OXFORD

Oxford Textbook of

# Obstetric Anaesthesia

# Oxford Textbooks in Anaesthesia

**Oxford Textbook of Anaesthesia for the Elderly Patient**
Edited by Chris Dodds, Chandra M. Kumar, and Bernadette Th.Veering

**Oxford Textbook of Anaesthesia for Oral and Maxillofacial Surgery**
Edited by Ian Shaw, Chandra M. Kumar, and Chris Dodds

**Principles and Practice of Regional Anaesthesia, Fourth Edition**
Edited by Graeme McLeod, Colin McCartney, and Tony Wildsmith

**Oxford Textbook of Cardiothoracic Anaesthesia**
Edited by R. Peter Alston, Paul S. Myles, and Marco Ranucci

**Oxford Textbook of Transplant Anaesthesia and Critical Care**
Edited by Ernesto A. Pretto, Jr., Gianni Biancofiore, Andre De Wolf, John R. Klinck, Claus Niemann, Andrew Watts, and Peter D. Slinger

**Oxford Textbook of Obstetric Anaesthesia**
Edited by Vicki Clark, Marc Van de Velde, and Roshan Fernando

# Oxford Textbook of Obstetric Anaesthesia

Edited by

**Dr Vicki Clark, MB. ChB., FRCA**
Consultant Anaesthetist
Simpson Centre for Reproductive Health
Royal Infirmary
Edinburgh, UK

**Professor Marc Van de Velde, MD, PhD, EDRA**
Professor of Anesthesiology
Department of Cardiovascular Sciences
KU Leuven
Chair
Department of Anesthesiology
UZ Leuven
Leuven, Belgium

**Dr Roshan Fernando, MB. ChB., FRCA**
Consultant Anaesthetist and Honorary Senior Lecturer
Department of Anaesthesia
University College London Hospitals NHS Foundation Trust
London, UK

# Dedications

**Vicki Clark**

To Richard and my parents, colleagues, and patients, all of whom in their different ways, helped to make this textbook possible. Their contributions, known and unknown, small or large, have all been invaluable and my thanks go to them.

**Roshan Fernando**

To all my family who have supported me throughout my career and especially to my wife Anelia and our little girl Nia for making it special.

**Marc Van de Velde**

To my parents, Karel and Vera, for their everlasting love and support.

To my loving wife Eva, for making my life complete.

To Juliette, Ella, Bas, Michiel, and Sofie for bringing joy, laughter and warmth into my life. I couldn't dream of better kids.

# Preface

Providing obstetric anaesthesia in the delivery suite and maternity theatre presents a challenge to every practising anaesthetist. Not only are there two patients to consider, often with opposing needs, but the physiology and anatomy of the pregnant woman varies significantly from her non-pregnant counterpart. Furthermore, many procedures are done as emergencies with additional risk factors. And in recent years, the complexity of care of the pregnant population has been increased by factors such as rising maternal age and co-morbidities which in the past may have precluded pregnancy. There is therefore a need for a comprehensive, up-to-date textbook covering all aspects of care for parturients including recent approaches to neuraxial anaesthesia, new technologies, drugs, protocols, and guidelines.

This textbook brings together international contributors who are experts in their fields and who have provided in-depth, evidence-based chapters on obstetric anaesthesia with practical information and guidance that we hope will be of value for those working in the maternity environment wherever they happen to practise.

# Contents

# Abbreviations

| | |
|---|---|
| 5-HT | 5-hydroxytryptamine (serotonin) |
| AAGBI | Association of Anaesthetists of Great Britain and Ireland |
| AAP | American Association of Pediatrics |
| ACOG | American College of Obstetricians and Gynecologists |
| ACTH | adrenocorticotropic hormone |
| AD | autosomal dominant |
| ADE | absorption, distribution, metabolism, and elimination |
| AED | antiepileptic drug |
| AFE | amniotic fluid embolism |
| AFLP | acute fatty liver of pregnancy |
| AHD | acquired heart disease |
| AIH | autoimmune hepatitis |
| AKI | acute kidney injury |
| ALP | alkaline phosphatase |
| ALT | alanine transaminase |
| ANA | antinuclear antibody |
| AP | alkaline phosphatase |
| APACHE | Acute Physiology and Chronic Health Evaluation |
| APH | antepartum haemorrhage |
| APS | antiphospholipid syndrome |
| aPTT | activated partial thromboplastin time |
| AR | autosomal recessive |
| ARDS | acute respiratory distress syndrome |
| AROM | artificial rupture of the membranes |
| ART | assisted reproductive technology |
| ASA | American Society of Anesthesiologists |
| ASD | atrial septal defect |
| ASM | airway smooth muscle |
| AST | aspartate transaminase |
| ATP | Adenosine triphosphate |
| AUROC | area under the receiver operating characteristic curve |
| AV | atrioventricular |
| AVM | arteriovenous malformation |
| BMI | body mass index |
| bpm | beats per minute |
| BPP | biophysical profile score |
| cAMP | cyclic adenosine monophosphate |
| CBG | corticosteroid-binding globulin |
| CD | Caesarean Delivery |
| CDC | Centers for Disease Control and Prevention |
| CEI | continuous epidural infusion |
| CEMACH | Confidential Enquiry into Maternal and Child Health |
| CEMD | Confidential Enquiry into Maternal Deaths |
| CF | cystic fibrosis |
| CGRP | calcitonin gene-related peptide |
| CHD | congenital heart disease |
| CI | confidence interval |
| CIPCEA | computer-integrated patient-controlled epidural analgesia |
| CK | creatine kinase |
| CKD | chronic kidney disease |
| CMACE | Centre for Maternal and Child Enquiries |
| CMV | cytomegalovirus |
| CNB | central neuraxial blockade |
| CNS | central nervous system |
| CO | cardiac output |
| $CO_2$ | carbon dioxide |
| COX | cyclooxygenase |
| CPAP | continuous positive airway pressure |
| CPR | cardiopulmonary resuscitation |
| CRH | corticotropin-releasing hormone |
| CS | Cushing's syndrome |
| CSA | Continuous Spinal Anaesthesia |
| CSE | combined spinal–epidural |
| CSF | cerebrospinal fluid |
| CSH | cranial subdural haematoma |
| CTG | cardiotocography |
| CTPA | computed tomography pulmonary angiography |
| CVA | cerebrovascular accident |
| CVC | central venous catheter |
| CVS | cardiovascular system |
| CXR | chest X-ray |
| CYP | cytochrome p450 |
| DAS | Difficult Airway Society |
| DCM | dilated cardiomyopathy |
| DDI | decision to delivery interval |
| DHPR | dihydropyridine |
| DIC | disseminated intravascular coagulation |
| DKA | diabetic ketoacidosis |
| DM | diabetes mellitus |
| DMARD | Disease modifying anti-rheumatic drugs |

| | |
|---|---|
| DPG | diphosphoglycerate |
| DVT | deep vein thrombosis |
| EA | epidural anaesthesia |
| $EC_{50}$ | median effective concentration |
| ECC | excitation–contraction coupling |
| ECG | electrocardiogram |
| ED | Ehlers–Danlos |
| $ED_{50}$ | effective dose in 50% of subjects |
| $ED_{95}$ | effective dose in 95% of subjects |
| EFM | electronic fetal monitoring |
| EP | ectopic pregnancy |
| EPAU | early pregnancy assessment unit |
| EREM | extended-release epidural morphine |
| ERPHD | European Registry on Pregnancy and Heart Disease |
| ESBL | extended-spectrum beta-lactamase |
| ESC | European Society of Cardiology |
| ESRD | end-stage renal disease |
| ETT | endotracheal tube |
| EUA | examination under anaesthetic |
| FAS | fetal alcohol syndrome |
| FBC | full blood count |
| FBS | fetal blood sampling |
| FDA | Food and Drug Administration |
| FER | frozen embryo replacement |
| FET | frozen embryo transfer |
| $FEV_1$ | forced expiratory volume in 1 second |
| FFN | fetal fibronectin |
| FHR | fetal heart rate |
| FIGO | Federation Internationale des Gynécologues et des Obstétriciens |
| FLF | fetal lung fluid |
| FPG | fasting plasma glucose |
| FRC | functional residual capacity |
| FSH | follicle-stimulating hormone |
| FVC | forced vital capacity |
| GA | general anaesthesia |
| GABA | gamma-aminobutyric acid |
| GBS | Guillain–Barré syndrome |
| GDM | gestational diabetes mellitus |
| GFR | glomerular filtration rate |
| GGT | gamma-glutamyl transferase |
| GH | gestational hypertension or growth hormone |
| GI | gastrointestinal |
| GMC | General Medical Council |
| GnRH | gonadotropin-releasing hormone |
| GOR | gastro-oesophageal reflux |
| GP | general practitioner |
| hCG | human chorionic gonadotropin |
| HCM | hypertrophic cardiomyopathy |
| HDU | high dependency unit |
| HELLP | haemolysis, elevated liver enzyme levels, and low platelet count |
| HIT | heparin-induced thrombocytopenia |
| HLHS | hypoplastic left heart syndrome |
| HPA | hypothalamic–pituitary–adrenal |
| HR | heart rate |
| HSV | herpes simplex virus |
| HUS | haemolytic uraemic syndrome |
| ICD-10 | International Classification of Diseases, tenth revision |
| ICNARC | Intensive Care National Audit and Research Centre |
| ICP | intracranial pressure |
| ICS | inhaled corticosteroid |
| ICSI | intracytoplasmic sperm injection |
| ICU | intensive care unit |
| IE | infective endocarditis |
| IHD | ischaemic heart disease |
| IIH | Idiopathic intracranial hypertension |
| ILCOR | International Liaison Committee on Resuscitation |
| IM | intramuscular |
| INR | international normalized ratio |
| IR | interventional radiology |
| ITP | idiopathic thrombocytopenic purpura |
| ITU | intensive therapy unit |
| IUGR | intrauterine growth restriction |
| IV | intravenous |
| IVC | inferior vena cava |
| IVF | in vitro fertilization |
| LA | local anaesthetic |
| LABA | long-acting beta-2-agonist |
| LAST | local anaesthetic systemic toxicity |
| LBP | low back pain |
| LDH | lactate dehydrogenase |
| LFT | liver function test |
| LH | luteinizing hormone |
| LMA | laryngeal mask airway |
| LMN | Lower Motor Neuron |
| LMWH | low-molecular-weight heparin |
| LOR | loss of resistance |
| LOS | lower oesophageal sphincter |
| LRTA | leukotriene-receptor antagonist |
| LSB | lumbar sympathetic block |
| LUD | left uterine displacement |
| MAC | minimum alveolar concentration |
| MAHA | microangiopathic haemolytic anaemia |
| MBRRACE-UK | Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the United Kingdom |
| MCA | middle cerebral artery |
| MCV | mean cell volume |
| MDE | Maternal Death Enquiry |
| MELD | Model of End Stage Liver Disease |
| MEWS | Modified Early Warning Score |
| MFS | Marfan syndrome |
| MG | myasthenia gravis |
| MH | malignant hyperthermia |
| MHRA | Medicines & Healthcare products Regulatory Agency |
| MHS | malignant hyperthermia-susceptible |
| MI | myocardial infarction |
| MLAC | minimum local analgesic concentration |
| MLAD | minimum local analgesic dose |
| MMR | maternal mortality ratio |
| MPM | Mortality Probability Model |
| MRI | Magnetic Resonance Imaging |

| | |
|---|---|
| MRSA | meticillin-resistant *Staphylococcus aureus* |
| NA | neuraxial anaesthesia |
| NAFLD | non-alcoholic fatty liver disease |
| NAP | National Audit Project |
| NICE | National Institute of Health and Care Excellence |
| NMB | neuromuscular blockade |
| NMDA | N-methyl-D-aspartate |
| NO | nitric oxide |
| NSAID | non-steroidal anti-inflammatory drug |
| NT | nuchal translucency |
| NYHA | New York Heart Association |
| $O_2$ | oxygen |
| OAA | Obstetric Anaesthetists' Association |
| ODP | operating department practitioner |
| OGTT | oral glucose tolerance test |
| OHSS | ovarian hyperstimulation syndrome |
| OR | odds ratio/Operating Room |
| PAC | pulmonary artery catheter |
| $PaCO_2$ | arterial partial pressure of carbon dioxide |
| PAI | plasminogen activator inhibitor |
| PAPP-A | pregnancy-associated plasma protein-A |
| PB | pudendal block |
| PCA | patient-controlled analgesia |
| PCB | paracervical block |
| PCEA | patient-controlled epidural analgesia |
| $PCO_2$ | partial pressure of carbon dioxide |
| PCR | polymerase chain reaction |
| PD | pharmacodynamics |
| PDPH | postdural puncture headache |
| PDPM | postdural puncture meningitis |
| PEEP | positive end-expiratory pressure |
| PEF | peak expiratory flow |
| PEFR | peak expiratory flow rate |
| PG | prostaglandin |
| PIP | positive inspiratory pressure |
| PK | pharmacokinetics |
| PND | paroxysmal nocturnal dyspnoea |
| PPCM | peripartum cardiomyopathy |
| PPH | postpartum haemorrhage |
| PPROM | preterm premature rupture of membranes |
| PPSP | persistent postsurgical pain |
| PRB | pregnancy-related backache |
| PROM | premature rupture of membranes |
| PSO | paramedian sagittal oblique |
| PT | prothrombin time |
| PTE | pulmonary thromboembolism |
| PVB | paravertebral block |
| RA | rheumatoid arthritis |
| RBC | red blood cell |
| RBF | renal blood flow |
| RCOG | Royal College of Obstetricians and Gynaecologists |
| RCT | randomized controlled trial |
| REM | rapid eye movement |
| RHD | rheumatic heart disease |
| RR | relative risk |
| RSI | rapid sequence induction |
| RYR1 | ryanodine |
| SA | spinal anaesthesia |
| SABA | short-acting beta-2-agonist |
| SAD | supraglottic airway device |
| $SaO_2$ | arterial oxygen saturation |
| SAPS | Simplified Acute Physiology Score |
| SCASMM | Scottish Confidential Audit of Severe Maternal Morbidity |
| SCI | spinal cord injury |
| SGA | small for gestational age |
| SH | spinal haematoma |
| SIGN | Scottish Intercollegiate Guidelines Network |
| SLE | systemic lupus erythematosus |
| SNP | single nucleotide polymorphism |
| SSRI | selective serotonin reuptake inhibitor |
| SSS | single-shot spinal |
| SV | stroke volume |
| SVR | systemic vascular resistance |
| SVT | supraventricular tachycardia |
| T1D | type 1 diabetes |
| T2D | type 2 diabetes |
| $T_3$ | triiodothyronine |
| $T_4$ | thyroxine |
| TAP | transversus abdominis plane |
| TB | tuberculosis |
| TBG | thyroxine-binding globulin |
| TCPC | total cavopulmonary connection |
| TENS | transcutaneous electrical nerve stimulator |
| TM | transverse median |
| TSH | thyroid-stimulating hormone |
| TT | thrombin time |
| TTP | thrombotic thrombocytopenic purpura |
| TTTS | twin-to-twin transfusion syndrome |
| TV | tidal volume |
| UDCA | ursodeoxycholic acid |
| UFH | unfractionated heparin |
| UKHCDO | United Kingdom Haemophilia Centre Doctors' Organisation |
| UKOSS | UK Obstetric Surveillance System |
| ULN | upper limit of normal |
| UMN | Upper Motor Neuron |
| V/Q | ventilation/perfusion |
| VAPS | visual analogue pain scale |
| VAS | visual analogue scale |
| VBAC | vaginal birth after caesarean |
| VD | vaginal delivery |
| VRS | verbal rating score |
| VSD | ventricular septal defect |
| VT | ventricular tachycardia |
| VTE | venous thromboembolism |
| vWD | von Willebrand disease |
| vWF | von Willebrand factor |
| WFSA | World Federation of Societies of Anaesthesiologists |
| WHO | World Health Organization |

**M. Joanne Douglas**, Professor Emeritus, Department of Anesthesiology, Pharmacology and Therapeutics, University of British Columbia and BC Women's Hospital, Vancouver, Canada

**Timothy J. Draycott**, Professor, Department of Women's Health, Southmead Hospital, Bristol

**Kate Drummond**, Department of Neurosurgery, The Royal Melbourne Hospital; Department of Surgery, University of Melbourne; Melbourne Brain Centre at The Royal Melbourne Hospital, Melbourne, Australia

**W. Colin Duncan**, Senior Lecturer in Reproductive Medicine, University of Edinburgh; Consultant Gynaecologist, Simpson Centre for Reproductive Health, Royal Infirmary, Edinburgh, UK

**Robert A. Dyer**, Professor and Second Chair, Department of Anaesthesia, University of Cape Town, Cape Town, South Africa

**Thomas Erb**, Professor of Anaesthesia, Departement of Anaesthesia, University Children's Hospital beider Basel, Basel, Switzerland

**Roshan Fernando**, Consultant Anaesthetist and Honorary Senior Lecturer, Department of Anaesthesia, University College London Hospitals NHS Foundation Trust, London, UK

**Timothée Fraisse**, Pharmaceutical Medicine Specialist, MFGI, Lyon, France

**Miguel Garcia**, Specialist Registrar in Anaesthesia, Department of Anaesthesia, University Hospitals Bristol, Bristol, UK

**Michael A. Gatzoulis**, Professor of Cardiology, Department of Cardiology, Royal Brompton Hospital and National Heart and Lung Institute, Imperial College, London, UK

**Thierry Girard**, Professor of Anaesthesia, Department of Anesthesiology, Operative Intensive Care, Preclinical Emergency Medicine and Pain Management, University Hospital Basel, Basel, Switzerland

**Ian A. Greer**, Vice-President, The University of Manchester; Dean, Faculty of Medical and Human Sciences, The University of Manchester; Director, Manchester Academic Health Science Centre (MAHSC), Manchester, UK

**James Griffiths**, Department of Anaesthesia, Royal Women's Hospital, Melbourne; Department of Pharmacology and Therapeutics, University of Melbourne, Melbourne, Australia

**Suni Halder**, Consultant Anaesthetist, Nuffield Department of Anaesthesia, John Radcliffe Hospital, Oxford University NHS Foundation Trust Hospitals, Oxford, UK

**Rachel Hignett**, Consultant Anaesthetist, Simpson Centre for Reproductive Health, Royal Infirmary of Edinburgh, Edinburgh, UK

**David Hill**, Consultant Anaesthetist, Ulster Hospital, Belfast, UK

**Beverley J. Hunt**, Professor of Thrombosis & Haemostasis, Kings College and Consultant in Departments of Haematology, Pathology and Rheumatology, Guy's & St Thomas' NHS Foundation Trust, London, UK

**Tauqeer Husain**, Consultant Anaesthetist, Department of Anaesthesia & Perioperative Medicine, University College Hospital, London, UK

**Sudhir Immani**, Consultant Anaesthetist, Obstetric Anaesthesia Clinical lead, University Hospital Waterford, Republic of Ireland

**Rehana Iqbal**, Consultant Anaesthetist, Lecturer in Medical Ethics & Law, St. George's University Hospitals NHS Foundation Trust, London, UK

**Yves Jacquemyn**, Gynaecologist, Antwerp University Hospital, Belgium

**Ewen D. Johnston**, Department of Neonatology, Simpson Centre for Reproductive Health, Royal Infirmary of Edinburgh, Edinburgh, UK

**Ross Junkin**, Consultant Anaesthetist, Department of Anaesthesia, University Hospital Crosshouse, Kilmarnock, UK

**Oonagh Keag**, Registrar in Obstetrics & Gynaecology, Simpson Centre for Reproductive Health, Royal Infirmary of Edinburgh

**Mirjana Kendrisic**, Department of Anaesthesia and Intensive Therapy, General Hospital Sremska Mitrovica, Sremska Mitrovica, Serbia

**Marian Knight**, Research Professor in Public Health, National Perinatal Epidemiology Unit, Nuffield Department of Population Health, University of Oxford, Oxford, UK

**Oliver Kraemer**, Obstetrics and Gynaecology, Clinica Santa Chiara, Locarno, Switzerland

**Anneke Kwee**, Gynaecologist, University Medical Center Utrecht, The Netherlands

**Sapna Ladani**, Specialist Training Registrar in Haematology and Honorary Clinical Lecturer, University Hospitals of Leicester, Leicester, UK

**Pierre-Antoine Laloë**, Consultant in Anaesthetics, Calderdale Royal Hospital, Halifax, UK

**Ruth Landau**, Professor of Anesthesiology, Associate Director of Obstetric Anesthesia, Columbia University Medical Center; Director of the Center for Precision Medicine, Department of Anesthesiology, Columbia University College of Physicians & Surgeons, New York, USA

**Eldrid Langesaeter**, Department of Anesthesiology, Division of Emergencies and Critical Care, and National Resource Centre for Women's Health, Oslo University Hospital, Oslo, Norway

**Patricia Lavand'homme**, Department of Anaesthesiology, St Luc Hospital University Catholic of Louvain Medical School, Brussels, Belgium

**Serene Leo**, Consultant, KK Women's and Children's Hospital, Singapore

**David M. Levy**, Consultant Anaesthetist, Nottingham University Hospitals NHS Trust, Nottingham, UK

**York-Mui Liu**, Research Fellow in Obstetric Anaesthesia, Department of Anaesthesia, University College London Hospital, London, UK

**John Loughrey**, Consultant Anaesthetist, The Rotunda Hospital, Dublin, Ireland

**Nuala Lucas**, Consultant Anaesthetist, Northwick Park Hospital, Harrow, Middlesex, UK

**Ioanna Mavridou**, Consultant Anaesthetist, Department of Anaesthesia, University College London Hospital, London, UK

**Grace McClune**, Consultant Anaesthetist, Royal Infirmary, Little France, Edinburgh, UK

**Elizabeth M. McGrady**, Consultant Anaesthetist, Department of Anaesthesia, Glasgow Royal Infirmary and Princess Royal Maternity Unit

**Alistair G. McKenzie**, Consultant Anaesthetist, Simpson Centre for Reproductive Health, Royal Infirmary of Edinburgh, Edinburgh, UK

**Simon Millar**, Consultant Anaesthetist, Department of Anaesthesia, Royal Alexandra Hospital, Paisley, UK

**Alistair Milne**, Consultant Anaesthetist, Department of Anaesthesia, Royal Infirmary, Little France, Edinburgh, UK

**Vibeke Moen**, Consultant Anaesthetist, Department of Anaesthesia and Intensive Care, Kalmar County Hospital, Kalmar, Sweden

**Wint Mon**, Research Fellow in Obstetric Anaesthesia, Department of Anaesthesia, University College London Hospital, London, UK

**Neil A. Muchatuta**, Consultant Anaesthetist, Department of Anaesthesia, St Michael's Hospital, University Hospitals Bristol, Bristol, UK

**Mary C. Mushambi**, Consultant Anaesthetist, Leicester Royal Infirmary, Leicester, UK

**Catherine Nelson-Piercy**, Professor of Obstetric Medicine, Women's Health Academic Centre, King's Health Partners, London; Consultant Obstetric Physician, Guys and St. Thomas' NHS Foundation Trust and Imperial College Healthcare NHS Trust, London, UK

**Patchareya Nivatpumin**, Assistant Professor, Department of Anesthesiology, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand

**Jane E. Norman**, Professor of Maternal and Fetal Health, University of Edinburgh; Director of the Tommy's Centre for Maternal and Fetal Health, Edinburgh, UK

**Geraldine O'Sullivan**,† Previously Consultant Anaesthetist, Guy's & St. Thomas NHS Trust Hospital, London, UK

**Clemens Ortner**, Assistant Professor, Department of Anesthesiology and Pain Medicine, University of Washington Medical Center, Seattle, WA, USA

**Michael J. Paech**, Winthrop Professor and Chair of Obstetric Anaesthesia Pharmacology, Pharmacy and Anaesthesiology Unit, School of Medicine and Pharmacology, The University of Western Australia, Perth, Australia

**Outi Palomäki**, Senior Consultant in Obstetrics and Gynaecology, Tampere University Hospital, Finland

**Rajesh Pandey**, Consultant Anaesthetist, Leicester General Hospital, Leicester, UK

**Sue Pavord**, Consultant Haematologist and Senior Lecturer in Medical Education, University Hospitals of Leicester, Leicester, UK

**Linzi Peacock**, Consultant Anaesthetist, Simpson Centre for Reproductive Health, Royal Infirmary of Edinburgh, Edinburgh, UK

**Elspeth E. Pickering**, Consultant Anaesthetist, Magill Department of Anaesthesia, Chelsea and Westminster Hospital, London, UK

**Borislava Pujic**, Department of Anaesthesia, Gynaecology & Obstetrics, University Hospital, Clinical Centre of Vojvodina, Novi Sad, Serbia

**Fabienne Roelants**, Department of Anaesthesiology, St Luc Hospital University Catholic of Louvain Medical School, Brussels, Belgium

**Eva Roofthooft**, Department of Anesthesiology, ZNA Middelheim and Paola Children's Hospital, Ziekenhuis Netwerk Antwerpen, Antwerp, Belgium

**Francesca Russo**, Department of Obstetrics and Gynecology, Fetal Medicine Unit, University Hospitals Leuven, Leuven, Belgium

**Ieva Saule**, Anaesthetist, East Midlands School of Anaesthesia, Nottingham, UK

**Helen Scholefield**, Consultant Obstetrician, Liverpool Women's NHS Foundation Trust, Liverpool, UK

**Alex Tiong Heng Sia**, Professor and Chairman of Medical Board, KK Women's and Children's Hospital and Duke-NUS Graduate Medical School, Singapore

**Maria-Elisabeth Smet**, Department of Obstetrics and Gynaecology, University Hospitals Leuven, Leuven, Belgium

**Ban Leong Sng**, Adjunct Assistant Professor and Senior Consultant, KK Women's and Children's Hospital and Duke-NUS Graduate Medical School, Singapore

**Mieke A. Soens**, Department of Anesthesiology, Perioperative and Pain Medicine, Brigham and Women's Hospital, Boston, MA, USA

**Ulrich J. Spreng**, Head of Department of Anaesthesia and Intensive Care, Baerum Hospital, Vestre Viken HT, Baerum, Norway

**Gary M. Stocks**, Consultant Anaesthetist, Queen Charlotte's Hospital, Du Cane Road, London, UK

**Wendy H. L. Teoh**, Adjunct Assistant Professor, Duke-NUS Graduate Medical School Singapore; Senior Consultant, Department of Women's Anesthesia, KK Women's & Children's Hospital, Singapore

**Roulhac D. Toledano**, Assistant Clinical Professor of Anaesthesiology, SUNY Downstate Medical Center; Director of Obstetric Anesthesia, NYU Lutheran, Brooklyn, NY, USA

**Derek J. Tuffnell**, Consultant in Obstetrics and Gynaecology, Bradford Royal Infirmary, Bradford, UK

**Kristel Van Calsteren**, Department of Development and Regeneration, KU Leuven; Obstetrics and Gynecology, University Hospitals Leuven, Leuven, Belgium

**Marc Van de Velde**, Professor of Anesthesiology, Department of Cardiovascular Sciences, KU Leuven; Chair, Department of Anesthesiology, UZ Leuven, Leuven, Belgium

**Tim Van Mieghem**, Consultant in Obstetrics and Gynecology, Department of Obstetrics and Gynecology, Fetal Medicine Unit, University Hospitals Leuven, Leuven, Belgium

**Johan Verhaeghe**, Professor of Medicine, Department of Maternal Care, University Hospital Gasthuisberg, Leuven, Belgium

**Chris Verslype**, Professor of Medicine, Department of Hepatology, University Hospital Gasthuisberg, Leuven, Belgium

**Petri Volmanen**, Chief Physician, Programme for Patient safety, Institute of Health and Welfare, Helsinki, Finland

**Michelle Walters**, Consultant Anaesthetist, William Harvey Hospital, East Kent Hospitals University Foundation NHS Trust, Ashford, UK

**Mark Wigginton**, Consultant Paediatric Anaesthetist, Leeds Children's Hospital, Leeds Teaching Hospitals NHS Trust, Leeds, UK

**Kate Wiles**, NIHR Doctoral Research Fellow in Obstetric Nephrology, King's College, London, UK; Guys and St. Thomas' NHS Foundation Trust, London, UK

**Steve Yentis**, Consultant Anaesthetist, Chelsea and Westminster Hospital, London; Honorary Reader, Imperial College London, London, UK

**Gordon Yuill**, Consultant Obstetric Anaesthetist, Department of Anaesthesia, Stepping Hill Hospital, Stockport, UK

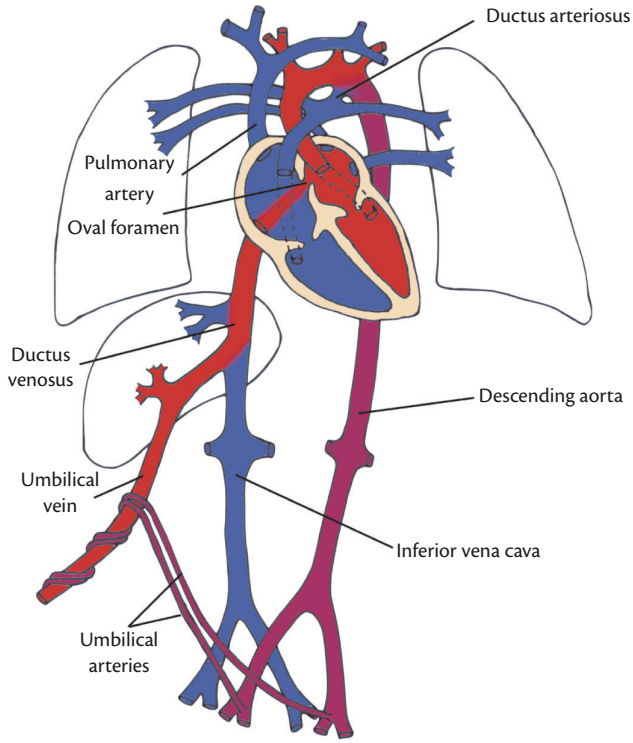

**Figure 4.1** The fetal circulation before birth. Fetal circulation is characterized by three shunts: (1) ductus venosus, (2) oval foramen, and (3) ductus arteriosus. Blood flow is directed to bypass the liver in the ductus venosus. From the right atrium oxygenated blood flows through the oval foramen into the left atrium, left ventricle, and into the aorta.

| PHYSIOLOGICAL PARAMETERS | 3 | 2 | 1 | 0 | 1 | 2 | 3 |
|---|---|---|---|---|---|---|---|
| Respiration Rate | ≤8 | | 9–11 | 12–20 | | 21–24 | ≥25 |
| Oxygen Saturations | ≤91 | 92–93 | 94–95 | ≥96 | | | |
| Any Supplemental Oxygen | | Yes | | No | | | |
| Temperature | ≤35.0 | | 35.1–36.0 | 36.1–38.0 | 38.1–39.0 | ≥39.1 | |
| Systolic BP | ≤90 | 91–100 | 101–110 | 111–219 | | | ≥220 |

PART 1

# History of obstetric anaesthesia

# CHAPTER 1

# Historic timeline of obstetric anaesthesia

Alistair G. McKenzie

## Events up to 1950

**Antiquity to the 1840s**

The severity of the pain of labour has been recognized for millennia, featuring in many books of the Old Testament of the Bible.[1] It was widely believed inappropriate to interfere with this 'women's heritage'—pain was considered to have a dual role: punishment and redemption.[2] Indeed, in 1591, Eufame MacCalyean was executed in Edinburgh, Scotland, having been found guilty of many charges, including requesting a witch to relieve the pains of childbirth.[3] In 1777, Anton Mesmer introduced mesmerism and by 1836, French physician Dr Grubert of Lyons suggested applying this to provide pain relief in labour—but held back, not wishing to defy the book of Genesis.[4] Within a decade, attitudes changed and mesmerism was used to alleviate labour pains: in January 1844 by JP Lynell of Manchester, United Kingdom,[5] and in March 1846 by WB Fahnestock of Lancaster, Pennsylvania, United States.[6] In the early 1840s, James Young Simpson, Professor of Midwifery in Edinburgh, United Kingdom, was using a large dose of laudanum (tincture of opium) to facilitate turning the fetus in labour.[7] Soon after the introduction of general anaesthesia (GA; ether) by William Morton on 16 October 1846, it was James Young Simpson who would revolutionize obstetrics by adopting ether to facilitate delivery.

## General anaesthesia, analgesia, and amnesia

### Introduction of inhalation anaesthesia in obstetrics

**1847 (19 January)**

James Young Simpson (Edinburgh) (Figure 1.1) was the first in the world to administer ether (by inhalation) in obstetrics.[8] He then searched for an anaesthetic agent more suitable for use in obstetrics.

**1847 (25 January)**

First ether anaesthesia for caesarean section was administered by SJ Tracey at St Bartholomew's Hospital, London. This was reported in the *London Medical Gazette* with the comment that 'prolonged exhibition of ether was not allowed lest it might interfere with the contraction of the uterus'.[9]

**1847 (February)**

Adam Hammer was the first in Germany to use ether for pain relief in labour.[10]

**1847 (March)**

James Young Simpson wrote: 'it will be necessary to ascertain anaesthesia's precise effects, both upon the action of the uterus and on the assistant abdominal muscles; its influence, if any, upon the child; whether it has a tendency to haemorrhage or other complications.'[8] Unfortunately this was not followed up for nearly a century.

**1847 (April)**

The first obstetric anaesthetic in the United States was by Dr Nathan Cooley Keep, who administered ether for relief of labour pain to Fanny Longfellow, wife of the poet Henry Wadsworth Longfellow (who also participated in the administration).[11]

**1847 (May)**

NI Pirogoff in Russia expounded on the rectal route for administration of ether in obstetrics.[12]

**1847 (8 November)**

James Young Simpson was the first to use chloroform in obstetrics. A week later he published the second edition of a pamphlet describing the inhalation of chloroform in 50 cases. Thereafter, for the rest of his life, he promoted chloroform.[13]

**1847 (December)**

James Young Simpson published *Answer to the Religious Objections*,[14] a pamphlet in which he rather exaggerated potential religious objections to anaesthesia/analgesia for childbirth—to get the public on his side.[15]

**1853**

John Snow smelled ether on the breath of neonates delivered from mothers who had received ether, surmising placental transmission.[16]

**1853 (April)**

John Snow administered chloroform to Queen Victoria during the birth of her eighth child, Prince Leopold.

**1857 (April)**

Queen Victoria again received chloroform from John Snow for the birth of her ninth child (Princess Beatrice). Many authors have declared that this *narcose à la reine* set the seal of respectability on obstetric analgesia; however this may be mythical: the chloroformings of the Queen were not well publicized,[17] excepting

**Figure 1.1** James Young Simpson (1811–1870) in 1850. He was first to use ether in obstetrics in January 1847, introduced chloroform in November 1847, and championed analgesia in childbirth.
Image courtesy of the Royal College of Physicians of Edinburgh.

**Figure 1.2** Stanislav Sigismund Klikovich (1853–1910)—the first (1880) to use nitrous oxide in obstetrics.
Reproduced from *Materials for the history of scientific and applied activities in Russia in the realms of zoology and allied branches of knowledge during the last 35 years 1850–90* by A. Bogdanov, Moscow, 1892.

London's social elite.[18] Anaesthesia for childbirth progressively became commonplace through public acclaim.

**1858**

John Snow noted that Dr EW Murphy and Dr E Rigby pioneered relief from pain by inhalation in obstetric cases without loss of consciousness—though this condition was not called 'analgesia' at that time.[19]

**1866**

Robert Ellis, Obstetric Surgeon to the Chelsea, Brompton and Belgrave Dispensaries in London, described his alcohol-ether-chloroform apparatus for use in obstetrics.[20]

**1874**

Swiss obstetrician (in Basel), Paul Zweifel, deduced placental transfer by demonstrating that chloroform was present in the umbilical blood of neonates born to chloroformed mothers.[21] He wondered whether this could be a factor in neonatal jaundice, but this was never found to be so.

**1880**

Stanislav Sigismund Klikovich (Figure 1.2), a doctor in St Petersburg, Russia, was the first to use nitrous oxide in obstetrics—he administered it with oxygen.[22]

**1928–32**

National Birthday Fund for Maternity Services was inaugurated in London with an address by Lucy Baldwin (the Prime Minister's wife). In 1930, this became the National Birthday Trust Fund, which proceeded to organize supply of chloroform in glass capsules (brisettes) for analgesia in labour, including administration by supervised midwives. Within 10 years these were withdrawn because of high mortality. An alternative was the Mennell chloroform inhaler (modified Junker bottle).[25]

**1933**

RJ Minnitt in Liverpool, United Kingdom, modified the McKesson oxygen therapy apparatus for self-administration of nitrous oxide with air in labour.[26]

**1934–35**

Wesley Bourne (Canada) used cyclopropane[27] and also divinyl ether in obstetrics.[28]

**1936**

Minnitt produced the 'Queen Charlotte' model of his gas-air analgesia apparatus,[29] which was approved by the Central Midwives Board for use by midwives.

**1937**

Professor Chassar Moir designed an attachment for the above-mentioned apparatus, which allowed a limited amount of pure nitrous oxide to be inhaled before continuing with the mixture.[30] (This invalidated the endorsement for use by midwives.)

**1943**

Inhalation of Trilene® was found to be a useful method of analgesia in labour. In **1949**, the 'Emotril' draw-over inhaler was designed.[31]

## Parenteral amnesia—The Vogue for 'Twilight Sleep'

**1902**

'Dammerschlaf' (twilight sleep), a technique of initial injection of morphine with hyoscine (scopolamine) and repeat doses of the latter, was used for labour by von Steinbuchel of Graz, Austria.[11]

**1906**

Carl J Gauss of Freiburg, Germany, popularized twilight sleep, reporting 1000 cases.[11] The injections were subcutaneous or intramuscular. Media coverage led women in Europe and the United States to demand twilight sleep from their obstetricians. Of course there was a depressant effect on the newborns.[11]

## Rectal agents including Avertin® for pain relief in labour

**1926**

Rectal tribromoethanol (Avertin®) was introduced for basal narcosis and was soon adopted to provide amnesia in childbirth. Problems encountered were prolongation of labour and respiratory depression in the neonate. By the 1950s, it was usually reserved for treatment of eclampsia.[35,36]

**1930**

Gwathmey (New York) introduced a rectal mixture of ether with quinine, alcohol, and olive oil. This was given in combination with hypodermic morphine and intramuscular (IM) magnesium sulphate.[37]

**1935**

Rosenfield and Davidoff (Boston) used rectal paraldehyde for amnesia, in combination with oral Nembutal®.[38]

**1939**

McCormick (Indiana) modified Gwathmey's technique for rectal ether mixture (having devised apparatus for administration) by omitting quinine, and giving oral pentobarbitone sodium (Nembutal®) instead of IM magnesium sulphate.[39]

## Obstetric flying squad

**1929**

Professor E Farquhar Murray (Newcastle-upon-Tyne, United Kingdom), addressing the Edinburgh Obstetric Society, conceived the idea of an obstetric flying squad—for domiciliary treatment of obstetric emergencies.[40]

**1932**

The first operational squad began at Bellshill (near Glasgow), Scotland—called the 'Special Outdoor Treatment Unit'.[40]

**1935**

The Bellshill unit comprised two doctors and two nurses, who travelled by automobile with apparatus for blood transfusion or intravenous (IV) saline; they had access to 25 universal blood donors.[41]

**1948**

Obstetric flying squads had been established in many centres in the United Kingdom.[42]

**1940–50**

In the Bellshill unit, most anaesthetics were administered by junior doctors: Pentothal® (79%), chloroform (12%).[43]

## From 'Twilight Sleep' to IV barbiturates

**1934**

Katherine Lloyd-Williams (Royal Free Hospital, London) published her book *Anaesthesia and Analgesia in Labour* which included the barbiturates sodium amytal, Nembutal®, pernocton, and sodium evipan (hexobarbitone).[44]

**1934**

Irving et al. at the Boston Lying-in Hospital, United States, researched the effects of popular methods of analgesia, and recommended oral Nembutal® (pentobarbitone sodium) combined with hypodermic scopolamine. There some practitioners began to avoid morphine because it induced neonatal respiratory depression.[38]

**1940**

The synthetic opioid pethidine (meperidine, Demerol®) was first used in labour by Benthin in Germany.

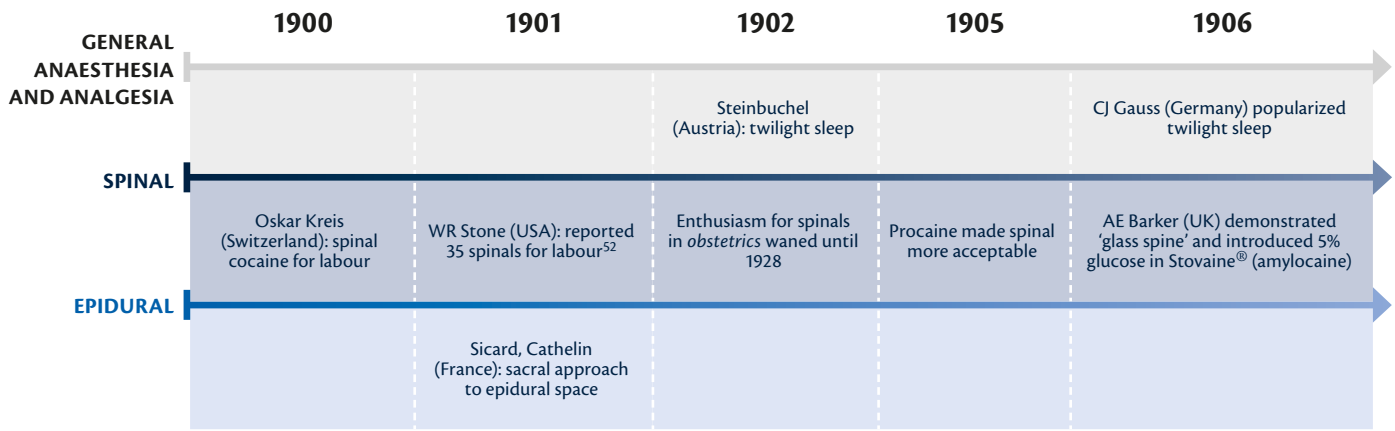
**1943**

Gilbert and Dixon (Baltimore) were first in the United States to use Demerol in obstetrics.[45]

**1944**

Spitzer was the first to use pethidine for obstetric analgesia in Britain.[46]

**Figure 1.3** Anaesthesia timeline 1900–1983.



**1945**

IV pentothal began to be advocated, particularly for caesarean delivery.[47]

## Resuscitation of the newborn

**1934**

Resuscitation of the newborn was often the task of the attending anaesthetist. Instruction in Katherine Lloyd-Williams' book included: clearing the airway, administration of carbon dioxide and oxygen, hypodermic Lobeline, and gentle compression of the chest (no mention of intubation); other stimulant drugs were camphor, Coramine®, and Cardiazol®.[44]

## Acid aspiration syndrome

**1946**

Curtis L Mendelson (Figure 1.4), obstetrician at the New York Lying-in Hospital, reported 66 cases of aspiration of gastric contents during obstetric anaesthesia. Five of the patients aspirated solid material and two of these died of asphyxia. The patients who aspirated liquid (none of whom died) had a different clinical picture: respiratory distress and chest X-ray appearance of soft mottled densities which cleared in 7–10 days. Mendelson showed that instillation of dilute acid into the lungs of anaesthetized rabbits produced a similar syndrome.[49]

## Concept and introduction of regional anaesthesia in obstetrics

**1848**

James Young Simpson introduced the *concept* of chemical local anaesthesia (LA), experimenting with the application of chloroform and other substances to animals and humans.[50] Unfortunately Simpson lacked both LA agent (cocaine introduced 1884) and the means to inject it (hypodermic needle and syringe introduced by Alexander Wood 1853). If these had been available to him, he would almost certainly have introduced LA in obstetrics.

**1900**

Sixteen years after Carl Koller introduced the use of cocaine for LA (1884) and 2 years after August Bier performed the first deliberate spinal, Oskar Kreis in Basel, Switzerland, was the first to try intradural spinal block using cocaine for analgesia in labour.[51] Enthusiasm for spinal block waned until after 1905 (see later).

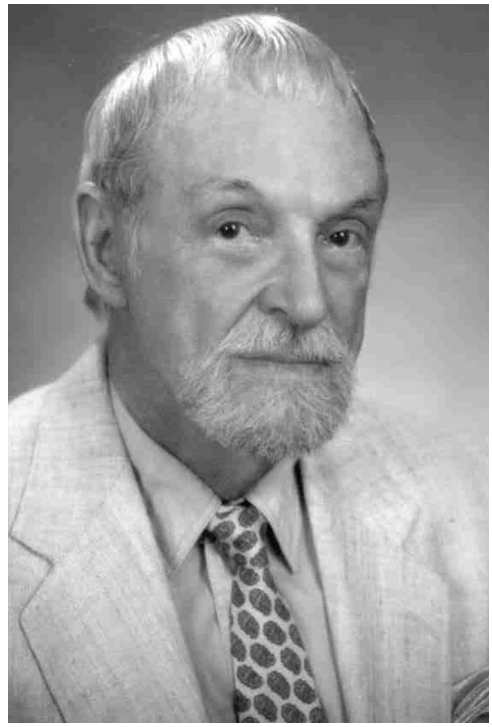


**Figure 1.4** Curtis L Mendelson (1913–2002) described the acid aspiration syndrome of pregnancy in 1945.
Image courtesy of Professor J Roger Maltby, author of *Notable Names in Anaesthesia*, London, 2002.

