| X-ray lumbar spine<br>X-ray CT lumbar spine<br>X-ray CT abdomen | 1.0 to 10 | 1/10,000 to 1/1000 |
| X-ray CT pelvis<br>X-ray CT pelvis and abdomen<br>X-ray CT, pelvis, abdomen, and chest | 10–50 | 1/1000 to 1/200 |

CT, computed tomography.

# Haematology

## Changes in coagulation

(Chapter 2)
See Table A2.15 for reference ranges for thromboelastography parameters.

See Table A2.16 for ROTEM reference limits.

# Intrapartum care

## Bishops score

(Chapter 12)
Bishops score assesses how readily patients will go into labour after an induction (Table A2.17):

- Scores of less than 5 = unfavourable
- Score of more than 5 = favourable.

## The planes of Hodge

(Chapter 12)
The planes of Hodge are used to assess the progress of labour and to ascertain the engagement of the fetal head. There are four horizontal parallel planes:

I the superior strait, high in the pelvis

II the level of the inferior aspect of symphysis pubis

III the level of ischial spines

IV the level of the tip of coccyx.

**Table A2.12** STAN events and CTG findings that warrant an intervention within 20 minutes

| | Intermediary CTG | Abnormal CTG | Pre-terminal CTG |
|---|---|---|---|
| Episodic T/QRS rise | >0.15 | >0.1 | Immediate delivery |
| Baseline T/QRS rise | >0.01 | >0.05 | |
| Biphasic ST | Three biphasic ST events | Two biphasic ST events | |

Reproduced from Amer-Wahlin I, Arulkumaran S, Hagberg H, Maršál K, Visser G. Fetal electrocardiogram: ST waveform analysis in intrapartum surveillance. *BJOG: An International Journal of Obstetrics and Gynaecology*, volume 114, issue 10, pp. 1191–1193, Copyright © 2007 John Wiley & Sons.

## Kleihauer acid elution test

- Also known as Kleihauer–Betke test or Kleihauer–Betke stain.
- This test is used to measure the amount of fetal haemoglobin in the maternal blood which has been transferred during the pregnancy in Rhesus-negative mothers.
- The percentage of fetal blood cells compared with maternal cells (FMH) is calculated from a blood slide which has been subjected to an acid bath to remove adult haemoglobin and Shephard's stain to highlight fetal haemoglobin.
- Flow cytometry is a more sensitive method to measure FMH but is not available in all hospitals.

Data from Betke K, Kleihauer E. Fetaler und bleibender Blutfarbstoff in Erythrozyten und Erythroblasten von menschlichen Feten und Neugeborenen. *Blut*, volume 4, issue 4, pp. 241–249 Copyright © 1958 Springer.

## Risk factors for placental abruption

- Abruption in a previous pregnancy
- Pre-eclampsia
- Fetal growth restriction
- Non-vertex presentation
- Polyhydramnios
- Increasing maternal age
- Multiparity
- Low body mass index
- Pregnancy following assisted reproduction techniques
- Intrauterine infection
- Premature rupture of membranes
- Abdominal trauma
- Smoking
- Drug misuse—in particular, cocaine and amphetamine use in pregnancy.

Reproduced from: Royal College of Obstetricians and Gynaecologists. *Antepartum Haemorrhage*. Green-top Guideline No. 63. London: RCOG; 2011, with the permission of the Royal College of Obstetricians and Gynaecologists.

## Risk factors of placenta praevia

- Previous placenta praevia
- Previous caesarean delivery—risk increases with increasing number of previous caesarean deliveries
- Previous termination of pregnancy
- Multiparity

**Table A2.13** Three-tier fetal heart rate interpretation system

| | Baseline rate | Baseline FHR variability | Accelerations | Decelerations |
|---|---|---|---|---|
| Category I | 110–160 beats per minute | Moderate | Present or absent | Early deceleration—absent or present<br>Late or variable deceleration—absent |
| Category II | Bradycardia—not accompanied by absent baseline variability<br>Tachycardia | Minimal baseline variability<br>Absent variability with no recurrent decelerations<br>Marked baseline variability | Absence of induced acceleration after fetal stimulation | Recurrent variable decelerations accompanied by minimal or moderate baseline variability<br>Prolonged deceleration >2 minutes but <10 minutes<br>Recurrent late decelerations with moderate baseline variability<br>Variable decelerations with other characteristics such as slow return to baseline, overshoots, or 'shoulders' |
| Category III | Absent baseline FHR variability and any of the following:<br>Recurrent late decelerations<br>Recurrent variable decelerations<br>Bradycardia<br>Sinusoidal pattern | | | |