**1908**

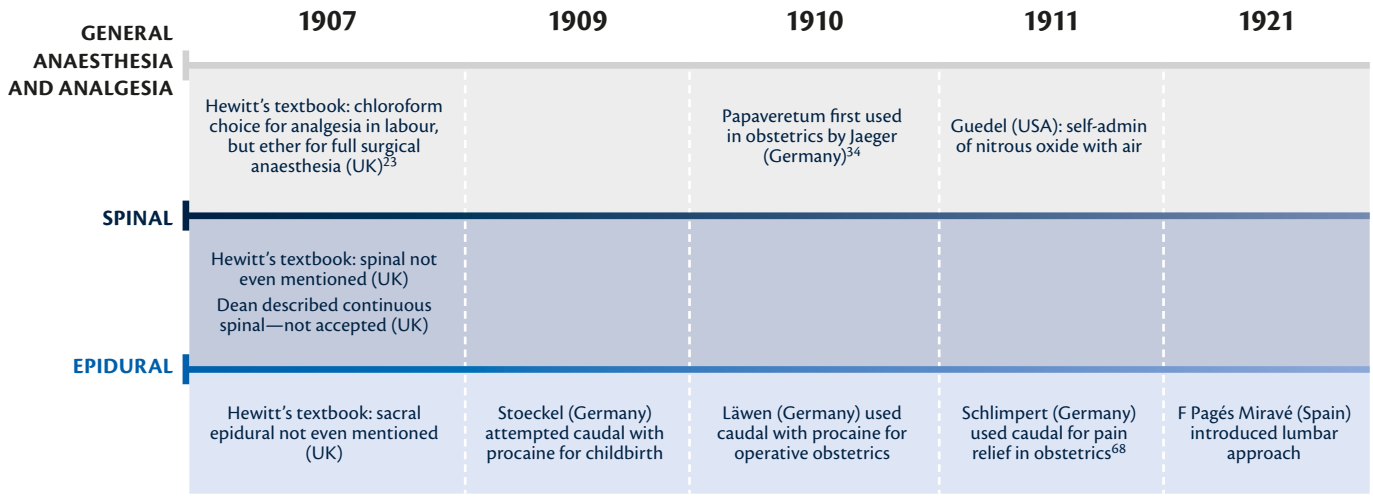
Pudendal block was described by WB Muller in Germany.[53]

**1909**

Uptake of caudal analgesia (sacral epidural) in obstetrics (see later).

**1926**

Paracervical block was described by Gellert in Germany.[54]



## Spinal anaesthesia

### Uptake of spinal anaesthesia … and decline by 1948

**1905**

Popularization of procaine facilitated uptake of spinal anaesthesia as it caused less irritation of meninges; concurrent factors in the United States were availability of finer needles which reduced spinal headache, and rubber gloves (introduced by WS Halsted in 1890) and development of aseptic technique.[55]

**1906–07**

AE Barker in the United Kingdom demonstrated the 'glass spine', showing the importance of curves and gravity, and introduced 'heavy' Stovaine® (amylocaine) made hyperbaric by the addition of glucose.[56]

**1907**

Henry P Dean described 'continuous spinal anaesthesia', but this was not accepted at the time.[57]

**1912**

Babcock (Philadelphia) rendered Stovaine® hypobaric by addition of 10% alcohol.[55] It was not known then that 10% alcohol is potentially neurotoxic.

**1927**

George Pitkin (New Jersey) introduced hypobaric spinocaine (procaine + alcohol).[55]

Ephedrine was first used to restore blood pressure (BP) during spinal anaesthesia.[58]

**1928**

George Pitkin also rendered procaine hyperbaric, and was the first to use this for delivery: his so-called controllable spinal anaesthesia.[59]

**1940**

Walter Lemmon (Philadelphia) revived 'continuous spinal anaesthesia' using novocaine (procaine) with a malleable needle and special rubber tubing attached to the hub.[63]

**1944**

EB Tuohy described alternative technique: passing a size 4 ureteral catheter *through* a 15-gauge spinal needle.[64]

**1948**

An article by Bourne and Williams drew attention to serious problems of spinal anaesthesia in obstetrics: maternal collapse, headache, and neurological complications.[67]

## Epidural analgesia

### Uptake of epidural analgesia

**1901**

In Paris, J Sicard (neurologist) and F Cathelin (urologist) independently used the sacral approach to the epidural space.[68]

**1909**

Though initially sceptical, German obstetrician and gynaecologist Walter Stoeckel in Marburg noted Cathelin's publication, and attempted to use 'sacral anaesthesia' with procaine to achieve painless child birth.[69]

**1910**

Arthur Läwen in Leipzig, Germany, also used the sacral approach to inject procaine in operative obstetrics. He favoured the sitting position and used sodium bicarbonate to alkalinize novocaine chloride, which increased rate, onset, and duration; this had a high success rate and he renamed the method 'extradural anaesthesia'.[68]

**1921**

The lumbar approach was introduced by Fidel Pagés Miravé in Madrid, Spain, who published *Metameric Anaesthesia*. He died on active service soon after and the method was temporarily forgotten.[68]

**1928**

Pickles and Jones (Providence, Rhode Island) reported 28 deliveries under single-shot procaine injected into the sacral hiatus.[70]

**1930**

Eugan Bogdan Aburel (Figure 1.5), a Romanian doctor working in Paris, published five papers on the afferent innervation of the uterus.[71]

**1931**

Aburel presented a paper on continuous caudal and lumbo-aortic plexus block for pain relief in childbirth.[71]

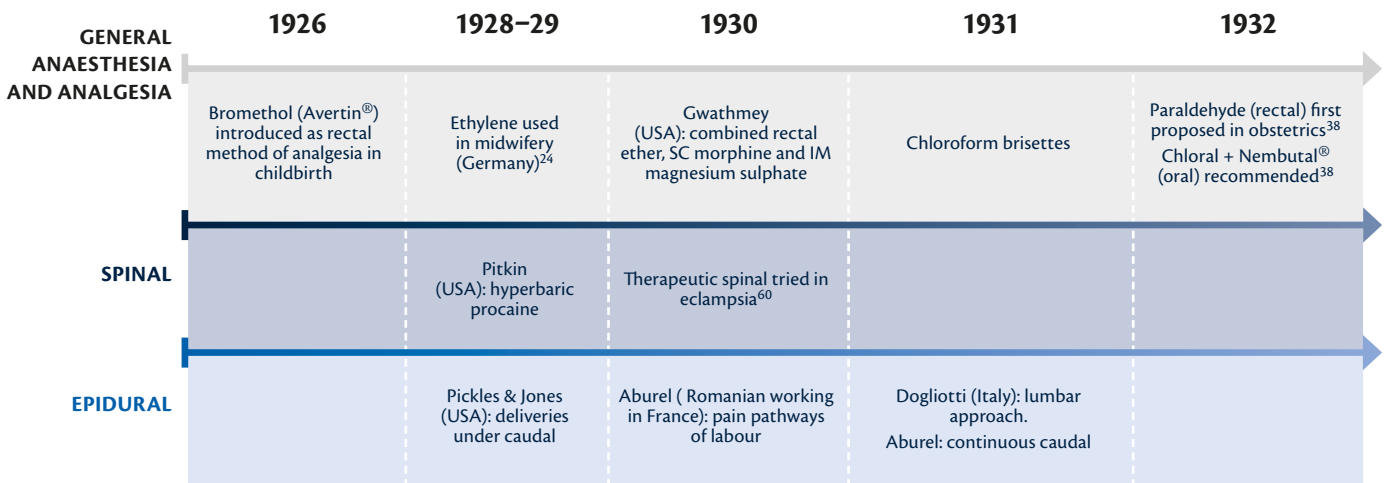


**Figure 1.5** Eugen Bogdan Aburel (1899–1975) described the pain pathways of labour in 1930 and continuous caudal analgesia in 1931.
Reproduced with permission from I Curelaru and L Sandu, 'Eugen Bogdan Aburel (1899–1975)', *Anaesthesia*, Volume 37, p. 663, Copyright © 1982 John Wiley & Sons.

**Figure 1.6** Robert A Hingson (1913–1996) popularized continuous caudal analgesia in 1942, introducing plastic catheters and malleable steel needles.
Image courtesy of the Wood Library-Museum of Anesthesiology, Schaumburg, Illinois.

**1931**

Turin surgeon, Achille Maurio Dogliotti, unaware of Pagés Miravé's work, published a paper on the lumbar approach in *Societa Piemontese di Chirurgia*, and popularized the technique.[68]

**1933**

John GP Cleland (Oregon City, Oregon), unaware of Aburel's work, researched the afferent innervation of the uterus and published on the use of paravertebral blocks for painless childbirth, and *caudal catheter* for analgesia in the second stage of labour.[72]

**1938**

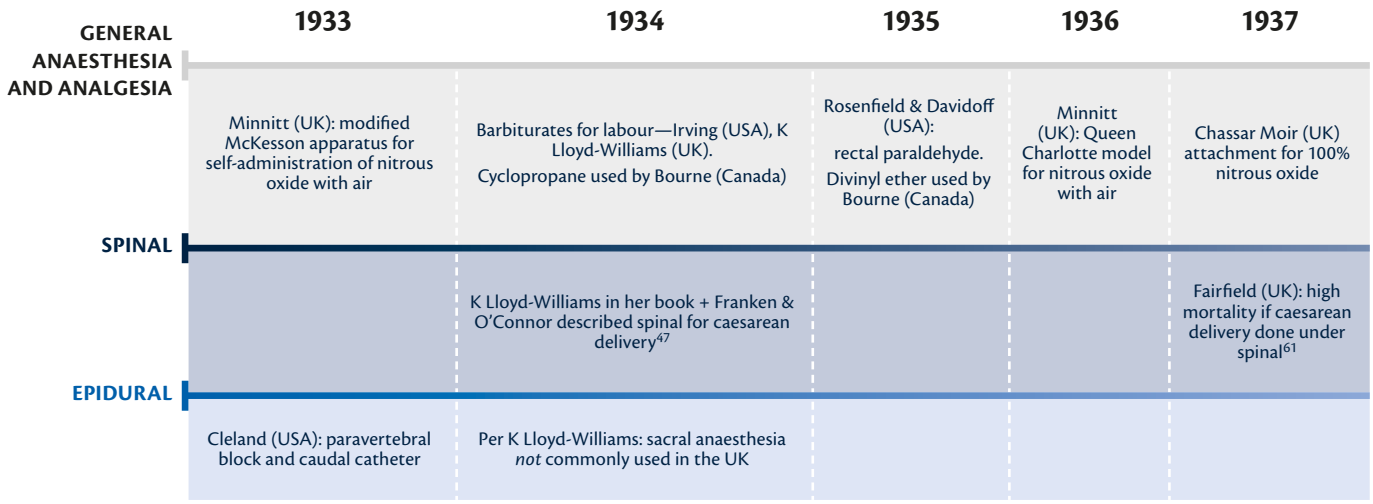
Graffagnino and Seyler of New Orleans were the first to use epidural lumbar block in labour (single shot).[73]

**1942**

Robert Hingson (Philadelphia) (Figure 1.6) and Waldo Edwards (Staten Island, New York) popularized continuous caudal analgesia.[74]

**1945**

Edward Boyce Tuohy at the Mayo Clinic described a 15-gauge needle with a Huber point (tip designed by Ralph Huber) and a stilette, manufactured by Becton Dickenson.[77] The Huber-tip



prevented plugging with tissue and enabled choice of direction of a catheter through the needle.

**1949**

Manual Martinez Curbelo in Havana, Cuba, described use of the above-described Tuohy needle for continuous epidural injection of procaine via silk catheter (lumbar or low thoracic levels) in 59 surgical cases (including gynaecology).[78]

**1949**

C Flowers, obstetrician at Baltimore (independently) used the Tuohy needle with the first plastic catheter (polyethylene) in obstetrics.[79]

**1949**

Torsten Gordh (Karolinska Hospital, Stockholm) published the first clinical account of lidocaine, an amide-type LA with more penetrative power and less toxicity than all previous LAs (esters).[80] This major advance would have a profound influence on events from the 1950s onwards.

## Events from 1950 onwards

### Non-pharmacological methods of analgesia

**1950**

Although Grantly Dick Read (general practitioner in England) first published *Revelation of Childbirth* in 1942, it was from about 1950 that his method of education and relaxation really became popular.[81]

**1950**

Velvosky and Nicolaiev in the Soviet Union employed a method of psychological preparation with hypnosis and oxygen.[11]

**1952**

Fernand Lamaze, Director of the Metal-Workers Lying-in Hospital in Paris, introduced the Lamaze Method of psychoprophylaxis, which became popular throughout France and was also popularized in the United States.[11]

**1954**

Grantly Dick Read republished his book under the title *Childbirth Without Fear.*[81]

**1965**

Publication of the gate control theory of pain by Melzack and Wall instigated interest in transcutaneous electrical nerve stimulation (TENS).

**1975**

Leonid Persianinov in Russia claimed good analgesia in labour by electroanalgesia—the application of low-intensity current to the forehead and mastoid processes.[82]

**1980**

TENS was reported as a safe and useful analgesia method in labour. Two pairs of electrodes were placed on the lower back and low intensity background current applied, with controls to increase the amplitude for contractions.[83] This method has remained quite popular for early labour in the United Kingdom.

### Resuscitation of the newborn

**1953**

Virginia Apgar, anaesthetist (Professor) at Columbia Presbyterian Hospital, New York, described a simple, reliable system for evaluating newborns: the Apgar score.[84] In time, this was adopted worldwide.

**1957**

Bingham (Northern Ireland), reported on current practice: 'gastric oxygen' was used pending availability of a person competent to perform tracheo-bronchial toilet and intubation.[85]

## Demission of anaesthetists from neonatal resuscitation

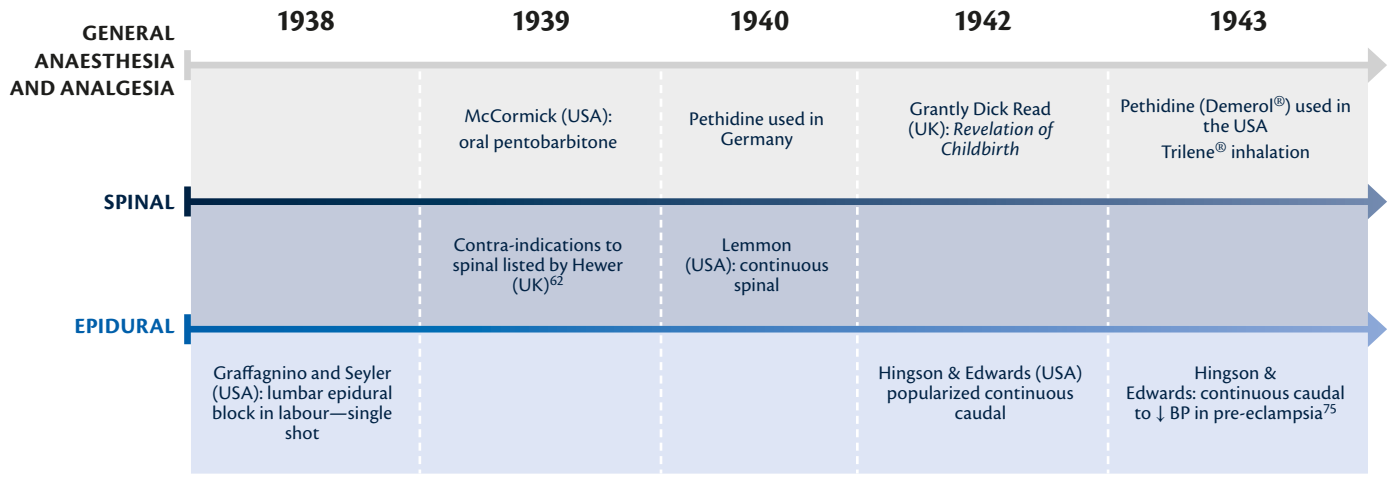
Although Moir and Thorburn's textbook of 1986[119] still had a chapter on neonatal resuscitation, this was gradually eschewed by obstetric anaesthetists, whose full attention was required for the mother. This was borne out by a case in the Confidential Enquiry into Maternal Deaths (CEMD) in the United Kingdom 1997–99 where the anaesthetist was distracted by resuscitating the baby.[209]

## General anaesthesia and analgesia

### Developments in use of inhalation anaesthetic agents

**1953**

The problem of delayed chloroform poisoning was noted.[86]



**1956**

Halothane was introduced and soon was embraced for GA in obstetric practice.

**1962–85**

Methoxyflurane was tried for labour analgesia in North America in 1962 and in the United Kingdom in 1966.[87] In 1970, it was approved for obstetric analgesia in the United Kingdom at a concentration of 0.35% in air via a Cardiff inhaler. Owing to concerns about renal impairment, it was withdrawn around 1985.

**1990s**

Isoflurane superseded halothane.

**2000**

Sevoflurane became commonly used.

### The response to Mendelson's paper

**1951**

Morton and Wylie noted the difficulties of thorough gastric emptying by means of a stomach tube.[89]

**1956**

JM Holmes advocated induction of vomiting with apomorphine to empty the stomach as an alternative to passing a wide-bore stomach tube.[92]

**1957**

Bingham reported on 'balanced anaesthesia' for caesarean delivery in 614 cases between 1948 and 1956. Initially reserved for cases of vomiting during surgery, intubation was then adopted routinely. About half the patients received thiopentone, suxamethonium, pethidine, nitrous oxide, and oxygen with no added volatile anaesthetic agent. Cyclopropane was used in 246, gallamine in 368, and gallamine or d-tubocurarine in 132 cases.[85]

**1957**

Dinnick, concurring with Mendelson, suggested that prophylactic antacids could prevent the acid-aspiration syndrome.[93]

**1959**

Hamer-Hodges et al. published a series of 2000 patients of whom 1529 had an operative delivery, describing the use of thiopentone, suxamethonium, and intubation for caesarean delivery, which was safe for both mother and baby. This technique was developed for fetal interests rather than protection of the mother from aspiration. Further details were atropine (vagolytic essential with light GA), no pre-oxygenation, and 60% nitrous oxide with oxygen.[94]

**1961**

Brian Sellick (Middlesex Hospital, London) described his manoeuvre of cricoid pressure to hold back stomach contents during induction of anaesthesia.[95] This was gradually adopted in British practice.

**1962**

Bannister and Sattilaro suggested that a pH below 2.5 was critical for aspirate to cause severe lung reaction.[96]

**1965**

Selwyn Crawford (Birmingham, United Kingdom) provided guidelines for fasting in labour.[98,101]

**1966**

Taylor and Pryse-Davies (Queen Charlotte's Maternity Hospital, London) repeated some of Mendelson's work and recommended routine administration of antacids before anaesthesia: magnesium trisilicate mixture.[100]

**1974**

Roberts and Shirley reported that (in addition to pH < 2.5) the volume of gastric aspirate (>25 mL) was critical to development of severe lung damage.[102]

**1974**

Gertie F Marx (Figure 1.7) and Girvice W Archer (New York) demonstrated the marked desaturation of pregnant women within 60 seconds of apnoea (compared with non-pregnant controls), thereby emphasizing the importance of preoxygenation at induction of GA and prompt re-oxygenation following endotracheal intubation.[103]

**1978**

Wilson in Edinburgh demonstrated that the main determinant of delayed gastric emptying in labour is the administration of narcotic analgesics, whereas epidural analgesia has little or no effect on gastric emptying.[104]

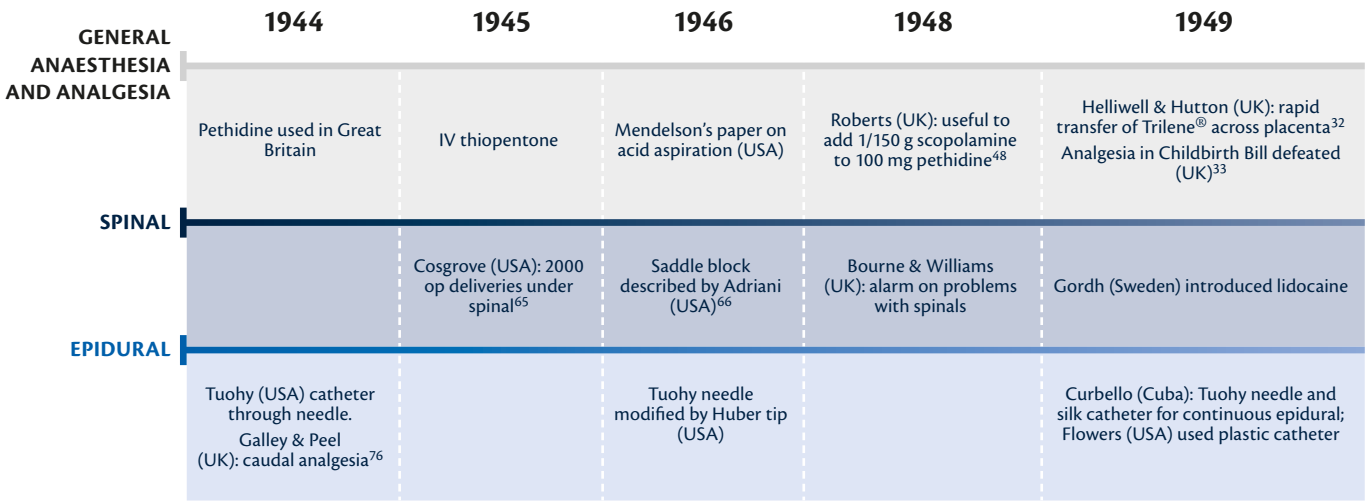


**Figure 1.7** Gertie Florentine Marx (1912–2004) practised and taught epidural analgesia in obstetrics from 1945 over five decades in New York. She published prolifically and became known as 'the mother of obstetric anaesthesia'. She was the second woman (the first was Virginia Apgar) to receive the Distinguished Service Award of the American Society of Anesthesiologists, and a long spinal needle was named in her honour.
Image courtesy of the Wood Library-Museum of Anesthesiology, Schaumburg, Illinois.

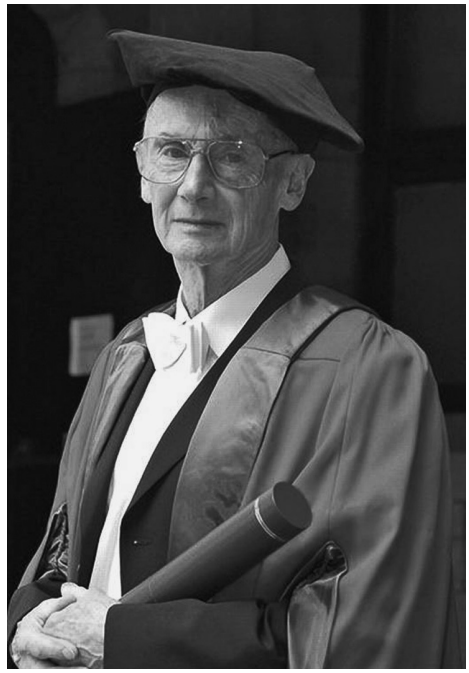

**Figure 1.8** Michael E. Tunstall (1928–2011) introduced Entonox in 1961, described a 'failed intubation drill' in 1976, and advocated use of an 'isolated forearm technique' to avoid awareness under general anaesthesia for obstetrics in 1977.
Image courtesy of Mrs A Tunstall, Aberdeen, UK

**1979**

Gibbs et al. (Florida) reported that aspiration of particulate antacid produced severe lung pathology,[105] and went on to state that non-particulate antacid (0.3 M sodium citrate) was preferable.[106]

## Entonox®

**1961**

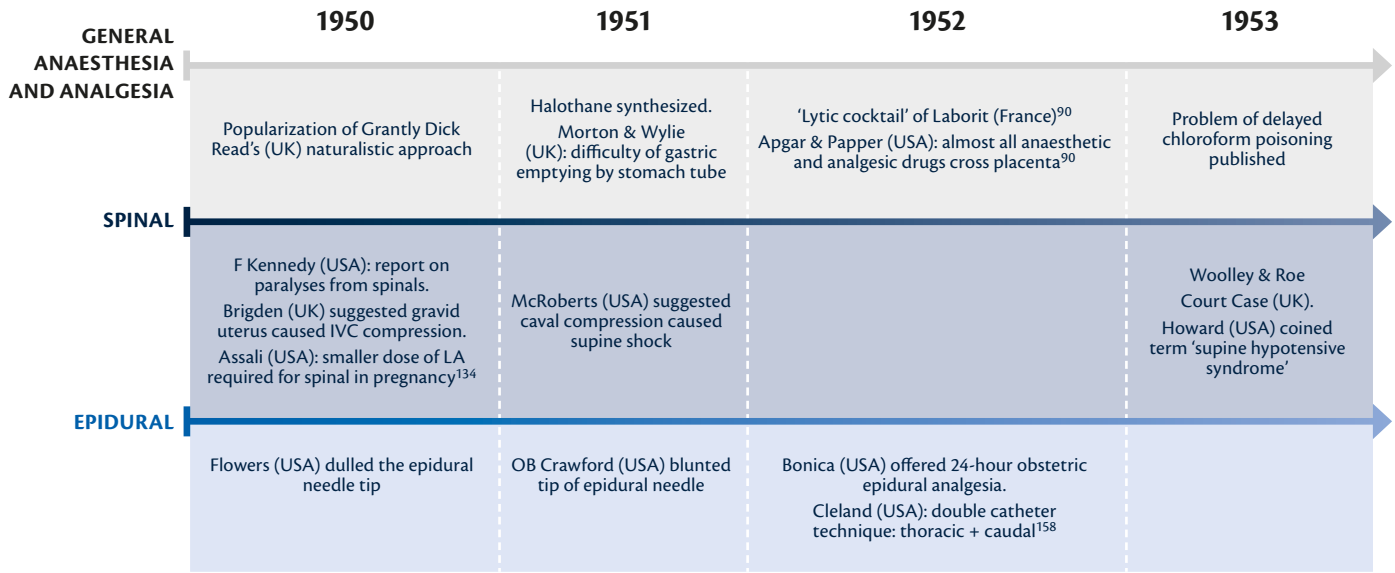
Work by Michael E Tunstall (Portsmouth, England) (Figure 1.8) in conjunction with British Oxygen Company produced a pre-mix of nitrous oxide and oxygen in equal proportions (Entonox®), which was rapidly adopted for inhalation analgesia in labour.[108]

**1962**

Cole and Nainby-Luxmore drew attention to possible fetal compromise due to low maternal oxygen levels with 'gas and air'.[109]

**1963**

Nevertheless, nitrous oxide with as low as 20% oxygen, continued to be self-administered in obstetrics, using the new 'Lucy Baldwin' machine.[110]



**1970**

Approval for 'gas and air' was withdrawn in the United Kingdom.

## Awareness

**1969**

Wilson and Turner in Edinburgh published a seminal paper on awareness during caesarean delivery under GA. At that time the usual GA for caesarean delivery was based on the original 'Liverpool technique' of ventilation with nitrous oxide and oxygen *only*—at least until after delivery. In their series of 150 patients they reported unpleasant recall in 17.5% of cases.[111] By appearing in the *BMJ* this paper reached a wide general readership, and was instrumental in the decline of the original 'Liverpool technique'.

**1970**

Moir (Glasgow) recommended 0.5% halothane with 50% each of nitrous oxide and oxygen, plus a muscle relaxant as a suitable general anaesthetic for caesarean delivery: this provided safety, no increase in haemorrhage, minimal neonatal depression, and a much lower incidence of awareness.[112]

**1977**

Tunstall advocated use of an isolated forearm (IFA) technique to avoid awareness under GA for obstetrics.[113]

## The obstetric flying squad

**1957**

Stabler enunciated the principles for obstetric flying squads.[114]

**1960**

Adamson et al. described results for 138 GAs given by the Edinburgh squad—in the majority, open chloroform was used. He suggested use of a specialist anaesthetist.[114]

**1951–61**

In 305 anaesthetics given by the Bellshill squad, the usual method was thiopentone (98%); gastric lavage was carried out before induction. The equipment carried by the team included an oxygen cylinder, Ambu respirator, laryngoscope, and endotracheal tubes, but apparently intubation was infrequent.[43]

**1961**

Argent and Evans described use of thiopentone and suxamethonium followed by intubation, and maintenance of anaesthesia with nitrous oxide, oxygen, and ether, but spontaneous ventilation. The equipment was bulky.[114]

**1967**

Dallas recommended thiopentone, suxamethonium, endotracheal intubation, and intermittent positive pressure respiration with air from an Ambu bag, thus using light equipment.[114]

**1969**

Davies (Cambridge, United Kingdom) described portable equipment aiming for pre-oxygenation, IV barbiturate, suxamethonium, endotracheal intubation, and positive pressure respiration with nitrous oxide and oxygen, using intermittent suxamethonium.[114]

**1970s–1980s**

By 1976, improvements in UK provision of antenatal care and obstetric management and decline in home deliveries (<4%) called into question the justification for continuing the flying squads.[40]

In 1980, a survey found that over half the squads answered ten or fewer calls per annum—most were subsequently disbanded.[115]

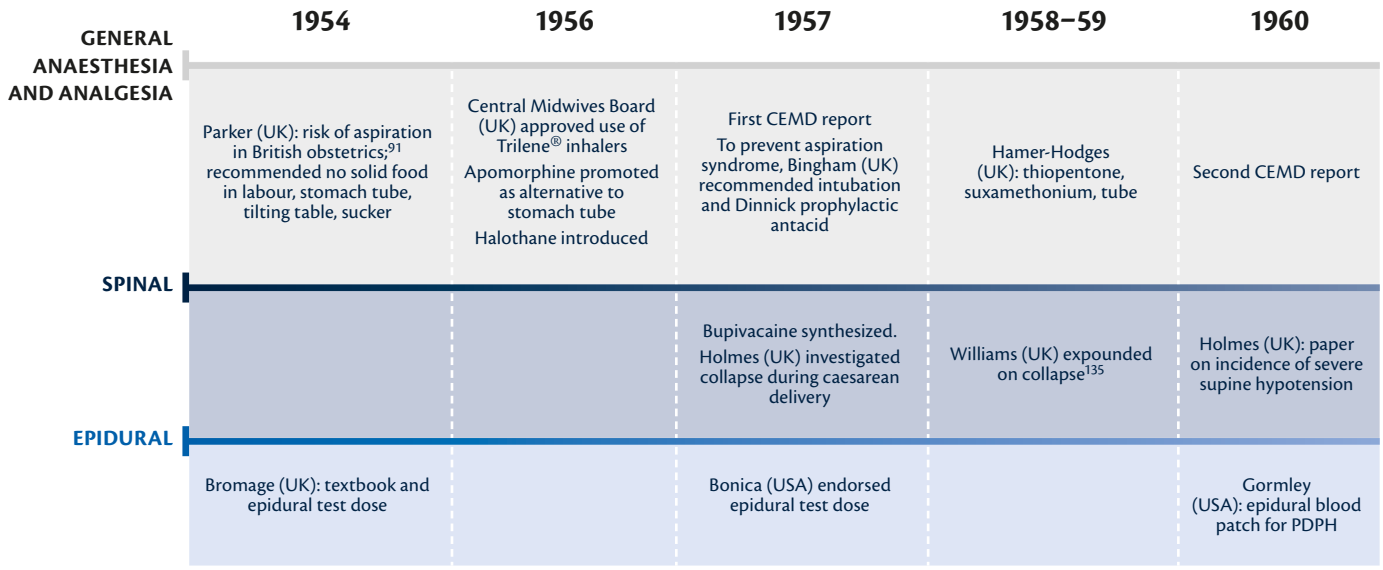
## Advances in airway management and prevention of Mendelson's syndrome

**1980s**

Tunstall's failed intubation drill (first described in 1976) was widely adopted.[116]

**1984**

Cormack and Lehane provided a laryngoscopy grading system.[117]



**1986**

Modern 'rapid sequence induction' (RSI) had developed piecemeal through successive CEMD reports and was described in standard textbooks.[119]

**1986**

Laryngeal mask airway (LMA) introduced.

**1989**

The CEMD report for 1982–84 suggested use of $H_2$-receptor antagonists and ranitidine became standard practice.[121]

**1990**

It was suggested that the LMA should be considered for rescuing the airway in cases of difficult intubation.[122]

### *Reduction of deaths from pulmonary aspiration*

By **1994** the reduction in deaths from pulmonary aspiration was attributed to prophylaxis with $H_2$ receptor antagonists.[124] By the **late 1990s**, there had been a dramatic swing to spinal anaesthesia instead of GA for operative obstetrics in the United Kingdom, Germany, France, and the United States, which probably contributed even more to the continued decline in such deaths.

### *Cricoid pressure revisited*

**2003**

A magnetic resonance imaging study by KJ Smith et al. (Hamilton, Ontario) revealed the alignment of the oesophagus to be lateral to the cricoid cartilage in more than 50% and application of cricoid pressure increased this lateral displacement to 90%.[127]

This has called into question the use of cricoid pressure in RSI.

### Remifentanil

**2004**

A case series of remifentanil technique in GA for caesarean delivery was published.[128] Since then remifentanil infusion has become recognized as useful for the following indications: intraoperative analgesia, avoidance of hypertensive response to intubation, avoidance of neuromuscular blocking agents, intraoperative control of BP in pre-eclampsia, AND reducing volatile requirements.

**Box 1.1** The Foster Kennedy report

- In 1950, Foster Kennedy, a neurologist trained at The National Hospital for Neurology and Neurosurgery, London, but working in New York, published a review entitled 'The grave spinal cord spinal paralyses caused by spinal anaesthesia'.
- This described a collection of catastrophic sequelae following spinal anaesthesia, with detailed neurological but little anaesthetic information.
- Published in *Surgery, Gynecology and Obstetrics*, the paper was widely read by surgeons, and led to some decline in spinal anaesthesia in the United States.
- It fuelled a far greater decline in spinal anaesthesia in the United Kingdom, where concern was further generated by the publicity about the Woolley and Roe case (Box 1.2).

Data from Kennedy F, Effron AS, Perry G, The grave spinal cord paralyses caused by spinal anaesthesia, Surgery, *Gynecology and Obstetrics*, 1950; 91: 385–98.

## Spinal anaesthesia

### Near demise of spinal anaesthesia in the United Kingdom

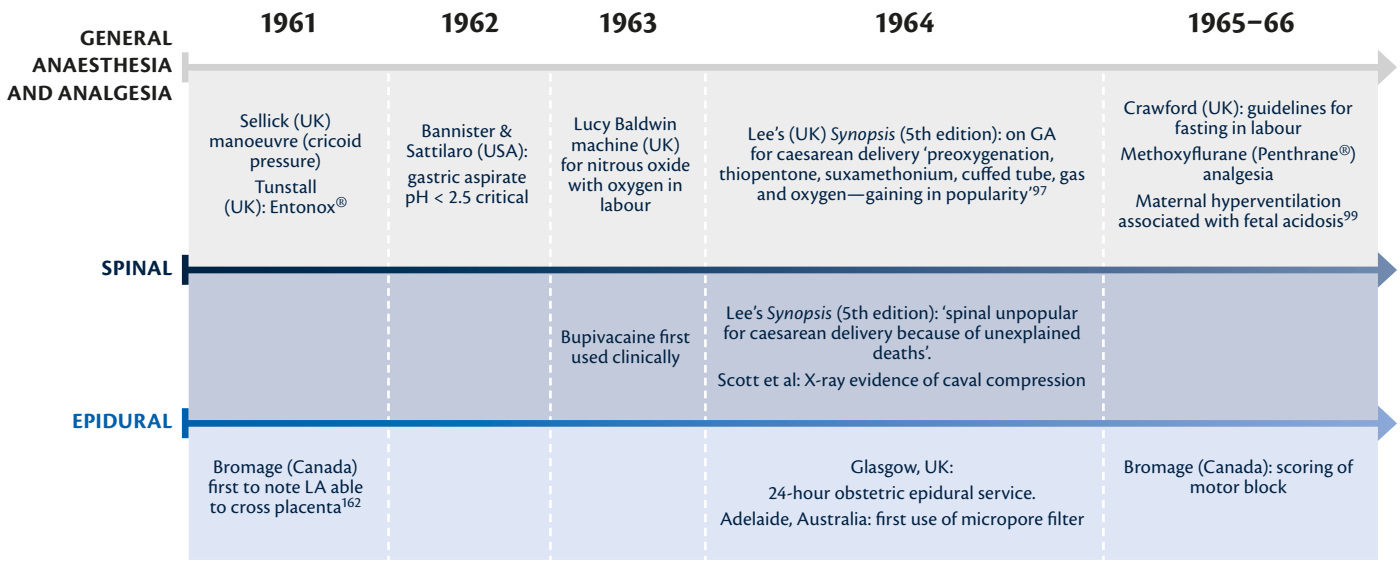
The concern generated by Bourne and Williams' paper (1948) was cemented by two other (non-obstetric) events:

**1950**

The Foster Kennedy report—see Box 1.1.[131]

**1953**

The Woolley and Roe case—see Box 1.2.[132]



**Box 1.2** The Woolley and Roe case

- In October 1947 at Chesterfield Hospital in England, Albert Woolley underwent a semilunar cartilage removal and Cecil Roe had a hydrocele repaired, both under spinal anaesthesia on the same operating list, by the same anaesthetist.
- By the next day both men developed lower limb paralysis and incontinence, which progressed to permanent paraparesis.
- They sued the Ministry of Health, the case coming to court in October 1953.
- The judge ruled that inadvertent contamination of the LA had occurred, with no negligence.
- The plaintiffs received no compensation.
- Following the case there was a profound decline in spinal anaesthesia in the United Kingdom.

Data from Cope RW, The Woolley and Roe Case; Woolley and Roe versus Ministry of Health and Others, *Anaesthesia*, 1954; 9: 249–70.

Spinal anaesthesia went into decline in the UK for nearly 30 years (though it remained in favour for obstetric use in the United States).

## Elucidation of the supine hypotensive syndrome of pregnancy

**1950**

Brigden, Howarth, and Sharpey-Schafer at St Thomas' Hospital, London, suggested that in the supine position the gravid uterus could cause obstruction to flow in the great veins of the abdomen.[133]

**1951**

McRoberts in Houston, Texas, suggested caval compression as the cause of supine shock in pregnancy.[133]

**1953**

Howard in Dallas, Texas, concurred with McRoberts, coining the term 'supine hypotensive syndrome'.[133]

**1957**

Anaesthetist Frank Holmes in Edinburgh suggested that caval compression was compounded by vasodilatation due to spinal block to cause sudden circulatory collapse during caesarean delivery under spinal anaesthesia.[133]

**1960**

Holmes published on the incidence of severe supine hypotension in advanced pregnancy (8.2%) and on management by turning the patient semi-lateral.[133]

**1963**

Anaesthetist Bruce Scott (Figure 1.9) and obstetrician Melville Kerr (Simpson Memorial Maternity Pavilion, Edinburgh) concluded from inferior vena cava (IVC) pressure measurements that in the supine position the gravid uterus occluded the IVC, but there was also collateral flow, which was adequate in most cases.[133]

**1964**

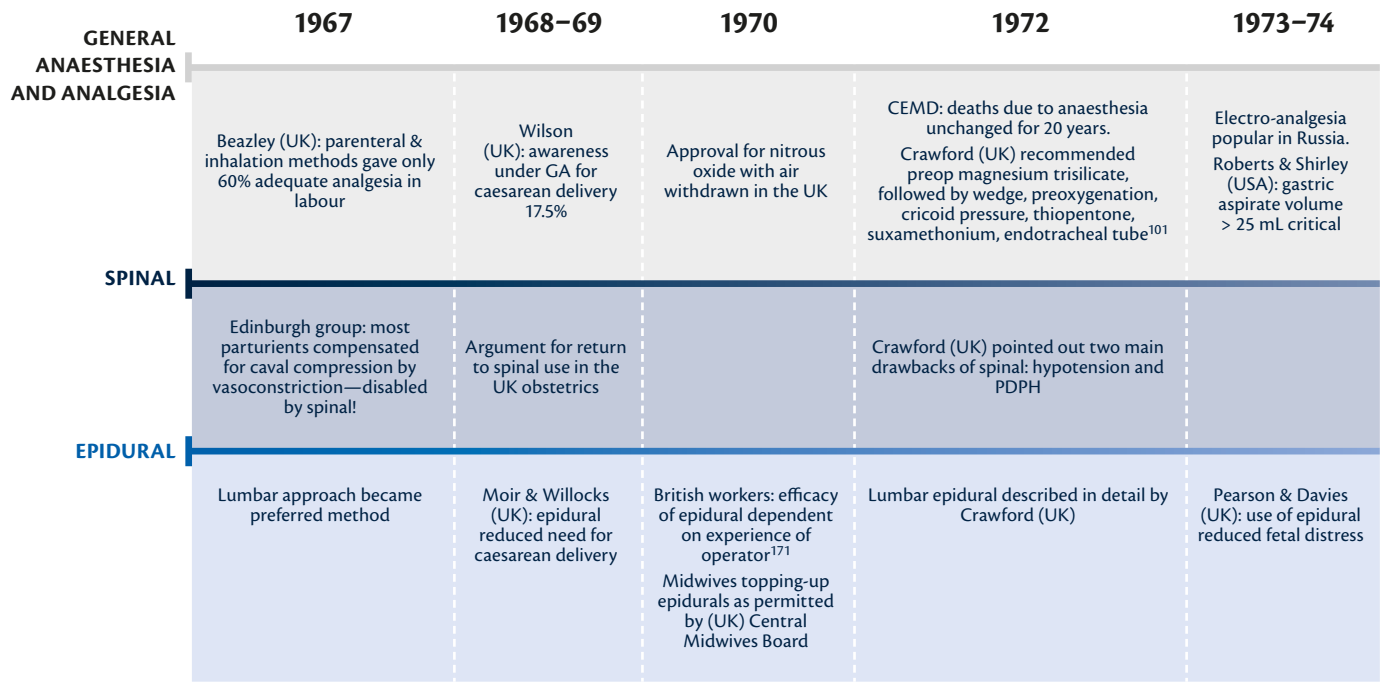
Scott, Kerr, and radiologist Samuel in Edinburgh produced the first X-ray evidence of caval compression in late pregnancy.[133]

**1967**

Lees, Scott, Kerr and Taylor in Edinburgh used invasive monitoring to demonstrate that most pregnant women could compensate for IVC compression by increase in SVR (vasoconstriction).[133] This mechanism was disabled by spinal anaesthesia.

**1968**

Bieniarz, working with R Caldeyro-Barcia in Montevideo, Uruguay, reported that the gravid uterus also compressed the abdominal aorta.[133]



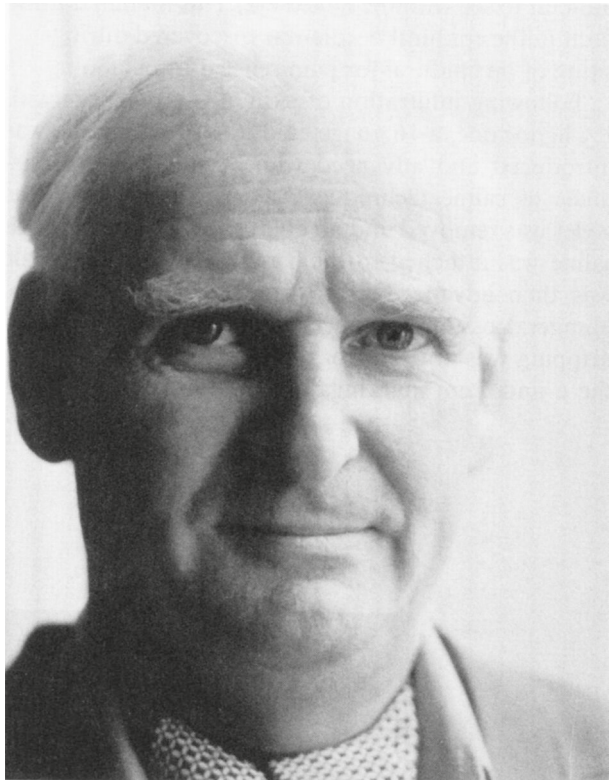


**Figure 1.9** D Bruce Scott (1926–1998) played a key role in elucidation of the supine hypotensive syndrome of late pregnancy (1960s), developed knowledge about the circulatory effects of epidural anaesthesia, studied local anaesthetic toxicity, and was renowned as a teacher. He was the second President of the Obstetric Anesthetists' Association.
Photograph in Department of Anaesthesia, Critical Care & Pain Medicine, Royal Infirmary of Edinburgh.

**1969**

By this time it was clear that supine hypotension could be avoided by lateral tilt, and there was some argument for a return to spinal subarachnoid block in obstetrics.[136]

**1972**

Selwyn Crawford in Birmingham, United Kingdom, conducted a trial of tilt versus non-tilt of patients undergoing caesarean delivery under GA; the status of the neonates revealed the importance of tilt for fetal welfare—Crawford recommended a tilt angle of 15°.[133]

## The resurgence of spinal anaesthesia in the United Kingdom

**1980s**

In the United Kingdom, spinal anaesthesia for obstetrics (although popular in some countries) was considered too problematic: 64% incidence of hypotension,[139] 24% incidence of headache,[139] and unpredictability of spread of plain (isobaric) 0.5% bupivacaine.[140] Hypotension could be managed with vasopressors and the spread controlled by use of hyperbaric solutions and positioning to enhance thoracic curvature. But, owing to the high incidence of postdural puncture headache (PDPH) in the obstetric population, the epidural remained the usual form of neuraxial anaesthesia for caesarean delivery until the availability of reliable pencil point needles.

**Early 1990s**

Although designs of pencil-point spinal needles had been published by Whitacre[141] (USA) in 1951 and Sprotte[142] (Germany) in 1987, it was not until the 1990s that these became widely used in obstetric anaesthesia practice.

**1992**

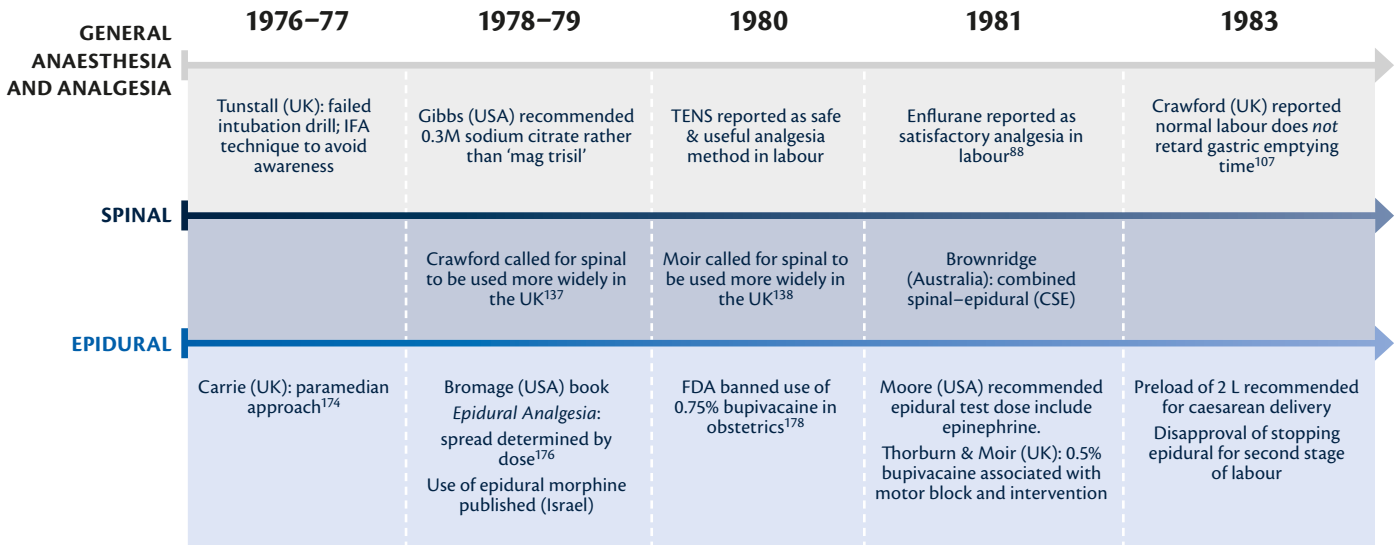
A study at the University of Natal, South Africa showed that rapid crystalloid preload caused unacceptable increases in central venous pressure (CVP) yet did not prevent spinal-induced hypotension at caesarean delivery.[143]

**1995**

Obstetric anaesthetists in Glasgow confirmed that preloading was not required to prevent spinal-induced hypotension at caesarean delivery—vasopressor use was more effective.[145]

**1995**

I Russell in Hull, United Kingdom, began to add diamorphine to intrathecal hyperbaric 0.5% bupivacaine to improve



postoperative analgesia following spinal anaesthesia for caesarean delivery.[146]

**1998**

A study in Belfast, United Kingdom, found that addition of intrathecal diamorphine also improved intraoperative analgesia during spinal anaesthesia for caesarean delivery (reduced need for intraoperative analgesic supplementation.[147] The technique was adopted widely in the United Kingdom, becoming established practice.

**1999**

In the United Kingdom, to manage spinal-induced hypotension at caesarean delivery, 95% of obstetric anaesthetists used boluses of ephedrine as the sole vasopressor.[148]

**2003**

A study in Leeds, United Kingdom, found that the optimum dose of intrathecal diamorphine to prevent intraoperative supplementation of spinal anaesthesia for caesarean delivery was 0.4 mg.[149]

**2004**

Ngan Kee (Hong Kong) showed that during spinal anaesthesia for elective caesarean delivery, phenylephrine infusion to maintain BP at 100% of baseline conferred the best outcome for both mother (less nausea) and baby (highest umbilical artery pH).[150]

**2006**

In the United Kingdom, use of phenylephrine as first-line vasopressor by obstetric anaesthetists had increased to 51%.[148]

**2010**

A study in the United Kingdom found that for high-risk caesarean deliveries, choice of phenylephrine versus ephedrine made no difference to fetal acidosis.[148]

## Epidural analgesia

### Advances in epidural analgesia

**1952**

John Bonica at Tacoma, Washington was one of the first to offer a 24-hour obstetric anaesthesia service with emphasis on continuous caudal or epidural analgesia.[157]

**1954**

Philip Bromage (then in England) (Figure 1.10) published the first edition of his textbook on epidural analgesia, in which he described a test dose to safeguard against 'total spinal' and systemic toxicity.[159]

**1957**

Bonica et al. opined that the test dose manoeuvre was extremely valuable, though not an absolute safeguard.[160]

**1957**

New LAs became available, synthesized by Bo Af Ekenstam (laboratories of Bofors Nebel-Pharma): mepivacaine (1956), bupivacaine, and ropivacaine (1957).

**1960**

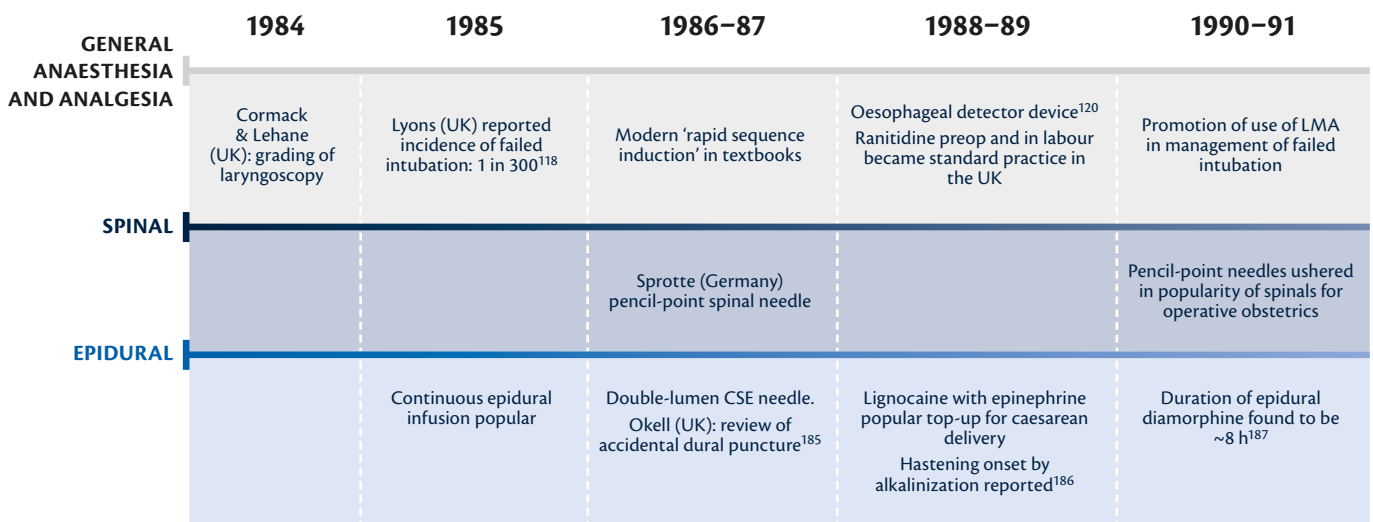
The 'blood patch' method of treating PDPH was introduced by Gormley of Pennsylvania.[161] In time, this would become the gold standard of treatment.

**1963**

Bupivacaine was first used clinically, but did not become commonly used in obstetrics until the 1970s.

**1964**

Probably the first 24-hour epidural service in the United Kingdom was established at the Queen Mother's Hospital, Glasgow, by Donald D Moir: this utilized intermittent top-ups with lignocaine.



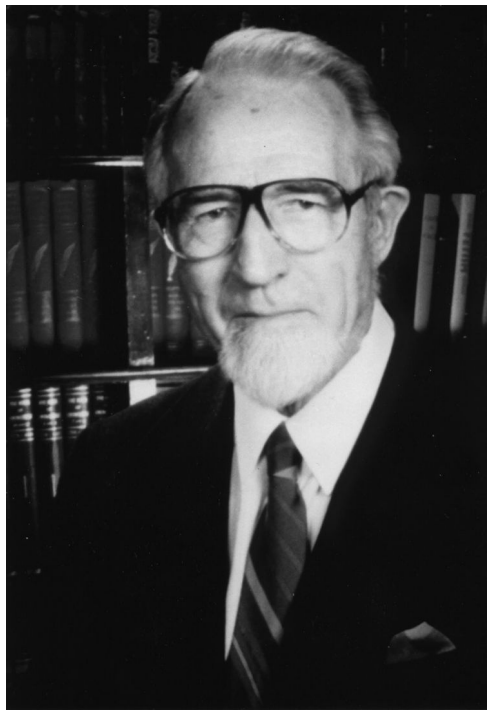


**Figure 1.10** Philip Raikes Bromage (1920–2013) published a textbook on epidural anaesthesia in 1954 and introduced a scoring system for motor block in 1965. Portrait photograph reproduced with kind permission from McGill Department of Anesthesia, Montreal, Canada.

**1965**

Bromage (then Professor at McGill University, Montreal) introduced a scoring system for motor block.[163]

**1967**

The lumbar approach to the epidural space became preferred to caudal.

**1968**

Moir and Willocks reported on 300 continuous and 62 single-shot epidural blocks (using lignocaine with epinephrine) administered during labour at the Queen Mother's Hospital, Glasgow.[164] Besides analgesia, indications for the continuous method included incoordinate uterine action, severe pre-eclampsia, and selected cases of cardiac and respiratory disease. The single-shot method was found to be excellent for forceps delivery where it also reduced blood loss.

### *Advances in epidural needles and catheters*

**1950–1970s**

In the United States, R Hustead and OB Crawford blunted the Tuohy needle, while J Weiss added wings.[165] In 1960, in the United Kingdom, J Alfred Lee (author of *A Synopsis of Anaesthesia*), added 1 cm-wide alternate black and metallic markings to the shaft of the epidural needle[166]—this reduced the incidence of dural puncture. DB Scott in 1964 described prolonging the hub to prevent kinking of the catheter.[167]

Regarding the epidural catheter, Lee in 1962 described a nylon catheter with a non-patent tip, lateral eye, and length calibrations.[168]

From the above, there developed the modern epidural needle and catheter.

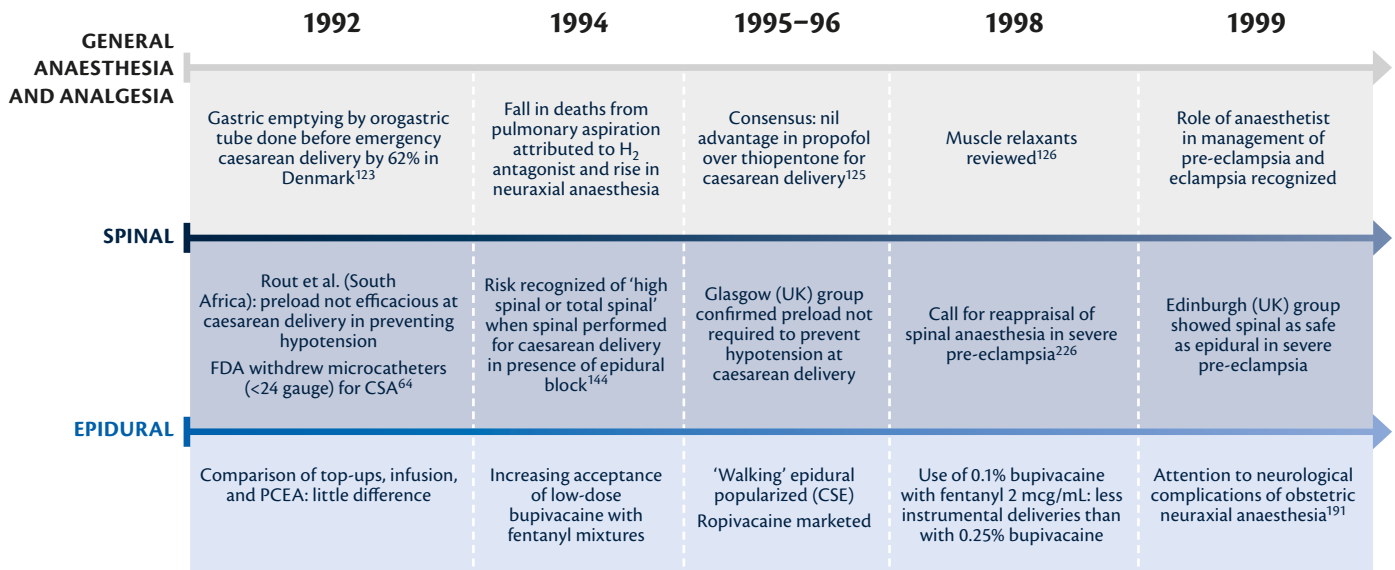
### *Adoption of micropore filters for epidural catheters*

**1964–1970s**

1961–64 saw the need for scrub-up before each epidural top-up to maintain sterility: this was frequent owing to the short duration of lidocaine. Various mechanical schemes were designed to avoid touching syringe/catheter; these were cumbersome.

Developments in the plastics industry combined with increased demand for micropore filters in microbiology led to mass production.

1964 James Saunders (Adelaide, Australia) was the first to use in obstetrics.



1965 Bruce Scott (Edinburgh) attached 0.2 μm millipore filters to epidural catheters.

1972 J Desmond was probably first to use the filters in North America.

1975 J Selwyn Crawford (Birmingham, United Kingdom) recommended the filters.

1977 E Abouleish in the United States disputed the need.

From the late 1970s the filter became a standard component of the epidural pack.[169]

**1970s**

Bupivacaine top-ups superseded lidocaine.

### Labour analgesia: parenteral/inhalational versus epidural

Reasons advanced for resistance to epidurals included:

- parenteral/inhalation methods adequate
- concerns that epidural was detrimental to fetus.

**1967**

Beazley et al. found that only 60% of women had adequate analgesia from parenteral and inhalation methods in labour.[170]

**1968**

Moir and Willocks found that epidural analgesia reduced the need for caesarean delivery for maternal distress.[164]

**1974**

Pearson and Davies found that epidural analgesia avoided fetal depressant effects of potent opioid and sedative drugs.[172]

**1974**

Crawford reported that epidural analgesia did not reduce uterine tone.[173]

**1978**

Jouppila demonstrated that epidural analgesia did not diminish measured placental blood flow (radioactive clearance method).[175]

### Epidural anaesthesia for caesarean delivery

**Late 1970s**

There was an upsurge of interest in epidural analgesia for caesarean delivery in the United Kingdom.[177]

**1980s**

Epidural anaesthesia was commonly used for caesarean delivery in the United Kingdom. By 1983, a preload of 2 L of Hartmann's solution was recommended to protect against hypotension.[179]

### Further advances in epidural analgesia

**1979**

Publication of the use of epidural morphine at the Hadassah Hospital, Jerusalem, captured the interest of all anaesthetists, including those in obstetrics.[180]

**1981**

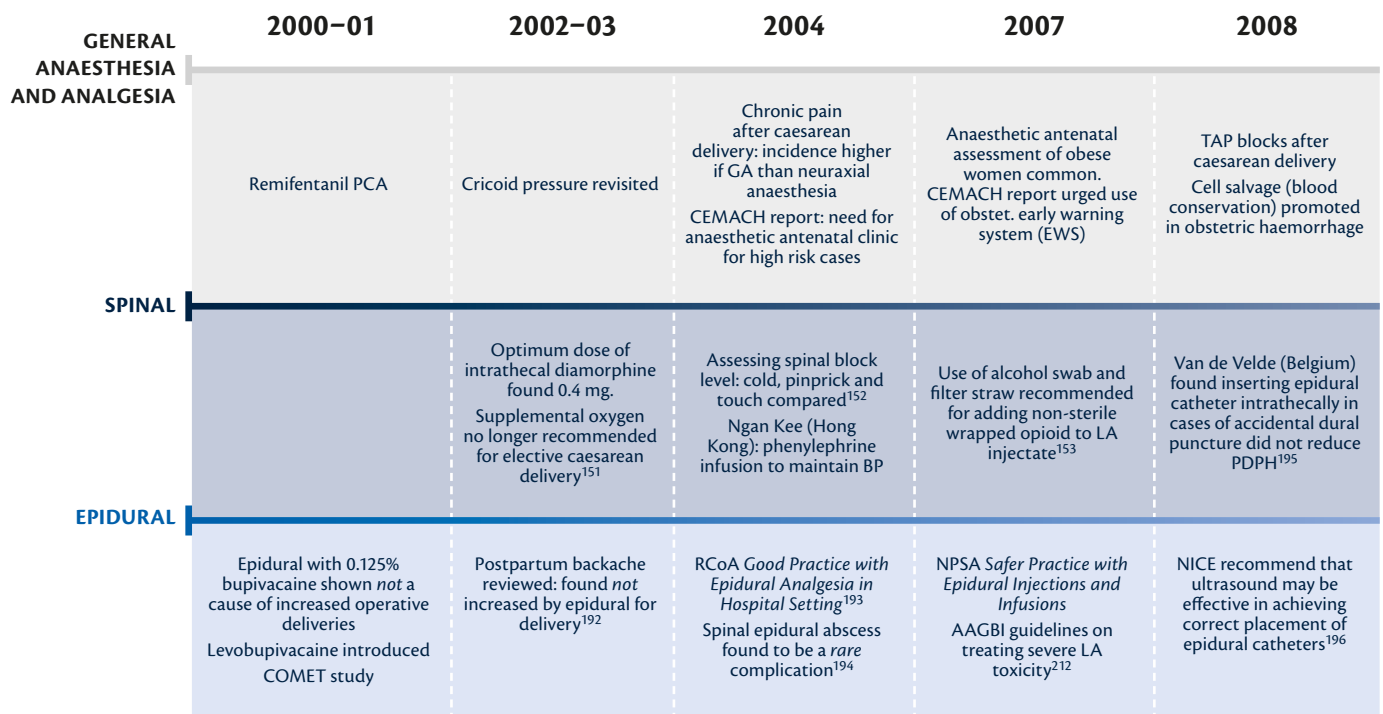
Moore and Batra recommended that the test dose include epinephrine 15 mcg to diagnose inadvertent IV injection (this dose of epinephrine consistently raised heart rate during the first minute after injection).[181]

**1980s**

Continuous epidural infusion for pain relief in labour became popular. There were many papers on epidural infusion versus top-ups.

*Infusion advantages:*

- Maintenance of stable level of analgesia[182,184]
- More stable heart rate and BP[183]



- Less frequent need for bolus.[182,184]

*Infusion disadvantages:*

- Increased total dose of LA[184]
- Potential for increased motor block.[182]

**Early 1990s**

Low-concentration bupivacaine with fentanyl solutions were popularized (the addition of fentanyl was synergistic and could reduce the amount of bupivacaine).[188]

**Mid 1990s**

Patient-controlled epidural analgesia (PCEA) in labour was popularized.[189]

**1996**

Having been first used clinically in 1993, ropivacaine was marketed in the United Kingdom.[190] Promoters suggested it would reduce undesirable motor block. However, it was not commercially competitive against racemic bupivacaine, as by this time excellent results were being obtained with low-concentration bupivacaine/fentanyl mixtures.

## Combined spinal–epidural techniques

**1981**

P Brownridge (Adelaide) described CSE technique for caesarean delivery.[198]

**1986**

Following publication on CSE by the Romanian, Ioan Curelaru, in 1979, Karl Wiegand in Germany worked on a double-lumen CSE needle for which a patent was granted.[68]

**1995**

'Walking' epidural in labour concept was popularized by BM Morgan (Queen Charlotte's & Chelsea Hospital, London) and advanced the usage of CSE.[199]

## Audits of maternal mortality and morbidity

### The confidential enquiries into maternal deaths for England and Wales

**1957**

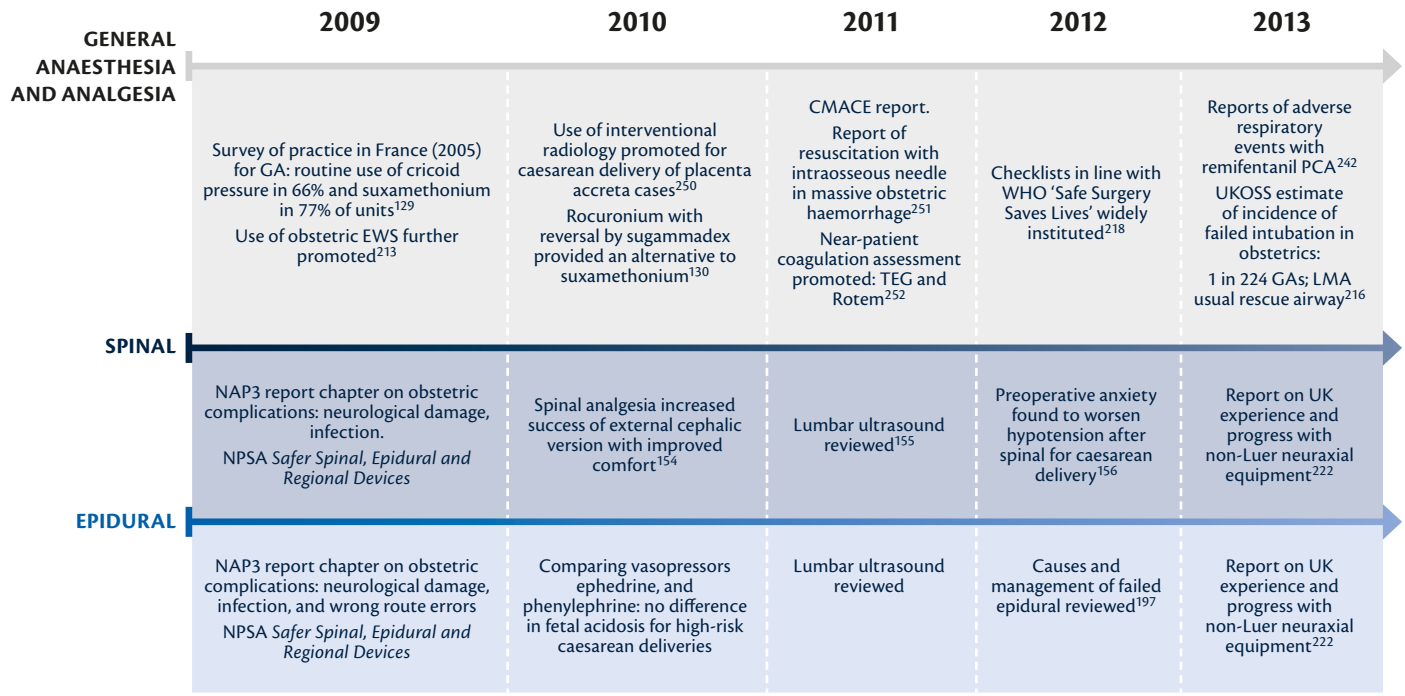
The first report of the CEMD in England and Wales for the triennium 1952–54 was published. Anaesthetists were involved from the start. Initially there were 44 maternal deaths for every 1000 deliveries. Notable details in the first report[200] included:

- a total of 49 deaths attributable to anaesthesia
- 32 deaths following inhalation of stomach contents
- six deaths under chloroform
- two cases in which the obstetrician 'managed' anaesthesia and delivery single-handed
- in addition to the 49 deaths ascribed to anaesthesia, at least 20 more were identified where anaesthesia was contributory.

Haemorrhage was the second commonest direct cause of death—in the years following 1957 it became appreciated that the anaesthetist could play a major role in management of haemorrhage.

**1960**

In the report for 1955–57, endotracheal intubation was advised for patients with full stomach and for forceps in the lithotomy position.[201]



**1972**

By this time it was evident that the number of deaths due to anaesthetic complications had remained unchanged for nearly 20 years.[202] This stimulated interest in neuraxial analgesia as an alternative method.

**1979**

The report for 1973–75 included 13 deaths from inhalation of gastric contents despite antacids—in 12, cricoid pressure was not properly applied. There were two deaths from 'total spinal' complication of epidural analgesia. The report emphasized the need for experienced anaesthetists (rather than unsupervised trainees) and for monitoring the patients.[203]

**1986**

The report for 1979–81 showed that anaesthesia was the third commonest cause of maternal death. Causes again included inhalation of stomach contents (eight) and difficulty with endotracheal intubation (eight cases—four oesophageal intubations). There were three deaths from haemorrhage with poor anaesthetic management; three patients with severe kyphoscoliosis died from respiratory problems. The authors recommended a drill for management of bleeding and early multidisciplinary consultation for patients with kyphoscoliosis.[204]

### The confidential enquiries into maternal deaths in the United Kingdom

**1991**

The first UK report (for 1985–87) revealed six deaths due to problems with tracheal intubation, one death due to inhalation of gastric contents, and one death (patient with severe congenital heart disease) due to cardiovascular collapse under epidural anaesthesia. The authors commented that a failed intubation drill should be agreed and practised; extra anaesthetic apparatus for a difficult intubation was suggested.[205]

**1994**

In the report for 1988–90 there were five deaths due to anaesthesia, with the following causes: problems with tracheal tube (one), hypotension during spinal anaesthesia followed by pulmonary oedema from excess IV fluid (one), substandard postoperative care (one), and aspiration of gastric contents (two). Also there were ten deaths to which anaesthesia contributed, involving haemorrhage, bronchospasm, and possible aspiration. Recommendations included:[124]

- provision of $CO_2$-analyser
- monitoring by pulse oximetry
- giving $H_2$-receptor blocking drugs to all patients who may require anaesthesia
- emptying the stomach before extubation
- adequate IV access and provision of blood products for suspected haemorrhage cases
- use of postoperative pain relief service.

**1996**

The report for 1991–93 revealed a maternal mortality rate of six per 100,000 maternities—nearly 12-fold less than the rate of 70 for 1952–54.[206] The top four causes of direct deaths were thrombosis/thromboembolism, hypertensive disorders, early pregnancy, and haemorrhage—anaesthesia was ranked eighth. There were eight deaths directly attributable to anaesthesia (substandard care in seven); causes included hypoxia and airway obstruction (five), acute respiratory distress syndrome (two), and failure of tissue perfusion (one). All the direct deaths associated with anaesthesia for caesarean delivery involved the use of GA.

### Morbidity audit

**1998**

Noting the falling numbers of maternal deaths in the United Kingdom (revealed by the CEMD report for 1991–93), Mantel et al. in South Africa proposed that more useful information might be obtained from audit of severe acute maternal morbidity or 'near miss'.[207]

**2000**

Scottish Assessors for the CEMD began a series of pilot exercises, which led to collection of data on defined categories of severe maternal morbidity in all consultant-led maternity units in Scotland: the *Scottish Confidential Audit of Severe Maternal Morbidity* (SCASMM), which has produced nine reports funded by NHS Quality Improvement Scotland—the latest in March 2013.[208]

**2001**

The Report on CEMD in the United Kingdom for 1997–99[209] (and subsequent reports) included information on 'near misses' and severe maternal morbidity based on the Scottish audit of these outcomes.

### Confidential Enquiry into Maternal and Child Health (CEMACH)

**2004**

The report on CEMD in the United Kingdom for 2000–02 came for the first time under the auspices of CEMACH and marked 50 years of this audit.[210]

There were six direct deaths due to anaesthesia—all associated with GA, that is, nil attributable to neuraxial anaesthesia. Of these, three were due to difficult intubation, two resulted from hypoventilation in isolated sites, one from anaphylaxis. In addition there were 20 deaths in which perioperative anaesthetic management contributed (five cases of substandard perioperative care and five cases of substandard management of haemorrhage; in addition there were two deaths in women who declined blood products).

Nevertheless, the report revealed that anaesthesia for caesarean section had become 30 times safer than it had been in the 1960s.

**2007**

The CEMACH report for 2003–05 again included six direct deaths due to anaesthesia. Four of the patients were obese and three of these died of fatal airway complications. The other three anaesthetic deaths were due to a cardiac arrest in a septic patient, LA toxicity from a drug error (IV bupivacaine), and a haemothorax secondary to CVP line insertion. For the first time the report identified a top ten of recommendations, the following being most relevant to anaesthetists: [211]

- in pre-eclampsia, treat systolic hypertension of 160 mmHg or more
- any patient with a previous caesarean delivery should have placental localization
- ensure regular training (obstetric 'skills and drills')
- implement a modified early obstetric warning score (MEOWS) system

- urgent guidelines for obesity, sepsis, and pain/bleeding in early pregnancy.

### Centre for Maternal and Child Enquiries (CMACE)

**2011**

The triennial review on maternal deaths in the United Kingdom for 2006–08 was published by CMACE,[214] the new name adopted by CEMACH on becoming an independent charity in 2009. The report revealed that sepsis had become the leading cause of direct maternal death, with a reduction in deaths due to thromboembolism and haemorrhage. There were seven direct deaths due to anaesthesia: four from postoperative complications, two from failure to ventilate, and one from leucoencephalitis. Again the report listed a top ten of recommendations, notably:

- treat systolic hypertension above 150 mmHg
- address clinical skills and training: 'Back to Basics'
- routine use of MEOWS chart
- communication and early referral of high-risk cases to specialists
- appropriate multidisciplinary specialist care for serious medical conditions
- serious incident reporting.

### UK Obstetric Surveillance System (UKOSS)

**2005**

A joint initiative began between the Royal College of Obstetricians and Gynaecologists and the National Perinatal Epidemiology Unit (United Kingdom). Surveys of rare disorders have been conducted through a monthly card mailing to nominated obstetricians, midwives, and anaesthetists in each hospital in the United Kingdom with a consultant obstetric unit.[215]

### Mothers and babies: reducing the risk through audits and confidential enquiries across the UK (MBRRACE-UK)

**2010**

Competitive tender was invited for the UK Confidential Enquiries into Maternal Deaths, and this was won by MBRRACE-UK.[217]

### Audit of complications of central neuraxial block and efforts to improve safety

#### *Systemic toxicity*

**2001**

Levobupivacaine introduced.

Wrong route of drug administration:

- 2007 National Patient Safety Agency (NPSA) in England—Patient Safety Alert 21: safer practice with epidural injections and infusions[219]
- 2009 NPSA Patient Safety Alert—Safer Spinal (intrathecal), Epidural and Regional Devices.[220]

#### *Neurological sequelae*

**2008**

National Institute for Health and Clinical Excellence (NICE) in England and Wales—suggested making use of ultrasound for guiding catheterization of epidural space.[196]

**2009**

The Report of the Third National Audit Project of the Royal College of Anaesthetists—*Major Complications of Central Neuraxial Block in the United Kingdom* (NAP3)—included a chapter on obstetric practice.[221]

#### *Epidural haematoma and infection*

**2009**

The NAP3 Report included incidence and pointed out how to deal with coagulopathy and use of anticoagulants, and provided guidelines for avoiding infection including epidural abscess.[221]

## Role of the anaesthetist in the management of pre-eclampsia and eclampsia

**1980s**

Pre-eclampsia was recognized as one of the main indications for epidural analgesia in labour (provided coagulation profile satisfactory).[119]

For caesarean delivery, epidural anaesthesia was recommended with the proviso that any tendency to hypotension must be carefully controlled;[223] spinal anaesthesia was often discouraged because of a presumed risk of severe hypotension.

**1992**

A study by Hood challenged the view that spinal anaesthesia was unsafe in severe pre-eclampsia.[224]

**1995**

Wallace et al. at the Parkland Hospital (Dallas, Texas) compared three methods of anaesthesia for caesarean delivery of severe pre-eclamptics: general, epidural, and CSE—they found no severe hypotension in the spinal group and all methods acceptable.[225]

**1999**

Obstetric anaesthetists in Edinburgh confirmed that spinal was as safe as epidural anaesthesia in severe pre-eclampsia; indeed they suggested spinal to be preferable on grounds of better intraoperative analgesia.[227]

**2005**

The Edinburgh group further found that severe pre-eclampsia conferred an ability to sustain arterial pressure after spinal block for caesarean delivery, as these patients required less vasopressor compared with normotensive parturients.[228]

**Progress in eclampsia 2002–04**

The Magpie Trial (2002) revealed that magnesium sulphate halves the risk of eclampsia.[229]

It was recognized that the obstetric anaesthetist has a key role in the emergency management of imminent and manifested eclamptic seizures—airway management and prompt commencement of magnesium sulphate infusion—team performance improvable by simulation drills.[230]

## Role of the anaesthetist in the management of labour and postoperative pain

**1980s**

The few contraindications to epidural analgesia were enumerated. It was recognized that the offer of epidural analgesia would often persuade a parturient to accept augmentation with oxytocin; and

(besides pain relief) there were many other indications for epidural analgesia in labour: pre-eclampsia, multiple pregnancy, and cardiac and respiratory disease.[119]

Thorburn and Moir pointed out that repeated boluses of 0.5% bupivacaine for epidural analgesia in labour was associated with profound motor block and increased intervention. In this group, spontaneous deliveries were reduced to 31%, compared with 53% for 0.25% bupivacaine.[231]

For the second stage of labour it was noted that allowing epidural analgesia to wear off increased maternal distress without improving outcome—and that such practice should be discouraged.[232]

#### 1990s

Use of 0.1% bupivacaine with fentanyl 2 mcg/mL for epidural analgesia (compared with 0.25% bupivacaine) was shown to reduce instrumental deliveries.[233]

Comparison of intermittent top-ups, infusions, and PCEA found little difference in delivery outcome.[234]

Use of the 'walking' epidural, although enabling mobilizing, did not appear to confer any change in delivery outcome compared with the above.[235]

A study on mobilizing found that this made no difference to duration of labour or delivery outcome.[236]

While recognizing that fluid preload was not required for epidural analgesia using dilute bupivacaine, it was also noted that preloading may temporarily decrease uterine activity.[237]

The minimum local analgesic concentration (MLAC) of epidural bupivacaine was shown to increase with progression of labour.[238]

#### 2000

Loughnan et al. (London) in a randomized study found that epidural analgesia with 0.125% bupivacaine was not associated with increases in either instrumental or operative deliveries.[239]

#### 2001

Comparative Obstetric Mobile Epidural Trial (COMET) study in the United Kingdom found a reduced *instrumental* vaginal delivery rate with CSE and low-dose infusion techniques compared with traditional epidural.[240]

#### 2001

Remifentanil patient-controlled anaesthesia (PCA) was introduced as alternative analgesia in labour, especially where epidural not an option.[241]

#### 2004

A study in Denmark found that chronic pain after caesarean delivery was higher with GA compared to neuraxial anaesthesia.[243]

#### 2008

McDonnell in Galway, Ireland introduced transversus abdominis plane (TAP) block for analgesia after caesarean delivery.[244]

## Advances in management of major obstetric haemorrhage—role of the anaesthetist

#### 1950s

Although David Massa (Anaesthesia Resident) at the Mayo Clinic introduced the plastic 'Rochester' cannula,[245] metal needles (e.g. Mitchell) were still commonly used for IV access.

#### 1964

Deseret introduced the Angiocath, a PVC, hypodermic-style needle with flash-back chamber and flow control plug.[245]

#### 1970s

Glass bottles as containers for IV fluids and blood were superseded by plastic bags. These both reduced risk of air embolism and permitted pressurization for rapid infusion.

#### 1980s

The Report on CEMD for 1976–78 emphasized the need for a simple protocol for anticipation and treatment of postpartum haemorrhage.[246] This was re-emphasized in the report for 1979–81, which recommended a drill for management of bleeding.[204]

#### 1990s

Rapid infusers with blood warming capability were improved (e.g. the 'Level 1' series) and recommended.[247]

Autologous blood transfusion (cell salvage) was promoted[248] and developed.

#### 2000 onwards

Novel medical, surgical, radiological, and haematological interventions were developed, with anaesthetists establishing a key role in management.[249] Also multidisciplinary working practices were encouraged and national guidelines implemented.[250]

## Professional organizations and associations

#### 1968

An informal group of interested anaesthetists met in Liverpool, United Kingdom, at the invitation of Dr THL Bryson (Liverpool) and Dr M Lewis (Belfast)—and hatched the idea of the Obstetric Anaesthetists' Association (OAA).

#### 1969

The OAA was constituted at a spring meeting in Glasgow hosted by Dr DD Moir—the inaugural elected president was Dr JS Crawford (Birmingham) (Figure 1.11).

At a meeting in Kansas City, Missouri, the initial plans for a parallel organization were made.

#### 1970

At Nashville, Tennessee, the Society for Obstetric Anesthesia and Perinatology (SOAP) was founded—the first president was Robert F Hustead, MD.

#### 1987

Responding to the Report on CEMD in England and Wales for 1979–81, the OAA in conjunction with AAGBI published a report outlining far-sighted proposals for improving the quality and safety of obstetric anaesthesia in the United Kingdom.[253]

#### 1992

The OAA launched its official journal: the *International Journal of Obstetric Anesthesia*.

**Figure 1.11** Jeff Selwyn Crawford (1922–1988) published the first edition of *Principles & Practice of Obstetric Anaesthesia* in 1959, provided guidelines for fasting in labour (1965), designed a wedge to provide lateral tilt of the pregnant woman placed supine (1972), and was inaugural President of the Obstetric Anesthetists' Association.

PART 2

# Maternal and fetal physiology

# CHAPTER 2

# Physiological changes associated with pregnancy

Roulhac D. Toledano

## Introduction

Pregnancy triggers significant systemic and organ-specific changes that start soon after conception, become more marked as gestation advances and during labour and delivery, and, most commonly, resolve in the early postpartum period. These physiological alterations, which serve to accommodate the developing fetus and the increased metabolic demands of pregnancy, as well as to prepare the parturient for blood loss at delivery, are generally tolerated well in healthy females. However, they may compromise the parturient with pre-existing or pregnancy-related disease, unmask and/or worsen previously unidentified disease, and complicate the anaesthetic management of pregnant patients presenting for obstetric or non-obstetric surgery. They may also alter diagnostic and laboratory criteria and limit the management and treatment options available to obstetric patients. As a result, an understanding of the anatomical, functional, and biochemical adaptations to pregnancy is essential for health care providers. This chapter reviews the organ-specific and systemic changes associated with pregnancy, with emphasis, when applicable, on how they affect anaesthetic management.

## The central nervous system

The central nervous system (CNS) undergoes significant changes during pregnancy (see Table 2.1). Pregnant women experience slight changes in pain perception and pain threshold (see Chapter 15), decreases in anaesthetic requirements, problems with attention, concentration, and memory,[1] disruptions in sleep patterns, increased dependence on the sympathetic nervous system, and, possibly, an increase in cerebral blood flow,[2] without detectable changes in cerebrovascular autoregulation.[3] The clinical implications and mechanism of many of these changes remain unclear or difficult to quantify.

### Anaesthetic requirements

The minimum alveolar concentration (MAC) of volatile agents during general anaesthesia is reduced in pregnancy. In an early study, Palahniuk and colleagues found that the MAC for halothane and isoflurane was 25% and 40% lower, respectively, in pregnant ewes compared to non-pregnant controls.[4] A subsequent study in rabbits by Datta et al. proposed that the MAC of halothane correlated inversely with progesterone levels.[5] Other investigators postulated that increased concentrations of endorphins and dynorphins may increase the pain threshold and affect anaesthetic requirements.[6] Studies of human subjects by Chan and colleagues found similar decreased MAC requirements starting early in pregnancy, reporting the MAC of isoflurane to be reduced by 28% at 8–12 weeks' gestation.[7] In another study of females undergoing elective termination of pregnancy, investigators determined median decreases in the MAC of halothane and enflurane of 27% and 30%, respectively, at 8–13 weeks' gestation.[6] Labour appears to decrease the MAC of volatile agents even further.[8] Chan and other investigators determined that the MAC of isoflurane remained decreased (by roughly one-third) for 24–36 hours postpartum and returned to non-pregnant values by 72 hours.[9]

Although it is difficult to extrapolate these findings to other gestational stages of pregnancy and to all volatile agents, it appears that maternal anaesthetic requirements for volatile agents are reduced early in pregnancy and return to normal levels by postpartum day 3. As a result, it has become standard over the past several decades to administer less than 1 MAC of volatile agent (0.5–0.75%), with or without nitrous oxide, during caesarean delivery under general anaesthesia. The reduced MAC has been considered adequate to anaesthetize the mother, with minimal tocolytic and neonatal depressant effects. A target 0.5 MAC of sevoflurane and up to 1 MAC of desflurane also appears not to inhibit the frequency and amplitude of myometrial contractions induced by exogenously administered oxytocin.[10]

The routine use of low concentrations of volatile agents for caesarean delivery under general anaesthesia has contributed to a higher incidence of intraoperative awareness and subsequent recall among parturients. Indeed, investigators have begun to question whether a decreased MAC during pregnancy correlates with

**Table 2.1** Central nervous system changes of pregnancy

| Parameter | Change |
|---|---|
| Pain threshold | Increased |
| MAC of volatile agents | Decreased |
| Local anaesthetic requirements | Decreased |
| Cerebrovascular autoregulation | No change |

*Data are conflicting.

enhanced brain sensitivity to volatile anaesthetic effects; if not, pregnant and non-pregnant patients may require similar doses of anaesthetics to prevent intraoperative awareness.[11] Although the incidence of intraoperative awareness during caesarean delivery has declined to an estimated 0.26%, prevention of this untoward complication remains a challenge for obstetric anaesthetists balancing concerns for uterine tone, maternal anaesthetic depth, and fetal well-being.[12] In the absence of a definitive monitor and reproducible clinical signs to assess anaesthetic depth, investigators have recently advocated a target of 0.7 MAC, which corresponds to a bispectral index value below 60 yet does not appear to increase the incidence of uterine atony and neonatal depression, during caesarean delivery under general anaesthesia.[12] Supplemental nitrous oxide, particularly in emergency caesarean deliveries, may further minimize the risk of awareness. Other investigators concur that a target of less than 0.8–1.0 MAC will provide sufficient maternal unconsciousness without affecting neonatal outcomes, blood loss, or uterine contraction in response to oxytocin.[13] Despite notable progress, intraoperative awareness remains a highly undesirable outcome with the potential for long-term sequelae, such as post-traumatic stress disorder, in a small subset of patients. Intraoperative awareness may also present a medicolegal challenge for anaesthetists.

### Local anaesthetic requirements

Local anaesthetic requirements for both peripheral and neuraxial anaesthetic procedures appear to be reduced in obstetric patients, most likely as a collective result of anatomical, mechanical, and biochemical changes. Neuraxial local anaesthetic requirements are reduced early in pregnancy, presumably due to chronic exposure to progesterone, and reach 40% of non-pregnant requirements by term gestation. An increase in epidural fat content during pregnancy and the distension of the epidural venous plexus by the enlarging uterus contribute to this dose reduction by decreasing both the volume of the epidural space and of cerebrospinal fluid (CSF) per spinal segment. Decreases in the specific gravity and pH of CSF during pregnancy may also contribute to the observed decreased requirements of spinally administered local anaesthetics. These dose requirements return to baseline within 24 hours postpartum.[14]

### The autonomic nervous system

Pregnant patients develop increasing reliance on the sympathetic nervous system throughout pregnancy. This phenomenon, which peaks at term and returns to baseline within 2 days postpartum, accounts in part for the occasional severe haemodynamic derangements associated with the sympathectomy of neuraxial blockade, as well as the relatively high pressor requirements that otherwise healthy parturients experience during spinal anaesthesia.[15] The downregulation of the parasympathetic nervous system towards term gestation, in turn, may have a sparing effect, preventing more frequent episodes of severe bradycardia in the setting of high sympathectomies.

## The cardiovascular system

The cardiovascular system undergoes several changes during pregnancy, including increases in plasma volume, red blood cell (RBC) mass, and cardiac output (CO) and decreases in blood pressure and systemic vascular resistance (SVR) (see Table 2.2).

**Table 2.2** Cardiovascular changes of pregnancy

| Parameter | Change |
|---|---|
| Plasma volume | Increased |
| RBC mass | Increased |
| Cardiac output | Increased |
| Blood pressure | Decreased |
| Systemic vascular resistance | Decreased |
| Myocardial contractility | No change/increase* |

*Data are inconclusive.

Although myocardial contractility remains unchanged, or is, possibly, slightly increased, the increased CO may unmask underlying or pregnancy-related heart conditions or precipitate acute deterioration in patients with previously asymptomatic heart disease. Aortocaval compression, neuraxial procedures, and general anaesthetics may further contribute to maternal cardiac decompensation and fetal compromise.

### Cardiac output

An increase in CO begins as early as 5 weeks' gestation and continues throughout pregnancy, peaking at 28–34 weeks' gestation and, again, during the second stage of labour. At its height during pregnancy, CO reaches 50% above baseline. It increases an additional 15–25% during early labour and the active phase of labour, and reaches 50% above term pregnancy values during the second stage of labour. The highest CO, however, is in the immediate postpartum period, when it reaches 80% above prelabour values. Uterine involution and the resultant autotransfusion, which outpaces blood loss at delivery, accounts in part for the postpartum increase in CO. Cardiac patients are at particular risk during this period.

Both an increased stroke volume (SV) and heart rate (HR) contribute to the increased CO of pregnancy, but the former contributes to a greater degree (see Figure 2.1). SV increases early in pregnancy and declines very slightly at term. The maternal HR increases as early as 5 weeks' gestation and reaches 15–20 beats/min above baseline by 32 weeks' gestation.[16] At term, sustained maternal tachycardia is primarily responsible for the high CO.

### Aortocaval compression

Maternal positioning influences the pregnancy-induced increase in CO. Sharp reductions in CO are seen in some women in the supine position as early as 18–20 weeks' gestation, if not earlier, when the enlarging uterus begins to compress the inferior vena cava (IVC) and, less often, the aorta. The IVC may become partially or completely occluded, resulting in dramatically decreased venous return to the right atrium and a related decrease in CO. Collateral circulation through the paravertebral and azygos veins only partially compensates for the decreased venous return. At term, aortocaval compression in the supine position may reduce CO by as much as 30%, and up to 15% of parturients experience signs and symptoms of the supine hypotensive syndrome, including hypotension, sweating, bradycardia, syncope, nausea and vomiting, and mental status changes.[17] Uteroplacental perfusion also decreases as a result of decreased uterine blood flow and increased uterine venous pressure, compromising fetal well-being.

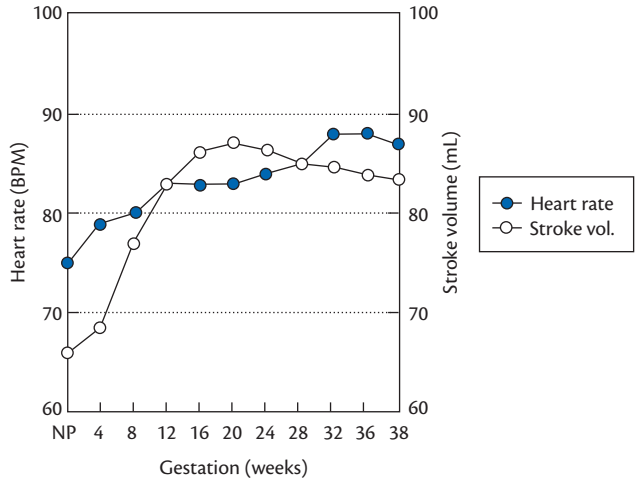

**Figure 2.1** This figure was published in *Creasy & Resnik's Maternal-Fetal Medicine: Principles and Practice*, RK Creasy, R Resnik, JD Iams, *et al* (eds), Maternal Cardiovascular, Respiratory, and Renal Adaptation to Pregnancy, p.102–9, Copyright Elsevier (2009). Adapted from *Americal Journal of Physiology – Heart and Circulatory Physiology*, Robson SC, Hunter S, Boys RJ, ***et al***. Serial Study of Factors Influencing Changes in Cardiac Output during Human Pregnancy, 256, 4, 1989, p. H1060, ©The American Physiological Society (APS).