Reproduced with permission from George Macones, Gary Hankins, Catherine Spong, *et al.*, The 2008 National Institute of Child Health and Human Development Workshop Report on Electronic Fetal Monitoring: Update on Definitions, Interpretation, and Research Guidelines, *Obstetrics & Gynecology*, Volume 112, Issue 3, pp. 661–666, Copyright © 2008 Wolters Kluwer Health, Inc.

**Table A2.14** Liver function tests in pregnancy

| | Non-pregnant | Pregnant |
|---|---|---|
| Albumin (g/L) | 33–41 | 24–31 |
| AST (U/L) | 1–30 | 1–21 |
| ALT (U/L) | 1–40 | 1–30 |
| Bilirubin (micromol/L) | 3–22 | 3–14 |
| ALP (U/L) | 25–100 | 125–250 |

This table was published in *Anesthesiology: Churchill's Ready Reference*, Michael Mythen *et al*, The Labour Ward, p. 163, Copyright Elsevier (2010).

- Advanced maternal age (> 40 years)
- Multiple pregnancy
- Smoking
- Endometrial deficiency secondary to:
  - uterine scar
  - endometritis
  - manual removal of placenta
  - curettage
  - submucous fibroid
- Assisted conception.

Reproduced from: Royal College of Obstetricians and Gynaecologists. *Antepartum Haemorrhage*. Green-top Guideline No. 63. London: RCOG; 2011, with the permission of the Royal College of Obstetricians and Gynaecologists.

## Amnioinfusion

A technique used to increase the amount of amniotic fluid around the fetus during pregnancy. Using ultrasound guidance, a needle is inserted into the uterine cavity and either saline or Hartmann's solution is infused until the level of amniotic fluid is normal. This procedure may be repeated if oligohydramnios occurs.

**Table A2.15** Preoperative and postoperative TEG thromboelastography parameters

| | Pregnant (preoperative) n = 50; mean (2 standard deviations) | Pregnant (postoperative) n = 50; mean (2 standard deviations) | Non-pregnant reference range; 2 standard deviations |
|---|---|---|---|
| R time (min) | 7.0 (1.0–13.0) | 6.6 (2.4–10.8) | 4–8 |
| K time (min) | 2.0 (0.2–3.8) | 1.8 (0.4–3.2) | 0–4 |
| MA (mm) | 75.4 (64.6–86.2) | 76.4 (66.8–86.0) | 54–72 |
| Alpha angle (degree) | 64.8 (47.6–82.0) | 67.3 (53.5–81.1) | 47–74 |
| Ly30 (%) | 1.6 (0–8.8) | 0.7 (0–4.9) | 0–8 |
| CI | 1.2 (–5.4–7.8) | 1.8 (–3.4–7.0) | –3–3 |

## Atosiban

This oxytocin receptor agonist is used as a tocolytic agent to delay preterm delivery. It is licensed for use in the United Kingdom. It is significantly more expensive than nifedipine.

## Nifedipine

This is a calcium channel antagonist. Although no direct comparison has been made comparing the efficacy of nifedipine with atosiban, a systematic review adjusted for indirect comparison showed that nifedipine was associated with a non-significant trend towards increased likelihood of delay in delivery by 48 hours.