General and neuraxial anaesthesia impair sympathetic tone and compromise the normal physiological response to aortocaval compression, exacerbating maternal hypotension and further reducing cardiac preload and output. Although data are inconclusive, left uterine displacement (LUD) with either a wedge placed under the patient's right side or a 15–20° tilt of the operating table should be maintained during all procedures involving pregnant women after mid-gestation. During caesarean deliveries, LUD should be maintained until the baby is delivered; studies have demonstrated improved Apgar scores and reduced neonatal depression in the setting of LUD.[18] Employing LUD is also an essential, initial component of successful cardiopulmonary resuscitation of pregnant patients in cardiac arrest, as the obstructive effects of the gravid uterus on the great vessels attenuate the efficacy of compressions. Occasionally, manual displacement of the uterus to the left, for example, during an acute episode of fetal hypoxia, right uterine displacement, or additional LUD of up to a 30° tilt may be required to relieve IVC compression and maintain maternal and fetal well-being. Assuming the lateral recumbent position or a knee–chest position may also help to maintain CO during procedures, such as spinal or epidural placement.

## Blood pressure and systemic vascular resistance

In general, both arterial blood pressure and SVR decrease during pregnancy, although several factors affect blood pressure measurements, including maternal age, positioning, gestational age, comorbidities, and parity. The systolic and diastolic blood pressures begin to drop at 7 weeks' gestation, but the diastolic pressure decreases to a greater extent, reaching 10 mmHg (1.33 kPa) below baseline at 24–32 weeks. This discrepancy accounts for the slight increase in pulse pressure in the early third trimester. Thereafter, both the systolic and diastolic pressures rise slowly towards prepregnant values, although they increase above baseline during labour. The magnitude of this increase is dependent on the patient's position and the degree of pain she experiences during labour, as well as the intensity of uterine contractions.

SVR begins to decrease as early as 5 weeks' gestation as a result of the potent vasodilating effects of progesterone and prostacyclin and, as pregnancy progresses, the low-resistance uteroplacental circulation. Endothelium-derived factors such as nitric oxide may also initiate vasodilation early in pregnancy. The decrease in SVR rises progressively after 14–24 weeks' gestation, and represents a 21% decrease from baseline by term.

## Blood volume

Cardiovascular changes of pregnancy can be attributed in part to several haematological changes. Plasma volume expands gradually throughout pregnancy, starting as early as 6 weeks' gestation and peaking at 32–34 weeks. Sodium and water retention contribute to an average gain in plasma volume of 1200–1600 mL by the third trimester, which represents roughly a 45% increase above non-pregnant values.[19] A portion of this retained fluid is transferred into the interstitial space as a result of low colloid oncotic pressure during pregnancy. The RBC mass increases also, beginning at 8–10 weeks' gestation, but a disproportionate increase in plasma volume contributes to a relative anaemia of pregnancy. Despite increased erythropoiesis, haemoglobin, haematocrit, and blood viscosity decrease during pregnancy.

## Cardiac evaluation

Cardiovascular changes during pregnancy affect the physical findings on cardiac examination, as well as cardiac diagnostic test results (see Table 2.3). The enlarging uterus shifts the heart to the left, slightly anterior, and in a transverse direction, resulting in a cephalad and lateral shift of the maximal cardiac impulse. The leftward shift also contributes to an enlarged cardiac silhouette on chest radiograph and, as pregnancy progresses, a left axis deviation on electrocardiogram (ECG). Additional changes that may be detected on ECG include sinus tachycardia, premature atrial and ventricular contractions, periods of supraventricular tachycardia and ventricular extrasystoles, shortened PR and uncorrected QT intervals, fleeting ST segment and T wave changes, inverted T waves in leads V1, V2, and, less commonly, V3, an attenuated Q wave in lead aVF, and a Q wave and inverted T waves in lead III. The increased incidence of cardiac arrhythmias during pregnancy is attributed in part to a stretching of the cardiac conduction pathways related to the increased SV and resultant cardiac chamber enlargement, as well as to hormonal and autonomic changes. Pregnant women in their late thirties and forties are more likely to have comorbidities that predispose them to arrhythmias. Women who were successfully treated for heart disease as infants and have

**Table 2.3** Changes detected on cardiac evaluation during pregnancy

| | |
|---|---|
| Left axis deviation by 3rd trimester | Tachycardia, other arrhythmias |
| Left ventricular enlargement | Audible splitting of S1 |
| Prominent jugular venous pulsation | Tricuspid, pulmonic regurgitation |
| Detectable venous hum | Audible 3rd heart sound |
| Audible systolic ejection murmur | Premature atrial contractions |
| Leftward point of maximal impulse | Premature ventricular contractions |

now reached childbearing age may also have arrhythmias and residual cardiac anomalies.

Several additional changes can be detected on cardiovascular examination. The left and right ventricles may be palpable as a result of the hyperdynamic circulation, although palpation becomes more difficult as the breasts and abdomen continue to enlarge. Prominent jugular venous pulsations, basal crepitations due to atelectasis from compression by the gravid uterus, and lower extremity oedema may be among the physical findings during normal pregnancy. Heart murmurs and heart sounds that are difficult to hear in non-pregnant individuals become more audible during pregnancy. A grade II systolic ejection murmur is commonly auscultated over the pulmonary and tricuspid areas, and a third heart sound is often present late in pregnancy. There is an audible splitting of S1 and, in the third trimester, S2, and the venous hum is common in pregnancy. Tricuspid and pulmonary regurgitation occurs in the majority of pregnant patients at term, while mitral valve regurgitation occurs in roughly one-third of patients. Diastolic murmurs may uncommonly be detected as a result of the increased blood flow, but more likely represent pathological conditions that warrant further investigation.

On echocardiogram the left ventricle is enlarged as a result of a 50% increase in mass at term. The eccentric hypertrophy is a result of an increase in the size rather than number of cardiomyocytes. Right-sided regurgitation is commonly detected, and may persist until the early postpartum period. Valvular annular dilatation and, less commonly, a small pericardial effusion of no known clinical significance may also be visualized.

## The respiratory system

The respiratory system undergoes profound hormonal, circulatory, and mechanical alterations during pregnancy. Pregnant women may experience shortness of breath, nasal congestion, tachypnoea, epistaxis, sleep-disordered breathing, snoring, and voice changes, among other signs and symptoms that often worsen as gestation advances. Pregnancy is also accompanied by increased pulmonary blood flow, structural changes to the thoracic and rib cages, a 4 cm elevation of the diaphragm, and alterations in the balance of bronchoconstrictor and bronchodilator prostanoids. Of particular clinical relevance, pregnancy is marked by airway changes that may contribute to difficult and failed intubations, as well as changes in lung function and oxygen consumption that lead to prompt desaturation during periods of apnoea. Maternal weight gain, breast enlargement, predisposition to gastro-oesophageal disorders, and comorbidities, such as obesity and pre-eclampsia, as well as the occasional emergent nature of obstetric cases, compound these challenges.

### Lung volumes and capacities

Alterations in respiratory function during pregnancy can be attributed to anatomical and hormonal changes, as well as to changing metabolic demands. With upward uterine displacement of the diaphragm and a related 35–45% decrease in chest wall compliance, expiratory reserve volume and residual volume fall by 25% and 15%, respectively.[20] As a result, functional residual capacity (FRC) drops markedly after 5 months' gestation, reaching 80% of prepregnancy values by term. Supine positioning, obesity, and the induction of general anaesthesia exacerbate this decrease. Tidal volume (TV) increases by 45% early in pregnancy, primarily as a result of the respiratory stimulant effects of increased serum progesterone levels, while inspiratory reserve volume increases very slightly. Vital capacity and total lung capacity show little to no change (see Figure 2.2). Airflow mechanics, as measured by forced expiratory volume in 1 second ($FEV_1$) and the $FEV_1$/forced vital capacity (FVC) ratio, peak expiratory flow rates, and the shape of the flow–volume curve are also unchanged during pregnancy. These changes in lung volumes, capacities, and airflow mechanics are summarized in Table 2.4.

### Ventilation and arterial blood gases

There are several clinical implications of the changes in lung function during pregnancy. Minute ventilation increases up to 45% above baseline, primarily as a result of the increase in TV from roughly 500 to 700 mL per breath. The increase in minute ventilation, which starts during the first trimester and remains constant or increases slightly towards term, overcompensates for the increased carbon dioxide production during pregnancy and contributes to a decrease in the arterial partial pressure of carbon dioxide ($PaCO_2$), which reaches approximately 30 mmHg (4.0 kPa) already early in pregnancy. An increase in renal excretion of plasma bicarbonate partially compensates for this respiratory alkalosis, but the pH remains slightly more alkalotic than the normal state (see Table 2.5). Respiratory alkalosis results in a leftward shift in the oxyhaemoglobin dissociation curve, increasing the affinity of maternal haemoglobin for oxygen. An increase in erythrocyte 2,3-diphosphoglycerate during pregnancy, though, shifts the curve to the right, favouring oxygen transfer to the fetus (see Figure 2.3). Although alkalosis in the CSF and blood normally suppress hypoxic drive, women experience a twofold increase in the hypoxic ventilatory response during pregnancy.[21]

Pregnancy-induced hyperpnoea also contributes to a change in arterial oxygenation tension. The arterial partial pressure of oxygen ($PaO_2$) increases slightly during pregnancy, ranging from 107 mmHg (14.3 kPa) in the first trimester to 103 mmHg (13.7 kPa) in the third trimester, a process that may facilitate oxygen transfer across the placenta. However, increased oxygen consumption, which reaches up to 60% above baseline at term, may account for a $PaO_2$ of less than 100 mmHg (13.3 kPa) in many pregnant patients by mid-gestation. A lower $PaO_2$ may also result from small airway closure and the related ventilation/perfusion (V/Q) mismatch that occurs when closing capacity exceeds FRC. A reduced CO, as seen when parturients assume the supine position, may further reduce the $PaO_2$.

### Apnoeic hypoxaemia

Decreased FRC, coupled with increased oxygen consumption, results in rapid oxygen desaturation during periods of apnoea in pregnant patients. Labouring, obese, and septic obstetric patients, and, in particular, obese labouring patients, appear to be at greatest risk for developing hypoxaemia rapidly during even short periods of apnoea, such as upon induction of general anaesthesia for caesarean delivery or during eclamptic seizures.[22] Oxygen consumption increases throughout pregnancy and reaches its peak at term, when it averages 331 mL/min at rest and 1167 mL/min with exercise.[23] It increases an additional 40–75% during labour, and even more in obese pregnant women in labour, although these

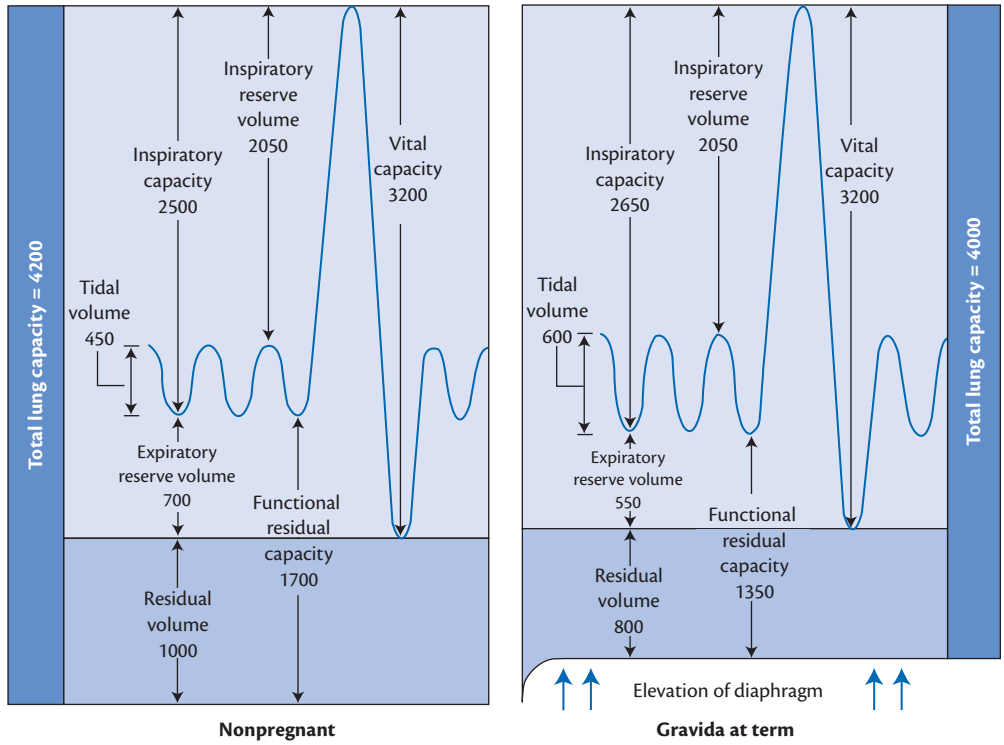

**Figure 2.2** Changes in lung volumes during pregnancy.

increased metabolic requirements can be mitigated by effective analgesia, such as epidural blockade.[24] Simultaneously, parturients have reduced oxygen storage in a smaller FRC. The net effect is a reduced apnoea tolerance in pregnancy and in conditions that contribute to additional imbalances between oxygen consumption and FRC.

Studies have demonstrated that oxygen desaturation occurs more rapidly during periods of apnoea in pregnancy. McClelland and colleagues found that the median time required for arterial oxygen saturation ($SaO_2$) to fall below 90% after complete denitrogenation was 4 min 52 s in pregnant subjects, compared to 7 min 25 s in non-pregnant subjects.[25] All subjects in this simulation study desaturated to an $SaO_2$ below 40% in less time than deemed necessary to resume spontaneous ventilation after the administration of 1 mg/kg intravenous succinylcholine.[26] The study also found that, across all subjects that were preoxygenated, the pregnant subjects desaturated from 90% to 40% $SaO_2$ in 35 s, compared to 45 s in non-pregnant subjects. The labouring patient with a body mass index (BMI) of 50 kg/m$^2$ exhibited the fastest arterial desaturation, falling below 90% in 98 s, compared to 292 s in a standard pregnant patient.[22] These findings highlight the importance of limiting the number and duration of attempts at laryngoscopy and of re-establishing ventilation promptly after unsuccessful intubation. Finally, McClelland et al. demonstrated an almost directly proportional relationship between apnoea tolerance and preoxygenation status, although a plateau was reached in which increasing time spent preoxygenating resulted

**Table 2.4** Respiratory changes during pregnancy

| Lung volumes, capacities, and airflow mechanics | Change |
|---|---|
| Tidal volume | +33–45% |
| Expiratory reserve volume | –20–25% |
| Inspiratory reserve volume | +5% |
| Residual volume | –15–20% |
| Total lung capacity | –5% |
| Vital capacity | No change |
| Inspiratory capacity | +6–15% |
| Functional residual capacity | –20% |
| $FEV_1$ | No change |
| $FEV_1$/FVC | No change |
| Peak expiratory flow | No change |
| Flow–volume loop | No change |

**Table 2.5** Arterial blood gas measurements during pregnancy

| Parameter | Non-pregnant | Pregnant |
|---|---|---|
| pH | 7.4 | 7.4–7.44 |
| $PaO_2$ (mmHg) | 100 | 103–107[a] |
| $PaCO_2$ (mmHg) | 40 | 30 |
| $HCO_3$ (mEq/L) | 24 | 20 |

[a]Note that the $PaO_2$ may vary in each trimester.

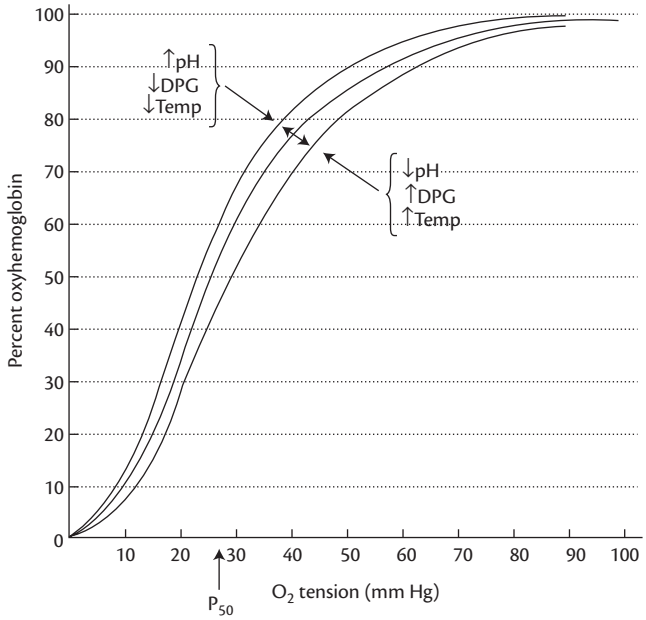

**Figure 2.3** Oxyhaemoglobin dissociation curve.

in gradually less benefit to apnoea tolerance. Two minutes of complete denitrogenation by tidal breathing of 100% oxygen with a tight-fitting facemask, a process that is accelerated by the reduced FRC and increased minute ventilation of pregnancy, provided roughly 3.5–6 min before the $SaO_2$ fell below 90% in normal, healthy parturients at term.[27]

## Airway changes during pregnancy and labour and delivery

Airway changes during pregnancy and over the course of labour and delivery complicate the perioperative management of parturients. Swelling of the oropharyngeal tissue, a decrease in the size of the glottic aperture, and mucosal friability are present from early gestation until several days postpartum, but are most pronounced near term and during labour and delivery. Fat deposition related to maternal weight gain, increased tongue size, an increase in airway connective tissue, fluid retention, capillary engorgement, and decreased soft tissue mobility contribute to these changes. Full dentition in the majority of women of childbearing age, enlarged breasts, inappropriately applied cricoid pressure during attempts at tracheal intubation, and the fact that parturients undergoing emergency caesarean delivery during general anaesthesia are rarely fasted compound concerns about the obstetric airway, particularly for anaesthetists and trainees with little experience administering general anaesthetics to this patient population.

Although recent data suggest that the incidence of difficult or failed intubations in obstetric patients is decreasing, whether or not the maternal airway is more difficult anatomically is still debated in the literature.[28] Using standardized photography, Pilkington and colleagues documented an incidence of 36% and 42% of Mallampati class 3 and class 4, respectively, in obstetric patients at 12 weeks' gestation; the respective rates were 29% and 56% at 38 weeks' gestation, which represent a 34% increase in class 4 airways.[29] A deterioration in airway classification, as manifested by an increased incidence of Mallampati class 3 and class 4 airways and a significant decrease in oropharyngeal area and volume, continues throughout labor, and, in a recent study, was found to be unrelated to the duration of labour and intravenous fluid administration (see Figure 2.4).[30] The presence of comorbidities, such as obesity and pre-eclampsia, and excessive fluid administration may magnify these changes. While an increasing Mallampati score does not necessarily correspond with difficult tracheal intubation,[31] Rocke et al. determined that the relative risk (RR) of difficult intubation in pregnant women with class 3 airways was 7.58 times greater compared with those with class 1 airways.[32] The RR reached 11.3 in pregnant women with class 4 airways, indicating that using various combinations of risk factors may enable preoperative prediction of difficult airway encounters.[32] Because

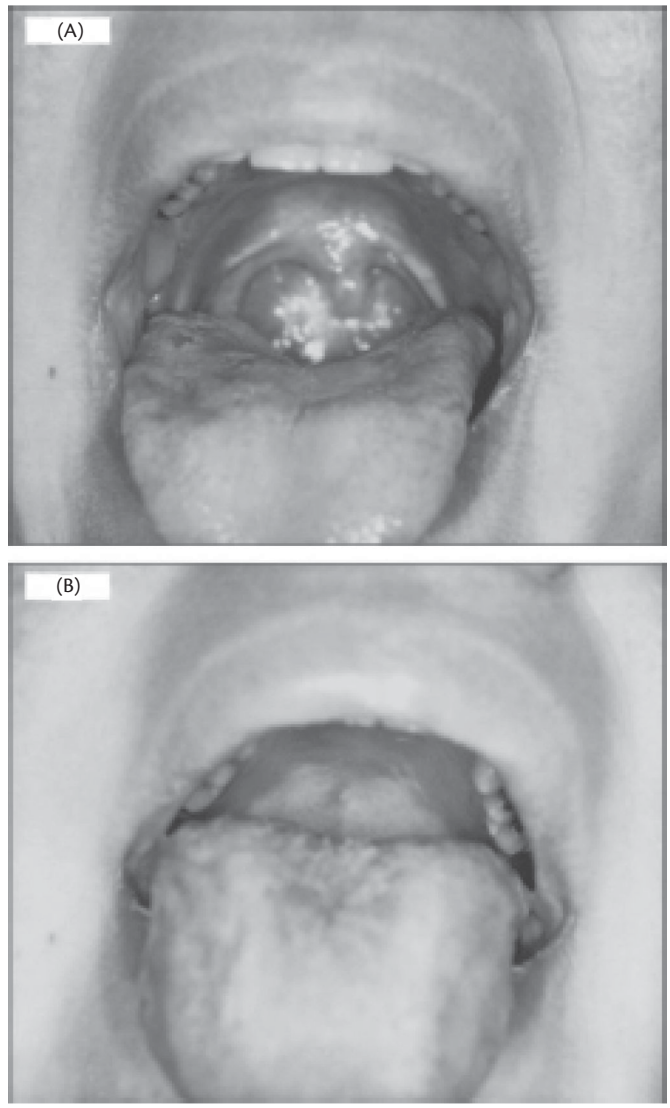

**Figure 2.4** Airway changes during labour and delivery. (A) Prelabour (B) Postlabour.

labour and delivery is associated with additional airway changes, it is essential to reassess the Mallampati classification and other aspects of the airway in labouring women who present for caesarean delivery prior to initiation of an anaesthetic.

Although anaesthesia-related maternal mortality is rare, airway catastrophes remain the leading cause of death from general anaesthesia in the obstetric population.[33] As a result, maintaining constant vigilance and pursuing strategies to manage the obstetric airway are paramount. Access to video laryngoscopes and other airway adjuvants, availability of a short-handle laryngoscope, optimization of maternal positioning and preoxygenation, familiarity with the emergency airway algorithm for obstetric patients, immediate availability of experienced anaesthesia providers, and early initiation of neuraxial blockade in patients with known or suspected difficult airways may help minimize or avoid airway complications in obstetric patients. Avoidance of nasal intubation and nasal suctioning, preparedness to use a smaller endotracheal tube (6.0 or 6.5 mm), and limiting the number and duration of attempts at intubation are essential measures to decrease complications associated with excessive bleeding and airway oedema. Early identification of patients at risk for emergency operations, such as those with dysfunctional labour, ongoing communication with the obstetrics team, and continued vigilance during emergence and recovery, when complications arise with equal or greater frequency,[34] may help to avoid difficulties in the airway management of individual patients. While aspiration prophylaxis, restriction of oral intake of solids, and rapid sequence induction (RSI) with cricoid pressure have never been proven to reduce maternal morbidity,[35] they are still considered by most practitioners to be standards of care.

## Haematology and immunology of pregnancy

Pregnancy is marked by significant changes in plasma volume, RBC mass, and leucocyte number and function, as well as in the delicate balance between clot formation and thrombosis prevention. Notable changes in platelet count and function also affect a small percentage of both healthy pregnant women and those with coexisting disease. Many of these haematological and immunological adaptations to pregnancy prepare the mother for blood loss at delivery and optimize maternal–fetal immunologic interactions. However, they may also predispose the parturient to venous thromboembolism (VTE) during pregnancy and to haemorrhagic complications in the peripartum period. This section reviews the haemostatic system, common platelet disorders, and changes in the immunologic system during pregnancy.

### Haemostasis

The haemostatic system, which establishes a delicate balance between clot formation and prevention of thrombosis, undergoes profound local and systemic changes during pregnancy (see Table 2.6). Broadly speaking, pregnancy is a prothrombotic state associated with increased clotting capacity and decreased anticoagulant and fibrinolytic activity. Concentrations of von Willebrand factor (vWF) and factors VII, VIII, IX, X, and XII increase to varying degrees (see Table 2.7). Fibrinogen (factor I) levels also increase, reaching a mean value of 450 mg/dL during pregnancy.[36] Levels of factors II and V, however, remain stable, and the concentration of factor XI decreases slightly. The activity of anticoagulant protein S declines to roughly one-third of normal during the second and third trimesters, decreasing even further in the setting of caesarean delivery or infection.[37] A related increased resistance to activated protein C contributes to the observed increase in thrombin formation during pregnancy. With regard to proteins that inhibit clot lysis, plasminogen activator inhibitor (PAI) types 1 and 2, triple, if not quadruple, during pregnancy, and peak at term. This increase is attributed to rich sources of PAI-1 in the uterine decidua and to placental production of PAI-2.[38] Venous stasis resulting from compression of the IVC and adjacent vessels by the enlarged uterus further increases the risk of VTE, which may be sixfold higher during pregnancy.[39]

While pregnancy is a prothrombotic state, obstetric complications associated with impaired decidualization or haemorrhage into the decidua may result in massive haemorrhage and disseminated intravascular coagulation (DIC) more swiftly than anticipated. Under normal conditions, a progesterone-mediated increase in tissue factor (TF) and, secondarily, PAI-1 in the uterine decidua serves to mediate haemostasis during the third stage

**Table 2.6** Haematological parameters

| Parameter | Non-pregnant adult | Term parturient | General trend |
|---|---|---|---|
| Erythropoietin (U/L) | 4–27 | 14–222 | Increased |
| Haemoglobin (g/dL) | 12–15.8 | 9.5–15 | Decreased |
| Haematocrit (g/dL) | 35.4–44.4 | 28–40 | Decreased |
| Mean corpuscular haemoglobin (pg/cell) | 27–32 | 29–32 | No change |
| Mean corpuscular volume ($m^3$) | 79–93 | 81–99 | No change |
| Platelet ($10^9$/L) | 165–415 | 146–429 | Decreased |
| RBC count ($10^6$/$mm^3$) | 4–5 | 2.7–4.4 | Decreased |
| White blood cell count ($10^3$/$mm^3$) | 3.5–9.1 | 5.9–16.9 | Increased |

**Table 2.7** Changes in coagulation and fibrinolytic parameters during pregnancy

| Parameter | Change |
|---|---|
| Factor I (fibrinogen) | Increased |
| Factor VII (proconvertin) | Increased |
| Factor VIII (antihaemophilic factor) | Increased |
| Factor IX (Christmas factor) | Increased |
| Factor X (Stuart–Prower factor) | Increased |
| Factor XII (Hageman factor) | Increased |
| vWF (von Willebrand factor) | Increased |
| PAI-1, PAI-2 | Increased |
| Factor II (prothrombin) | No change |
| Factor V (proaccelerin) | No change |
| Factor XI (plasma thromboplastin antecedent) | Decreased |
| Protein S | Decreased |

of labour, protecting the mother from haemorrhagic complications.[40] However, the principal role of decidual TF in maintaining haemostasis is jeopardized in conditions of impaired decidualization, such as placenta accreta, ectopic pregnancy, and placenta praevia. Decidual TF also appears to play a central role in haemorrhagic complications associated with placenta abruption; high levels of TF in the setting of inadequate haemostasis lead to excessive thrombin formation, exhaustion of clotting factors, hypofibrinogenaemia, and, possibly, DIC.[41] Massive haemorrhage from any of several other obstetric complications, including uterine atony, retained products of conception, amniotic fluid embolism, uterine inversion, and birth trauma, as well as from trauma, sepsis, and large-volume blood transfusions may also rapidly evolve into DIC in obstetric patients.

## Physiological anaemia of pregnancy

A disproportionate expansion of maternal plasma volume relative to the increase in RBC mass during pregnancy results in physiological anaemia. Beginning as early as 6 weeks' gestation, plasma volume progressively expands until it reaches 45% above baseline by 32–34 weeks. This increase appears to be mediated by enhanced aldosterone activity, an oestrogen- and nitric oxide-mediated increase in plasma renin activity early in pregnancy, and the reduced plasma osmolality at which vasopressin is secreted during pregnancy, and correlates with the observed increase in plasma-mature adrenomedullin.[42] RBC volume, on the other hand, declines early in pregnancy, reaches prepregnancy values by 16 weeks' gestation, and peaks at term. The ultimate rise in RBC mass to 17–30% above baseline is due to an increase in erythropoietin activity, but does not match the plasma expansion during earlier gestation. Haemodilution results in characteristically lower RBC, haemoglobin, and haematocrit counts, but does not alter the mean corpuscular volume or the mean corpuscular haemoglobin concentration during pregnancy (see Table 2.6). The average haemoglobin concentration of parturients at term is 12.5 g/dL, somewhat above the World Health Organization's cut-off of 11 g/dL for anaemia of pregnancy.[43] Failure to meet the increasing iron, vitamin $B_{12}$, and folate requirements during pregnancy can lead to further declines in haemoglobin and haematocrit concentrations and result in pathological anaemia. Overall, the disproportionate increase in plasma volume and RBC mass observed in normal pregnancy results in decreased blood viscosity, which reduces resistance to blood flow through the uteroplacental circulation, and sufficient hypervolaemia to ensure delivery of vital nutrients to the fetus, maintain maternal blood pressure in the setting of decreased vascular tone, and prepare the mother for blood loss at delivery.

## Platelet number and function

The platelet count falls by an estimated 10% during normal pregnancy, with the greatest drop occurring in the third trimester.[44] However, roughly 8% of pregnant women have or develop some form of more severe thrombocytopaenia, as defined by a platelet count below $150 \times 10^9$/L.[45] Incidental thrombocytopaenia of pregnancy, also known as gestational thrombocytopaenia, affects up to 5% of these patients,[46] and accounts for an estimated 75% of all cases of thrombocytopaenia during pregnancy.[47] This benign condition, which usually presents in the third trimester and resolves within 7 days postpartum, is due primarily to haemodilution that results from the increase in plasma volume during pregnancy.[48] Although the literature is inconclusive, a mild intravascular coagulation within the uteroplacental circulation that leads to increased platelet destruction and that is compensated for by increased, albeit inadequate, platelet production may also play a role in the pathogenesis of gestational thrombocytopaenia.[49] Increased platelet aggregation in response to epinephrine and arachidonic acid, among other things, and an immune-mediated component may further contribute. In general, patients with gestational thrombocytopaenia have no prior history of thrombocytopaenia in the non-gravid state, remain asymptomatic throughout pregnancy, and do not require any medical therapy. Up to one-fifth of these patients may experience a recurrence in subsequent pregnancies, and there is little to no known risk of neonatal thrombocytopaenia in infants born to these mothers. In the absence of a coexisting platelet disorder, patients with gestational thrombocytopaenia usually maintain platelets counts greater than $70 \times 10^9$/L. If platelets fall below this cut-off or if the patient experiences any clinically significant bleeding, other sources of thrombocytopaenia must be considered.

An estimated 25% of the cases of significant thrombocytopaenia during pregnancy are due to disease processes that may lead to bleeding complications in the peripartum period or that may indicate a more complex underlying disorder.[50] Of these, the majority is related to hypertensive disorders of pregnancy, and a small portion is secondary to immune processes, such as idiopathic thrombocytopenic purpura (ITP). ITP, which affects an estimated 2 per 1000 pregnant[51] women, must be distinguished from gestational thrombocytopaenia because of potential, albeit uncommon, bleeding complications for both mother and neonate. Patients with ITP have a history of bleeding in the non-pregnant state, may have platelet counts below $70 \times 10^9$/L, although the median range in one large study was $85 \times 10^9$/L,[52] present with low platelet counts early in pregnancy, and may not experience resolution of the disease after delivery. A mild, progressive decline in count may be observed as gestation advances. Treatment with corticosteroids, intravenous immunoglobulin, immunosuppressive agents, and, in refractory cases, splenectomy, most often in the second trimester, may be necessary, although conservative management of this autoimmune disorder is increasingly common.[53] Because ITP is a quantitative, rather than qualitative platelet disorder, routine management also appears to be appropriate prior to initiation of neuraxial blockade, provided platelet count remains above a certain, practitioner-specific or institutional-specific range. Neonates of mothers with ITP are at risk of thrombocytopaenia; parturients with ITP are at increased risk of peripartum haemorrhage.

## The immune system

The blood leucocyte count rises steadily as gestation advances and during the puerperium, while chemotaxis and adherence functions of some polymorphonuclear leucocytes decrease, starting at the second trimester and continuing until term. Markers of inflammation, such as C-reactive protein, the erythrocyte sedimentation rate, and complement factors C3 and C4, are also elevated to varying degrees at different gestational ages. In general, normal leucocyte counts during gestation range from 5000 to 12,000/μL and average 14,000–16,000/μL during labour and in the early postpartum period. The aetiology of this increase has

not been elucidated, but may be related to a reappearance of leucocytes that had been previously sequestered. The distribution of cell types also changes during pregnancy, as manifested by a significant increase in granulocytes and CD8 T lymphocytes and a sharp reduction in CD4 T lymphocytes and monocytes during the third trimester.[54] Overall, depressed leucocyte function appears to be of little clinical significance, but may account in part for pregnancy-related remission of some autoimmune disorders, as well as the mildly increased susceptibility of pregnant women to certain infections.

The immunology of pregnancy is complex and has not yet been fully elaborated, although several theories have been proposed. Briefly, one long-standing theory regarding how the fetus evades maternal rejection proposes that the placenta serves as a mechanical barrier, barring interaction between fetal antigens and the maternal immune system. However, more recent evidence suggests that the trophoblast–decidual interface is not impermeable, as evidenced by the fact that fetal cells circulate in the maternal blood long after delivery.[55] Another theory proposes that pregnancy is a state of systemic immune suppression, which permits the mother to tolerate the foreign fetus and partially explains the improvement in some autoimmune diseases often observed during pregnancy. However, critics of this theory challenge that an intact maternal immune system appears to evade infection despite chronic exposure to pathogens. Additional theories propose deletion of immune cells that recognize paternal alloantigens from the maternal immune system, a state of localized immune suppression, and a lack of placental expression of certain human leucocyte antigens, among others, and are beyond the scope of this chapter.[56]

## The gastrointestinal system

The gastrointestinal (GI) system undergoes several changes during pregnancy, many of which have been attributed to changes in the hormonal milieu. In general, pregnant women are prone to develop disorders of the oropharynx, ranging from benign changes in taste perception[57] and salivary composition[58] to gingival bleeding associated with periodontal disease; of the stomach, oesophagus, and intestines, such as gastro-oesophageal reflux (GOR), hyperemesis gravidarum, and constipation and bloating; and of the anorectum, including haemorrhoids, anal fissures, proctitis, and faecal incontinence.[59] Mechanical and, primarily, hormonal changes in the GI system that may predispose pregnant women to pulmonary aspiration are of particular clinical relevance to anaesthesia providers.

### Gastro-oesophageal reflux

GOR affects an estimated 30–50% of pregnant women at some stage during pregnancy, although the true incidence may be as high as 80% in some patient populations.[60] While it occasionally represents an exacerbation of pre-existing disease, it most often develops *de novo* during pregnancy, presenting late in the first trimester, worsening as gestation advances, and resolving soon after delivery.[61] Heartburn is a common symptom of reflux, but a small percentage of patients remain asymptomatic throughout pregnancy. Risk factors for symptomatic disease appear to be advancing gestational age, pre-existing GOR, and multiparity, although the data are conflicting.[62]

The pathogenesis of reflux during pregnancy has not been fully elucidated in the literature, but progesterone-induced changes in the lower oesophageal sphincter (LOS) tone are believed to play a primary role. Briefly, in the first trimester of pregnancy the LOS decreases its responsiveness to stimuli that normally serve to increase pressure and minimize reflux. Thereafter, LOS pressure falls progressively until it reaches 30–50% of prepregnancy values by 36 weeks' gestation, and gradually rebounds over the course of 1–4 weeks postpartum.[63] Mechanical displacement of the stomach upward and laterally by the enlarging uterus, most commonly in the second half of gestation, appears to play a secondary role.

The clinical implications of the high incidence of GOR among parturients remain unresolved in the literature. Recent data suggest that reflux is unlikely to be a significant risk factor for pulmonary aspiration, particularly in the setting of normal gastric emptying (see 'Gastrointestinal Motility and Acidity').[64] Indeed, anaesthesia providers routinely anesthetize patients with GOR without using full stomach precautions. In the obstetric population, recent studies have reported the successful performance of caesarean deliveries in healthy term parturients using laryngeal mask airways[65] in lieu of tracheal intubation, as well as the provision of labour analgesia with subanaesthetic concentrations of volatile agents via facemask without adverse sequelae.[66] Increased awareness of nil per os (NPO) guidelines, routine use of aspiration prophylaxis, and the broadening indications for regional anaesthesia in the obstetric population have contributed to a marked decline in the incidence of pulmonary aspiration.

### Gastrointestinal motility and acidity

Recent studies have cast doubt on the traditional dogma that pregnant women have increased gastric acidity, increased gastric volume, and decreased gastric motility, prompting a more liberal approach to full stomach precautions in pregnancy.[67] Historically, pregnancy has been associated with delayed gastric emptying has been attributed to all obstetric patients, presumably due primarily to hormonally induced changes in gastric motility. However, studies that measure gastric transit time by the absorption of orally administered acetaminophen[68] and ultrasound,[69] among other methods, have determined that there is no change in gastric emptying during pregnancy.

Gastric acid production also appears to be either unchanged or decreased during pregnancy. Van Thiel et al.'s early study evaluating gastric pH in pregnant volunteers at 12, 24, and 36 weeks' gestation and at 1 and 4 weeks postpartum found no difference in basal gastric pH or in peak acid output during pregnancy compared with postpartum values.[70] Similarly, a non-invasive radiotelemetry study used to assess gastric acidity and the effects of antacids in term parturients and non-pregnant women found no significant difference in basal gastric acidity between the two subject groups.[71] A study comparing gastric pH in pregnant women scheduled for caesarean delivery and in non-pregnant patients undergoing elective surgery, however, found a slight difference in pH ($2.4 \pm 1.4$ vs $3.0 \pm 1.9$, $P < 0.05$), but no difference in serum gastrin levels.[72] The lower pH among the pregnant patients may be attributable to their higher level of preoperative anxiety. The finding that the frequency and severity of peptic ulcer disease decreases during pregnancy may reflect decreased acid production, although it may be related to diet and other factors.[73]

In contrast to the findings that pregnant women have normal gastric emptying and unchanged or reduced gastric acid production, labouring pregnant women and women who have received systemic[74] or neuraxial opioids[75] have delayed gastric emptying and may be at increased risk for pulmonary aspiration. Carp and colleagues performed ultrasound examinations of the stomach contents in 39 parturients in active labour and found that up to two-thirds of labouring women had evidence of solid food particles, independent of the interval between the last oral intake and the ultrasound scan.[76] Investigators also performed ultrasound examination of stomach contents in postpartum women and non-pregnant volunteers and found that 19 of 20 postpartum patients had food particles in their stomachs 4 hours after a standardized meal compared with 4 of 21 in the non-pregnant group.[77] Gastric emptying returns to prepregnancy measurements within 24 hours after delivery.[78] Gastric pH, which may decrease during labour, has also been found to be similar to that of non-pregnant, fasting individuals scheduled for elective surgery by 18 hours postpartum.[79]

### Aspiration precautions

Many of the traditional pulmonary aspiration precautions have not been proven to reduce the frequency or severity of aspiration, yet there is sufficient evidence that such precautions are reasonable and, in most cases, unlikely to cause harm. Preoperative fasting, pharmacological prophylaxis, and careful patient positioning, among other things, play an important role for anaesthetists caring for pregnant patients who may present at any gestational age for obstetric or non-obstetric surgery under regional or general anaesthesia. Current American Society of Anesthesiologists (ASA) guidelines permit clear liquids during labour, clear liquids up to 2 hours prior to scheduled caesarean delivery, and fatty solids up to 8 hours prior to scheduled surgery. Other national organizations have similar recommendations (see Obstetric Anaesthetists Association guidelines in Appendix 1). In practice, labouring women may be required to refrain from oral intake, although this trend appears to be changing towards a more liberal approach. The ASA Task Force on Obstetric Anesthesia has supplemented these recommendations with an additional aspiration prophylaxis regimen of timely administered non-particulate antacids, $H_2$ receptor antagonists, and/or metoclopramide.[80] A recent review supports the use of $H_2$ receptor antagonists and non-particulate antacids, but found that neither proton pump inhibitors nor metoclopramide was effective, although this observation is not consistent.[81] RSI and maintenance of cricoid pressure until proper endotracheal tube placement is confirmed also remain standards of practice for emergency obstetric surgery and, in most cases, for elective caesarean delivery under general anaesthesia, although inappropriately applied cricoid pressure may cause more harm than benefit and neither practice has been proven to decrease the incidence of aspiration. Other manoeuvers that appear to minimize the risk of aspiration and improve maternal and fetal safety include maintenance of LUD until the baby has been delivered, use of a ramp (such as the Troop Elevation Pillow®) to elevate the patient's shoulders and achieve the sniffing position, and, possibly, positioning the patient in a 20–30° head-up position to lengthen the apnoeic time before hypoxaemia develops.[82] Continued vigilance during extubation, emergence, and recovery is also required.

## Hepatic and biliary function

Hepatic function changes during pregnancy, although hepatic blood flow remains unchanged. The gallbladder also undergoes characteristic changes during pregnancy, many of which predispose pregnant patients to obstetric cholestasis.

### The liver

The liver is displaced in a posterosuperior direction by the gravid uterus, but does not change in size or volume. Hepatic blood flow also remains unchanged during pregnancy, at roughly 25–35% of CO. Hepatic function, however, undergoes significant changes, many of which are reflected in liver function test results (see Table 2.8). Alkaline phosphatase levels increase up to fourfold, primarily due to placental production, and return to normal within 3–6 weeks after delivery. Plasma cholesterol and triglyceride levels also increase from baseline. In contrast, liver transaminases (alanine transaminase and aspartate transaminase) and gamma-glutamyl transferase decline during pregnancy, but may peak in the first several days to a week postpartum, most commonly in response to obstetric interventions, such as caesarean delivery. Serum albumin levels also decline, primarily as a result of increased plasma, contributing to a dramatic decrease in colloid oncotic pressure and predisposing pregnant women to oedema formation. Maternal bilirubin levels remain unchanged during pregnancy, despite transfer of small volumes of fetal bilirubin into the maternal circulation.

Several other changes in liver function are also attributed to increased levels of oestrogen and progesterone. Stigmata associated with advanced liver disease, such as spider naevi and palmar erythema, may be detected in normal, healthy pregnant patients and have no clinical significance in this context.[83] Oestrogen is also believed to accelerate the production of fibrinogen and several other coagulation factors, while progesterone plays a role in the increase in cytochrome P450 isoenzyme levels. Coagulation abnormalities that increase bleeding tendency, though, are not normal in pregnancy and point to underlying disease or the exogenous administration of anticoagulants. Finally, production of specific binding proteins, including thyroxine-binding globulin (TBG) and corticosteroid-binding globulin (CBG), increases during pregnancy, decreasing the free portion of certain hormones.

### The gallbladder

Changes in gallbladder function during pregnancy are attributed largely to elevated levels of reproductive hormones, which

**Table 2.8** Liver function tests during pregnancy

| Test | Result |
|---|---|
| Alkaline phosphatase | 2- to 4-fold increase by term |
| Liver transaminases (ALT, AST) | Decrease by term |
| Cholesterol | Increase |
| Gamma-glutamate transaminase | No change to slight decrease |
| Triglycerides | 2- to 3-fold increase |

contribute to biliary stasis, prolonged intestinal transit, and increased levels of cholesterol in the bile and predispose pregnant and postpartum patients to gallstone formation. A genetic component may render some pregnant women particularly susceptible to the cholestatic effects of reproductive hormones, contributing to the elevated incidence of obstetric cholestasis among certain patient populations, such as women of South Asian and South American descent. Multiparity, advancing gestation, history of cholestasis, twin gestation, and an elevated prepregnancy BMI[84] appear to be additional risk factors for intrahepatic cholestasis of pregnancy.

Parturients with gallbladder disease are more likely than healthy pregnant counterparts to have peripartum complications, such as fetal arrhythmias, meconium-stained amniotic fluid, intrauterine demise, and spontaneous preterm labour, which are thought to be related to elevated maternal and/or fetal serum bile acids.[85] They are also more likely to present to the delivery suite for early induction of labour, most often at 37 weeks' gestation, and to the main operating theatre for cholecystectomy, one of the most common non-obstetric surgeries during pregnancy. During the first year postpartum, gallbladder disease is among the most common non-obstetric cause of maternal hospital admission.[86]

## The genitourinary system

Changes in kidney function and in uterine anatomy and blood flow present early in pregnancy and have profound clinical implications, particularly as gestation advances.

### The upper and lower urinary tracts

Kidney, ureteral, and bladder changes accompany different stages of pregnancy. Anatomically, the kidneys elongate by 1–1.5 cm and increase in volume by 30%, partly in response to a 50–85% increase in renal blood flow (RBF) that starts early in the first trimester, peaks at 26 weeks, and declines slightly at term.[87] Relaxin, a hormone secreted by the corpus luteum, the decidua, and the placenta appears to play a role in the initiation and modulation of augmented renal hemodynamics.[88] Nitric oxide may also play a role, contributing to renal vasodilation and increased renal plasma flow and glomerular filtration rate (GFR). The renal pelvices, calyces, and ureters begin to dilate as early as 7 weeks' gestation due to both the vasodilating effects of progesterone and, later, the mechanical compression of the ureters at the pelvic brim. A protective effect of the sigmoid colon on the left, dextrorotation of the uterus, and positional compression by the right ovarian vein contribute to more marked ureteral dilation on the right. Hormonal changes also affect the bladder and urethral mucosa, which becomes more hyperaemic and congested. Although data are conflicting, the bladder develops an increased capacity and becomes displaced upwards and anteriorly by the gravid uterus; by the third trimester, it protrudes markedly into the abdomen and undergoes additional anatomical distortions. The net result of many of these anatomical changes is an increased incidence of ascending urinary tract infections (UTIs), hydronephrosis, and symptomatic urolithiasis during pregnancy. Indeed, urological emergencies account for a small percentage of the estimated 1–2% of non-obstetric operations among pregnant women reported annually in the United States.

Increased RBF and decreased renal vascular resistance contribute to changes in kidney function during pregnancy. The GFR begins to increase soon after conception, reaches a 40–65% increase above prepregnant levels by the beginning of the second trimester, and tapers, if not decreases, towards term.[89] This increase in GFR, from roughly 100 mL/min to 150 mL/min, leads to a decrease in serum creatinine, urea, and uric acid concentrations and an increase in the urinary excretion of albumin, low-molecular-weight proteins, amino acids, water-soluble vitamins, and glucose. Additional changes in kidney function during pregnancy include alterations in osmoregulation, manifested by decreased serum osmolality, and an increased urinary excretion of bicarbonate, which serves to compensate for the respiratory alkalosis of pregnancy. The decrease in serum bicarbonate that accompanies increased urinary bicarbonate excretion may diminish the buffering capacity of blood. Changes in the renin–angiotensin–aldosterone system contribute to a dramatic plasma volume expansion during pregnancy, and elevated levels of erythropoietin contribute to the expansion in RBC mass that peaks at term.

These changes in renal function result in characteristic clinical and laboratory findings that must be distinguished from pathological states (see Table 2.9). Mild glucosuria is a normal finding during pregnancy and is not diagnostic of diabetes mellitus (DM); by the third trimester, glucose excretion increases significantly in healthy pregnant individuals and may reach three times higher than non-pregnant values. If DM is suspected, a glucose challenge test must be performed. Mild proteinuria below 300 mg/24 h is also common during pregnancy, although further investigation may be warranted to rule out UTIs or previously undetected kidney disorders. Significant proteinuria in the setting of new onset hypertension, however, is highly suggestive of pre-eclampsia. During normal pregnancy, serum albumin decreases in association with plasma volume expansion and increased urinary excretion. An abnormally high urinary excretion of albumin occurs in patients with pre-eclampsia and contributes to more significant intravascular contraction. Serum creatinine and urea levels decrease to 0.5–0.6 mg/dL and 9 mg/dL, respectively, during pregnancy; higher values may suggest underlying renal disease, although they are within normal limits for non-pregnant patients. Sodium retention, which results in part from stimulation of the renin–aldosterone system, contributes to increased total body water and plasma volume. As a result, a mild hyponatraemia develops during pregnancy, and thirst and water retention occur at a different, lower plasma

**Table 2.9** Kidney function during pregnancy compared with the non-pregnant state

| Test | Pregnancy | Non-pregnant |
|---|---|---|
| Plasma blood urea nitrogen | 9–12 mg/dL | 11–20 mg/dL |
| Plasma Cr | <1.0 mg/dL | <1.3 mg/dL |
| Plasma Na | 130–140 mEq/L | 135–145 mEq/L |
| Plasma $HCO_3$ | 18–20 mEq/L | 22–28 mEq/L |
| Urinary protein excretion | <300 mg/24 h | <150 mg/24 h |
| Plasma albumin | 2.5–3.2 g/dL | 3.5–4.5 g/dL |

sodium concentration in pregnant compared with non-pregnant patients.[90] Serum uric acid, which is expected to decrease by roughly 25–30% by mid-gestation, reaches non-pregnant levels by term. Elevated serum uric acid levels may indicate poor kidney function and be suggestive of pre-eclampsia in the setting of new onset hypertension. Tests that are commonly used to evaluate kidney function, such as the Cockroft–Gault formula and the estimated GFR from the Modification of Diet in Renal Disease formula, may not reflect the true GFR during pregnancy.[91] A 24-hour urine collection for creatinine clearance is a cumbersome test of debatable accuracy during pregnancy;[92] if used to assess renal function during pregnancy, a 30% increase above the prepregnancy value should be expected. Finally, the increased GRF may also alter clearance of medications that are excreted through the kidney.

### The uterus

The uterus, normally pear-shaped, expands more in length than width and exits the pelvis by 12 weeks' gestation. Thereafter, it displaces the intestines laterally and superiorly and ultimately rotates rightward in the abdominal cavity, impeded by the rectosigmoid on the left. The term uterus pushes the liver in a posterosuperior direction, forces the diaphragm upward roughly 4 cm, and shifts the heart leftward. When the parturient is erect, the abdominal wall supports the enlarging uterus; in the supine position, the uterus rests on the vertebral column and the great vessels.

Uteroplacental blood flow, derived primarily from the uterine and ovarian arteries, increases from roughly 50 mL/min at 10 weeks' gestation to 450–700 mL/min, or greater, near term. Hormonal-induced increases in arterial diameter and decreases in vascular resistance as gestation advances contribute to this increase. Uterine venous drainage also increases during pregnancy, a process facilitated by changes in venous calibre and distensibility. Uterine blood flow, which is not autoregulated, declines in the presence of factors that increase uterine vascular resistance or decrease perfusion pressure. For example, it decreases during contractions, particularly during prolonged periods of hypertonus, and during episodes of acute or chronic maternal hypertension and hypotension. It also diminishes in response to certain exogenously administered α-adrenergic agonists, including epinephrine used to evaluate intravascular epidural cannulation. Ephedrine is an exception to this generalization on account of its primary β-adrenergic effect.[93]

Modern obstetric anaesthesia practice has changed with the better understanding of factors that affect uterine blood flow. The efficacy of the traditional epidural 'test dose' with an epinephrine-containing local anaesthetic has been challenged in part due to concerns that decreased uteroplacental blood flow may accompany a positive test result. Additionally, concerns about the adverse effects of high levels of circulating maternal catecholamines related to stress or anxiety have led some practitioners to reassess the wisdom of withholding premedications from parturients in certain clinical scenarios. For example, the administration of a single dose of intravenous anxiolytic medication, such as midazolam, during epidural placement for labour analgesia, for pregnant women undergoing non-obstetric surgery, and for patients scheduled for caesarean delivery may be appropriate for individual patients. One double-blinded, randomized, placebo-controlled trial of 60 parturients undergoing caesarean delivery who received either 1 mcg/kg of fentanyl and 0.02 mg/kg of midazolam or placebo immediately prior to spinal anaesthesia found no difference between groups in neonatal outcomes (Apgar score, continuous oxygen saturation, neurobehavioral scores) or maternal recall of the birth.[94] Finally, maternal hypotension related to neuraxial procedures, hypovolaemia, supine hypotensive syndrome, or haemorrhage, among other things, is an important cause of suboptimal uterine blood flow and warrants immediate correction, including maintenance of LUD, appropriately timed intravenous administration of crystalloid or colloid fluids, and appropriate use of vasopressors, to optimize maternal and fetal well-being. It is also important to bear in mind that the increased uterine blood flow at term, which accounts for at least 10% of maternal CO, places patients with obstetric complications at risk for significant haemorrhage. Additional factors that affect uteroplacental blood flow are covered in greater detail in Chapter 3.

## Endocrinology

Pregnant women experience profound changes in glucose metabolism, as well as in thyroid, pituitary, and adrenal gland function. Some of these changes may predispose pregnant patients to disease states, such as ketosis, hypothyroidism, and hyperthyroidism, particularly in the absence of strict glycaemic control and nutritional supplements. They may also adversely affect fetal growth and development.

### Glucose metabolism

Profound changes in maternal metabolism during pregnancy serve to accommodate increased maternal energy needs and fetal growth requirements. In general, pregnant patients experience increased insulin secretion in conjunction with a progressive insulin resistance, as well as fasting hypoglycaemia and postprandial hyperglycaemia. Increased levels of growth hormone (GH), cortisol, and human placental lactogen (HPL), among other diabetogenic hormones, account for the progressive insulin resistance of pregnancy, although the precise mechanism has not been elucidated. Broadly speaking, insulin resistance permits preferential use of fatty acids, triglycerides, and ketone bodies for maternal fuel sources, while preserving glucose and amino acids for the fetus. Fetal glucose levels are maintained at roughly 80% of maternal serum levels by facilitated diffusion across the placenta down a concentration gradient. Amino acids are actively transported across the placenta.

Several factors contribute to decreased maternal fasting glucose, including increased plasma volume, reduced hepatic glycogen stores, and the increasing demands of the fetoplacental unit as gestation advances. The increased fetal needs and accelerated maternal metabolic rate, coupled with relative insulin deficiency and reduced glycogen stores, place the mother at risk for ketosis, particularly during the second and third trimesters. Without adequate oral or intravenous nutrients, the mother may swiftly deplete glycogen stores and resort to lipolysis and ketone body production, a process frequently referred to as 'accelerated starvation of pregnancy'.[95] Changes in postprandial glucose levels, on the other hand, are mild in healthy pregnant women, but may be exaggerated in obese women who exhibit more insulin resistance than non-obese counterparts.

Pregnancy in diabetic patients may be complicated by congenital malformations, prematurity of the newborn, fetal hypoglycaemia, fetal macrosomia, birth related injuries, an increased risk of perinatal mortality,[96] maternal diabetic ketoacidosis (DKA), and an increased incidence of maternal comorbidities, such as chronic hypertension, pregnancy-induced hypertension, and diabetic nephropathy. The likelihood of caesarean delivery and neonatal admission to the intensive care unit is also higher in diabetic parturients compared with healthy counterparts. DKA during pregnancy is associated with a high morbidity and mortality for both mother and fetus, although advances in management have vastly reduced the risk of mortality. As in the non-pregnant population, DKA occurs in the setting of insulin deficiency (relative or absolute) with a concurrent increase in glucagon. Increased glucose production, decreased glucose utilization in the peripheral tissues, and lipolysis with ketone body formation ensue. Sequelae include osmotic diuresis and maternal dehydration, with associated water and electrolyte disturbances, as well as a decrease in maternal pH from ketone body accumulation. If fluid loss is severe, cardiovascular collapse and shock may result. The fetus commonly develops a non-reassuring heart rate pattern, which most often resolves once maternal fluid and electrolyte imbalances are corrected.

Given the sharp worldwide rise in maternal obesity in recent decades, it is likely that obstetric anaesthesia providers will be caring for diabetic pregnant patients both on the labour and delivery unit and in the main operating suites with increasing frequency. It is essential that the anaesthetist bear in mind the type of maternal DM and the nature and extent of end-organ involvement, as well as the patient's medical regimen and most recent glucose level. Management involves balancing insulin therapy in patients with type 1 diabetes to prevent both DKA and hypoglycaemic episodes. For patients with type 2 diabetes, avoiding hyperglycaemic, hyperosmolar syndromes that can lead to dehydration, decreased uterine perfusion, and electrolyte imbalances is essential.[97] Of note, general anaesthesia may mask the signs and symptoms of hypoglycaemia, and patients with autonomic dysfunction related to DM, as well as patients in DKA, may exhibit profound haemodynamic instability following neuraxial anaesthesia. Finally, as the incidence of obesity and type 2 diabetes rises in the obstetric population, anaesthesiologists may encounter additional, related challenges, such as difficulties with the maternal airway, intravenous access, monitoring, positioning, transport, and neuraxial anatomy.

## Thyroid function

Several biochemical changes in thyroid function, many of which are of minor consequence in conditions of iodine sufficiency, occur at different stages of pregnancy (see Figure 2.5).[98] During the first trimester, human chorionic gonadotropin (hCG), which shares structural similarities with thyroid stimulating hormone (TSH, thyrotropin), stimulates TSH receptors in thyroid tissue, leading to a transient increase in free thyroxine ($T_4$). Through a feedback loop, increased levels of thyroid hormones suppress TSH. As a result, between 8 and 14 weeks' gestation, relatively low TSH with mildly elevated free $T_4$ is not uncommon and of little clinical significance. However, certain conditions that are associated with increased levels of hCG, such as molar pregnancy or hyperemesis gravidarum, may cause a prolonged or exaggerated increase in $T_4$ and lead to transient thyrotoxicosis.

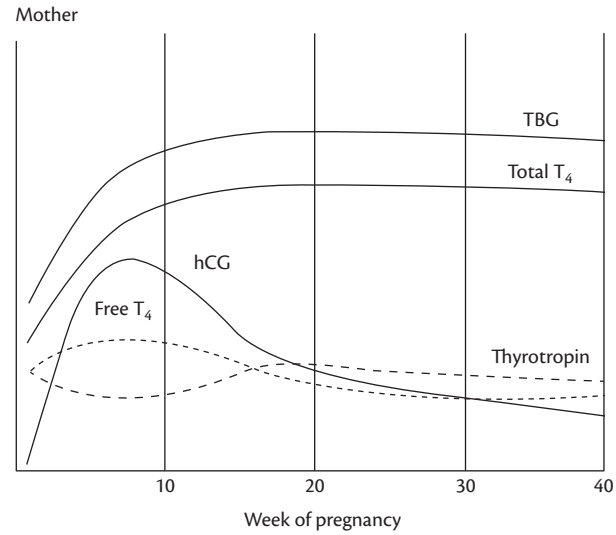

**Figure 2.5** Relative changes in maternal and fetal thyroid function during pregnancy.

Additional changes in thyroid function are related to either rising oestrogen levels or to modifications in the peripheral metabolism of thyroid hormones.[99] Elevated circulating oestrogen promotes increased production of binding proteins, such as TBG, from the liver. The two- to threefold increase in basal TBG leads to a reduction in the free, active thyroid hormones, $T_4$ and triiodothyronine ($T_3$), and, in turn, stimulation of the hypothalamic–pituitary–thyroid axis. Slightly elevated TSH levels are common during this stage of pregnancy, after the first trimester and continuing to term, but generally remain within the reference range. When dietary iodine is plentiful, there is only a mild change in free hormone levels, but several complications related to low $T_3$ and $T_4$ may occur in iodine-deficient states. Of note, total (free and bound) $T_4$ and $T_3$ levels are increased during this stage as a result of the increased production of TBG and reduced clearance induced by the hyperoestrogenic state; it is important to distinguish between free and total thyroid hormone levels and to bear in mind the trimester-specific normative data when interpreting laboratory values.[100] Another change in thyroid activity, most commonly during the second half of pregnancy, is related to the activity of three enzymes that catalyse the deiodination of thyroid hormones. Briefly, two of these enzymes are abundant in the placenta and may alter thyroid hormone levels (low $T_3$ and high reverse $T_3$).

The pathological states that result from iodine-deficient hypothyroidism or from hyperthyroidism, which has multiple possible aetiologies, are of particular clinical relevance to anaesthesia providers. The increase in renal clearance of iodine during pregnancy, in conjunction with increased sequestration of iodine by the feto-placental unit, contributes to iodine deficiency in the absence of nutritional supplements. Reduced dietary iodine results in chronic thyroid stimulation, which manifests with increased TSH, increased thyroglobulin levels in the thyroid gland, and goitrogenesis. In the absence of iodine deficiency, the differential diagnosis of goitre during pregnancy includes Graves' disease, excess

iodine intake, Hashimoto's thyroiditis, lymphoma, and thyroid cancer, among others.

Graves' disease is by far the most common cause of hyperthyroidism during pregnancy, although other aetiologies, such as toxic multinodular goitre, hyperemesis gravidarum, and gestational trophoblastic disease, should be considered in the differential diagnosis.[101] Of these, management of hydatidiform mole poses a particular challenge, as evacuation of molar pregnancy may be accompanied by thyroid storm, trophoblastic emboli, severe haemorrhage, DIC, and cardiopulmonary arrest, among other things.[102] Adequate intravenous access, invasive haemodynamic monitors, immediate availability of blood products, and premedication with antithyroid drugs and beta-adrenergic blockers may be required prior to surgical treatment of a hydatidiform mole.[103]

Thyroid storm, a life-threatening exacerbation of thyrotoxicosis, is rare during pregnancy, but may also be precipitated by labour, caesarean delivery, infection, and pre-eclampsia.[104] Signs and symptoms of hyperthyroidism and this rare complication may be incorrectly attributed to the hypermetabolic state of pregnancy. Sustained tachycardia, weight loss, goitre, ophthalmopathy, GI symptoms, elevated free $T_3$ and $T_4$ with suppressed TSH, and, in the case of thyroid storm, thermoregulatory dysfunction and CNS changes, including delirium and agitation, may be suggestive of active, and possibly life-threatening, thyroid dysfunction. Treatment of pregnant women in crisis is similar to that of non-pregnant patients, and includes propylthiouracil, iodine, dexamethasone, beta-adrenergic blockers, such as propranolol, labetalol, or esmolol, fluid hydration, and nutritional support.[105] Of note, fetal bradycardia, hypoglycaemia, and intrauterine growth restriction are associated with prolonged beta-adrenergic therapy. Successful use of esmolol in a parturient in an acute situation without adverse sequelae to the mother or fetus has been reported.[106]

## The pituitary gland

The pituitary gland enlarges during pregnancy, reaching its peak size in the immediate postpartum period and returning to normal dimensions within 6 months of delivery.[107] Clinically, this oestrogen-mediated hyperplasia results most notably in rising levels of prolactin (PRL) throughout gestation, which may adversely affect pregnant women with pre-existing prolactinomas. In contrast to PRL, GH secretion from the pituitary decreases, starting in the second half of pregnancy when the placenta increases production of a GH variant.[108] Pregnant women with acromegaly, though, will experience an increase in both pituitary and placental GH secretion. Adrenocorticotropic hormone levels increase progressively later in pregnancy, most likely as a result of placental production and despite elevated levels of bound and free cortisol.[109] Other anterior pituitary hormones experience fluctuating levels during pregnancy: TSH levels decline early in pregnancy, but return to the normal range as gestation advances, and luteinizing hormone and follicle-stimulating hormone levels decrease during the first trimester in response to placental sex steroid production.[110] With regard to the posterior pituitary, oxytocin levels increase throughout pregnancy, rising further at term and peaking during the second stage of labour. Arginine vasopressin is released at a lower plasma osmolality and is metabolized more rapidly in pregnant patients compared with non-pregnant counterparts.

Anaesthetic implications of an enlarged pituitary gland, placental production of pituitary hormones, and changes in the hypothalamic–pituitary axis are rare. However, pituitary enlargement may predispose parturients to Sheehan's syndrome, an uncommon hypopituitarism specific to parous women caused by anterior pituitary lobe necrosis in the setting of obstetric haemorrhage.[111] Pregnant patients with acromegaly may experience any of the complications normally associated with the disease, including soft tissue changes, carbohydrate intolerance, overt diabetes, hypertension, and cardiac disease. The soft tissue changes do not appear to affect the genital tract or otherwise complicate vaginal delivery. Pregnancy-related insulin resistance is an additive risk among acromegalic obstetric patients.

## The adrenal glands

The adrenal glands, which are responsible for the production of mineralocorticoids, glucocorticoids, and sex steroids, undergo several changes during pregnancy. Bound and free, metabolically active cortisol levels increase progressively during pregnancy due to a combination of factors, including increased production, an oestrogen-mediated increase in CBG in the liver, and a decrease in metabolic clearance. Urinary free cortisol levels are elevated in parturients due to the two- to threefold rise in cortisol levels by term.[112] Renin activity peaks early in pregnancy and declines in the third trimester, coinciding with a rise in angiotensin II.[113] The net result is that plasma aldosterone levels increase roughly 20 times above non-pregnant levels by late gestation. This increase correlates with other physiological changes of pregnancy, including the increase in GFR and the sharp rise in progesterone, which competitively inhibits both aldosterone-mediated sodium retention and sodium-potassium exchange.[114] Overall, the activation of the renin–angiotensin–aldosterone system during pregnancy appears to result from the decreased vascular responsiveness to angiotensin II, despite elevated levels, and to the related fall in blood pressure.[115] It also contributes to the increase in plasma volume. With regard to sex steroids, testosterone levels are low to normal until late second trimester, but increase thereafter and may exceed non-pregnant values at term.

Of the many physiological and potential pathological changes of the adrenal glands during pregnancy, phaeochromocytomas, which occur in roughly 1 per 50,000 pregnancies, pose particular diagnostic and therapeutic challenges.[116] The typical presenting symptoms, including heart palpitations, headaches, sweating, episodic elevations in blood pressure, nausea, vomiting, and visual changes, may be misdiagnosed as pre-eclampsia/eclampsia or attributed to exacerbations of the normal physiological changes of pregnancy. Plasma catecholamine levels or 24-hour urine testing for catecholamines and their metabolites should be evaluated in all pregnant patients who present with any combination of these signs and symptoms, particularly before 20 weeks' gestation. Magnetic resonance is the imaging test of choice for localization of the tumour, and is considered safe in pregnancy. Ultrasonography, also safe during pregnancy, is not sensitive in identifying extra-adrenal phaeochromocytomas, which comprise roughly 10% of these neuroendocrine tumours. Computed tomography is not recommended due to fetal exposure to ionizing radiation.

## The musculoskeletal system

Pregnant women commonly experience changes in the musculoskeletal system that contribute to a high incidence of low back pain (LBP), distort the anatomical landmarks that are traditionally used to identify the L3–4 interspace, and complicate neuraxial procedures. Hormonal changes are thought to contribute to both LBP and to changes in the perivertebral ligamentous structures. The ligamentum flavum, for example, becomes softer and more difficult to distinguish from other structures during epidural needle advancement. Weight gain during pregnancy, which often exceeds the recommended 12.5 kg, and the progressive accentuation of lumbar lordosis as gestation advances make it difficult for term parturients to attain appropriate positioning during neuraxial procedures and most likely contribute to the perception of narrow interspaces during attempts to initiate epidural placement using the midline approach. The accumulation of adipose tissue in the epidural space may increase the posterior epidural space depth in parturients, as well as alter local anaesthetic dose requirements and spread. Maternal obesity also contributes to an increase in the skin to epidural space distance and presents additional challenges for obstetric anaesthesia providers.

### Maternal obesity

Maternal obesity poses several challenges to obstetric anaesthesia providers. Obese parturients are a high-risk group for perioperative airway catastrophe, often have unidentifiable anatomical landmarks for initiation of neuraxial procedures, and have a higher risk of anaesthesia-related mortality than non-obese pregnant counterparts.[117] Several factors contribute to difficult airway management in this patient population, including a high prevalence of obstructive sleep apnoea, a vastly reduced FRC, increased baseline oxygen consumption, and a predisposition to develop pronounced narrowing of the pharyngeal airway during pregnancy.[118] In addition, maternal obesity is associated with an increased risk of thromboembolism, cardiovascular disorders, hypertensive disorders of pregnancy, and gestational diabetes, as well as a higher risk of emergency caesarean delivery[119] and surgery for postpartum haemorrhage.[120] These and other complications associated with maternal obesity are covered in detail in Chapter 39.

### Low back pain

Back pain may affect over 70% of women at some point during their pregnancy and, based on findings from several randomized controlled trials and prospective cohort studies, appears unrelated to the type of analgesia, if any, received by the parturient.[121] LBP presents in a small percentage of patients towards the end of the first trimester. However, the incidence increases dramatically as gestation advances.[122] Although the severity of LBP improves for the majority of patients after delivery, up to 40% of patients report ongoing musculoskeletal pain during the first 18 months postpartum and up to one-fifth of these women experience severe ongoing LBP.[123] Unfortunately, a large percentage of patients who experience LBP in their first pregnancy will have recurrent symptoms in subsequent pregnancies, and up to 19% of women who experience LBP in an initial pregnancy report avoidance of future pregnancies for fear of recurrent musculoskeletal pain.[124]

The aetiology of LBP during pregnancy is multifactorial, although hormonal and mechanical factors predominate. Relaxin, a hormone known to be involved in pelvic connective tissue remodelling in several mammalian species, appears to contribute, although its role has not been confirmed.[125] The increasing lumbar lordosis as gestation advances, which places additional strain on the lower back and alters the centre of gravity, the increased spinal load related to fetal weight, weight gain during pregnancy, the decreased stability of the pelvic girdle, muscular dysfunction, pre-existing LBP, and maternal age also play a role. Whether mode of delivery affects the incidence of LBP is debated in the literature. However, epidural analgesia does not appear to independently affect the incidence.[126] Regardless of the aetiology, LBP during pregnancy rarely requires medical intervention and responds to postural changes, exercises, and activity. Patient education is another cornerstone in the management of LBP during pregnancy.

## Key points

- The MAC of volatile agents is reduced during pregnancy; the routine administration of <1 MAC, however, may contribute to a higher incidence of intraoperative awareness and postoperative recall among pregnant women.
- Volatile agents contribute to a reduction in both myometrial contractility and myometrial response to oxytocin in a dose-dependent fashion.
- Both plasma volume and RBC mass increase during pregnancy, but the former increases to a greater extent, resulting in a physiological anaemia.
- Airway changes resulting in worsening airway classification have been observed over the course of pregnancy and during labour and delivery. Worsening airway classification appears to correspond with difficult tracheal intubation in pregnant women undergoing caesarean delivery during general anaesthesia.
- Thrombocytopaenia is the most common coagulation disorder during pregnancy. Most pregnant women experience a 10% drop in platelet count. Up to 5% experience gestational thrombocytopaenia, a benign condition that does not require medical therapy or cause clinically significant bleeding.
- Gastric pH and gastric emptying time do not differ significantly between pregnant and non-pregnant patients, but heartburn is relatively common in parturients and may predispose parturients to GOR.
- Uterine blood flow increases to a maximum of 700 mL/min at term, which represents 10% of CO.
- GFR increases by up to 65% above baseline during pregnancy, resulting in serum creatinine and urea levels of 0.5 mg/dL and 9 mg/dL respectively.
- Both decreased FRC and increased oxygen consumption contribute to rapid oxygen desaturation during periods of apnoea during pregnancy.
- CO increases throughout pregnancy, reaching its peak at 80% above prelabour values immediately postpartum as a result of the autotransfusion associated with uterine involution.

- Although blood flow to the liver remains at its prepregnant range of 25% of CO, hepatic function changes dramatically during pregnancy.
- Pregnancy is marked by an increased coagulation activity and decreased anticoagulation and fibrinolytic activity.
- LBP affects an estimated 80% of pregnant patients at some point during pregnancy.
- Obesity, a growing problem among industrial countries, is associated with a higher risk of emergency caesarean deliveries, maternal airway catastrophes, difficult initiation of neuraxial blockade, and maternal mortality.

# CHAPTER 3

# Placenta and uteroplacental perfusion

Marie-Pierre Bonnet and Anne Alice Chantry

## Introduction

The placenta is a dynamic organ from fetal origin with specific characteristics. Its anatomy changes throughout the pregnancy. The placenta has three main functions that are all necessary for adequate embryonic and fetal development: fetal protection and nutrition, and hormonal secretion. The chorionic villus, located in the intervillous space, is the main placental unit implicated in the exchanges between mother and fetus.

Any change in placental development and function can have a negative effect on fetal well-being. Uteroplacental perfusion is the major determinant of fetal oxygenation and nutrient delivery, but due to its limited autoregulation, it is particularly dependent on maternal haemodynamics. Consequently, any significant decrease in maternal blood pressure or cardiac output can affect uteroplacental perfusion and hence can impact on the fetus, with potential lethal consequences for the fetus.

Most anaesthetic drugs, except for neuromuscular blocking agents, can cross the placental barrier and directly affect the fetus. Indirectly, the anaesthetic technique can affect the fetus by disturbing uteroplacental perfusion. As such, anaesthetists caring for pregnant women should have excellent knowledge of the placenta, its function, and the determinants of uteroplacental perfusion.

## Placental development, anatomy, and uteroplacental perfusion

### Early development of the placenta

After being fertilized in the external third of the Fallopian tube, the egg moves towards the uterine cavity. During its progression, the fertilized egg is subject to some intrinsic modifications, the first divisions leading to the blastocyst stage at day 5. The blastocyst corresponds to the primitive stage of the fetus and the placenta, with on one hand, the trophoblast (future placenta and membranes) and on the other hand, the endoderm (corresponding to the future fetus).

Six days after fertilization, the blastocyst joins the uterine epithelium. At that stage, the trophoblast differentiates into an inner layer, the cytotrophoblast, and an outer layer, the syncytiotrophoblast. This syncytiotrophoblast proliferates and penetrates the external third of the endometrium, and then extends to create a sea of circulating maternal blood (lacunar network), establishing the uteroplacental circulation. This process constitutes the beginning of implantation. About 10 days after fertilization, implantation into the endometrium is complete and the syncytiotrophoblast develops all around the egg (Figure 3.1).[1,2]

From day 13, the extravillous cytotrophoblast cells invade the syncytiotrophoblast and are responsible for endometrial spiral uterine artery remodelling. This represents the primary development of the chorionic villi, which constitute the functional units of the human placenta in its definitive structure from 3 weeks of gestation. During the following weeks, part of the modified endometrium, called the basili decidua, forms some incomplete divisions, the septa. A cotyledon is composed of several chorionic villi included between two septa. As the pregnancy goes on, the fetus grows and is progressively exteriorized with its membranes out of the endometrium, while the placenta partly implanted in the endometrium constitutes the functional interface between mother and fetus.

Excessive trophoblastic invasion can be responsible for pathological presentations, such as choriocarcinoma, a malignant trophoblastic cancer deriving from the placenta, or placenta accreta, which is a pathological invasion by the chorionic villi of the superficial myometrium leading to an abnormally deep attachment of the placenta to the uterus.

### Embryology of the uteroplacental perfusion

During the first trimester, placental development occurs in specific and optimum conditions for angiogenesis and vasculogenesis: low oxygen concentrations and anaerobic metabolism.[3,4] From the second week of gestation, clusters of extravillous cytotrophoblastic cells obstruct the diameter of uterine spiral arteries to limit diffusion of nutrients and oxygen towards the developing fetus and to activate remodelling of the endothelium of uterine spiral arteries. This remodelling deeply modifies the structure of the endothelium: cells of the smooth uterine muscle are replaced by cytotrophoblasts and spiral arteries become dilated, inelastic, and non-contractile, resulting in a low-resistance, poorly regulated uteroplacental perfusion. After 3 weeks of gestation, the chorionic villi have their definitive structure (Figure 3.2). The syncytiotrophoblast borders the intervillous space and is directly in contact with maternal blood.

After 10 weeks of gestation, clusters of cytotrophoblasts that were obstructing the spiral arteries progressively disappear and arterial maternal blood fills the intervillous space without resistance. Consequently, the oxygen tension in the intervillous space

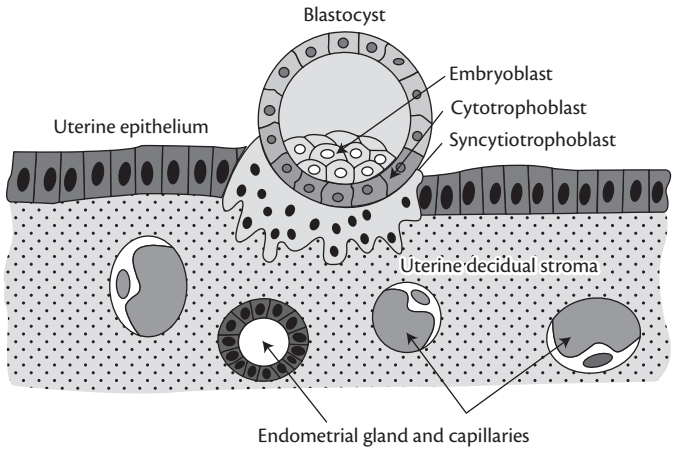

**Figure 3.1** During implantation of the blastocyst, trophoblast cells in direct contact with maternal tissues syncytially fuse and give rise to the syncytiotrophoblast. Only this multinucleated tissue is able to penetrate the uterine epithelium and to implant the developing embryo.

increases throughout the first trimester of pregnancy from 2.7 to 8.0 kPa (20 mmHg to 60 mmHg).[5] Maternal placental circulation is fully established at the end of the first trimester of pregnancy. Thereafter, the placental structure remains stable. However until the end of pregnancy, chorionic villi continue to grow, divide, and become more numerous, parallel to the increasing needs of nutrient, exchange, and endocrine functions of the placenta.

Abnormal trophoblastic invasion of the endometrium could have different consequences. Insufficient trophoblastic invasion induces abnormal remodelling of the uterine spiral arteries and generates low placental perfusion and placental hypoxia. This phenomenon not only impacts on fetal development, with an increased risk of fetal growth restriction, but it can also be responsible for maternal endothelium dysfunction leading to pre-eclampsia.[6,7] Pregnancy hypertensive disorders appearing before 34 weeks of gestation are related to an abnormal trophoblastic invasion,[8] whereas pre-eclampsia occurring after 34 weeks of gestation seem to be associated with normal trophoblastic invasion in the first weeks, but with late atherosclerotic changes in spiral arterioles.[9,10]

## Macroscopic anatomy of the placenta

The placenta constitutes the interface between the fetus and the endometrium. Placentation can take place anywhere in the uterine

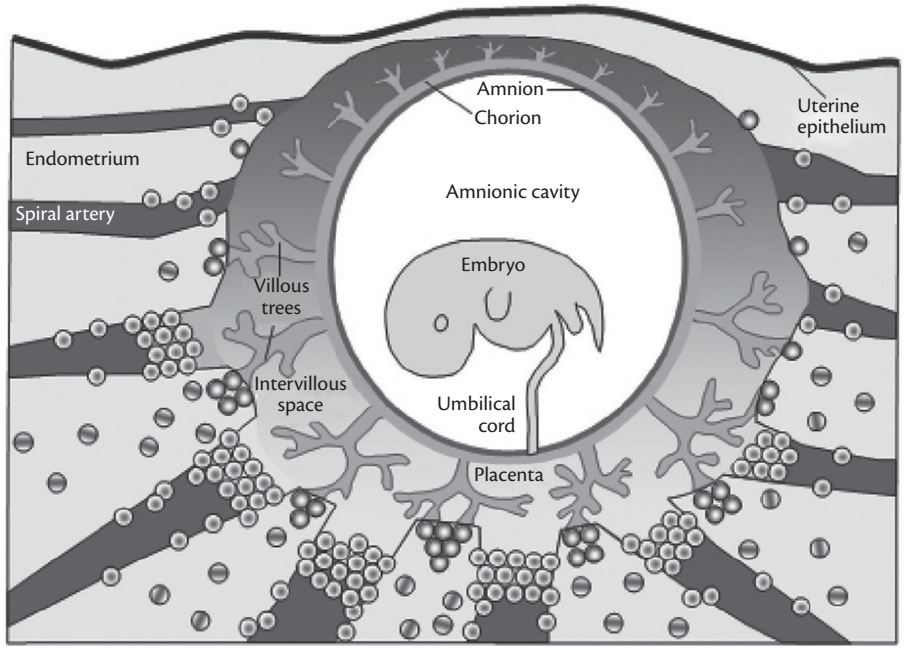

**Figure 3.2** Schematic representation of the developing embryo and its surrounding tissues at about 8–10 weeks of pregnancy. The amnionic cavity with the embryo inside is marked off by the amnion that has already contacted the chorion. From the chorion, villous trees protrude into the intervillous space where some villi have direct contact with the basal plate (anchoring villi). At these sites, trophoblastic cell columns are the source for all extravillous trophoblast cells invading maternal tissues. Interstitial trophoblast cells derived from these columns invade endometrium and myometrium, while a subset of these cells penetrates the spiral arteries first as intramural and then as endovascular trophoblast cells. Onset of maternal blood flow into the placenta starts in the upper regions of placenta (the abembryonic pole) where development is slightly delayed. The local high concentrations of oxygen contribute to the regression of villi at the abembryonic pole. This in turn leads to the formation of the smooth chorion, the fetal membranes.

cavity, but is generally located on the upper third of the cavity and extends towards the uterine fundus. In case of placenta praevia, the placenta is implanted in the lower segment of the uterus (0.3–3% of pregnancies), and induces a risk for severe obstetric haemorrhage. This pathological placental localization can also be responsible for fetal malposition and fetal growth restriction, due to the low vascularization of this uterine area.

The human placenta is haemochorial, meaning that maternal blood directly bathes fetal tissues. Until 9–10 weeks of gestation, its structure is very thin. From 12 weeks of gestation, it grows dramatically, reaching at that time 18–20 cm in diameter and being 3 cm thick. At term, its weight is normally equivalent to a sixth of the fetal weight, from 400 to 600 g. But the placental weight/fetal weight ratio changes throughout pregnancy: during the first trimester, the placenta weighs more than the fetus; then from 14–16 weeks of gestation the placental weight/fetal weight ratio is around 1; and afterwards, the fetus becomes heavier than the placenta. This ratio reflects fetal well-being and is an indicator of an ongoing healthy pregnancy.

The mature placenta has two different faces. The chorionic face is the smooth fetal face, which is composed of two membranes: the amnion and the chorion. Made up of different layers, the amnion is the thin inner membrane (0.02–0.5 mm),[11] directly in contact with the amniotic fluid and covering the umbilical cord. It delimits the amniotic cavity. The outer membrane in contact with the endometrium becomes the chorial plate of the placenta. On the fetal side of the placenta, fetal vessels deriving from the umbilical vessels can be observed. These vessels also vascularize the chorion and transfer nutrients by diffusion to the amnion. The Benckiser syndrome is a fetal haemorrhage, often severe, resulting from the rupture of one or more velamentous praevia fetal vessels.

On the other placental side, called the maternal side or basal plate, cotyledons can be seen. These cotyledons result from the pooling of numerous villous trees tightly packed together. The basal plate is composed of modified endometrium and is in contact with the myometrium during the whole pregnancy. After birth, as a result of uterine contractions, the basili decidua (modified endometrium) separates from the myometrium for placental delivery.

The intervillous space, the place where maternofetal exchange occurs, is exactly localized between the chorial plate and the basal plate.

## Anatomy of uteroplacental perfusion

Fetal–maternal exchange occurs in the intervillous space containing the chorionic villi. Its overall surface is estimated at 12 $m^2$ at term, whereas the functional surface of exchange is estimated at 1.8 $m^2$. The intervillous space overall contains a total volume of 150 mL of maternal blood, renewed three or four times per minute. The intervillous space is perfused by the uteroplacental arteries, derived from the remodelling of the uterine spiral arteries, which are themselves branches of the hypogastric arteries. Ovarian arteries also contribute for a small proportion to uteroplacental perfusion (10–20%). Uterine blood flow represents 3.5% of cardiac output in early pregnancy and 15–20% at term.

Oxygenated maternal blood comes from the uterine spiral arteries into the intervillous space, exchanges occurring at the level of the chorionic villi. Nutrients and oxygen enter the embryonal circulation by allantoidal vessels, future umbilical vessels (one vein, two arteries) coming from the terminal portion of the abdominal aorta or primitive arteries of the fetus. In the fetal vascular system, the umbilical vein transports the oxygenated blood and the umbilical arteries drain the fetal blood poorly concentrated in oxygen. This blood goes back to the basal plate through the intervillous space and is drained by uteroplacental veins located in the endometrium, and then by the uterine veins.

## Regulation and measurement of uteroplacental perfusion

To maintain normal oxygen and nutrient delivery to the feto-placental unit, the uteroplacental perfusion increases 15–20-fold during pregnancy. At term, it represents 15–20% of cardiac output. Due to the trophoblastic endothelial invasion and functional denervation of the spiral arteries, the uteroplacental circulation is usually considered as maximally vasodilated, with little or no ability for autoregulation. As a consequence, the uteroplacental perfusion mainly depends on maternal blood flow, and a decrease in uteroplacental perfusion can be observed in different circumstances (Table 3.1):

- Any significant maternal hypotension (i.e. in case of maternal hypovolaemia, sympathetic blockade in the context of neuraxial anaesthesia or analgesia, use of vasodilatory drugs, or aorto-caval compression syndrome).
- Excessive vasoconstriction of the uterine arteries secondary to maternal hypertension, use of vasopressors, or catecholamines. Changes in $PO_2$ and $PCO_2$ can also have an impact on spiral artery tone: chronic hyperoxia and hypocapnia induce a decrease in uteroplacental perfusion.
- Frequent and prolonged uterine contractions and uterine hypertonus decrease uterine venous return and can also reduce uteroplacental perfusion.

Any change in uterine circulation directly impacts on the intervillous circulation. But even if the uteroplacental circulation is a widely dilated low-resistance system with a perfusion that is largely pressure dependent, there is still a place for moderate regulation. Prostacyclin and nitric oxide, by maintaining vasodilatation and inducing refractoriness to vasoconstrictor substances

**Table 3.1** Causes of decreased uteroplacental perfusion

| | |

| Increased uterine venous pressure | Frequent and prolonged uterine contractions/ uterine hypertonus<br>During uterine contractions |

such as angiotensin II,[12] seem to play a major role in the control of the fetoplacental circulation. Prostacyclin is a prostaglandin $I_2$ usually produced by the vascular endothelium. During pregnancy, production of prostacyclin increases because of uterine vascular production.[13] Similarly, the endothelial synthesis of nitric oxide by the uterine arteries increases during pregnancy secondary to a greater nitric oxide synthase activity.[14]

Uteroplacental perfusion can be evaluated by various methods. The most common one is Doppler ultrasonography.[15] Measurement of red blood cell velocity of blood flowing through the uterine arteries allows estimation of uteroplacental blood flow. Moreover, several indices of vascular impedances can be calculated by using the arterial velocity waveform: the Pulsatility Index (PI), calculated as the difference between the peak systolic and the end diastolic flow velocity, divided by the mean flow velocity, and the Resistance Index (RI), estimated by comparing systolic and diastolic waveforms. Normally, the uterine vascular bed is a low-resistance circuit and flow continues throughout diastole. As resistance increases, diastolic velocity decreases in relation to systolic flow and the RI increases. Finally, Doppler ultrasonography is a non-invasive method that gives rapid results but with some limitations: the reproducibility of the measurement greatly depends on the examination of the same portion of uterine artery, precise measurements are also required otherwise inducing large errors in blood flow estimation. These limitations should be kept in mind when interpreting uteroplacental blood flow by Doppler ultrasonography.

## Placental physiology

Placental functions differ with species, and results from animal studies should be interpreted with caution. The human placenta has multiple functions: it acts as a barrier, and an endocrine organ, and it is responsible for transfer of respiratory gases and nutrients to the fetus.

### Transport mechanisms through the placenta

Substances are transported through the placenta by different mechanisms:

#### Passive diffusion

Passive diffusion is mainly driven by the concentration gradient across the membrane, without expenditure of cellular energy. It includes molecules of low molecular weight and not linked to proteins. Most drugs are transferred by this mechanism.

#### Facilitated diffusion

As for passive diffusion, the concentration gradient is responsible for the transfer through the membrane but with a maximum rate (saturation), determined by the number of membranous carrier protein complexes ('facilitators') and by the interaction between the carrier and the substance being transported. This is the main transportation route of relatively lipid-insoluble molecules. Some other substances can also be transported linked to another molecule, mostly sodium, whose concentration gradient facilitates the transfer of the first substance (secondary active transport or co-transport), and without cellular energy expenditure.

#### Active transport

Active transport involves the transport of a substance across cell membranes needing a protein membrane carrier, and requiring cellular energy. Usually, it occurs against a concentration, electrical, or pressure gradient. These protein carriers protect the fetus against foreign and potentially teratogenic compounds.

#### Pinocytosis

In pinocytosis, molecules are surrounded by the cell membrane, and can cross the cytoplasm to fuse with the other side of the cell. This process requires energy and concerns large molecules.

Several factors impact on the transplacental transfer of a substance and can affect maternal–fetal exchange (Table 3.2):

- Molecular weight and lipophilic quality of the substance: provided the molecular weight is lower than 1000 Da, the lower the molecular weight, the greater the diffusion; highly lipid-soluble drugs penetrate the cell membrane easily, but can also lead to trapping of drugs within placental tissue.
- Maternal and fetal plasma pH changes the ionization of drugs according to their pKa. Fetal pH is lower than maternal pH. Weak bases are more ionized and accumulate in the fetus. Fetal acidosis greatly enhances maternal-to-fetal transfer of basic drugs, such as local anaesthetics and opioids ('ion trapping').[16]
- Protein binding: only the free part of the drug diffuses through the placenta, in particular for non-lipophilic or ionized molecules. Plasma protein concentrations and in particular albumin and alpha-1-glycoprotein concentrations in the mother and the fetus influence the placental transfer of the drug. Typically, albumin concentration is higher in fetal plasma than in maternal plasma. Consequently the fetal concentration of a substance with strong binding to albumin will be higher than its concentration in maternal blood. Fetal blood typically contains 40% of the alpha-1-glycoprotein maternal concentrations.
- Maternal plasma concentration of the substance, and the kinetics of its concentration (depending on the dose, and on the mode of administration). Both define for a substance a fetal exposition time.

**Table 3.2** Major maternal factors modifying transplacental transfer of a substance

| Factor | Increased transplacental transfer | Decreased transplacental transfer |
|---|---|---|
| Molecular weight | <1000 Da | >1000 Da |
| Lipid solubility | Lipophilic | Hydrophilic |
| pH vs pKa determining the amount of ionized drug | High proportion of un-ionized drug<br>Fetal acidosis | High proportion of ionized drug |
| Protein binding | High unbound fraction<br>Alpha-1-glycoprotein binding | Low unbound fraction<br>Albumin binding |
| Maternal plasma concentration | High | Low |
| Uteroplacental blood flow | High | Low |
| Placental fixation and metabolism | Low | High |

- Uteroplacental perfusion, directly influencing the transfer of lipophilic substances, but with a weak impact on low lipophilic and ionized substances.
- Surface and thickness of the exchange zone, particularly in the context of vasculoplacental pathology (pre-eclampsia).
- Placental fixation or metabolism of drugs (e.g. corticosteroids).

## Protective functions of the placenta

The placenta is an imperfect protective barrier for the fetus against substances circulating in the maternal blood: many small xenobiotics cross the placenta by simple diffusion, and some bigger ones can be transported by specific systems. However, several protective mechanisms also take place in the placenta, reducing the transfer of some potentially toxic substances. One of these protective systems is the production of cytochrome P450 isoenzymes, metabolizing certain drugs and xenobiotics.[17] There are also export pumps on the maternally facing membrane of the syncytiotrophoblast, such as multidrug resistance proteins, placenta-specific ATP-binding cassette proteins, breast cancer resistance protein, and mitoxantrone resistance-associated protein.[18] These pumps remove toxic substances from the fetal circulation.

Most proteins cannot cross the placenta barrier. But maternal antibodies, mainly immunoglobulins G, are transported through the placenta by pinocytosis and provide passive immunity to the fetus. However, some virus, such as *Cytomegalovirus*, rubella, varicella, polio, coxsackie viruses, and, in a minority of cases, HIV (1.5–2% of pregnancies in HIV-positive mothers[19]), can infect the fetus. Generally, bacteria and parasites do not cross the placenta. Only *Toxoplasma gondii* and *Treponema pallidum* can be transmitted to the fetus through the placenta.

Thus, the protective role of the placenta is not perfect, and the best protection against maternal–fetal transmission of infection is primary prevention.

## Placental endocrine functions

The placenta has polyvalent endocrine functions. It produces peptide and steroid hormones (Table 3.3), essential for pregnancy, and some placental proteins, whose role is still not well defined.