**Table A2.17** Bishops score

| Cervical features | Scores | | | |

**Table A2.18** The Quintero classification system

| Stage | Classification |
|---|---|
| I | There is a discrepancy in amniotic fluid volume with oligohydramnios of a maximum vertical pocket (MVP) ≤ 2 cm in one sac and polyhydramnios in other sac (MVP ≥ 8 cm). The bladder of the donor twin is visible and Doppler studies are normal |
| II | The bladder of the donor twin is not visible (during length of examination, usually around 1 hour) but Doppler studies are not critically abnormal |
| III | Doppler studies are critically abnormal in either twin and are characterized as abnormal or reversed end-diastolic velocities in the umbilical artery, reverse flow in the ductus venosus or pulsatile umbilical venous flow |
| IV | Ascites, pericardial or pleural effusion, scalp oedema or overt hydrops present |
| V | One or both babies are dead |

Reproduced from: Royal College of Obstetricians and Gynaecologists. *Management of monochorionic twin pregnancies*. Green-top Guideline No. 51. London: RCOG; 2008, with the permission of the Royal College of Obstetricians and Gynaecologists. Adapted by permission from Macmillan Publishers Ltd: *Journal of Perinatology*, volume 19, pp. 550–5, Quintero RA *et al.*, Staging of twin-twin transfusion syndrome, copyright (1999).

### The Quintero classification system of staging twin-to-twin transfusion (TTTS)

The Quintero system of staging TTTS is shown in Table A2.18.

### Lovset manoeuvre

This manoeuvre is used for a vaginal breech delivery when the arms are extended above the baby's head. Once the scapula is visible, the operator holds the baby by the hips and rotates the body up by 180° to bring the arm in front of the face. The operator is then able to sweep the arms down across the face to free it. The body is then returned to the anterior position and the procedure repeated to free the other arm as needed.

### Mariceau–Smellie–Veit manoeuvre

This manoeuvre is used to help deliver the fetal head in a vaginal breech delivery. An assistant applies suprapubic pressure on the mother. The operator then inserts their left hand into the vagina and uses their index and middle fingers to palpate and press on the fetal maxilla to bring the head into flexion. The palm of the left hand should rest on the fetal chest and the right hand is placed on the shoulder of the fetus and gently pulls the fetus in the direction of the fetal pelvis.

### Burns–Marshall manoeuvre

This manoeuvre is used to facilitate the delivery of the fetal head in a vaginal breech delivery. Once the trunk has been delivered and the nape of the neck is visible under the pubic arch, the baby's trunk is then gradually lifted and brought up to the mother's abdomen by the operator holding the ankles with their right hand and swinging the baby upwards. The operator's left hand should be there to guard the perineum as the head is being delivered.

## Medicolegal issues

### Parental responsibility

Parental responsibility is held by all mothers. A father may also have parental responsibility if he was married to the mother at the time of the child's birth, if he jointly registered the birth with the mother (from 1 December 2003 onwards), or if he attained parental responsibility through agreement with the child's mother or through a court order. Parental responsibility may also be held by a legally appointed guardian, the local authority who has care of the child, or a person with an emergency protection order for the child (https://www.gov.uk/parental-rights-responsibilities/who-has-parental-responsibility).

The following cases are discussed further within Chapter 29:

- *Bartley* v *Studd* [1995]
- *Bolam* v *Friern Hospital Management Committee* [1957]
- *Bolitho* v *City and Hackney H.A.* [1998]
- *R* v *Bateman* [1925]
- *R* v *Adomako* [1994]
- *Crawford* v *Board of Governors of Charing Cross Hospital* [1953]
- *Early* v *Newham Health Authority* [1994]
- *Wickline* v *California* [1986]
- *Kent* v *Griffiths* [2000]
- *Chester* v *Afshar* [2004]
- *Re C* [1994]
- *B v NHS Hospital Trust* [2002]
- *Hewer* v *Bryant* [1970]
- *Re W (A Minor) (Medical Treatment)* [1992]
- *Gillick* v *West Norfolk and Wisbech Area Health Authority* [1986]
- *Re L (medical Treatment: Gillick Competency)* [1998]
- *Burke* v *United Kingdom* [2006]
- *HE* v *NHS Trust* [2003]
- *Re MB* [1997]
- *Re S* [1992]
- *Norfolk and Norwich NHS Trust* v *W* [1996]
- *Tameside and Glossop Acute Services Trust* v *CH* (a patient) [1996]
- *St George's Healthcare NHS Trust* v *S, R V Collins and others, ex parte S* [1998]
- *R* v *Bourne* [1939]
- *Re F* [1989]
- *X* v *Y* [1988]
- *W* v *Egdell* [1990]
- *Palmer* v *Tees HA* [2000]
- *Nicholas Lewis* v *Secretary of State for Health & Michael Redfern* [2008]
- *Wilsher* v *Essex Area HA* [1988].