From a very early stage in pregnancy, the placenta produces progesterone and oestrogens by converting steroid precursors with placental enzymes. Then, it releases them into both maternal and fetal circulations. The corpus luteum also produces progesterone, but by the ninth week of gestation, it atrophies and the placenta becomes the main producer of circulating progesterone and oestrogens. Peptide hormones, close to the hypothalamic and hypophyseal hormones, are also secreted by the placenta, such as placental growth hormone (GH), human chorionic gonadotropin (hCG), human placental lactogen, and a number of growth factors (endocrine gland-derived vascular endothelial growth factor, epidermal growth factor, insulin-like growth factors, and platelet-derived growth factor). All of these factors play a key role in embryonic and fetal growth and allow the placenta to influence and control the fetal environment.[20]

Progesterone inhibits uterine contractions. Oestrogens act as specialized growth hormones for the mother's reproductive organs.[21] hCG helps prolong the life of the corpus luteum in early pregnancy. With oestradiol and glucocorticoids, it also stimulates the cytotrophoblast cell fusion and the functional differentiation of the villous trophoblast.[22] Human placental lactogen modulates embryonic development and stimulates the production of insulin-like growth factors, insulin, adrenocortical hormones, and pulmonary surfactant.[23] It may also play a role in angiogenesis.[24] Placental GH may be involved in maternal adjustment to pregnancy and in placental development via an autocrine or paracrine mechanism.[25]

**Table 3.3** Main endocrine functions of the placenta

| Hormones | Functions |
|---|---|
| **Steroids** | |
| Progesterone | Inhibition of uterine contractions |
| Oestrogens (oestrone, oestradiol, oestriol) | Growth hormone for the mother's reproductive organs (breasts, uterus, cervix and vagina)<br>Stimulation of the cytotrophoblast cell fusion and of functional differentiation of the villous trophoblast |
| **Peptide hormones** | |
| Placental growth hormone (GH) | Maternal adjustment to pregnancy<br>Placental development<br>Stimulation of the production of insulin-like growth factors |
| Human chorionic gonadotropin (hCG) | Prolongation of the life of the corpus luteum<br>Stimulation of cytotrophoblast cell fusion and of functional differentiation of the villous trophoblast |
| Human placental lactogen | Modulation of embryonic development<br>Stimulation of the production of insulin-like growth factors, insulin, adrenocortical hormones and pulmonary surfactant<br>Angiogenesis |
| **Growth factors** | |
| Endocrine gland-derived vascular endothelial growth factor (EG-VEGF)<br>Epidermal growth factor (EGF)<br>Insulin-like growth factor (IGF)<br>Platelet-derived growth factor (PGF) | Role in fetal-placental growth throughout gestation |

## Metabolic functions of the placenta

Apart from its protective and endocrine functions, the placenta is responsible for all exchanges between the mother and the fetus. This organ provides oxygen, water, carbohydrates, fatty acids, amino acids, vitamins, minerals and other nutrients to the fetus from the maternal circulation. Simultaneously, it removes carbon dioxide and other waste products from the fetal circulation. The placenta also requires oxygen and nutrients for itself, and removes its own metabolites.

### Transfer of respiratory gases

The respiratory function of the placenta is five times less efficient than the lung for oxygen transfer, but the large surface of exchange partly compensates for this. Oxygen diffusion through the placenta is poor, and oxygen transfer mainly depends on oxygen partial pressure gradient between maternal blood in the spiral arteries (13.3 kPa) and fetal blood (2.2–3.7 kPa). Despite low oxygen partial pressures in the intervillous space, the fetal oxygen blood content is high enough (23 mL per 100 mL of blood) to provide aerobic metabolism. Indeed, the oxygen affinity is higher for fetal haemoglobin than for maternal haemoglobin, and the fetal haemoglobin concentration is between 17 and 20 g/dL. In case of maternal anaemia, a 50% or more decrease in haemoglobin maternal level is needed to impact on fetal oxygen transfer. Oxygen transfer from the mother to the fetus is about 80 mL/min, for a fetal oxygen consumption of 8 mL/kg fetal body weight.[26] A rate-limiting factor for oxygen transfer is the uteroplacental perfusion. Fetal hypoxia is observed in case of a 50% or more decrease in uteroplacental blood flow. Conversely, carbon dioxide is 20 times more diffusible than oxygen and haemoglobin affinity for carbon dioxide is lower for fetal haemoglobin than for maternal haemoglobin.

### Transport and metabolism of carbohydrates

For the fetus, the main source of energy is glucose. As fetal gluconeogenesis is very poor, fetal glucose mainly comes from the maternal circulation. Glucose transfer occurs via facilitated diffusion with a number of glucose transporters (GLUTs) involved, located both at the maternal blood-facing and the fetal capillary-facing membranes of placental tissues. Cellular distribution of GLUTs changes during pregnancy, suggesting modifications in their functions between early and late pregnancy.[27] Only 28% of the absorbed glucose is transferred to the fetus, due to placental glucose consumption.[28]

### Transport and metabolism of amino acids

Amino acids are needed for fetal protein synthesis and metabolism. As amino acid concentration is higher in the umbilical venous blood than in the maternal blood, transport of amino acids from the mother to the fetus is active, involving amino acid transporters that require energy coming from the large sodium gradient generated by Na,K-ATPase pumps.[29]

### Transport and metabolism of lipids

As they are lipophilic, the large majority of free fatty acids cross the placental membrane through a simple passive diffusion mode, except arachidonic acid, which is actively transported.[30]

## Transplacental transfer of anaesthetic drugs

The study of placental drug transfer encounters several methodological limitations: first, wide interspecies variation in placental anatomy and physiology limit the extension of results from animal to human studies;[31] second, experimental studies on drug transport performed on human placental slices or isolated villi, membrane vesicles, homogenates, or tissue culture cells do not take into account the dual perfusion (maternal and fetal) of the placenta *in situ*; finally, due to ethical concerns for maternal and fetal safety, clinical studies are rarely performed. Most of the time, data on the placental transfer of anaesthetic agents have been extrapolated from measurements of drug concentrations in the maternal and umbilical cord blood at the time of delivery allowing the calculation of the ratio of umbilical vein/maternal artery or vein concentrations. This ratio, called the fetal/maternal (F/M) ratio, is used as a surrogate of drug transplacental transfer, the umbilical vein blood concentration representing the fetal blood concentration of the drug. For a given drug, a high F/M ratio suggests a high placenta transfer. Large inter- and intra-individual variations of these ratios reported across studies highlight the fact that maternal and fetal concentrations are also influenced by maternal drug metabolism, the placenta, the fetus, and by intrapartum changes. Consequently, these kinds of studies need large numbers of study subjects. *In vitro* models of dual-perfused human placenta have also been developed and are now validated for the study of maternal–fetal transport. Placental transfer can also be reported as a ratio referred to as the index transfer. This is defined as the ratio of the drug clearance/reference compound clearance (i.e. creatinine, or tritiated water) and allows interplacental comparisons. Transplacental transfer of the main anaesthetic drugs has been studied using these types of methods.

With the exception of neuromuscular blocking agents, all anaesthetic drugs are lipophilic and consequently migrate through the placental barrier. However, the placenta itself may take up highly lipophilic drugs, creating a placental drug depot that limits placental transfer of these drugs. Major characteristics of drug transfer for anaesthetic drugs are listed in Table 3.4.

### Hypnotic drugs

The high lipophilic properties of induction agents enhance their transfer across the placenta.

Thiopental is the most widely studied anaesthetic drug. The thiopental F/M ratio is between 0.43 and 0.96, 1–3 minutes after its intravenous administration.[32] Thiopental is a highly protein-bound drug. Consequently, its transplacental transfer is strongly affected by maternal and fetal protein concentrations, with a greater free fraction in fetal blood (33). Thiopental transplacental transfer is higher than for midazolam (F/M ratio = 0.66) (34). However, due to its possible negative effect on the fetus, administration of midazolam to the mother is not recommended.[35]

For etomidate, the F/M ratio is 0.5, 6–10 minutes after injection,[36] but the use of etomidate for induction of anaesthesia is not recommended, as it has been associated with fetal transient hypocorticoid syndrome.[37]

Propofol F/M ratios between 0.2 and 0.8 have been reported 4–10 minutes after its intravenous administration.[38–40] The transplacental transfer of propofol is strongly influenced by maternal and fetal protein concentrations, placental clearance of propofol increasing with increasing fetal albumin concentrations. The free propofol concentration remains unchanged, indicating that the pharmacological effects of propofol on the fetus can be expected to be fairly constant and predictable based on maternal propofol concentrations.[41]

### Inhalation anaesthetic agents

Due to their high liposolubility and low molecular weight, inhaled anaesthetic agents cross the placenta very easily. In case of caesarean delivery under general anaesthesia, a prolonged induction–delivery time interval may induce neonatal general

**Table 3.4** Placental transfer of anaesthetic drugs

| Drug | Molecular weight (Da) | pKa | Lipid solubility | % protein binding | F/M ratio |
|---|---|---|---|---|---|
| Thiopental | 132 | 7.6 | 580 | 75 | 0.4–0.9 |
| Propofol | 178 | 11 | 4700 | 98 | 0.5–0.8 |
| Morphine | 285 | 7.9 | 1.4 | 30 | 0.61 |
| Fentanyl | 336 | 8.4 | 816 | 84 | 0.37–0.57 |
| Sufentanil | 386 | 8.0 | 1727 | 93 | 0.81 |
| Remifentanil | 376 | 7.1 | 50 | 70 | 0.55–0.88 |
| Suxamethonium | 399 | – | – | – | 0.02 |
| Rocuronium | 530 | – | – | 30 | 0.16 |
| Atracurium | 145 | – | – | 80 | 0.07 |
| Cisatracurium | 929 | – | – | – | – |
| Vecuronium | 558 | 8.9 | 16 | 90 | 0.11 |
| 2-Chloroprocaine | 271 | 8.9 | 0.14 | – | – |
| Lidocaine | 234 | 7.9 | 2.9 | 64 | 0.5–0.7 |
| Bupivacaine | 288 | 8.2 | 28 | 96 | 0.2–0.4 |
| Levobupivacaine | 288 | 8.1 | 28 | 97 | 0.3 |
| Ropivacaine | 274 | 8.0 | 3 | 90–95 | 0.2 |

anaesthesia. The transplacental transfer of nitrous oxide is very rapid, with an F/M ratio of 0.8 within 3 minutes of continuous inhalation.[42] There is no available data on the F/M ratio of desflurane and sevoflurane.

## Opioids

Transplacental transfer of lipophilic opioids mostly depends on the fetal pH and protein concentrations; it increases in case of fetal acidosis.

Sufentanil is the most lipophilic opioid currently used. An F/M ratio of 0.81 has been reported. Its transplacental diffusion is limited by linking with alpha-1-glycoprotein and its placental capture.[43]

Fentanyl is a highly lipid-soluble drug with high albumin binding. After maternal epidural administration, the F/M ratios reported are between 0.37 and 0.57,[44] but compared to sufentanil, fentanyl has lower lipophilic solubility. Consequently, in case of epidural or intrathecal administration, there is less binding of fentanyl onto the spinal cord, resulting in a higher systemic concentration and hence increased fetal fentanyl exposure.[44]

For remifentanil, the F/M ratio is around 0.55 when administered as patient-controlled analgesia for labour,[45] and 0.88 when it is given as a continuous intravenous infusion before or during caesarean delivery. It is rapidly metabolized by fetal esterases or redistributed, hence limiting its effects on the neonate.[46]

Morphine is a hydrophilic compound that exhibits membrane-limited transfer, with low placental tissue content and a fast washout. An F/M ratio of 0.61 has been reported 30 minutes after its intravenous administration.[47] Following morphine intrathecal administration, the Umbilical artery/maternal artery ratio is around 0.92, but the absolute fetal morphine concentrations are lower than those inducing neonatal side effects. The placental transfer of morphine is apparently not affected by the administration of naloxone.[47]

## Muscle relaxants

As muscle relaxants are fully ionized components, their transplacental transfer is very low. For succinylcholine, the F/M ratio is of 0.02. Succinylcholine is not detected in the umbilical venous blood after a single injection with a dose lower than 300 mg.[48] Concerning non-depolarized muscle relaxants, the F/M ratios are also very low, between 0.07 (atracurium) and 0.11 (vecuronium), but the fetal blood concentration increases over time.[49] No data are available on placental transfer of rocuronium. Maternal administration of muscle relaxants has no impact on neonatal well-being.

## Local anaesthetics

Local anaesthetics readily cross the placenta by simple diffusion. Even if there are differences in structure and lipid solubility between ropivacaine and bupivacaine, their placental transfer is comparable.[50] After epidural administration of bupivacaine, the F/M ratio is 0.31.[51] After intrathecal administration, this ratio is 0.34. Plasma umbilical venous bupivacaine concentration after intrathecal anaesthesia is 7% of that found after epidural anaesthesia.[52]

Lidocaine is bound to alpha-1-glycoprotein that decreases during pregnancy, leading to a higher free fraction of lidocaine in pregnant women than in non-pregnant controls.[53] In the acidotic fetus, 'ion trapping' phenomenon of local anaesthetic drugs is observed: as their pK is close to the physiologic pH, decreases in fetal pH increase the proportion of ionized local anaesthetic drugs, resulting in a large amount of local anaesthetic in fetal plasma. This phenomenon is classically described with all local anaesthetics and in particular with lidocaine.[16,54] For chloroprocaine as for lidocaine and bupivacaine, placental transfer increases linearly as the fetal pH decreases. But conversely to these two local anaesthetics, clearance of chloroprocaine does not return to

baseline when fetal pH is restored to 7.4. Maternal protein binding limits placental transfer of lidocaine and bupivacaine, but not of chloroprocaine.[16]

## Conclusion

The placenta is a dynamic organ with a complex structure constituting the anatomical and functional connection between the mother and the fetus. The main functional units of the placenta are the chorionic villi located in the intervillous space. The placenta helps to protect the fetus against some xenobiotics and infectious agents. Moreover, it releases many hormones involved in the development of pregnancy. Finally, the placenta provides oxygen and nutrients to the fetus while removing carbon dioxide and other waste products to ensure fetal growth.

As autoregulation of the placental circulation is limited, maternal haemodynamic status and uteroplacental perfusion should be kept stable to avoid any impact on fetal well-being, in particular while performing general or neuraxial anaesthesia.

With the exception of muscle relaxants, all anaesthetics drugs easily cross the placenta, and anaesthetists should be aware of their potential complications for the fetus and neonates.

# CHAPTER 4

# Fetal and neonatal physiology

Thierry Girard and Thomas Erb

## Fetal growth

Fetal development can be divided into different stages. During the embryonic period, which consists of the first 8 weeks, development of all major organ systems begins and crown–rump length (CRL) of the embryo is approximately 3 cm. The most accurate assessment of gestational age is by first-trimester ultrasound measurement of CRL (Tables 4.1 and 4.2).[1,2] The embryonic period is followed by the fetal period which is characterized by rapid body growth and differentiation of tissues and organ systems. Increase in weight and length is especially high during the third trimester as body stores of protein, fat, iron, and calcium are considerably enlarged.[3]

Overall, growth represents an interaction of genetic, epigenetic, and environmental factors, and endocrine and nutritional factors appear to be of critical importance. Exposure to teratogens *in utero* as well as antenatal illnesses and exposure to hazardous substances can have a negative influence on growth and development. Phases of growth occur within specific time intervals, affecting cell division and differentiation. Before and after birth, growth is mainly promoted by insulin-like growth factor 1 (IGF-1). Postnatal growth is dependent on growth and thyroid hormones.

Growth rate is highest during fetal life. Postnatally it is most pronounced directly after birth. The full-term infant adjusts growth to achieve a growth rate that will be followed for most of their childhood.

## Respiratory system

### The fetal lung

#### Developmental stages

Fetal lung development undergoes different stages, starting with the pseudoglandular period (5–16 weeks' gestation) where branching morphogenesis begins with the left and right main bronchi being formed out of the two bronchial buds. The two main bronchi then divide into secondary bronchi, which in turn continue branching into segmental and then terminal bronchi.[4] By 16 weeks, around 22 orders of branching airways are in place and major blood vessels have developed. In the canalicular period (16–26 weeks' gestation) each terminal bronchus dissects into at least two respiratory bronchioles, which consequently divide into three to six alveolar ducts. During this phase, blood supply steadily increases and a rapidly increasing number of capillaries are formed in the mesenchyme surrounding the airways. Towards the end of the canalicular period, differentiation of epithelial cells into types I and II begins. Type II epithelial cells produce surfactant, a phospholipid-rich fluid, which aids in reducing surface tension at the air–alveolar barrier.[3,5] The large majority of epithelial cells, however, thin out as type I epithelial cells. In the mature lung, these are flat cells that are part of the alveolar–capillary membrane, the blood–air barrier. By the end of the canalicular period the alveolar–capillary membrane is developed to such an extent as to enable gas exchange.

In the terminal sac or saccular period (24 weeks' gestation until birth), terminal sacs are formed as primitive alveoli. Due to their rapid maturation, fetal lungs reach a state by the 28th week of gestation where sufficient gas exchange in the primitive alveoli is possible in order for the premature infant to survive. With birth, however, lung development is not terminated, around 50 million alveoli (merely one-sixth of the alveoli found in the adult) are already developed.[6] During the alveolar period, which starts in the last few weeks of pregnancy and includes the first years after birth, the number of terminal sacs continues to grow. Millions of new primitive alveoli continually develop, which grow into respiratory bronchioles and eventually mature alveoli. The blood–air barrier continues to mature over the following years which leads to a significant gain of surface area. The large majority of primitive alveoli (around 85–90%) are formed during the first half year of life and the adult quantity of around 300 million alveoli is nearly reached at 18 months.[6] Lung growth goes on for approximately 15 more years until the chest is fully grown.

#### Fetal lung fluid

The fetal lung is filled with fetal lung fluid (FLF) which consists of a high chloride concentration, some protein, mucus from bronchial glands, and surfactant. It keeps the fetal lungs distended and can be thought of as a frame around which especially distal parts of the lungs can develop. Quantity and secretion rate of FLF increases with continuous growth of the fetus.[7] Volume is kept within physiological limits through distending pressure generated by liquid secretion and resistance to liquid efflux through the larynx.[8] The secreted liquid is passively moved into the trachea and oropharynx, where it is either swallowed by the fetus or released into the amniotic cavity.[3] FLF is an essential prerequisite for normal lung growth.

#### Changes at birth

A reduction of liquid secretion can start in the days preceding delivery and is intensified during labour[9,10] Removal of FLF occurs through a combination of mechanical drainage and liquid absorption across the lung epithelium. Only a small amount of fluid is thought to be expelled during birth.[11] Epithelial transcellular sodium channels are expressed, which drive liquid from the lumen into the interstitial space.[7] From there, pulmonary blood

**Table 4.1** Crown–rump length (CRL) measured by ultrasound. Values are median, as well as 5th and 95th percentile

| Gestational age (days) | CRL mean (mm) | CRL 5th/95th percentile |
|---|---|---|
| 50 | 10 | 5/15 |
| 60 | 20 | 15/25 |
| 70 | 30 | 25/35 |
| 80 | 50 | 40/55 |
| 90 | 65 | 55/75 |
| 100 | 80 | 75/90 |

and lymph capillaries start resorbing most of the fluid. These mechanisms are activated by a raise in perinatal epinephrine, vasopressin, cortisol, and aldosterone levels characteristic for labour and delivery.[12]

Partial pressure of oxygen ($PO_2$) ranges from 23 to 25 mmHg (3.0–3.3 kPa) before birth and augments to about 100 mmHg postnatally. This causes an acceleration of active liquid absorption. In the term infant, all lung fluid is absorbed after 2 hours of spontaneous breathing.[7] Premature infants can have difficulties with liquid removal and infants born by elective caesarean delivery are at increased risk for postnatal respiratory problems.[13]

## Surfactant

Pulmonary surfactant reduces surface tension at the physicochemical boundary between respiratory gases and respiratory epithelium in the lungs. Surfactant, which is synthesized, stored and secreted by type II alveolar epithelial cells, mainly consists of phospholipids as well as some proteins and carbohydrates.[14] Morphology of type II cells changes significantly in late gestation and surfactant production increases.[3]

### Corticosteroids

Antenatal corticosteroids have been given to women at risk for preterm labour for almost 40 years. Dexamethasone and betamethasone are most commonly used and show similar results (reduction of respiratory distress syndrome and intraventricular haemorrhage). Usually two doses are administered 24 or 12 hours apart. A repeat dose of betamethasone administered to women who remain at increased risk for early birth may be beneficial.[15,16]

Glucocorticoids influence gene expression and lead to gluconeogenesis, lipolysis, and proteolysis and are immunosuppressive. In the fetal lung, protein and phospholipid synthesis are accelerated and production of surfactant is stimulated.[17] There is, however, also an influence on antioxidant enzyme production, FLF absorption, and development of the lung.[18]

**Table 4.2** Table of fetal growth. Values are the 50th percentile (P10/P90)

| Gestational age (weeks) | Weight (kg) | Length (cm) | Head circumference (cm) |
|---|---|---|---|
| 24 | 0.65 (0.55/0.8) | 32 (29/34.5) | 22 (20.5/23.5) |

## Oxygen transport

### Fetal oxygen transport

Fetal haemoglobin F (HbF) has a substantially higher affinity for oxygen when compared to adult haemoglobin (HbA). Fetal oxygenation occurs via the umbilical vein following placental diffusion of oxygen. The $PO_2$ pressure gradient directly affects mitochondrial oxygen uptake. As gestation progresses, fetal blood oxygen affinity is gradually reduced and 2,3-diphosphoglycerate (DPG) levels rise. Near-term erythropoiesis synthesizes mainly HbA. At term, HbA constitutes one-quarter of total haemoglobin.

### Changes at birth

After birth, $PO_2$ increases significantly to values of 80 mmHg and higher and at the same time neonatal metabolism and muscle activity lead to a substantial increase in oxygen consumption. A radical change in oxygen-carrying parameters is needed. Haemoglobin oxygen affinity quickly decreases. This is partly caused by an increase of 2,3-DPG levels. $P_{50}$ (the oxygen tension at which Hb is 50% saturated), which is at 19.4 mmHg on the first postnatal day, increases to adult values of around 27 mmHg within the first 4–6 months. HbF is continually replaced with HbA and by 12 months, HbF is reduced to 2% of total hemoglobin.[3] Low-birth-weight preterm infants have lower 2,3-DPG concentrations, lower $P_{50}$, and higher Hb F levels, resulting in a smaller oxygen-unloading capacity.

## Control of breathing

### Fetal breathing movements

The traditional belief was that breathing begins after birth, but breathing movements are already in place long before birth. Fetal breathing movements occur in episodes of rapid eye movement (REM) sleep; they are irregular and end abruptly. During fetal breathing movements, the laryngeal abductor muscles are simultaneously activated.[19] Respiratory movements stimulate lung development and condition respiratory muscles.[20] Fetal breathing movements may also serve to sustain FLF volumes and consequently help uphold the degree of lung expansion needed for normal lung growth.[21]

### Spontaneous breathing

The mechanisms that initiate spontaneous breathing at birth are unknown. The widespread opinion has long been that labour and delivery cause transient fetal hypoxaemia. This was thought to stimulate peripheral chemoreceptors and consequently lead to an induction of extrauterine continuous breathing. Breathing was then thought to be continued postpartum through a series of other stimuli such as low temperatures and touch.[22] Later studies, however, have refuted this theory. Neither chemoreceptors[23]

nor sensory stimuli have any influence. Breathing can already be initiated *in utero* through cord occlusion or by raising arterial $PO_2$.[24]

### *Neonatal breathing*

Irregularities in breathing pattern frequently occur in neonates and especially in preterm infants.[25,26] During periodic breathing, phases of normal breathing alternate with apnoeic episodes of 5–10 seconds.[27] In term infants, periodic breathing is of no concern, as respiratory pauses are short and usually only cause a negligible decrease in heart rate. Apnoea, however, can lead to significant bradycardia especially in small preterm infants. Sleep state has a modulatory effect on quality of breathing. There are four different sleep states: quiet, REM, transitional, and indeterminate. Neonates spend around 30% of total sleep in the three phases of quiet, REM, and indeterminate sleep. With ageing, the percentage of REM sleep decreases and quiet sleep increases. During a REM sleep period, breathing can be completely irregular, leading to lower $PO_2$ values and hyperactive peripheral chemoreceptors.[28] Periodic breathing can be seen as a marker for apnoea, particularly in REM sleep. In healthy preterm infants, apnoea is most commonly of central origin but obstruction may contribute in a minority of cases.[29,30]

## Cardiovascular system

### Fetal circulation

Vascular development sets off early after gastrulation. Following differentiation and development of endothelial cell populations, two different processes are involved in blood vessel formation: vasculogenesis (*de novo* organization of blood vessels) and angiogenesis (remodelling and sprouting of pre-existing vessels.) Remodelling and maturation are mediated by molecular signals, influenced by many factors including hypoxaemia and haemodynamic forces.

Fetal circulation is unique in several aspects: on one side the fetus is connected to the placenta by two umbilical arteries and one umbilical vein. Oxygenated blood gets to the fetus via the umbilical vein and desaturated blood returns to the placenta via the umbilical arteries. On the other side, fetal circulation is characterized by three shunts, the ductus venosus, the oval foramen, and the ductus arteriosus, all serving to supply oxygen-sensitive organs (i.e. the brain and myocardium) with highly oxygenated blood (Figure 4.1).

Most of the blood from the umbilical vein bypasses the liver through the ductus venosus directly into the inferior vena cava. Only a small proportion of total blood flow goes into the liver passing the sinusoids and mixing with blood from the portal circulation. Of note, a sphincter mechanism located at the junction of the umbilical vein to the ductus venosus regulates the blood flow to the liver sinusoids. Furthermore, this mechanism is also of importance in the prevention of a sudden cardiac volume overload, as it closes if venous return following a uterine contraction is significantly increased. In the inferior vena cava, oxygen-rich blood blends with desaturated blood returning from the lower extremity and passing into the right atrium. In the heart, the majority of this blood passes through the oval foramen, an interatrial connection located in the atrial septum, to the left atrium and then left ventricle to be ejected in the ascending aorta. As the carotids and the coronary arteries are the first to diverge from the aortic arch, their areas of supply are best supplied with oxygen.

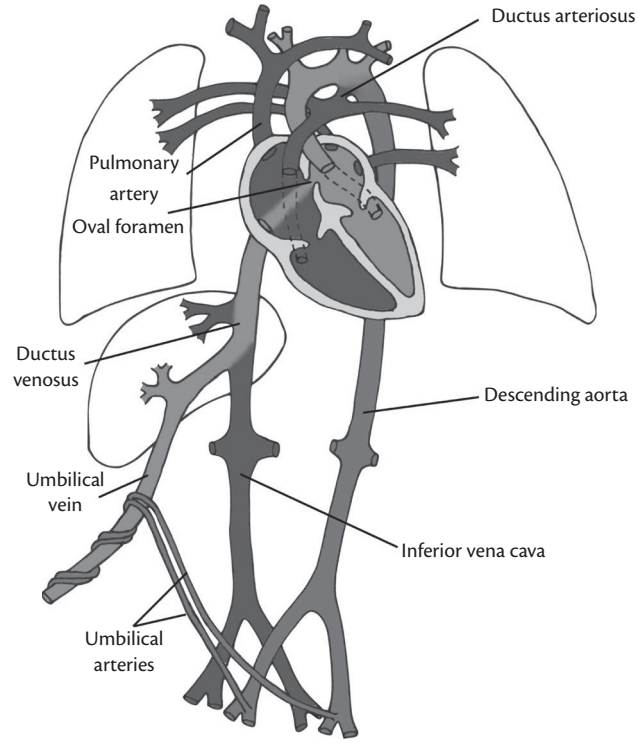

**Figure 4.1** (See colour figure section). The fetal circulation before birth. Fetal circulation is characterized by three shunts: (1) ductus venosus, (2) oval foramen, and (3) ductus arteriosus. Blood flow is directed to bypass the liver in the ductus venosus. From the right atrium oxygenated blood flows through the oval foramen into the left atrium, left ventricle, and into the aorta.

The third shunt, the ductus arteriosus, is a blood vessel connecting the pulmonary artery with the aortic arch. Because pulmonary vessels in the fetus have a high resistance, most of the blood from the right ventricle bypasses the not yet functioning lungs directly to the aorta. Only a small fraction of the blood circulates through the lungs and returns via pulmonary veins to the left atrium. In the umbilical vein, the oxygen saturation of the placental blood is about 80%. This high saturation is progressively reduced as this blood progresses through the fetal circulation mixing with desaturated blood in several places, first in the liver from blood returning from the portal system, then as previously mentioned, further mixing with deoxygenated blood takes place in the inferior vena cava as well as in both atria and finally at the border where the ductus arteriosus merges with the aortic arch. Blood returning to the placenta in the umbilical arteries has a saturation of about 55–60%.

### Blood pressure

Blood pressure is maintained within a physiological range by neural, hormonal, and metabolic mechanisms interacting locally and in particular on a central level.[31] A variety of peripheral sensors (arterial baroreceptors, chemoreceptors to measure $PO_2$, $PCO_2$, and pH, and mechanoreceptors to measure changes in blood volume) constantly monitor blood circulation and modulate the release of vasoactive hormones and autonomic tone to the heart

and the blood vessels.[32] Reflex arcs are integrated in central nervous cardiovascular centres. These mechanisms can already be found in the fetus and subsequently in the neonate. However, the newborn's capability to maintain adequate blood pressure and blood flow to the organs can be impaired if maturation is incomplete.[3]

### Arterial baroreflex

Arterial baroreceptors sense changes in vascular stretch in correlation to arterial pressure. This information is transmitted to the central nervous system, where parasympathetic and sympathetic activity is regulated.[31] Activation of the autonomic nervous system influences heart rate, contractility, peripheral vascular resistance, and effectively regulates arterial pressure oscillations.

Resets of the baroreflex to higher pressures arise at several occasions in the development (*in utero*, immediately after birth, and postnatally with increasing maturation) characterized by changes of the relationships of the arterial pressure—heart rate and of the pressure—sympathetic/parasympathetic nerve activities.[33,34]

### Cardiopulmonary reflex

Cardiopulmonary mechanoreceptors located in the four cardiac chambers, the great veins, and in the lungs respond to changes in blood volume by eliciting reflexes with effects on systemic haemodynamics. However, variations of total body water and intra- and extracellular fluid composition are large during fetal development and in the newborn.[35] This also affects the sensitivity of the cardiopulmonary baroreflex which also remains immature in the neonate.[3]

### Peripheral chemoreflex responses

Peripheral chemoreceptors are functional in the fetus and neonate. However, sensitivity and activity are reduced directly after delivery. This condition persists for the first postpartum days until an adaptation and resetting to higher oxygen tension levels takes place.

### Sympathetic nervous system

The sympathetic nervous system is considerably activated at birth, accompanied by a significant release of catecholamines.[36,37] This contributes to a number of haemodynamic changes, in particular heart rate, peripheral vascular resistance, and redistribution of blood flow.[38] Lung inflation and increased arterial oxygen tensions appear to have a negligible effect[39] whereas the change of ambient temperature that occurs at birth has been shown to induce sympathoexcitatory responses.[40]

### Humoral influences

The renin–angiotensin system is of importance during early intrauterine development, primarily influencing organogenesis.[41] With ongoing maturation, the predominant role is the adjustment of cardiovascular and renal parameters. Of note, renin plasma activity is highest during the first month of life, decreases significantly during the first year, and continues to decrease until adulthood.[42] Prematurely born children show considerably high activity levels which correlate inversely with postconceptual age. It remains obscure why renin activity is higher in young infants. Corticosteroids are essential for an infant's normal development. Endogenously produced cortisol is vital in facilitating changes in autonomic and baroreflex functions during maturation. Adrenal steroids have been shown to have a significant effect on blood pressure[43] and fetal exposure to exogenous glucocorticoids increases arterial blood pressure significantly affecting autonomic and endocrine control of cardiovascular function[44,45] which may persist after exposure. Nitric oxide (NO) is of importance in regulating fetal blood pressure and organ-specific vascular resistance. Acute blockade of endogenous NO production instantly leads to an increase of blood pressure and umbilico-placental resistance and consecutively decreases heart rate, renal blood flow velocity, and plasma renin concentration.[46]

## Changes at birth

With birth, a series of alterations transform the fetal circulation into the mature pattern dividing circulation into separate pulmonary and systemic components.

### Closure of ductus arteriosus

The process of closure of the ductus arteriosus starts almost directly after birth. There are two consecutive steps to the closing process. First, 'functional' closure takes place when the lumen is closed through constriction of smooth muscle in the first hours after birth.[3] This process is induced amongst other factors by an increase in arterial $PO_2$, a decrease in blood pressure caused by the decrease in pulmonary vascular resistance, and a decrease in prostaglandin $E_2$ ($PGE_2$) and quantity of $PGE_2$ receptors.[47] Over the course of the next few days, 'anatomical' closure takes place by a remodelling of the vascular walls. This includes thickening of the intima and loss of smooth muscle cells in the inner muscle media.[3] Complete obliteration takes at approximately 1–3 months, the obliterated ductus forms the ligamentum arteriosum.

#### *Persistent ductus arteriosus*

In 50% of term babies, the ductus arteriosus closes within the first 24 hours, and in almost all cases, closure has occurred within 3 days of birth. A persistent ductus arteriosus (PDA) is more commonly observed in preterm babies, especially in those with severe respiratory distress.[3] Here the down-regulation of $PGE_2$ receptors is reduced and local vasodilatory effects of $PGE_2$ persist.[3] Other factors that increase the risk of PDA are late-onset septicaemia,[48] small size for gestational age,[49] or excessive administration of fluid during first days of life.[50] Infants that are not caucasian or were given glucocorticoids before birth are less prone to be affected by PDA.[51,52]

### Closure of oval foramen

With closure of the ductus arteriosus blood flow in the lungs increases heavily, consequently leading to an increased pressure in the left atrium. At the same time, the pressure in the right atrium decreases. In combination with an infant's first breath this results in the oval foramen's septum primum being pressed against the septum secundum, resulting in a functional closure. Physiologically, the oval foramen is permanently obliterated after about 1 year through fusion of the two septa. In about 20%, complete obliteration does not occur, resulting in a patent foramen ovale.

### Closure of umbilical vessels and ductus venosus

Umbilical vessels are highly vasoactive and able to constrict so effectively that blood flow may become completely impaired. During normal conditions *in utero*, the umbilical vessels

predominantly remain in a state of almost complete relaxation in order to guarantee an adequate supply to the fetus.[3] Within the first minute after birth, blood flow is already reduced to less than 20% of normal fetal values. Similar to the closure of the ductus arteriosus, the umbilical arteries close shortly after birth through contraction of the smooth musculature in the vessel walls. Closure is thought to be mediated by a combination of different stimuli. These include thermal and mechanical parameters and a shift in oxygen tension, which then influence vasoactive agents such as bradykinin or serotonin.[53,54] Locally produced substances such as serotonin or mechanical stretching might also be responsible for closure.[54] Permanent obliteration by fibrous proliferation occurs around 2–3 months after birth. In the neonate, proximal parts of the umbilical arteries convert to the superior vesical arteries and distal sections become the medial umbilical ligaments. Closure of the umbilical vein and the ductus venosus take place briefly after that of the umbilical arteries. The obliterated umbilical vein transforms into the ligamentum teres hepatis and the obliterated ductus venosus forms the ligamentum venosum.

## Integumentary system

The skin is a complex organ with many critically important functions, some of which include maintaining fluid homeostasis, temperature regulation, and sensation. It acts as a physical barrier between the inside of the body and its environment and serves to protect an organism against possibly threatening surroundings. Besides its barrier functions it also serves as an indispensable tool in social interactions, behavioural communication, and perception.[55]

### Epidermal barrier

The most outward layer, the stratum corneum, has numerous protective purposes such as ultraviolet light protection, mechanical integrity and resilience, water proofing and repellency, permeability barrier, hydration, antioxidant and xenobiote defence, and cytokine signalling.[56,57] Its unique composition is due to structural proteins and ceramides that are covalently cross-linked. Together they form a cornified envelope which is insoluble and highly complex in order to fulfil all the above-mentioned functions.[58] The stratum corneum is formed by the end of the sixth month of gestation. Epithelial surfaces are predominantly generated towards the end of gestation; their development is highly coordinated and undergoes many structural and functional changes. Antenatal exposure to hormones, for example, glucocorticoids administered to the mother, can influence these processes,[59] as can premature birth, where the stratum corneum is inadequately formed.[60] The epidermal barrier is often dysfunctional in very low-birth-weight preterm infants.

### Vernix caseosa

*In utero*, the fetus is in a completely aqueous environment and is covered with vernix caseosa as a protective layer.[61] This complex proteolipid cellular cream has a waterproofing effect.[62] Vernix caseosa is created during the last trimester of gestation by sebaceous glands and communicates with the developing epidermis.[63]

### Changes at birth

The skin's protective role is particularly apparent perinatally when a fetus undergoes the transition from the warm, wet atmosphere of the womb to the much cooler, dry, non-sterile outside world full of physical, chemical, and mechanical threats. Suddenly, the infant is exposed to high oxidative stress and ultraviolet light and must accomplish multiple mechanisms, such as thermoregulation, that were not needed before birth and were carried out by the placenta.

#### Temperature control

*In utero*, fetal temperature is approximately half a degree higher than maternal temperature with heat produced by biochemical processes only.[3] At this point, fetal thermogenesis is suppressed and excess fetal heat is eliminated either by conduction or, in much greater part (85%), by convection through blood vessels to the placenta.[64] Thermoregulatory processes develop quite early in embryogenesis. Preterm babies born as early as 25 weeks' gestation are capable of thermogenesis; however, this is not as effective as in term babies.[65]

At birth, thermogenesis is immediately activated, triggered by heat loss due to lower ambient temperatures and evaporation of amniotic fluid from the skin. Mode of delivery influences thermoregulatory processes, as lower body temperatures of around 0.3°C are seen in term infants born by caesarean delivery.[66] Mechanisms of thermogenesis can be divided into three: shivering of skeletal muscle, non-shivering thermogenesis in brown adipose tissue (BAT), and futile cycling of ions in specialized heat-producing tissues. Non-shivering thermogenesis is most significant in the neonate. Shivering can be considered as a secondary measure, a backup system for substantial hypothermia. BAT is mainly located around the kidneys, in the interscapular area of the back and on the dorsal neck. Heat is generated on the basis that energy from mitochondrial respiration is not stored as ATP but given off as heat. BAT growth and activation are regulated by a number of hormonal and nervous components.[67] Central homeothermic mechanisms are generally not well developed at birth and call for processes regulated by the autonomous nervous system such as eccrine sweating, vasodilatation, and vasoconstriction, which also need time to develop.[3] Preterm infants are even more in danger of extensive heat loss due to several reasons. They have a higher surface area to mass ratio, lower endogenous sources of heat generation such as BAT, a limited epidermal barrier, and are unable to self-regulate with flexural positioning.

#### Acid mantle

Human skin is physiologically covered by an acid mantle, which serves as a defence against microorganisms and helps preserve the skin's barrier function. In the newborn, skin surface pH is in a neutral range and then continually becomes more acidic over the following few weeks. Mechanisms that induce this transition are thought to include active proton pump mechanisms and endogenous factors such as lactic acid from sweat, free fatty acid generation from metabolism of triglycerides in sebum, as well as metabolic by-products of bacterial colonization.

#### Bacterial colonization

As the infant is no longer in the sterile environment of the uterus, skin also needs to function as a barrier against infection.

Colonization of the skin begins as soon as the infant has its first contact with the outside world.[68] The process which leads to colonization is not entirely understood. What has been shown, however, is that there is an interaction between development of the acid mantle, local microenvironmental factors, as well as microorganism growth rate. Skin care practices and products also influence colonization. In vaginally born infants, the skin is swiftly colonized with *Staphylococcus epidermidis*, the most common vaginal organism before birth and also omnipresent in the environment.[69] After a few weeks, an infant's resident bacterial flora is very similar to that of the adult and characterized as non-virulent and consistent in quantity. In very low-birth-weight preterm infants, physiological colonization may overwhelm protective capabilities; *S. epidermidis* is the most frequent cause of nosocomial sepsis.

# Metabolism

## Fluid homeostasis

Postnatal adaptation induces large shifts in body fluids. In early gestation, total body water (TBW) makes up around 95% of total body weight. TBW gradually decreases during development and reaches 75% at term (Figure 4.2).[35]

TBW can be divided into intra- and extracellular volume. During the early stage of gestation, growth primarily occurs through cell division and therefore extracellular volume is very large. This leads to tissues with small cells encircled by an extensive layer of extracellular fluid. Extracellular volume decreases during the course of gestation due to a reduction of hyaluronan content, which has a high water-binding capacity. Meanwhile, intracellular volume increases with physiological growth of the existing cells during the second half of gestation.[35]

The distribution of fluids is determined by the equilibrium across the capillary membrane as well as by the balance between capillary permeability and lymphatic function. The fetus and neonate have low intravascular hydrostatic and oncotic pressures,[70] high permeability of the capillary wall, and high lymphatic flow compared to the adult. When compared to adults, the interstitial space of the fetus is larger.[3]

## Blood volume

Due to the volume of blood in the umbilical cord and the fetal side of the placenta, the fetus has a significantly larger blood volume when compared to the neonate. Total placentofetal blood volume at term is around 120 mL/kg, with 70 mL/kg in the fetus and 50 mL/kg being located in the placenta and umbilical cord.[71]

## Changes at birth

Uterine contractions during labour and delivery lead to a shift of fluids from the plasma to interstitial compartments with a concomitant decrease in total plasma volume. The contractions lead to a direct compression of the fetus,[72] which results in an increase in blood pressure and a reduction of circulating blood volume. Vasoactive hormones such as vasopressin, norepinephrine, cortisol, and atrial natriuretic peptide are also involved and have been reported to be at increased concentrations in the umbilical cord after vaginal delivery.[3] Severe hypoxia can induce a reduction in blood volume with a translocation of blood from the placenta to the fetus.[73] The increase in blood volume causes an increased capillary pressure which in turn leads to a higher transcapillary filtration of fluid.

Placental transfusion is the most important factor to influence blood and plasma volume during the first postnatal days.[71] Obviously gravity is an important contributing factor and the

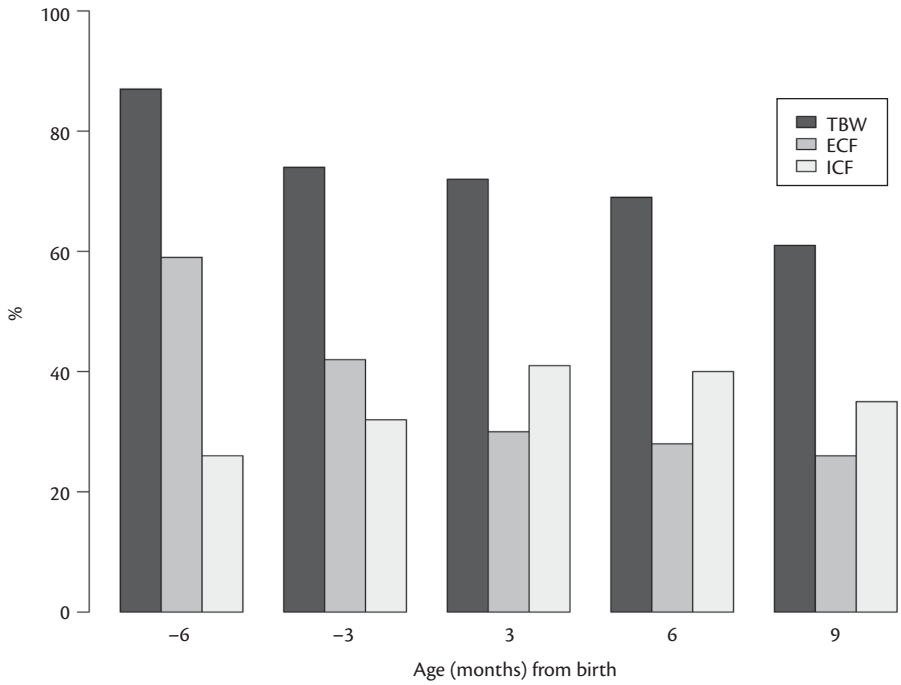

**Figure 4.2** Distribution of body water for total body water (TBW), extracellular fluid (ECF), and intracellular fluid (ICF).
Data from Friis-Hansen B. Body water compartments in children: changes during growth and related changes in body composition, *Pediatrics* 1961; 28:169–81, Copyright © 1961 American Academy of Pediatrics.

position of the neonate relative to the placenta before cord clamping is of great importance for fetoplacental or placentofetal transfusions. Further contributing factors are maternal hypotension, cord compression, and caesarean delivery. Placentofetal transfusion is promoted by intrauterine asphyxia, uterine contractions, and increases in maternal uterine blood flow.[71] Timing of umbilical cord clamping critically influences neonatal blood volume. Clamping the cord directly after birth leads to a haematocrit between 0.48 and 0.51.[74] If the cord is not clamped immediately, however, and the infant is held at or below level of the placenta, there is a gradual placentofetal transfusion.[71,74] Haematocrit measured 30–120 minutes after birth is then at 0.60–0.65. Placental transfusion causes neonatal blood pressure, central venous pressure, renal blood flow and urine flow to increase and can be used therapeutically.[71] There is a reduced incidence of anaemia in early infancy in term infants and in preterm babies severity of respiratory distress syndrome, incidence of intraventricular haemorrhage, late-onset sepsis, and the need for blood transfusions is also reduced.[75–77]

In the days after birth, a weight loss of approximately 10% is normal in healthy term infants because extracellular fluid is further reduced. In low- and extremely low-birth-weight neonates weight loss is even larger.

### Kidneys

Nephrogenesis undergoes different stages including a primitive kidney, the pronephros, an intermediate kidney, the mesonephros, and finally the permanent kidney, the metanephros. Renal development is completed by 34 weeks' gestation. Urine flow, renal blood flow, and glomerular filtration rate (GFR) continually increase during the second half of gestation.[78]

*In utero*, fetal homeostasis is mainly regulated by the placenta. During the third trimester, fetal renal function becomes more important. Function is regulated by endocrine, paracrine, and autocrine factors, and relative maturation of these determinants correlate with renal function.[3]

#### Changes at birth

A reduction in renal blood flow and GFR in neonates when compared to adults has to be considered especially in pharmacokinetics of renally excreted drugs.[79] Renal vascular resistance decreases immediately after birth, which leads to a continuous increase in renal blood flow. While kidneys in the fetus receive less than 5% of cardiac output, the percentage increases in the neonate to 15%. The low GFR of 5 mL/min at term increases rapidly after birth and is dependent on gestational age. It takes months for very low-birth-weight infants to achieve a normal GFR.[80]

### Liver

The liver is the largest internal organ and its functions can be categorized as synthesis and secretion of serum proteins, energy metabolism, and bile secretion. During early fetal life, the liver also has a haematopoietic function which decreases towards the end of gestation. Hepatocytes mature very early and are functional as early as the second month of gestation.[81]

#### Changes at birth

Bilirubin is an intermediate product of haem catabolism. After hepatic conjugation it is excreted via bile and urine. Bilirubin production is higher in the neonate than in adults, and even more so in the preterm infant.[82] Conjugation and excretion, however, are less efficient due to downregulation, which leads to physiologically elevated plasma bilirubin levels during the first week of life. Jaundice is the clinical sign of hyperbilirubinaemia and visible at the skin, sclera, and mucous membranes. Unlike adults and older children, where icterus is present at bilirubin levels of 2–3 mg/dL, the concentration can increase to above 5 mg/dL in the neonate before clinical signs become visible. Jaundice can be the only indication of hepatic dysfunction, and may precede kernicterus which can lead to brain injury and must therefore be quickly identified and treated.

### Glucose

*In utero*, fetal gluconeogenesis is virtually non-existent and the fetus is completely supplied via the placenta.[83] There is a substantial postpartum change in plasma concentration of glucoregulatory hormones. Plasma concentration of epinephrine, norepinephrine, and glucagon increase rapidly, while insulin levels decrease.[37] In the first hour after birth, plasma glucose levels reach a nadir. The subsequent rise in glucose levels reaches a plateau between 2 and 4 hours af.[84] Glucose levels partly depend on glucose intake during labour and delivery.[85] A healthy term neonate has plasma glucose levels that range between 2.2 and 4.5 mmol/L (40 and 80 mg/dL). As soon as feeding starts, glucose levels increase slightly.

Hypoglycaemia is most common during the neonatal period, particularly in the first 12–24 hours after birth. Detection and rapid treatment of hypoglycaemia are very important as failure to do so may have serious consequences. Glucose is the brain's prime energy source and lack of it can cause seizures and, if it is prolonged, permanent brain damage. There is no consensus as to what level or duration of hypoglycaemia can be determined to cause cerebral damage.[86] Hypoglycaemia is also a leading symptom of many endocrine disorders and inborn errors of metabolism, which need to be specifically diagnosed and treated.

Various clinical signs can point to hypoglycaemia including lethargy, somnolence, poor feeding, respiratory distress, apnoea, cyanotic episodes, sweating, staring spells, myoclonic jerks, and seizures.

## Sensory and nervous system

Human brain development is the result of extraordinary complex processes regulated by genetic and epigenetic factors. The developmental sequence transforms a discal accumulation of undifferentiated tissue into a neuronal network capable of storing and processing a vast amount of information.

Functionally, the developing brain is considerably determined by the operational state of chemical synaptic connections between neurons. As a result of this, the biochemical features of neurotransmission may differ markedly during development. This may result in differing functional balances of multineuronal networks at different ages. At birth, the vitally important centres are functioning with limited reserve.

### Pain perception

(See also Chapter 7.)

According to the International Subcommittee for the Study of Pain, pain is defined as 'an unpleasant sensory and emotional response associated with actual or potential tissue damage, or

described in terms of such damage'.[87] Pain perception is dependent on nociception, which is a sensory component that is neurophysiologically determined, and emotion, which is influenced by affective state, past experience, and development.[88] Historically there was a belief that a neonate did not feel pain due to immaturity of the nervous system.[88] Therefore invasive procedures and surgery were generally undertaken without pain relief or anaesthesia. More recently, neonatal pain research has shown, however, that the neonate is fully capable of experiencing pain.[89,90] There is also evidence that a fetus may be able to respond to painful stimuli.[91] Prevention or treatment of pain leads to better outcomes and fewer undesirable long- and short-term effects.[92] Nevertheless, this discussion was revived with the latest research in anaesthesia-induced neuroapoptosis.[93]

The basic mechanisms of fetal and neonatal pain perception correlate well with adult pain perception: noxious stimuli to peripheral sensory nociceptors are transmitted to sensory areas of the cerebral cortex via the spinal cord neurons. Nonetheless, differences based on immaturity of anatomical, physiological, and chemical parameters of the nervous system exist.

By the 20th week of gestation, cutaneous nociceptors are fully formed throughout the fetus[94] and at the end of gestation the density of nociceptors is similar to that in adults. The cutaneous withdrawal reflex, development of pain pathways of the spinal cord and brainstem, and facial responses to painful stimuli can be demonstrated as early as 24 weeks' gestation.[95] Early in gestation, substance P is the primary afferent nociceptive neurotransmitter. Pain sensitivity in the neonate might be higher than in later life because of lower pain thresholds, poor discriminative abilities, and augmented tendencies to sensitization (e.g. poorly developed descending inhibitory pathways).

### Markers associated with pain

Pain provokes a palette of reactions from the cardiovascular, respiratory, endocrine, metabolic, and immune system. Typically, heart rate and blood pressure increase, large fluctuations in transcutaneous oxygen tension arise, and a stress response is visible.[96] The term stress response describes hormonal and metabolic changes associated with trauma.[97,98] Pituitary, pancreatic, and adrenal hormones are released, which leads to a shift in metabolic balance.[97] There are also behavioural signs which indicate that the neonate is in pain. Responses are divided into four groups: simple motor responses, such as flexion and adduction of extremities; complex behavioural responses, such as altered sleep–wake cycles and irritability; facial expressions; and crying. There are specific expressions associated with pain, which become more distinctive as the infant ages.[99] Crying in response to pain is different from other crying behaviour and can be identified due to specific characteristics and acoustic qualities.[100]

### Pain assessment

Pain assessment in infants is challenging due to the lack of direct verbal communication and absence of validated quantitative methods of measurement.[101,102] It is best to use a multidimensional approach such as the Bernese Pain Scale for Neonates.[103]

### Effects of pain

Exposure to pain in the neonate may have long-term effects: the normal maturation of pain pathways is likely to be altered, and neuronal survival might be impaired by repetitive pain.[104] Cortisol levels stay elevated and changed behavioural and physiological reactivity to painful stimuli later in life have been demonstrated. This is especially the case in extremely low-birth-weight infants.[105] These are all argument supporting an adequate level of anaesthesia and analgesia in case of fetal or neonatal surgery. As previously mentioned, research in the field of anaesthesia-induced neuroapoptosis is growing.[106] Initial studies in rodents have been expanded to other species, such as primates.[107] It is far too early to draw firm conclusions about the clinical consequences of anaesthesia-induced neuronal-induced effects in the developing human being. Nevertheless, this is a topic which clearly needs further research and conclusions at this point include that unnecessary interventions must be avoided (at least in the developing brain) because we do currently not have alternatives[108] to performing anaesthesia in neonates undergoing surgical interventions.

## Conclusion

In conclusion, this chapter demonstrates the complexity of fetal and neonatal physiology with a focus on the complex transition from intra- to extrauterine life. In essence, this transition involves every organ system and knowledge of the most important aspects is a prerequisite to understanding pathophysiology of this transition.

# CHAPTER 5

# Maternal, fetal, and neonatal pharmacokinetics

Karel Allegaert and Kristel Van Calsteren

## Introduction: clinical pharmacology in special populations

Clinical pharmacology aims to predict drug-related effects based on compound- and population-specific pharmacokinetics (PK, concentration–time), and pharmacodynamics (PD, concentration–effect). The general PK principles of disposition and elimination of drugs apply, irrespective of population-specific characteristics (Figure 5.1). Consequently, dosing should be based on the physiological characteristics of the individual patient. Pregnancy and early infancy hereby warrant focused assessment. This is because important alterations in physiology affect drug disposition up to the level of clinical relevance.[1,2] Pregnancy results in extensive alterations in PK (concentration–time profile) with a subsequent extensive interindividual variability in drug response, in part driven by the hormonal changes. In general, renal elimination capacity is increased throughout pregnancy (i.e. higher glomerular filtration rate and higher active tubular transport). Similarly, the basal metabolic activity is also increased. This commonly results in higher drug metabolism (phase I and phase II processes), although these changes are in part also iso-enzyme specific. This, although rarely, may even result in reduced enzymatic activity during pregnancy. Finally, changes in body weight or binding capacity (protein changes, pH) will likely affect the volume of distribution. Similarly, duration of pregnancy, co-morbidity (e.g. pre-eclampsia), or labour itself may further affect variability in drug disposition.

Newborns are another very specific population. When we consider the physiological changes and the subsequent between-individual variability in characteristics, we need to take into account that maturational changes are most prominent in infancy.[3–5] Consequently, drug disposition (absorption, distribution, and subsequent elimination, either through metabolic elimination or through primary renal elimination (PK) in early infancy differs substantially from children or adults. In general, neonates have an overall low clearance capacity. Between-subject variability can be explained by covariates such as size, weight, organ function, co-administration of drugs, genetic polymorphisms, growth restriction, or disease characteristics.

## Maternal pharmacokinetics

### Pharmacokinetic alterations due to physiological changes during pregnancy

During pregnancy, multiple changes in physiology occur, affecting the major PK processes of a drug: absorption, distribution, metabolism, and excretion (ADME) (Table 5.1).[1,2,6] This may have therapeutic and toxic consequences for both the pregnant woman and the fetus. Due to ADME changes the pregnant patient may be exposed to subtherapeutic or toxic drug levels and an unwanted amount of drug may be delivered to the fetus.

During pregnancy, an increase in progesterone level is believed to be responsible for a delayed gastrointestinal motility and increased transit time, altering the drug *absorption* and enterohepatic circulation and resulting in lower peak levels but increased exposure.

The *distribution* of drugs may be altered during pregnancy as a result of the increase in fat stores as well as extracellular fluid volume and a plasma volume expansion by 50%. As a result of this volume expansion, a decrease in the (peak) serum concentration of many drugs has been documented.[7] Furthermore, the amniotic fluid may behave as a third space for water-soluble drugs, like methotrexate, mitoxantrone, or cefazolin, with prolonged exposure and delayed elimination resulting in both maternal and potentially fetal toxicity or prolonged effects.[8] Moreover, since the protein concentration of the amniotic fluid is very low, measured drug concentrations should be considered to be free concentrations (e.g. cefazolin). As pregnancy advances, the rate of plasma volume expansion exceeds the rate of albumin production, creating physiological dilutional hypoalbuminemia (i.e. the total amount of albumin is higher, but the plasma concentration is lower when compared to the non-pregnant state). Moreover, endogenous compounds like free fatty acids, steroids, and placental hormones occupy protein-binding sites, thus decreasing the protein-binding capacity of drugs. The overall effect is a decrease in binding capacity for albumin and, therefore, an increase in unbound drug. However, as more free drug is available for either hepatic biotransformation or renal excretion, the overall effect may be an unaltered free drug concentration. In contrast to albumin, serum alpha-1-acid glycoprotein concentrations were found to remain the same as those in non-pregnancy.[7]

The increased regional blood flow, including the hepatic blood flow, will lead to higher metabolic rates, or is a reflection of this higher metabolic activity. Besides these blood flow-related changes, the increased secretion of oestrogens (e.g. oestradiol) and progesterone in normal pregnancy affects *drug metabolism* in different ways. To further illustrate this, the higher rate of hepatic metabolism of certain drugs, such as phenytoin, is possibly a result of stimulated hepatic microsomal enzyme activity (cytochrome P450 (CYP)) induced by progesterone. On the other hand, the hepatic *elimination* of other drugs, such as theophylline

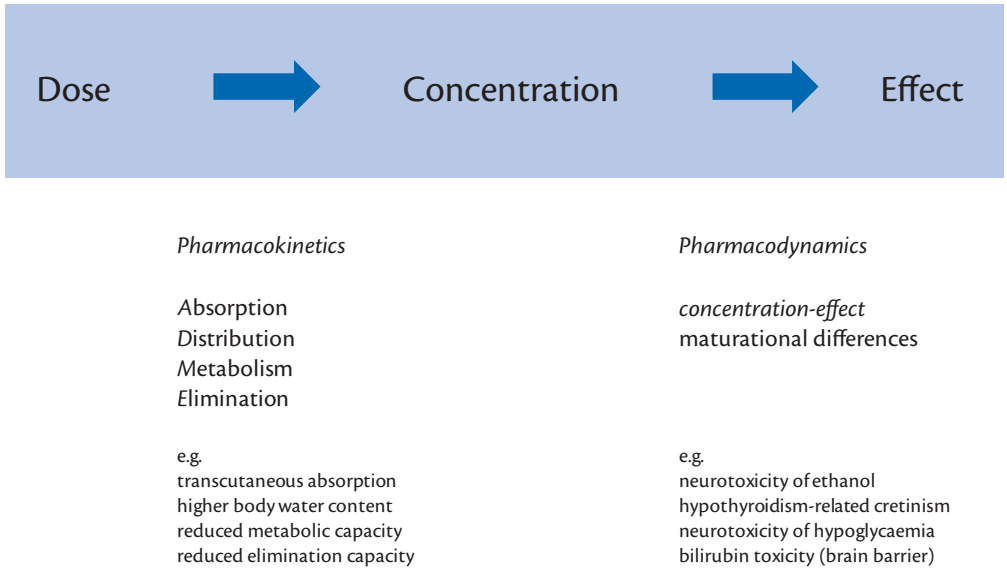

**Figure 5.1** Clinical pharmacology aims to predict the concentration–time profile (pharmacokinetics) and the concentration–effect profile (pharmacodynamics).

and caffeine, is reduced secondary to competitive inhibition of microsomal oxidases by progesterone and oestradiol. Finally, oestrogens stimulate the glucuronidation (UDP glucuronosyl transferase (UGT) enzymes), but not the sulphation capacity, resulting in increased clearance of compounds (e.g. propofol, paracetamol, and lamotrigine) cleared by UGT iso-enzymes. These hepatic alterations may be detrimental for drugs that need to be metabolized to become active, like cyclophosphamide (to phosphoramide mustard and acrolein, CYP2B6) or codeine (to morphine, CYP2D6), or vice versa, for drugs that need to be metabolized to become inactive. The same holds true for paracetamol, metabolized by the liver to paracetamol glucuronide (47–62%), and paracetamol sulphate (25–36%), and about 8–10% of paracetamol is oxidized to 3-hydroxy-paracetamol and the (hepatic) toxic metabolite *N*-acetyl-P-benzoquinone-imine (NAPQI) in non-pregnant adults. The overall higher paracetamol clearance and delivery is due to both higher glucuronidation and oxidation, but not sulphation. Finally, the cholestatic effect of oestrogen may interfere with the clearance of drugs, which are secreted in the biliary system (biliary drug transporters).[1,2,6]

As renal plasma flow increases by 25–75% and glomerular filtration rate by 50%, renally cleared drugs demonstrate enhanced elimination and lower steady-state serum concentrations,[7] but the renal function can be further affected by medical conditions (e.g. preeclampsia, pre-pregnancy renal failure, and lupus nephritis).

## Applications in the field of obstetric anaesthesia

Alterations in compound-specific PK and PD are in general heterogeneous, reflecting different pregnancy-related changes in each or several of the previously mentioned alterations. We aim to illustrate the pregnancy-related changes for compounds commonly administered by anaesthetists (Table 5.2). Aspects related to fetal exposure and breastfeeding will be discussed in dedicated subsections ('Transplacental Transport' and 'Applied Neonatal Pharmacology: Obstetric Anaesthesia and Breastfeeding' respectively) of this chapter.

Neuromuscular blocking agents illustrate the complexity of these changes. Plasma cholinesterase levels are decreased by 25% from early during pregnancy until the seventh day postpartum. Prolonged neuromuscular blockade with succinylcholine is uncommon, however, as the increased volume of distribution off sets the impact of decreased drug hydrolysis.[9] Vecuronium at a standard dose of 0.2 mg/kg has been shown to have a faster onset time and longer duration of action in pregnancy.[10] The onset time of rocuronium at a dose of 0.6 mg/kg is unchanged but also demonstrates a longer duration of action compared with non-pregnant patients.[11] Neuromuscular blocking agents whose elimination is organ independent also display altered PK. Cisatracurium, for example, undergoes Hoffman's elimination *in vivo*, and has a significantly more rapid onset and shorter duration of neuromuscular blockade in pregnant patients.[12] A similar exercise can be made for propofol. Due to the raised hepatic blood flow and the increased glucuronidation activity, propofol clearance is increased during pregnancy.[13] When focusing on PD, there are conflicting views regarding the half maximal effective concentration ($EC_{50}$) of propofol for loss of consciousness in pregnancy. Higuchi et al. reported that the $EC_{50}$ was not different from that in non-pregnant women, indicating that there is no need to decrease the propofol concentration for loss of consciousness when inducing general anaesthesia.[14] In contrast, Mongardon et al. described that the propofol effect-site concentration is decreased during early pregnancy.[15] Combining all observations, we suggest that a higher maintenance dose will be needed to attain the same level of anaesthesia, but the extent of the increase is unclear.

Paracetamol and non-steroidal anti-inflammatory drugs (e.g. ketorolac and ibuprofen) decrease opioid consumption with the aim to reduce opioid-related side effects. Preventive analgesia using non-opioid analgesic strategies is one of the pathways to improve postoperative pain while minimizing opioid-related side effects for both mother and newborn. Since paracetamol clearance is significantly higher at delivery, it might be prudent to decrease the interval between consecutive paracetamol doses

**Table 5.1** Physiological changes affecting pharmacokinetics

| Maternal physiological changes | | Effects of the placental–fetal compartment | |
|---|---|---|---|
| Absorption | Decreased gastrointestinal motility → slower, but more complete absorption<br>Increased gastric pH → affects ionization (absorption) of weak acids and bases<br>Ventilatory changes: hyperventilation and increased pulmonary blood flow → favours alveolar uptake | Placental barrier function | P-glycoprotein, multidrug resistance proteins, and breast cancer resistance protein are active transporters that work against a concentration gradient and protect the fetus against potential toxic effects of environmental toxins and other xenobiotics |
| Distribution | Plasma volume expansion by 50% → decrease in $C_{max}$<br>Mean increase in total body water is 8 L<br>More fat stores<br>Amniotic fluid may behave as a third space | Acid–base equilibrium effect | Non-ionized, highly lipid-soluble molecules penetrate the placenta more quickly than less lipid-soluble ionized molecules<br>Fetal plasma pH is slightly more acidic than the maternal<br>→ Ion trapping: weak bases in the maternal circulation will be non-ionized and easily cross the placenta, in the fetal blood they become ionized, resulting in a net movement from maternal to fetal compartment |
| Protein binding | Dilutional hypoalbuminemia<br>→ Increased unbound drug fraction<br>Steroid and placental hormones occupy protein binding sites | Protein binding | Maternal plasma albumin gradually decreases during pregnancy, while fetal albumin progressively increases<br>→ Since only unbound drugs cross the placenta, protein-bound drugs reach higher total concentrations in the fetus |
| Metabolism | Hepatic drug metabolism alterations by increased secretion of oestrogen and progesterone (induction of microsomal enzyme activity by progesterone, or competitive inhibition of microsomal oxidases by progesterone and oestradiol)<br>→ Drug metabolism can be increased, decreased, or remain stable | Fetoplacental drug metabolism | First-pass metabolic effect by placenta<br>Fetal liver metabolism: from 7–8 weeks postconception phase I (oxidation, dehydrogenation, reduction, and hydrolysis) and phase II (glucuronidation, methylation, and acetylation) enzymatic processes have been documented in the fetal liver; however, because of immaturity their contribution in drug elimination is marginal and most of the umbilical venous blood flow will bypass the liver via the ductus venosus to enter the fetal heart |
| Excretion | Increased renal blood flow and glomerular filtration rate (by 50%)<br>Cholestatic effect of oestrogen may interfere with clearance of drugs through the biliary system | Fetoplacental elimination | Elimination of drugs from the fetus primarily occurs by diffusion back to the maternal compartment<br>As most metabolites are more polar than their parent compounds, they are less likely to cross the placental barrier. This may result in metabolite accumulation in various fetal tissues<br>As pregnancy progresses, higher amounts of drugs are excreted into the amniotic fluid, reflecting maturation of the fetal kidney |

Data from Thomas SH, Yates LM. Prescribing without evidence – pregnancy. *Br J Clin Phamacol* 2012; 74:691–7; Pavek P, Ceckova M, Staud F. Variation of drug kinetics in pregnancy. *Curr Drug Metab* 2009; 10:520-9; and Krauer B, Krauer F, Hytten FE. Drug disposition and pharmacokinetics in the maternal-placental-fetal unit. *Pharmacol Ther* 1980; 10:301–28.

or increase the dose in the immediate postpartum to mimic the time–concentration profile aimed for in non-pregnant adults. However, increasing paracetamol dosing also results in higher oxidative metabolism during pregnancy. Consequently, we suggest that it may be more reasonable to anticipate a shorter, and less persistent analgesic effect of paracetamol in pregnant women due to the higher clearance, but not to increase the dose to avoid hepatoxicity. A similar extrapolation can be made for ketorolac. Ketorolac clearance is also significantly increased at delivery. Assuming that there is a given threshold plasma ketorolac concentration, that results in pain, the higher clearance during pregnancy will result in faster onset of pain. A decrease in the interval between consecutive administrations (at present, 8-hourly dosing) can be considered to maintain the ketorolac level above this threshold.[16–19]

Clearance of opioids will be higher at delivery. This does not necessary mean that the dose of any opioid needs to be higher, since this also includes metabolic clearance for 'prodrugs' like codeine (morphine), oxycodone (oxymorphone), or tramadol (*O*-demethyl tramadol); the phenotypic concentration–time relation will depend on simultaneous ongoing PK aspects (metabolic clearance, metabolite elimination clearance) in addition to covariates, including pharmacogenetics.[20,21] The specific risks related to maternal opioid exposure and breastfeeding are discussed in 'Transplacental Transport'.

## Transplacental transport

The major function of the placenta is to transfer nutrients and oxygen from the mother to the fetus and to assist in the removal of waste products from the fetus to the mother (see also Chapter 3). In

**Table 5.2** Illustrations of the impact of pregnancy on pharmacokinetics and pharmacodynamics of individual compounds commonly administered to pregnant women by anaesthetists. Issues related to placental transfer were not considered, although all compounds mentioned do cross the placental barrier

| Compound | Normal dose in an adult | Pregnancy-related changes |
|---|---|---|
| Cefazolin | 2 g, IV at induction, every 8 h prophylaxis, surgery | Higher distribution volume because of higher weight and lower albumin binding<br>Higher clearance because of higher renal clearance and higher free concentration<br>*Consequences*: lower peak, and shorter duration until below minimal inhibitory concentration pathogens<br>*Suggestion*: shorter time interval for a second dose, every 6 h? |
| Paracetamol | 2 g IV loading dose, 1 g every 8 h (postoperative) pain | Higher distribution volume because of higher weight and body composition (water-soluble)<br>Higher clearance because of higher metabolism (glucuronidation, but also oxidation)<br>*Consequences*: this likely results in less effective and shorter pain relief<br>*Suggestion*: consider multimodal analgesia, higher dose may result in more toxic metabolites |
| Propofol | 4 mg/kg or 2 mg/kg + 6 mg/kg/h | Higher clearance because of higher cardiac output/hepatic blood flow (high extraction drug)<br>Unsure about differences in pharmacodynamics<br>*Consequences*: recovery marginally quicker during pregnancy due to higher clearance<br>*Suggestion*: titration to effect |
| Tramadol | 3 mg/kg, 7 mg/kg/24 h | Higher distribution volume, higher metabolic clearance (metabolite has analgesic properties)<br>Higher renal elimination clearance of the mother compound and the metabolite<br>*Consequences*: higher clearance, in part compensated by higher metabolic clearance<br>*Suggestion*: Suggested doses are 50–100 mg IV/oral, every 2 h, max. 600 mg per 24 h consider higher loading, or perhaps more appropriate higher maintenance dose |

addition, it plays an important role in the synthesis of hormones, peptides, and steroids that are vital for a successful pregnancy. The placenta provides a link between the circulations of two distinct individuals but also acts as a barrier to protect the fetus from xenobiotics in the maternal blood. Similar to the blood–brain barrier, the placenta is described as an organ separating the maternal and fetal circulations. However, the term 'placental barrier' includes a false notion since the placenta is not a true barrier, but instead the placenta is the entry through which the fetus is exposed to chemicals.[22] The major and minor routes of drug disposition within the placental–fetal compartment are described in Table 5.1.

Most drugs cross the placenta by *passive diffusion*.[23] Therefore, the amount and rate of transfer is primarily determined by the concentration gradient of the drug between the maternal and fetal circulation and placental blood flow. Besides the physicochemical properties of drugs such as lipid solubility, ionization constant (pKa), molecular weight, and protein binding are critical for placental transfer. Uncharged, low-molecular-weight (<500 Da), lipid-soluble, and unbound compounds can easily cross the human placenta.[23]

While the maternal plasma albumin gradually decreases during pregnancy, fetal albumin concentration progressively increases and reaches its peak at term when it equals or even exceeds maternal albumin concentration. In contrast, fetal levels of glycoprotein alpha are much lower than maternal levels; therefore, the free fractions of basic drugs will be higher in the developing child.[7]

The maternal pH and fetal pH are significant determinants of placental transfer especially for weak acid or basic drugs with a pKa close to the plasma pH. The fetal plasma pH is usually slightly more acidic than the maternal. Consequently, weak bases will be mainly non-ionized and, therefore, able to easily penetrate the placental barrier. However, after crossing the placenta and making contact with the relatively acidic fetal blood, these molecules will become more ionized. This results in an apparent fall in fetal concentrations of the drug and leads to a concentration gradient, with subsequently a net movement from the maternal to the fetal system. This phenomenon is commonly referred to as ion trapping.[7]

Only a few drugs (e.g. ganciclovir, cephalexin, and some glucocorticoids) have been suggested to be transported across the placental barrier by *facilitated diffusion*, which requires the presence of a carrier substance within the placenta, but does not need any energy source.[22] Furthermore, *active transport* of drugs across the placental barrier has been described. It has been recognized that substrate transporting proteins are present in the fetus-derived epithelial cells that make up the exchange border between the fetal and maternal blood compartment. These include P-glycoprotein, multidrug resistance proteins, and breast cancer resistance protein. All active transporters may work against a concentration gradient but can become saturated. These protein pumps have been postulated to have evolved as a protective mechanism against the potential toxic effects of environmental toxins and other xenobiotics, and yet were shown to regulate the transfer of vinblastine, vincristine, paclitaxel, and doxorubicin.[22]

The placenta can exert a considerable first-pass *metabolic effect* on some drugs. Drugs that are not metabolized in the placenta would then enter the umbilical vein where the next fetal organ encountered is the fetal liver. However, most of the umbilical venous blood flow will bypass the liver via the ductus venosus to enter the fetal heart. Drugs that are metabolized in the fetal compartment contribute to direct fetal clearance.

Since the presence of enzymatic processes, including phase I (oxidation, dehydrogenation, reduction, and hydrolysis) and phase II reactions (glucuronidation, methylation, and acetylation

by transferases), has been documented both in the placenta and the fetus, drugs can be assumed to be metabolized to some extent in the fetoplacental compartment.[22,24] CYP enzymes in particular have been well characterized in the placenta at the level of mRNA, protein, and enzyme activity. CYP1A1, -2E1, -3A4, -3A5, -3A7, and -4B1 have been detected in the term placenta. While much less is known about phase II enzymes in the placenta, some enzymes, in particular UGT iso-enzymes, have been detected and shown to have specific activity towards marker substrates, suggesting a significant role of this enzyme in placental drug detoxification. The clinical relevance is, however, poorly understood.[22]

The activity of most fetal drug-metabolizing enzyme systems that have been measured in fetal tissues is lower than the one observed in adult tissues. Neither the exact developmental time frame, nor the mechanisms by which fetal enzymes become upregulated around birth, have been delineated in primates.[23] Nevertheless, significant concentrations of drug metabolites have been found in the fetus. It should be noted that the process of biotransformation usually renders the drug more water-soluble and thus more readily excreted by the kidney. This is of concern to the fetus when the drug undergoes metabolism in the fetal compartment, because the greater water-solubility of the metabolite will decrease the ability of the compound to be cleared from the fetus across the placenta. Few studies have evaluated the potential for the accumulation of metabolites in the fetus, because most drugs lose their biological activity when they undergo metabolism. However, some drugs are activated through metabolism, like cyclophosphamide.[23]

*Elimination* of drugs from the fetus occurs primarily by its diffusion back to the maternal compartment. Approximately 4% of the fetal cardiac output goes to the fetal kidneys. As pregnancy progresses, higher amounts of different drugs are excreted into the amniotic fluid, reflecting maturation of the fetal kidney. It is also possible that drugs diffuse across fetal skin, umbilical cord, and the fetal surface of the placenta to reach the amniotic fluid. Because this occurs by passive diffusion, drug movement can occur in both directions, allowing drugs to be cleared form the amniotic fluid as well. Generally it is assumed that most clearance of drugs from the amniotic fluid occurs through fetal swallowing. Although drugs can be measured in meconium, most drugs swallowed by the fetus are probably reabsorbed. Thus drug excretion in fetal urine is not a true loss from the fetus. Drugs that are 'trapped', for example, in meconium, fetal hair, or bones, would be reflected in direct fetal clearance.

Concerning the blood–brain barrier, preclinical research showed the underlying morphological feature of this barrier, the tight junctions between cerebral endothelial cells and between choroid plexus epithelial cells, is present from very early in embryological development. Therefore, while the blood–cerebrospinal fluid (CSF) barrier can be considered functionally and morphologically mature, the developing barrier has different characteristics than in adults. A decrease in both CSF/plasma concentration ratios for lipid-insoluble passive markers and CSF protein concentration is seen with increasing age.[25] Saunders et al. suggested this is due to changes in transcellular transfer and volume of distribution.[26] While the exact mechanisms remain unknown, available preclinical data on actual drug transfer suggests that compared to adults a higher blood–brain transfer of drugs might be seen in foetuses.[27,28]

When focusing on compounds commonly administered by anaesthetists, there are issues related to antibiotics and analgesics and fetal exposure. Pre-incisional administration of antibiotics compared to administration of antibiotics after caesarean delivery results in a decreased risk of developing post-caesarean endometritis, but also results in fetal exposure to antibiotics (e.g. cefazolin).[29] Administration of the same compound during fetal surgery does result in sufficiently high cefazolin concentrations in the maternal and the fetal compartment, but not in the amniotic cavity.[30] Administration of systemic opioids to the mother results in concentration-dependent fetal and neonatal sedation; this is also true for the very short-acting opioids like remifentanil.

## Clinical pharmacology in neonates: limited size, extensive variability

### Neonatal clinical pharmacology: an introduction

When a drug is prescribed, it is with the intention of attaining an anticipated therapeutic effect (e.g. sedation, pain relief, or muscular relaxation), preferably without disproportional or unanticipated side effects (e.g. prolonged sedation, hypotension, hepatic or renal impairment, or hypoventilation). Clinical pharmacology aims to predict such (side) effects based on compound-, population-, and patient-specific PK and PD.[4] PK describes the relationship between a concentration in a given compartment (e.g. plasma, CSF, or subcutaneous fluid) and time ('what the body does to the drug'). PD describes the relationship between a concentration at a given compartment and (adverse) effects ('what the drug does to the body'). Although the general principles of clinical pharmacology also apply to neonates, their specific physiological characteristics warrant a focused approach.[5] Effective and safe pharmacotherapy in young infants should be based on integrated knowledge concerning the evolving physiological characteristics of the infant who will receive the drug, and the PK and PD characteristics of a given drug: *developmental pharmacology reflects developmental physiology.*

Consequently, clinical pharmacology in neonates is as diverse and dynamic as the neonates themselves: beyond or in addition to median estimates, covariates of variability within this population are clinically relevant.[3] Growth and development throughout paediatric human life comprise a series of simultaneously ongoing physiological events that result both in growth and maturation, commonly subdivided into subpopulations (newborn, infancy, childhood, and adolescence). Across this paediatric life span, organ size and function change as does body composition and, ultimately, cellular function and metabolic activity. This will affect population-specific PK. In addition, some tissues may be more sensitive to pharmacological effects early in life, irrespective of a given concentration or exposure whereas others will be less. This will affect population-specific PD. There is already one order of magnitude difference in weight (0.5 to 5 kg) in the neonates currently hospitalized in neonatal intensive care units. The height velocity rate (10–20 cm/year) in the last trimester of pregnancy and the first months of extrauterine life, the increase in body weight (50% increase in the first 6 weeks, and three times in the first year of life), and the energy requirements of infancy all reflect the dynamics of a rapidly evolving biological system. From a clinical pharmacology perspective, the consequence of such

a rapidly evolving biology is that there is extensive within- and between-subject variability in drug disposition and effects. This maturation-related variability is further aggravated by interfering pathological processes (e.g. growth restriction, sepsis, associated cardiomyopathy, and organ failure) or treatment modalities (e.g. co-medication, extracorporeal membrane oxygenation, and surgical intervention). Maturational PK consider maturational changes in drug ADME, while maturational PD consider maturational changes in the concentration–effect profile, for example, differences in receptor expression, function, or specific tissue/organ maturational sensitivity (either more or less vulnerable). It is only after maturational PK has been considered that maturational differences in PD can be explored. The perception that the effects or side effects of a given drug are different in the newborn is often due to the fact that PK has not yet been adequately studied in this population.[3,4,5]

*Absorption* relates to physicochemical characteristics and patient factors that influence the translocation of a given compound from its exposure site (e.g. enteral, pulmonary, or cutaneous) to the bloodstream or another effect compartment. There is important variability in absorption characteristics in neonates. For oral bioavailability, gastric acid production, transit time, maturation of mucosal enzymes, and diet are covariates of this variability. The still absent gastric acid production in the first days of life results in faster and more extended penicillin absorption, but impairs oral absorption of some antifungal agents. Gastric emptying after breastfeeding is faster when compared to formula feeding. Rectal administration is more difficult to predict because of the shorter rectal ampulla. Percutaneous absorption is higher due to more limited keratinization of the skin together with a higher skin surface/weight ratio. This may result in population-specific side effects (e.g. iodine absorption resulting in hypothyroidism, hexachlorophene resulting in neurological deterioration, and eutectic mixture of local anaesthetics absorption resulting in methaemoglobinaemia).[4]

*Distribution* describes the transfer of a specific drug from one location to another (e.g. tissues, organs, and fluid spaces) within the body, and is commonly quantified by the distribution volume (Vd = total amount of drug/concentration). Body water constitutes 75–80% of body weight in the newborn while body fat is low but doubles in the first 6 months. The postnatal weight loss mainly relates to postnatal water losses.[5,31] These maturational aspects are of relevance in the distribution of either water- or fat-soluble drugs (e.g. higher distribution volume for aminoglycosides in preterm compared to term neonates). Protein-binding capacity is in general lower in neonates. Competitive binding with bilirubin on albumin may result in increased free bilirubin and subsequent kernicterus (e.g. sulphonamides and ceftriaxone). Although volume of distribution does not necessarily represent a physiological volume or space, it is commonly affected by maturational physiological changes such as body composition, regional blood flow, organ size, barriers, or plasma protein concentrations.

*Metabolism and elimination clearance* (i.e. excretion) together reflect the clearance capacity, that is, the volume of blood or plasma from which a drug is completely removed per unit of time. All individual iso-enzymes (e.g. cytochromes and glucuronidation enzymes) involved in drug metabolism display an iso-enzyme-specific, age-dependent phenotypic activity. Relevant alterations in drug metabolizing enzyme activity occur during development.[31] Renal elimination clearance mainly depends on glomerular filtration rate but renal tubular functions also display maturation. Glomerular filtration rate depends on age. Besides age, co-medication (e.g. indomethacin and ibuprofen) and disease characteristics (e.g. growth restriction) further contribute to the phenotypic variability.[4] Table 5.3 provides some compound-specific examples of the impact of developmental

**Table 5.3** Examples of the impact of developmental pharmacokinetics (*a*bsorption, *d*istribution, *m*etabolism, *e*limination) of individual compounds commonly administered to neonates by anaesthetists

| Compound | Pharmacokinetics | Relevance |
|---|---|---|
| Iodine disinfectant | Skin more permeable, skin surface/kg higher (*a*) | Higher absorption may suppress thyroid function |
| Inhalational agents | Higher alveolar ventilation/functional residual capacity ratio (*a*) | Faster wash in |
| Cefazolin | Lower protein-binding capacity results in higher distribution | Peak concentration is lower |
| | Volume (*d*), and higher free plasma fraction (*e*) | Bactericid effect relates to free concentration |
| | Lower glomerular filtration rate (*e*) | Lower clearance, prolonged duration of bactericid effect |
| Bupivacaine | Lower protein binding capacity (*d*) | Free concentration related to adverse effects |
| | Lower clearance (*e*) | Accumulation during continuous administration |
| Propofol | Lipophilic compound, lower distribution volume (*d*) | Peak concentration is higher |
| | Glucuronidation for metabolic clearance (*m*) | Accumulation during continuous or repeated administration |
| Paracetamol | Water-soluble compound, higher distribution volume (*d*) | Peak concentration is lower, less effective analgesia likely |
| | Glucuronidation for metabolic clearance (*m*) | Accumulation during repeated administration possible |
| Midazolam | Water-soluble compound, higher distribution volume (*d*) | Peak concentration is lower, effect? |
| | Clearance to metabolite (1-hydroxy) is low (*m*) | Metabolite is also sedative, less prolonged sedation. |
| | Elimination clearance of (1-hydroxy) midazolam is low (*e*) | Lower clearance results in prolonged sedation. |
| Codeine | Clearance to metabolite (morphine) is low (*m*) | Shorter or reduced analgesic effect |
| | Elimination of codeine and metabolite is low (*e*) | Accumulation of codeine or metabolite more likely, prolonged or more pronounced analgesia |

PK (ADME) in neonates for drugs commonly administered by anaesthetists.

However, neonatal PK is not just miniaturized adult PK. A minor route of elimination in adults may turn out to be the most relevant elimination route in a newborn, while not all elimination processes (e.g. drug metabolism versus subsequent elimination) mature simultaneously. Consequently, the concentration–time profile of a metabolite will not only depend on the metabolite formation as well as subsequent metabolite elimination. To illustrate the clinical relevance of such an integration, we refer to published observations on tramadol (demethylation, subsequent renal elimination), morphine disposition (glucuronidation, subsequent renal elimination clearance) and midazolam (oxidation and glucuronidation, subsequent renal elimination clearance) disposition in neonates.[32–34] All metabolites have a PD (e.g. analgesia, hyperalgesia, sedation, tolerance) impact. For all these compounds, accumulation of the metabolite can be anticipated in the newborn, not because of the already very effective phenotypic drug metabolism, but because of the even more defective subsequent elimination clearance.

To further illustrate the complexity and the need for an integrated approach—including neonatal ADME aspects—we would like to summarize the available information related to the initiation, success rates, and continuation of breastfeeding with specific emphasis on the use of and the exposure to analgesia-sedatives following maternal administration. Inadequate management of maternal pain is a commonly reported risk factor for failure of breastfeeding, while maternal exposure to analgesia-sedatives is a commonly perceived risk to breastfeed without much evidence in support of this practice.

## Applied neonatal pharmacology: obstetric anaesthesia and breastfeeding

Breastfeeding is the obvious reference nutrition for newborns and infants. However, initiation or continuation of breastfeeding often coexists with maternal drug use.[35] Consequently, the ultimate goal of using maternal medications during breastfeeding is dual. Firstly, one aims to provide effective and safe therapy for the maternal condition(s) for which the drug has been prescribed (e.g. post-caesarean analgesia, maternal co-morbidities, and pregnancy-related diseases). Simultaneously, one aims to assure protection of the nursing infant from any (relevant) adverse event related to the treatment of the mother. Only rarely do these goals overlap (e.g. maternal intake of galactogogues such as domperidone or metoclopramide to enhance milk production).[36] Despite the fact that lactating women are regular users of medications and that women are often advised to discontinue or stop nursing while taking a drug, there are only a limited number of drugs that have been identified as potentially harmful to the newborn.[37,38]

Using a prospective study design, Ito et al. documented in a cohort of 838 nursing infants with mothers taking medications that the incidence of adverse reactions was 11.2% (94/838).[39] All these events were classified as minor reactions, not necessitating medical attention. Antibiotics (19.3%), analgesics, including narcotics (11.2%), antihistamines (9.4%), sedatives, antidepressants, or antiepileptics (7.1%) were most commonly associated with adverse reactions. The reported adverse reactions were diarrhoea (antibiotics), drowsiness (analgesics, sedatives, antidepressants, antiepileptics), or irritability (antihistamines).[39] The incidence, the type of reactions, and the drugs associated are in line with the systematic literature review performed by Anderson et al.[37] Based on the evaluation of 100 published case reports, none were considered to be 'definite' using a standard ranking scale, while 47% were 'probable', and 53% were 'possible'. Drugs with central nervous system activity accounted for about 50% of the events.[37] These data suggest that—by taking a few simple precautions in drug selection and considering the infant's age—breastfeeding rarely needs to be discouraged or discontinued when a mother needs drug therapy.

As part of a multidisciplinary healthcare provider team, anaesthetists need to be aware of the general strategies applied to improve breastfeeding initiation and continuation rates, commonly referred to as the Baby Friendly Hospital Initiative (BFHI).[35] The ten steps to successful breastfeeding hereby provide a supportive pathway, enabling women to achieve their breastfeeding intentions as well as guidance for training of healthcare workers in breastfeeding support.[40,41] In addition, anaesthetists administer a limited number of drug classes that may warrant a focused discussion. Reading through the ten-step list (Box 5.1), some aspects are of general relevance and relate to awareness on the breastfeeding policy and the skills and knowledge needed to act and communicate in an effective and homogeneous way. Some specific issues may affect routine practices or habits of anaesthetists. This refers to the practice of *skin-to-skin* contact and the initiation of breastfeeding shortly after delivery (<0.5 hours), including after caesarean delivery.[35,42] This necessitates sufficient maternal alertness

**Box 5.1** The ten steps to successful breastfeeding (Baby Friendly Hospital Initiative, BHFI)

- Have a written breastfeeding policy that is routinely communicated to all health care staff.
- Train all health care staff in skills necessary to implement this policy.
- Inform all pregnant women about the benefits and management of breastfeeding.
- Help mothers initiate breastfeeding within a half-hour of birth.
- Show mothers how to breastfeed and how to maintain lactation, even if they are separated from their infants.
- Give newborn infants no food or drink other than breast milk unless medically indicated.
- Practice rooming-in—allow mothers and infants to remain together—24 hours a day.
- Encourage breastfeeding on demand.
- Give no artificial teats or pacifiers (also called dummies or soothers) to breastfeeding infants.
- Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

and short-acting, effective analgesia. The associations between maternal preferences for neuraxial techniques during labour, maternal characteristics (e.g. obesity and primiparity) or immediate skin-to-skin contact and successful breastfeeding is multifactorial, but the association between either postpartum pain or maternal sedation and breastfeeding failure has been consistently reported in the literature.[43] Consequently, obstetric anaesthesia should focus on effective, safe, reversible techniques and treatments which facilitate and do not hinder breastfeeding.

In essence, exposure of a nursing mother to any dose of drug ($D_m$) will result in—be it very limited—transfer of the drug into the human milk ($D_i$). However, concentrations reached in the human milk are usually quite low and oral bioavailability in the infant should also be considered before any relevant pharmacological exposure relative infant dose (RID) = $D_m/D_i \times$ absorption) and effect in the infant needs to be anticipated (Figure 5.2). The difference in drug level in the infant's plasma (a vs b) can be explained by the presence (a) or absence (b) of 'initial loading' related to prenatal, fetal exposure to the same compound.

Age also matters, since newborns seem to be more vulnerable to adverse effects when compared to infants and relates to the earlier discussed age-related changes in PK and PD. Finally, and often insufficiently stressed, accumulation relates to the duration of exposure and the initial concentration in the newborn. In the setting of continuation of treatment of the mother from pregnancy to postpartum, the fetus will likely already be exposed to the maternal drugs, and the newborn will already have an initial concentration of this compound at birth. The subsequent concentration will depend on the amount of exposure, the clearance capacity, and the distribution volume characteristics (e.g. postnatal weight losses).

## Opioids

Over the last few decades, the rate of breastfeeding has increased steadily in the developed world. During this time, opioid use in the general population has steadily increased as well. This means that the clinical experience with these compounds is still relatively limited in time with newly emerging data on codeine, oxycodone, methadone, and tramadol in recent years.[38,44] Applying the above-mentioned ADME issues, we should be aware that absorption of opioids after oral ingestion in neonates is common while the extent of exposure through a mother's milk will depend on maternal ingestion and metabolism. Neonatal clearance relates to either metabolic or renal elimination, but will be limited.[31] Such a setting has the potential to result in unanticipated side effects.

A pivotal case report in 2006 by Koren et al. on codeine-related morphine poisoning of a 13-day-old newborn reactivated the clinical research on maternal–infant PK of opioids through breastfeeding.[45] This study reconfirmed earlier case series on the association of maternal codeine exposure, maternal side effects (drowsiness, somnolence), and neonatal side effects (poor intake, weight loss, drowsiness, somnolence). A pharmacogenetic (PG) link between maternal ultrafast metabolizer status for CYP2D6 was documented, since this results in higher and faster conversion of codeine to morphine.[45] More recently, the same group documented that a combination of maternal genetic markers (CYP2D6 and P-glycoprotein polymorphisms) predicted 87% of the infant and maternal central nervous system depression cases with a sensitivity of 80% and a specificity of 87% in a cohort of 111 breastfeeding mother–infant pairs.[46]

The incidence of central nervous system depression in neonates breastfed by mothers receiving either oxycodone, codeine, or paracetamol was retrospectively compared in 533 breastfeeding mother–infant pairs. Lam et al. clearly showed that there was a 20.1% rate of depression in infants of breastfeeding mothers taking oxycodone, as compared with 16.7% and 0.5% in mothers treated with codeine or paracetamol respectively.[47] Methadone is somewhat special, since it is commonly used in a setting of maternal opioid addiction. Methadone is excreted into human milk (2–3% of weight-adjusted maternal dose), and there are data that suggest that these infants benefit from breastfeeding (blunted opioid withdrawal syndrome).[38] Finally, using a sparse sampling study design to assess transfer of tramadol and its *O*-desmethyl metabolite into transitional breast milk, the combined relative infant dose of 2–3% at steady-state was low. In the absence of differences in

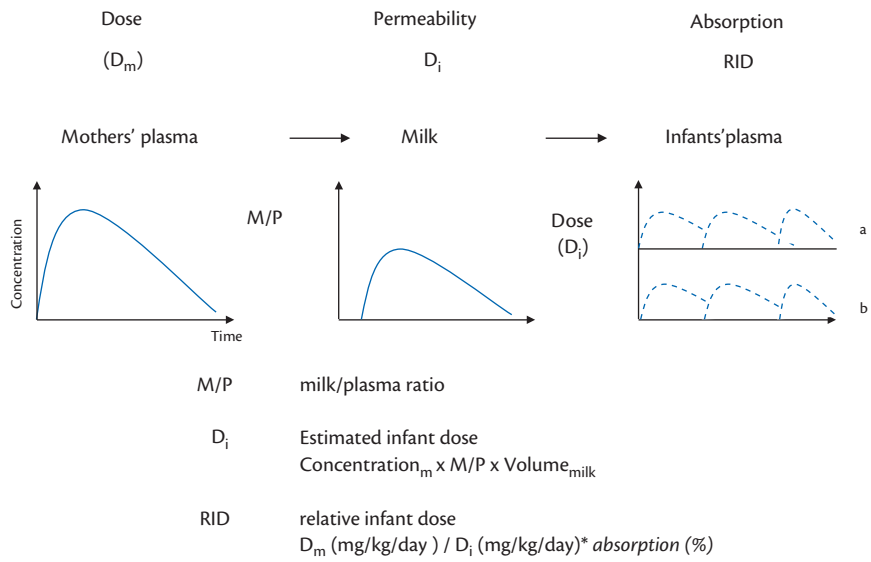

**Figure 5.2** Theoretical framework to explore the extent of neonatal drug exposure through breastfeeding following maternal drug administration.

neurobehavioral scores between exposed infants and controls, the authors concluded that short-term maternal use of tramadol is compatible with breastfeeding.[48]

There are also some additional clinically useful and relevant messages in the available observations on maternal codeine and oxycodone exposure. First, there is high concordance between maternal and neonatal central nervous system depression. As a consequence, when the mother exhibits depression, the baby should be examined by a paediatrician. Second, severe depression emerged after 4 days of use, when milk output increases, exposure increases, and exposure is prolonged. Therefore, any maternal need for opioids for more than 4 days after delivery warrants focused attention while the mother's need for adequate pain control should not be neglected.[49]

### Intravenous and inhalational anesthetics

Although the number of observations is limited, excretion of these compounds in human milk is not equal to infant exposure.[50] In the absence of subsequent enteral absorption, this remains without clinical symptoms. The same holds for inhalational agents in postpartum, while buccal resorption of etomidate has been observed. This only applies when these compounds are administered after delivery, since when administered during labour or delivery, placental passage and fetal accumulation may occur.