## Chiari malformations

These are malformations in the cerebellum and occur usually as a result of insufficient space within the posterior cranial fossa causing the cerebellum and brainstem to be pushed down through the foramen magnum and into the upper spinal canal (see http://www.ninds.nih.gov/disorders/chiari/detail_chiari.htm).

There are four different types:

- *Type 1*—there is extension of the cerebellar tonsils into the foramen magnum without brainstem involvement. This is the most common form and may be asymptomatic, with some cases found incidentally. This is the only type which may be acquired.
- *Type 2*—otherwise known as 'classic Chiari malformation', is where there is extension of both cerebellum and brainstem into the foramen magnum. In addition, the cerebellar vermis may be only partially complete or absent. This type of malformation is usually accompanied by a myelomeningocele. The term 'Arnold–Chiari malformation' specifically describes type 2 malformations.
- *Type 3*—the cerebellum, brainstem, and occasionally part of the fourth ventricle herniate through the foramen magnum and into the spinal cord. The herniated cerebellar tissue can also enter an occipital encephalocoele. This is the most serious form of Chiari malformation and is associated with severe neurological defects.
- *Type 4*—this is associated with an incomplete or underdeveloped cerebellum, otherwise known as 'cerebellar hypoplasia'. The cerebellar tonsils are found in their normal position but parts of the cerebellum are missing and there may be visible portions of the skull and spinal cord.

## The International Headache Society's classification of headache disorders: diagnostic criteria for postdural (post-lumbar) puncture headache

(Chapter 27)

A. Any headache fulfilling criterion C

B. Dural puncture has been performed

C. Headache develops within 5 days of dural puncture

D. Not better accounted for by another ICHD-3 diagnosis

# Psychiatric

## Risk factors for antenatal depression

- Maternal anxiety
- Life stress
- Prior depression
- Lack of social support
- Domestic violence
- Unintended pregnancy
- Relationship factors.

This guideline was produced only for NHS Scotland in 2010 by SIGN, and is due for review in 2016. The current status of SIGN guidelines in Scotland is available at http://www.sign.ac.uk. The grant of permission to any other person or body outside the UK to reprint or otherwise use the SIGN guidelines in any way is given on the strict understanding that such a person or body is not the intended user of the guidelines and the guidelines are used entirely at the person's or body's own risk. SIGN, Healthcare Improvement Scotland and NHS Scotland accept no responsibility for any adverse outcomes resulting from such use. Available from URL: http://www.sign.ac.uk.

## Risk factors for postnatal depression

- Past history of psychopathology and psychological disturbance during pregnancy
- Lack of social support
- Poor relationship with partner
- Recent life events
- Baby blues—an emotionally labile state experienced by the majority of women after childbirth, which commonly presents on the second or third postnatal day
- Obstetric complications
- History of abuse
- Low family income
- Lower occupational status
- Parents' perceptions of their own upbringing
- Unplanned pregnancy
- Unemployment
- Not breastfeeding
- Antenatal parental stress
- Antenatal thyroid dysfunction
- Coping style
- Longer time to conception
- Depression in fathers
- Having two or more children.

This guideline was produced only for NHS Scotland in 2010 by SIGN, and is due for review in 2016. The current status of SIGN guidelines in Scotland is available at http://www.sign.ac.uk. The grant of permission to any other person or body outside the UK to reprint or otherwise use the SIGN guidelines in any way is given on the strict understanding that such a person or body is not the intended user of the guidelines and the guidelines are used entirely at the person's or body's own risk. SIGN, Healthcare Improvement Scotland and NHS Scotland accept no responsibility for any adverse outcomes resulting from such use. Scottish Intercollegiate

Guidelines Network (SIGN). *Management of perinatal mood disorders*. Edinburgh: SIGN; 2012. (SIGN publication no. 127). [cited 16 07 2015]. Available from URL: http://www.sign.ac.uk.

### Risk factors for postpartum psychosis

- Pre-existing psychotic illness (especially bipolar disorder)
- Personal history of postpartum psychosis
- Antenatal admission for psychosis or bipolar disorder
- Family history of affective psychosis
- Discontinuation of mood stabilizer prophylaxis
- Primiparity
- Delivery complications.

This guideline was produced only for NHS Scotland in 2010 by SIGN, and is due for review in 2016. The current status of SIGN guidelines in Scotland is available at http://www.sign.ac.uk. The grant of permission to any other person or body outside the UK to reprint or otherwise use the SIGN guidelines in any way is given on the strict understanding that such a person or body is not the intended user of the guidelines and the guidelines are used entirely at the person's or body's own risk. ## Renal

### Renal function values in non-pregnant and pregnant women

(Chapter 2)
See Table A2.19 for renal reference ranges.

### Criteria for considering pregnancy in renal transplant recipients

1. Good general health for about 2 years after transplantation
2. Good stable allograft function [serum creatinine < 177μmol/L (2 mg/dL), preferably <133 μmol/L (<1.5 g/dL)]
3. No recent episodes of acute rejection and no evidence of ongoing rejection
4. Normal blood pressure on minimal antihypertensive regimen (only one drug)
5. Absence of, or minimal, proteinuria (< 0.50 g/day)
6. Normal allograft ultrasound (absence of pelvicalyceal distension)
7. Recommended immunosuppression:
   a. Prednisolone < 15 mg/day
   b. Azathioprine ≤ 2 mg/kg/day
   c. Cyclosporine or tacrolimus at therapeutic levels
   d. Mycophenolate mofetil (MMF) and sirolimus are contraindicated
   e. MMF and sirolimus should be stopped 6 weeks before conception is attempted.

**Table A2.19** Reference ranges for renal function in non-pregnant and pregnant women

| | Non-pregnant | Pregnant |
|---|---|---|
| Sodium (mmol/L) | 135–145 | 132–140 |
| Potassium (mmol/L) | 3.5–5.5 | 3.2–4.6 |
| Creatinine (mmol/L) | 0.06–0.1 | 0.04–0.08 |
| Urea (mmol/L) | 2.5–6.8 | 1.0–3.8 |

## Surgery

### Classification for operative vaginal delivery

(Chapter 12)
Royal College of Obstetricians and Gynaecologists. Green-top guideline 26: *Operative Vaginal Delivery*, 2011. https://www.rcog.org.uk/globalassets/documents/guidelines/gtg26.pdf

The classification for operative vaginal delivery, as adapted from the American College of Obstetrics and Gynecology 2000, has four classes: outlet, low, mid, and high.

OutletIn this situation the fetal head is low down in the pelvis so that it is in the perineum and the scalp is visible without the need to part the labia. The reference point is the sagittal suture and without exceeding rotation of 45°, it can be visualized in one of four positions:

- Anterioposterior diameter
- Right occiput anterior
- Left occiput anterior
- Posterior position.

#### Low

The most palpable part of the fetal scalp per vaginum is at station 2+ cm or more and is not in contact with the pelvic floor. There are two subcategories in this class depending on whether the degree of rotation is greater or less than 45° from the occipitoanterior position.

#### Mid

In this category, the most palpable part of the fetal scalp per vaginum is between the ischial spines and station 2+ cm. Again, there are two subdivisions depending on whether the degree of rotation from the occipitoanterior position is greater or less than 45°. Abdominal palpation should only be able to detect up to 1/5 of the fetal head.

#### High

This is not included in the classification as it is not recommended that operative vaginal delivery should be attempted if more than 2/5 of the fetal head may be palpated abdominally and the fetal head is assessed to be above the ischial spines per vaginum.

**Table A2.20** WHO Surgical Safety Checklist

| Before induction of anaesthesia (with at least nurse and anaesthetist) | Before skin incision (with nurse, anaesthetist and surgeon) | Before patient leaves operating room (with nurse, anaesthetist and surgeon) |
|---|---|---|
| **Has the patient confirmed his/her identity, site, procedure, and consent?**<br>• Yes<br>**Is the site marked?**<br>• Yes<br>• Not applicable<br>**Is the anaesthesia machine and medication check complete?**<br>• Yes<br>**Is the pulse oximeter on the patient and functioning?**<br>• Yes<br>**Does the patient have a:**<br>**Known allergy?**<br>• No<br>• Yes<br>**Difficult airway or aspiration risk?**<br>• No<br>• Yes, and equipment/assistance available<br>**Risk of >500m1 blood loss (7m1/kg in children)?**<br>• No<br>• Yes, and two /Vs/central access and fluids planned | • **Confirm all team members have introduced themselves by name and role.**<br>• **Confirm the patient's name, procedure, and where the incision will be made.**<br>**Has antibiotic prophylaxis been given within the last 60 minutes?**<br>• Yes<br>• Not applicable<br>**Anticipated Critical Events**<br>**To Surgeon:**<br>• What are the critical or non-routine steps?<br>• How long will the case take?<br>• What is the anticipated blood loss?<br>**To Anaesthetist:**<br>• Are there any patient-specific concerns?<br>**To Nursing Team:**<br>• Has sterility (including indicator results) been confirmed?<br>• Are there equipment issues or any concerns?<br>**Is essential imaging displayed?**<br>• Yes<br>• Not applicable (with nurse, anaesthetist and surgeon) | **Nurse Verbally Confirms:**<br>• The name of the procedure<br>• Completion of instrument, sponge and needle counts<br>• Specimen labelling (read specimen labels aloud, including patient name)<br>• Whether there are any equipment problems to be addressed<br>**To Surgeon, Anaesthetist and Nurse:**<br>• What are the key concerns for recovery and management of this patient? |
| This checklist is not intended to be comprehensive. Additions and modifications to fit local practice are encouraged. | Revised 1/2009 | © WHO, 2009 |

## WHO surgical safety checklist

(Chapter 20)
The World Health Organization Surgical Safety Checklist is shown in Table A2.20.

## WHO safer childbirth checklist

(Chapter 55)
The World Health Organization (WHO) developed the Safer Childbirth Checklist (www.who.int/patientsafety/implementation/checklists/childbirth/en/index.html) in response to the high mortality rate of pregnant women and neonates in low-resource settings, most of which were preventable. The checklist consists of 29 points, which address the major causes in low-income countries, of:

- Maternal death: haemorrhage, hypertensive disorders, obstructed labour, infection
- Intrapartum-related stillbirths: inadequate intrapartum management
- Neonatal deaths: infection, asphyxia, prematurity.

The checklist is divided into four sections and the points covered in each section are summarized in Table A2.21. This checklist is currently being trialled in over 100 hospitals and this study should be completed by 2015.

## Lucas classification

(Chapter 20)
For definitions of different grades of caesarean delivery according to the Lucas classification, see Table A2.22.

## Dupuis classification

(Chapter 20)

**Table A2.21** Summary of the WHO Safer Childbirth Checklist

| Section | Points covered |
|---|---|
| 1. On admission | Patient identity, basic monitoring, need for any treatment including magnesium sulphate and antimicrobials |
| 2. Just before pushing/ caesarean delivery | Appropriate equipment for delivery present, need for any antibiotics or magnesium sulphate |
| 3. Soon after birth (within 1 hour) | Identify any maternal bleeding and manage appropriately, need for any further neonatal care |
| 4. Before discharge | No further maternal bleeding, need for maternal or neonatal antibiotics, establishing feeding in neonate |

Data from http://www.who.int/patientsafety/implementation/checklists/childbirth/en/index.html.

**Table A2.22** The Lucas classification of caesarean delivery

| Grade | Definition |
|---|---|
| 1. Emergency | Immediate threat to life of woman or fetus |
| 2. Urgent | Maternal or fetal compromise which is not immediately life-threatening |
| 3. Scheduled | Needing early delivery but no maternal or fetal compromise |
| 4. Elective | At a time to suit the woman and maternity team |