### Benzodiazepines

Lorazepam, midazolam, or diazepam is commonly administered as an anxiolytic or sedation in a pre-anaesthesia setting. The mother compounds and some of the metabolites can be retrieved in human milk but concentrations remain very limited.[50,51] In 24 hours of human milk collection after a single dose in a pre-anaesthesia setting, only 0.005% of the maternal midazolam dose was retrieved. Taking the subsequent oral bioavailability (50–60%) into account, it is very reasonable to assume that the exposure will be limited when initially used after delivery. In contrast, plasma diazepam and its active metabolite (desmethyldiazepam) could be measured in neonates up to 7–10 days of postnatal age after single-dose administration to the mother during labour.[51] This relates to the much longer elimination half-life of diazepam, and when needed, short-acting benzodiazepines like midazolam are more appropriate.

### Non-opioid analgesics

Human milk and plasma levels of paracetamol were monitored in three lactating women after ingestion of a 500 mg dose of paracetamol postpartum. Paracetamol concentrations remained lower in human milk (milk/plasma ratio of 0.76). Since less than 0.1% of the maternal dose would be present in 100 mL of milk, breastfeeding need not be discontinued due to maternal paracetamol exposure.[52] Similarly, ibuprofen in human milk and serum was quantified in 12 patients who had ingested one 400 mg tablet of ibuprofen every 6 hours over a 24-hour period for relief of post-caesarean delivery pain. Ibuprofen was present in the serum with a half-life of approximately 1.5 hours, but could not be quantified in human milk.[53] Based on the lower limit of quantification (1 mcg/mL), less than 1 mg of ibuprofen per day is excreted in breast milk. Similar findings have been described for ketorolac.[54] Although all these compounds may result in exposure to the newborn or infant, the extent is limited and much lower than that clinical registered dosing for analgesia or temperature reduction.[19]

### Local anaesthetics

Local anaesthetics (e.g. lidocaine, bupivacaine, and ropivacaine) are commonly administered as part of regional anaesthetic techniques (e.g. regional pain block and epidural) and data are mainly available in mothers during labour or for anaesthesia during delivery.[55] Data on excretion of lidocaine and bupivacaine in human milk have been reported. Overall this exposure is limited with minor statistical significant, but clinically irrelevant differences. This is because absorption following oral ingestion is limited.

Based on the available observations, the use of systemic non-opioid analgesics, local anaesthetics as part of regional blocks, and inhalational or intravenous anaesthetics seems safe for nursing mothers. When systemic opioids are used, some clinical monitoring is warranted with specific emphasis on the duration of exposure (4 days pivotal) and the presence of any maternal sign of central nervous system depression.[49] Finally, the use of benzodiazepines should be limited with a preference for those with a shorter half-life. Under these circumstances, the most appropriate advice to a nursing mother undergoing anaesthesia is that she may reinitiate breastfeeding when she is sufficiently awake and feels strong enough to do so.

## Conclusion

Maternal, fetal, and neonatal physiology affects both the PK as well as the PD of drugs administered in this population, including drugs commonly administered by anaesthetists. We illustrated the potential clinical relevance, using the available compound-specific observations. Since drug transfer through breastfeeding may be the most common, but complex pharmacological interaction between mother and infant, we focused on the available evidence on safety and risks related to analgosedatives.

PART 3

# Fetal and neonatal assessment and therapy

# CHAPTER 6

# Antenatal and intrapartum fetal evaluation

Yves Jacquemyn and Anneke Kwee

## Introduction

The assessment of fetal well-being aims at reducing fetal/neonatal mortality and morbidity. The anaesthetist can be confronted with tests that evaluate fetal well-being in different ways. The results of these tests can provoke the obstetrician to decide to perform an unplanned caesarean delivery, which can result in the anaesthetist needing to provide anaesthesia for an urgent delivery. Also changes in the fetal heart rate (FHR) pattern after administration of epidural or systemic medication should be evaluated and when suspected to be abnormal the obstetrician should be informed and alerted. In this chapter, we describe different methods in use to assess fetal well-being and provide the reader with basic knowledge to aid their interpretation. We will only briefly discuss tests for fetal malformations (structural ultrasound and magnetic resonance imaging) and fetal biometry for intrauterine growth disorders. An overview of the methods discussed and their evaluation is given in Table 6.1.

Intrapartum fetal monitoring aims to identify fetuses at risk for neonatal and long-term injury due to asphyxia, triggering appropriate interventions to reduce neonatal morbidity. However, it is also important that the number of subsequent unnecessary obstetric interventions, with their associated maternal and neonatal morbidity, is limited as far as possible. The ideal method of monitoring has not yet been found, which is apparent from the fact that the number of obstetric interventions for suspected fetal distress has increased without neonatal outcomes having clearly improved.[1–3]

The terms fetal 'distress' and fetal 'compromise' are rather vague, imprecise, and non-specific. The Committee on Obstetric Practice of the American College of Obstetricians and Gynecologists has proposed using 'non-reassuring fetal status' instead.[4] For practical purposes we will consider fetal compromise as a fetus at risk of hypoxia and its consequences.[4]

Causes of fetal hypoxia are multiple but can be categorized as follows:

- Maternal: reduced maternal oxygenation such as in maternal lung disease or in case of diminished atmospheric oxygen content (e.g. living at high altitude).
- Uteroplacental: such as seen in pre-eclampsia and intrauterine fetal growth restriction due to failure of trophoblast invasion resulting in reduced maternal blood supply to the placental bed.
- Fetoplacental: impaired blood supply to the placenta such as in umbilical cord compression, maternal hypotension, or hypovolaemia.
- Fetal: intrinsic fetal diseases such as fetal anaemia and/or haemoglobinopathy.

During active labour, uteroplacental perfusion is markedly reduced since during every uterine contraction the pressure in the contracting myometrium is higher than the maternal systolic blood pressure, so blood flow to the placenta virtually ceases for the duration of a contraction. The healthy fetoplacental unit can compensate for this provided that there is a sufficient interval between contractions, which is not the case in situations of uterine hyperactivity, a frequent cause of fetal hypoxia. The accumulation of carbon dioxide will rapidly lead to respiratory acidosis (as described further) as long as aerobic metabolism is maintained. When oxygen drops further, lactate will be produced resulting in metabolic acidosis.

Cardiotocography (CTG) or electronic fetal monitoring was introduced in the 1970s without proven diagnostic accuracy, and its efficiency in improving neonatal outcome was never adequately evaluated.[5–7] A disadvantage of CTG is the high percentage of false-positive interpretations[8,9] due to high inter- and intra-observer variation.[10] In a high-risk population, during the phase of cervical dilatation the CTG shows anomalies in 10% of cases and this figure increases to 60–90% during the phase of active pushing. Without additional diagnostics, this leads to unnecessary interventions due to the large number of false-positive results and the relatively low prevalence of acidosis. With CTG anomalies, additional investigations should be performed.

Essentially, at the start of labour, women can be divided into low risk or high risk for fetal hypoxia. Examples of high-risk pregnancies are pre-existing maternal disease, complicated obstetric history, hypertensive disorders, intrauterine growth restriction (IUGR), ruptured membranes for more than 24 hours, or a post-date gestational age. During labour, women can become high risk because there is failure to progress, meconium-stained amniotic fluid, or a non-reassuring FHR. Low-risk women can be monitored by intermittent auscultation (IA), whereas high-risk women should be monitored by CTG and if non-reassuring by additional methods.

In this chapter, we provide an overview of different methods for fetal monitoring during pregnancy and labour: the screening

**Table 6.1** Overview of methods for fetal monitoring in low-risk and high-risk pregnancies for developing fetal hypoxia

| Method | Low risk | High risk | Comment |
|---|---|---|---|
| **Antenatal** | | | |
| Maternal fetal movement counting | No benefit | No data | |
| Biophysical profile score | No data, no indication | No benefit | |
| Uterine artery Doppler | Only to select high risk for development of fetal growth retardation and pre-eclampsia in later pregnancy | | Does not provide information from fetus |
| Umbilical artery Doppler | No benefit | Reduces fetal mortality | |
| Middle cerebral artery Doppler | No data, no indication | No added value to umbilical artery | Can be used to diagnose and follow fetal anaemia |
| Ductus venosus Doppler | No data, no indication | Moderate detection of fetal compromise, no added value to umbilical artery Doppler | |
| Non-computerized CTG | No benefit | No benefit when used as a single test | |
| Computerized CTG | No data | Significant reduction in perinatal mortality | |
| **During labour** | | | |
| IA | No data when compared to no monitoring<br>For more detail see CTG | No data | |
| Admission CTG | More caesarean deliveries than IA, no other differences | No data | |
| CTG during labour | When compared to IA:<br>No effect on perinatal death, cerebral palsy<br>Lowers neonatal convulsions<br>More instrumental vaginal deliveries<br>Non-significant rise in caesarean deliveries | | No studies have been performed specifying low- or high-risk women |
| FBS pH | Less caesarean deliveries than CTG alone<br>Less neonatal convulsions | | No studies without CTG<br>No studies comparing high- and low-risk pregnancies |
| FBS lactate | No effect on neonatal outcome<br>No effect on instrumental deliveries | | No studies without CTG<br>No studies comparing high- and low-risk pregnancies |
| STAN® | Compared to CTG alone:<br>No difference in metabolic acidosis<br>Less operative vaginal deliveries<br>Less need for neonatal intensive care<br>Less use of FBS | | No studies without CTG<br>No studies comparing high- and low-risk pregnancies |
| Fetal pulse oximeter | No difference in caesarean deliveries<br>No difference in metabolic acidosis | | No studies without CTG<br>No studies comparing high- and low-risk pregnancies<br>No longer commercially available |

CTG, cardiotocography; FBS, fetal blood sampling; IA, intermittent auscultation.
For details and references see text.

methods such as IA and CTG and additional methods such as fetal blood sampling (FBS) and ST-analysis of the fetal electrocardiogram (ECG). We focus on methods to detect fetal hypoxia and the pathophysiology of fetal hypoxia and refer to other chapters for a discussion on the potential causes of fetal hypoxia.

## Pathophysiology of fetal compromise and relation to fetal testing

In the fetus, gas exchange occurs in the placenta, while the fetal lungs are non-functional as far as gas exchange is concerned.

The fetal circulation is different as compared to the adult, the main differences being the mixing of oxygenated and deoxygenated blood returning to the heart and differential streaming patterns allowing oxygenated blood from the placenta to reach vital organs easily. For this purpose, extracardiac shunting (ductus arteriosus and ductus venosus) and intracardiac shunting (foramen ovale) are present. Figure 6.1 represents the normal fetal circulation. Umbilical venous blood is highly oxygen-saturated blood, about half of which supplies the liver, whilst the other half enters the ductus venosus to the inferior vena cava, where it meets the less oxygen-saturated systemic venous drainage from the lower fetal body. Both streams (from the abdominal inferior cava and from the ductus venosus) do not completely mix. Oxygenated ductus venosus blood flows preferentially through the foramen ovale, left atrium, left ventricle, and ascending aorta providing oxygen to the myocardium and brain.

Both the right and left ventricles perfuse the lower body organs. The output of the right ventricle is shunted from the pulmonary artery to the aortic arch by the ductus arteriosus. The right ventricular output contains desaturated venous blood from superior and inferior vena cava and from the coronary sinus. As it passes directly through the ductus arteriosus to the descending aorta this unoxygenated venous blood is preferentially returned to the placenta for re-oxygenation.

The sympathetic innervation of the fetal myocardium is incompletely developed, even at term; beta-adrenergic receptors are present at an early age explaining the immediate fetal tachycardia seen when beta-agonists, as used for tocolysis, are administered to the mother. Vagal innervation is complete by term. As pregnancy progresses, FHR comes under increasing parasympathetic dominance, resulting in a gradual decrease in heart rate, increase in variability, and increasing responsiveness as shown by both accelerations and decelerations. The fetal heart normally appears to operate near the top of its cardiac function curve; an increase in FHR will result in only a very small increase in cardiac output, while bradycardia can result in a major decrease in cardiac output.

FHR is regulated by a variety of systems including baroreceptors, chemoreceptors, the autonomic nervous system, the adrenal medulla, hormonal influences such as renin, angiotensin, vasopressin, natriuretic peptides, prostaglandins, endothelin, and endothelium-derived nitric oxide. The magnitude and clinical relevance of the relative contribution in regulating fetal cardiac function are matters of ongoing discussion.

The baroreflex means that after an acute increase in systemic arterial pressure (as seen, for instance, when the umbilical arteries are compressed) the FHR slows. Baroreceptors are present at the carotid sinus and are active through the vagal nerve. Chemoreceptors are present in the carotid artery and in the aorta. Carotid chemoreceptor stimulation causes hypertension and tachycardia, whereas aortic chemoreceptor stimulation results in bradycardia and only a mild increase in arterial blood pressure. The carotid receptors are less sensitive than the aortic receptors which explains why bradycardia is mostly seen in cases of fetal hypoxia. The autonomic control of the FHR shows maturation with advancing gestational age. This means that interpretation of the FHR pattern should take gestational age into account. Accelerations and periods of high variability (as discussed further) are seen less frequently before 30 weeks' gestational age, their absence in preterm gestation should not be interpreted as a sign of fetal distress.[11]

The human fetus demonstrates a variety of adaptations to hypoxia, including modifying these preferential

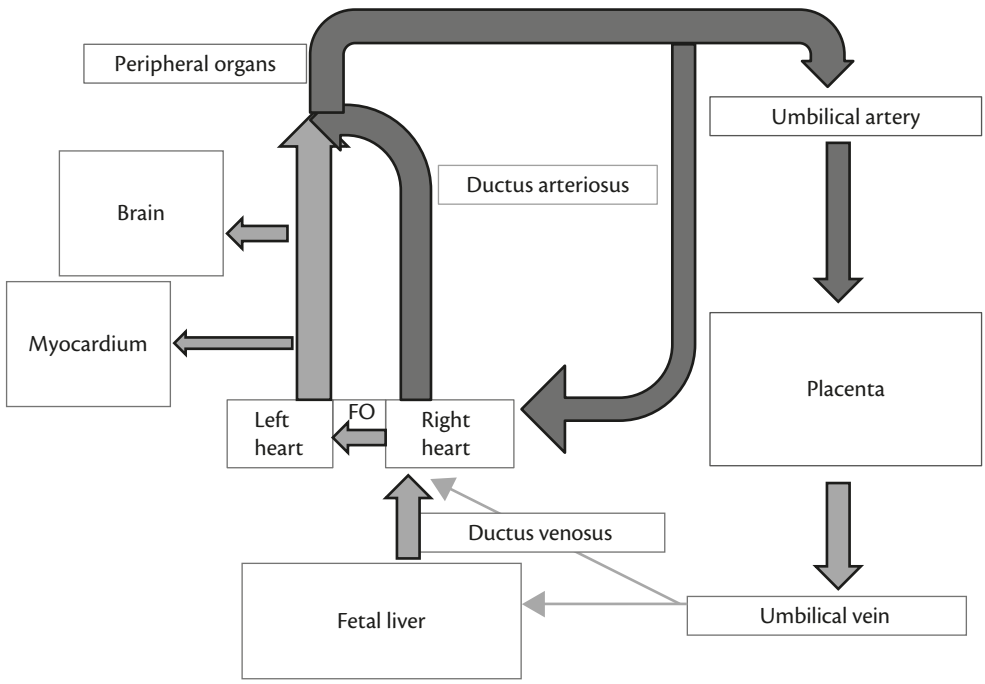

**Figure 6.1** Normal fetal circulation. FO, foramen ovale.

streaming patterns. The available tests detect different aspects of these adaptations.

In the normal fetal situation, adenosine triphosphate (ATP) as an energy carrier is produced via oxidative phosphorylation mainly from glucose, although the fetus can also use fats and proteins. ATP is present in cells in small amounts, its half-life is only seconds, and ATP must be quickly regenerated to match usage by cells. Mitochondria from fetal myocardium demonstrate higher oxidative phosphorylation than from adult myocytes, reflecting increased electron transport. When the oxygen level is insufficient, anaerobic metabolism occurs, resulting in only two molecules of ATP versus 24 molecules being produced per molecule of glucose. Hypoxia also results in by-products such as lactic acid, provoking metabolic acidosis. Finally, cellular metabolism is no longer sustained, resulting in cell damage and death.

Oxygen is provided to the fetus via the maternoplacental and fetoplacental exchange. Fetal respiratory acidosis occurs when carbon dioxide cannot be washed out. This can be caused by inadequate gas exchange across the placenta, but also by a high maternal arterial $PCO_2$ (which blocks the diffusional transfer of $CO_2$ from fetus to mother), or a combination of both. As the fetal pH will be lower both during metabolic and respiratory acidosis, some other measurement of fetal acid–base balance is necessary to differentiate between the two, including fetal lactate determination or calculating fetal base excess or deficiency based on $PCO_2$ measurement using different algorithms.

Damage is most acute in the fetal brain, myocardium, and kidneys. When fetal hypoxia occurs, redistribution of blood is preferentially to the fetal brain ('brain sparing'), the myocardium, and adrenal glands and this is at the expense of organs such as the lungs, liver, and kidneys. Except for the fetal cerebral circulation, autoregulation (the ability to maintain constant blood flow over a wide range of perfusion pressures) is not present in the placenta-umbilico-fetal system. We will now discuss briefly the effects and clinical correlations of fetal hypoxia on the adrenals, kidney, myocardium, and brain.

In case of hypoxia, the adrenal medulla will increase circulating plasma catecholamine concentrations. Stimulation of beta-adrenoreceptors in the myocardium activates glycogenolysis and enhances myocardial work performance and is related to an increase in the fetal T-wave amplitude in the ECG, which is used in fetal ST segment monitoring. The rise in T wave is due to a shift in potassium ions ($K^+$) as related to lactic acid transport, affecting myocardial cell membrane potential.

Reduced renal perfusion results in oliguria. In contrast, swallowing, the mechanism for elimination of amniotic fluid, is controlled by a relatively hypoxaemia-resistant hindbrain regulatory centre. Both factors combined result in reduced amniotic fluid volume or oligohydramnios.[12]

Myocardial response to hypoxia includes T-wave rise, as already mentioned. When energy balance can no longer be maintained by anaerobic metabolism and vasodilatation, ischaemia results. As the perfusion of the myocardium is directed from the outer (epicardial) to the inner (endocardial) surface, the more distal endocardial part will suffer from ischaemia first. This causes delay in repolarization in the endocardial face as compared to the epicardial level. The change in the sequence of repolarization (the endocardial part repolarizing later than the epicardial part) is reflected as a depression of the ST segment with or without a negative T wave in the fetal ECG, which is clinically detected using ST analysis. Any other factor altering the balance of performance and repolarization through the myocardium will cause similar changes, not necessarily related to fetal hypoxia, including prematurity, infections, cardiomyopathy, and cardiac malformations.[13,14]

Fetal cerebral circulation is characterized by arterial vasodilation in case of hypoxia. Such vasodilation can be clinically measured as a reduced resistance in the middle cerebral artery (MCA) as will be discussed further. The normal human fetus develops an increasingly complicated behavioural pattern from early to late pregnancy, including gross body movements, breathing movements, fine motor movements, and even including reactions to external stimuli such as noise and vibration. Fetal movements increase FHR, FHR variation, and accelerations. In case of cerebral ischaemia, these patterns are progressively lost in the inverse sequence as they were acquired, the reaction to external stimuli disappearing first, followed by loss of fine motor movements over stopping breathing movements, and finally complete immobility without any large body movements. Presence or absence of these behavioural patterns can be evaluated using the fetal biophysical profile. A normal biophysical profile is associated with normal healthy status and absence of normality possibly equals fetal distress.

## Antenatal prelabour fetal evaluation

### Assessment of fetal movement by the mother

Pregnant women recognize fetal movements from the second trimester although large interindividual variation exists.

Structured fetal movement counting, such as 'count to ten' fetal kicks, has been attempted as a method to reduce variation and diminish fetal death. However, in a randomized controlled trial (RCT) including 68,000 women[15] this did not result in improved outcome as compared to informally asking for fetal movements during standard antenatal care. Fetal movement charting has not been proven to be of benefit, but only one RCT has actually been performed in low-risk women and none in high-risk women.[16]

The compromised fetus presumably reduces its activity to decrease oxygen need. Any patient reporting fetal inactivity should be further examined, including CTG and ultrasound for fetal biophysical profile, but no study has ever reported on a comparison between different methods to manage reported decreased fetal movements.[17]

### Biophysical profile scoring and placental grading

#### *Fetal behavioural state*

Body movements and heart rate patterns in the human fetus reveal cyclicity that becomes more marked when reaching term. Nijhuis et al. first described four distinct behavioural states based on ultrasound and FHR recordings, which can be clearly determined at approximately 26 weeks.[18] Quiescence (state 1F) is characterized by no eye movements, no somatic movements except for the occasional startle, and a FHR pattern with little baseline variability, comparable to non-rapid eye movement (REM) sleep. When recording FHR such periods typically last for about 20 minutes, but may persist for 2 hours in normal term fetuses. State 2F is characterized by continuous eye movements, frequent bursts of somatic movements, and wide baseline variability and accelerations with movement, comparable to REM sleep. This state predominates, occurring approximately 40% of the time. State 3F shows no gross body movements, eye movements are continually

present, and FHR is stable but with a wider oscillation bandwidth than for state 1F. State 3F is seldom seen and it is debated whether this is really a distinct entity. State 4F is characterized by continuous eye movements with almost continuous somatic movements and a sustained tachycardia. With advancing gestational age, state 1F increases in time without a change in 2F, but with less time spent in an unidentifiable state. In case of IUGR, as a marker of chronic hypoxaemia, fetuses show a delay in the appearance of well-delineated states, indicating subtle disturbances of the central nervous system.

### *Biophysical profile score*

Animal studies have demonstrated that episodic fetal breathing movements (FBM) and fetal gross body movements (GBM) are inhibited by acute hypoxia.[19] This formed the basis for the development of a composite biophysical profile score (BPP) including markers of both acute (FBM, GBM, fetal tone, FHR reactivity) and chronic (amniotic fluid volume) fetal compromise.[20]

In case of IUGR and chronic fetal hypoxaemia, FBM and GBM generally decrease to minimize energy expenditure depending on the severity of the condition.[21]

The four acute markers have a different time relationship to become abnormal in case of fetal compromise. A non-reactive CTG (see 'Basic Principles' section of CTG) and absent FBM are early and sensitive, and as a consequence demonstrate a high false-positive rate; GBM and fetal tone change late. The risk for fetal metabolic acidosis and perinatal mortality increases with reductions in BPP.[22]

An overview of the scoring system as proposed by Manning et al. is given in Table 6.2.

A score of either 10 out of 10 or 8 out of 10 with normal amniotic fluid volume, or 8 out of 8 (without CTG) is indicative of fetal health and absence of distress, or better normal tissue oxygenation and absence of central acidaemia. It should be remembered that the test only represents the fetal metabolic situation at the time of the test; no good data are available to decide on the frequency at which the test should be repeated. The results are also influenced by gestational age and the normal cyclical pattern of fetal behaviour. FBM and GBM are more often absent at 26–33 weeks, resulting in falsely abnormal results.[21]

Even in the absence of metabolic acidosis, IUGR fetuses demonstrate less FBM and GFM.[23]

A score of 6/10 or less means a probability of tissue hypoxia and central acidaemia. There are no randomized trials indicating the best management in such circumstances. Clearly the BPP is more time-consuming and requires more technical skills than the CTG alone. It is accompanied by a very low false-negative rate in high-risk pregnancies (0.07%) but with a false-positive rate comparable to that of the CTG alone. In a meta-analysis of randomized trials comparing CTG alone and BPP, no difference was noted for perinatal mortality, low Apgar score, or incidence of caesarean delivery.[24] The available evidence no longer supports the use of BPP as a test for fetal well-being in high-risk pregnancies. There has been no study to evaluate BPP in low-risk pregnancies and this is not recommended.

**Table 6.2** Manning biophysical profile score

| Variable | Normal: score 2 | Abnormal: score 0 |
|---|---|---|
| Fetal breathing movements | 1 or more episodes of ≥20 s within 30 min | Absent or no episodes of ≥20 s within 30 min |
| Gross body movements | 2 or more discrete body/limb movements within 30 min (episodes of active continuous movement considered as a single movement) | <2 episodes of body/limb movement within 30 min |
| Fetal tone | 1 or more episodes of active extension with return to flexion of fetal limb(s) or trunk (opining an closing of hand considered normal tone) | Slow extension with return to partial flexion, movement of limb in full extension, absent fetal movement, or partially open fetal hand |
| Reactive fetal heart rate | 2 or more episodes of acceleration of ≥15 bpm and of >15 s associated with fetal movement within 20 min | 1 or more episodes of acceleration of fetal heart rate or acceleration of <15 bpm within 20 min |
| Qualitative amniotic fluid volume | 1 or more pockets of fluid measuring ≥2 cm in vertical axis | Either no pockets or largest pocket <2 cm in vertical axis |

## Doppler ultrasound

### *Basic principles*

Doppler ultrasound allows non-invasive evaluation of maternal and fetal haemodynamics. Blood flow is most often quantified either by a pulsatility index or by a resistance index, reflecting the downstream vascular resistance by quantifying differences between peak systolic and end-diastolic or mean velocity.

### *Maternal doppler*

#### Uterine artery

Trophoblast invasion in the uterine vessels has to occur early in the second trimester to allow increase in uterine perfusion and providing nutrient supply and gas exchange to the fetus. This invasion, destroying the muscular wall of the spiral arteries to the placenta, results in lowering the resistance to distal flow in the uterine arteries and is marked by a typical high end-diastolic velocity pattern in the uterine artery in pregnancy. Failure of trophoblast invasion of the spiral arteries results in increased resistance and decreased placental perfusion, possible fetal growth restriction, and pre-eclampsia. This results in a pathological Doppler pattern of the uterine artery with low diastolic velocity and an early diastolic notch. It has been demonstrated that screening with uterine artery Doppler is able to predict fetal growth restriction and pre-eclampsia. Uterine artery Doppler does not provide any information on the actual fetal status.

Other Doppler measurements of maternal circulation, including maternal cerebral circulation, have been studied but do not directly relate to fetal status.

### *Fetal doppler*

#### Umbilical artery

Umbilical artery Doppler (Figure 6.2) is a placental function test, closely related to umbilical artery pH.[25] The resistance to flow increases in the umbilical artery as placental fetal circulation is

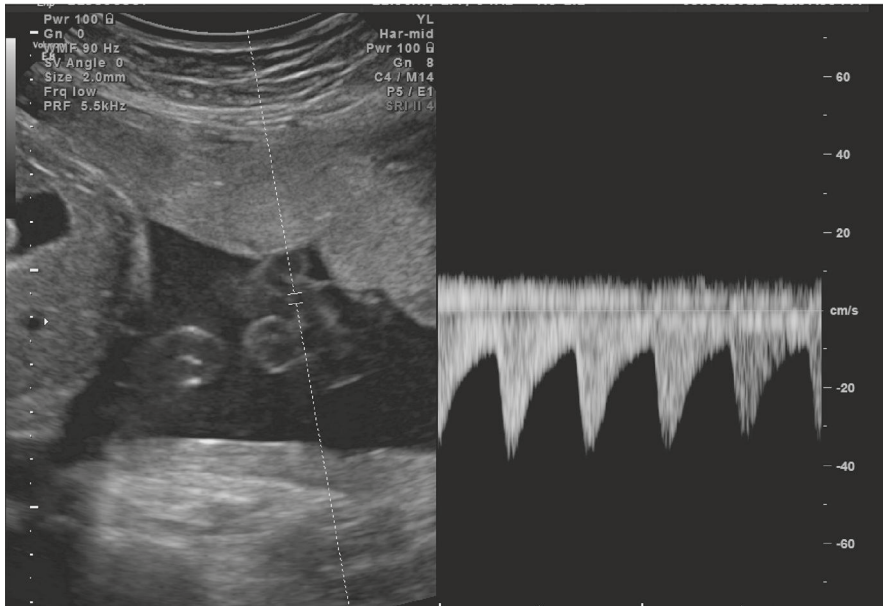

**Figure 6.2** Normal umbilical artery flow pattern.

compromised (higher placental impedance) resulting in low to absent and even reversed flow in the umbilical artery during fetal diastole (Figure 6.3). Resistance to flow has been expressed in different indices such as the resistance index and the pulsatility index, a higher index indicating worse fetoplacental circulation. RCTs have demonstrated a significant association between abnormal umbilical artery Doppler and adverse perinatal outcome. Umbilical artery Doppler allows differentiation between the constitutionally small fetus and the growth-restricted fetus.

The odds ratio for perinatal mortality in growth-restricted fetuses by absent diastolic flow is 4.0, in case of reversed diastolic flow this increases to 10.6. Absence of diastolic flow has a sensitivity of 78% for detecting hypoxia and 90% for detecting fetal acidosis on fetal blood at delivery. The positive predictive value ranges from 53% to 88%, the negative predictive value from 98% to 100%.[26]

Meta-analyses have demonstrated that in high-risk (including maternal hypertension and ultrasound-proven fetal growth restriction) pregnancies, umbilical artery Doppler ultrasound significantly reduces perinatal deaths (1.2% versus 1.7%). Number needed to 'treat' to prevent 1 fetal death is 203. This is true when Doppler is combined with other tests such as CTG or BPP, when one compares Doppler alone to CTG alone no difference was noted.[27] This means that umbilical artery Doppler is by itself never an indication for immediate intervention (such as caesarean delivery); every individual case should be evaluated based on all available parameters such as fetal growth, maternal health, gestational age, and CTG. In case of fetal IUGR and absent or reversed end-diastolic umbilical artery flow hospital admission and daily CTG are advised.[28]

In low-risk unselected pregnancies, no difference in outcome is found in a meta-analysis[29] for serious neonatal morbidity, low Apgar score, caesarean delivery, operative vaginal births, induction of labour, or neonatal resuscitation and perinatal death. Neither is there any effect when using umbilical artery Doppler intrapartum as reviewed by Farrell et al.[30]

**Middle cerebral artery**

In the normally developing fetus, the brain is an area of low vascular impedance. In cases of hypoxia, redistribution to the fetal brain is seen, as shown by lowering of the resistance in the MCA (Figures 6.4 and 6.5). When compared to umbilical artery Doppler, adding MCA Doppler does not seem to add any clinical benefit, although it is frequently performed to demonstrate brain-sparing effects. A systematic review and meta-analysis showed low predictive accuracy for adverse perinatal outcome (positive likelihood ratio 2.77, 95% confidence interval (CI) 1.93–3.96; negative likelihood ratio 0.58, 95% CI 0.48–0.69),[31] concluding that MCA Doppler has no or very limited added value as compared to umbilical artery Doppler and CTG. Another application of MCA Doppler is in the diagnosis and management of fetal anaemia: the velocity of blood flow in the cerebral artery correlates very well with fetal haemoglobin, the lower the haemoglobin the higher the velocity. MCA velocity measurement has been the non-invasive method to diagnose fetal anaemia and determine when delivery or intrauterine transfusion is mandatory.[32]

The fetal aorta and other arteries have been studied but have no additional benefit to clinical management.

Venous fetal Doppler has also been introduced as providing information from the precordial circulation. Pulsations in the umbilical vein, caused by retrograde transmission of atrial pressure mainly in the failing heart, are related to impending fetal demise.

The flow pattern in the ductus venosus demonstrates a typical M-shaped pattern (Figure 6.6) and, in contrast to other veins, reverse flow is not present in normal fetuses. During atrial systole, reduction in forward flow always occurs, producing the characteristic negative a-wave in the ductus venosus pattern. In case of defective placentation, cardiac afterload increases and the a-wave

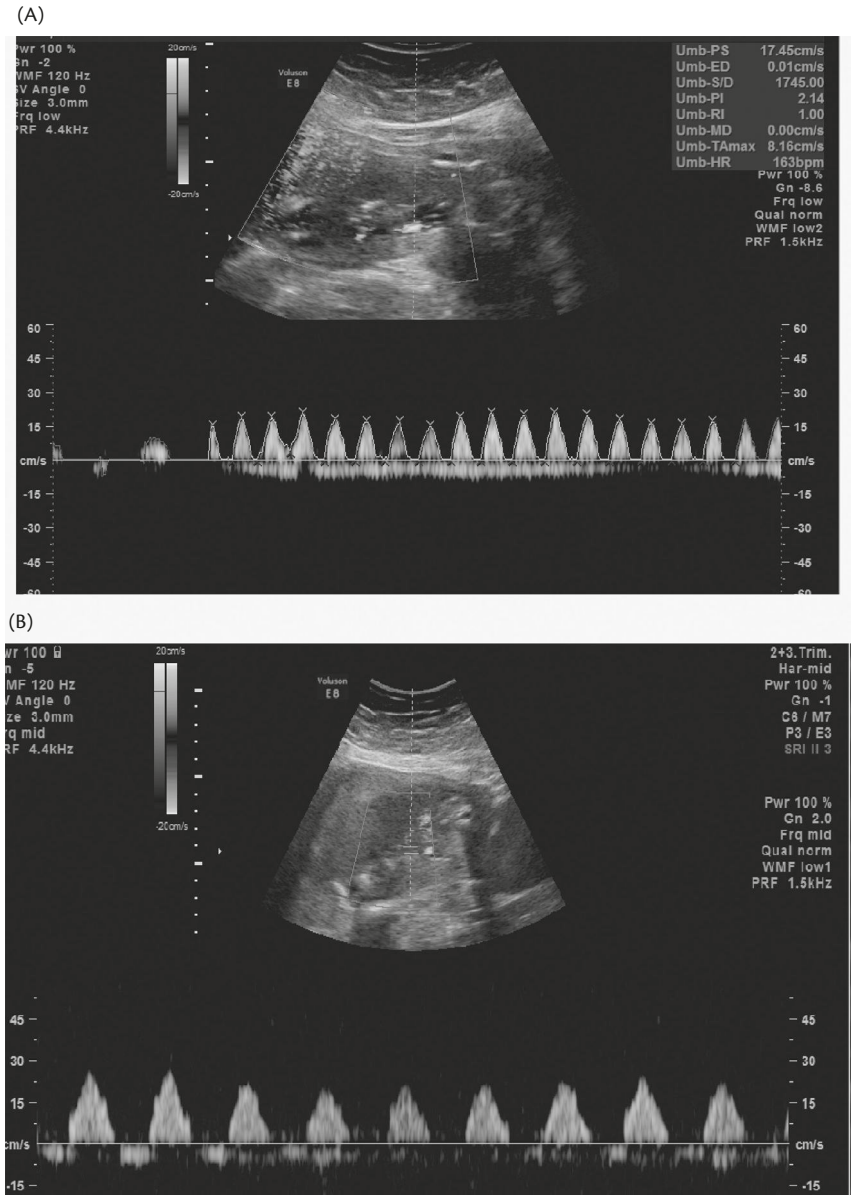

**Figure 6.3** (A) Absent and (B) reversed diastolic flow in the umbilical artery.

becomes progressively steeper. When evolving to a retrograde a-wave (Figure 6.7), this signifies significant cardiac impairment. Abnormal ductus venosus Doppler showed moderate predictive accuracy for compromise of fetal/neonatal well-being overall and perinatal mortality in high-risk pregnancies with placental insufficiency.[31]

## Cardiotocography

### *Basic principles*

CTG is the continuous recording of FHR and uterine activity. In the antepartum period, with intact membranes, the FHR can be recorded from an ultrasound transducer positioned on the abdomen of the mother. Multiple attempts have been done to record the fetal ECG through electrodes placed on the maternal abdomen, even leading to small commercialized systems. But in general, the quality of the signal and the percentage of time the signal is lost (usually ~30%) are still hampering applications for daily clinical use, although recently progress in the technical aspects has been made.[33] Uterine activity is assessed from a transducer placed on the abdomen of the mother. The CTG is the reflection of the interaction of fetal neurological status to cardiovascular reflex responses.

In some machines, fetal movement detection, called actography, has been incorporated, but this technique does not improve the assessment of fetal well-being.[34]

### *Interpretation of the prelabour FHR pattern and management*

Prelabour CTG, also called non-stress testing, has been accepted as a primary tool for pregnancies at risk. No benefit has ever been proven for routine prelabour CTG in normal low-risk pregnancies.

FHR patterns are affected by a variety of factors, as described in the paragraph on physiology, but also evolve during pregnancy with fetal maturation. Further diurnal variations are influenced by fetal behavioural states as mentioned earlier. In preterm

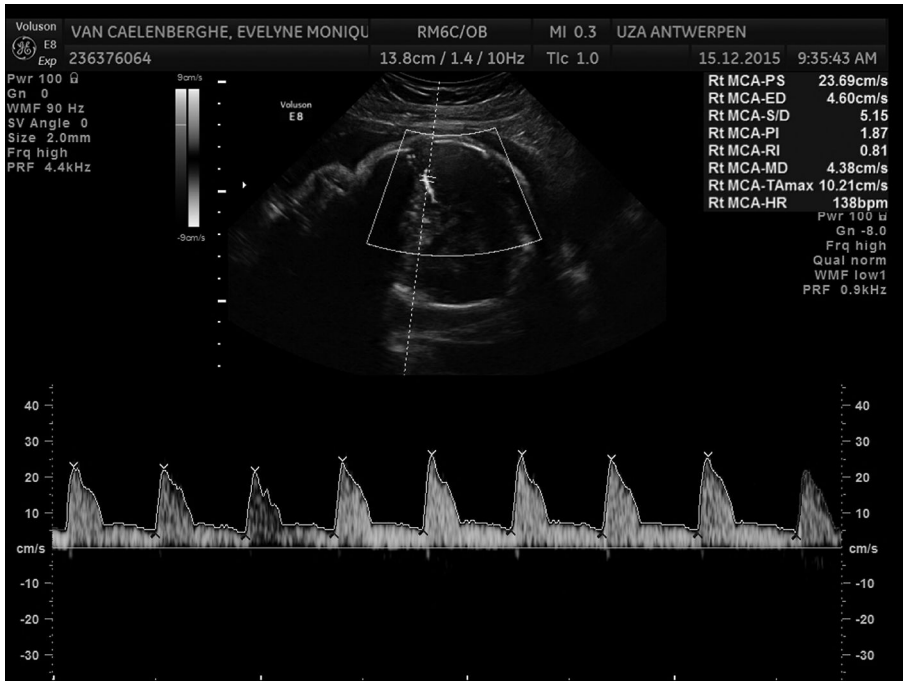

**Figure 6.4** Normal middle cerebral artery flow.

pregnancies (24–32 weeks), accelerations demonstrate a lower amplitude (10 beats per minute (bpm)) and brief spontaneous decelerations, commonly called spikes, associated with movements are often recorded.[11,35]

Maternal factors also influential; medication such as narcotics, magnesium, beta-blocking agents, or corticosteroids diminish FHR variability or may lower mean heart rate. Postprandial rise in glycaemia also activates fetal heart rate variability. A non-stress test is preferably performed with the mother lying with slight left lateral tilt to avoid aortocaval compression and its resulting FHR changes.

The interpretation of an antepartum CTG includes evaluation of the timing and quality of the recording, evaluation of the basic FHR, FHR variability, accelerations, decelerations, and eventually some uterine activity.

Interpretation of a CTG trace of low technical quality should be avoided. Due to the fetal quiet sleeping state, a trace should at least be 20 minutes in duration, preferably 30 minutes.

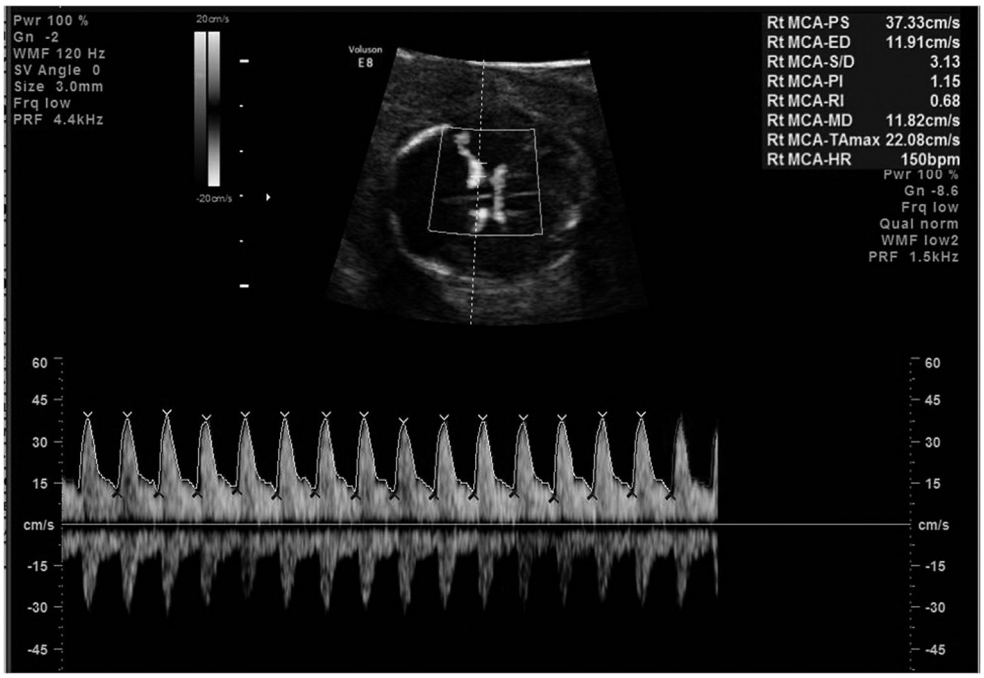

**Figure 6.5** Dilated cerebral artery with decreased resistance.

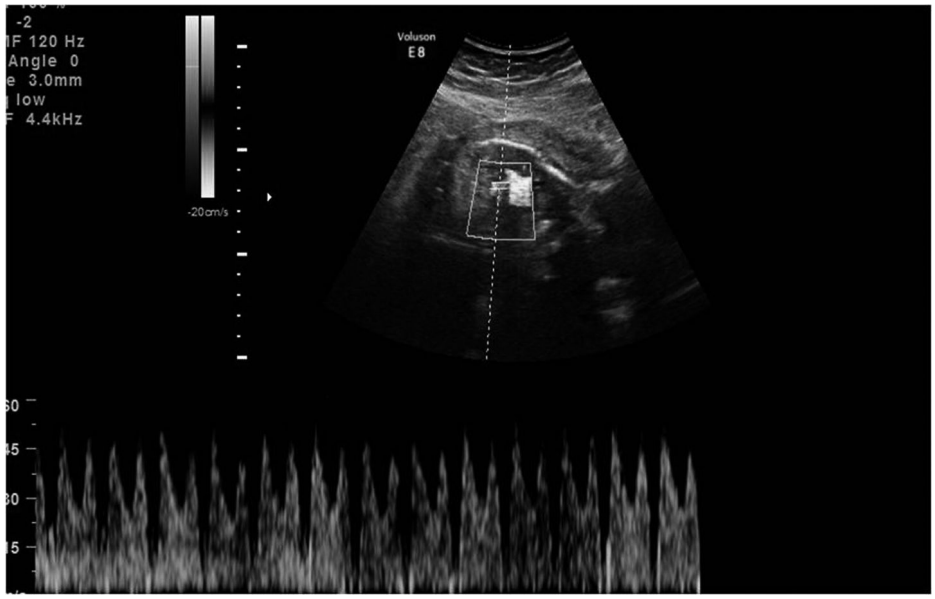

**Figure 6.6** Normal M-shaped ductus venosus flow pattern.

The baseline FHR is defined as the heart rate registered for at least 10 consecutive minutes and is expressed as bpm. The basic rate diminishes during pregnancy from round 145 bpm at 24 weeks to 135 bpm at term. In a term pregnancy, normal basal FHR is between 110 and 150 bpm (Figure 6.8), tachycardia is more than 150 bpm, and bradycardia less than 110 bpm.

Tachycardia (Figure 6.9) can be transient and physiological as in fetal state 4F, but can also be associated with fetal anaemia, maternal fever, fetomaternal infection, or maternal medication such as betamimetics. A rise in maternal adrenaline due to stress or pain can also cause a period of fetal tachycardia. Maternal hyperthyroidism can also cause fetal tachycardia due to transplacental passage of thyroid hormone or thyroid stimulating antibodies. Rarely, fetal heart rhythm disorders, mainly re-entry tachycardia, cause fetal tachycardia first noticed on a CTG.

Mild bradycardia between 100 and 110 bpm is mostly benign, but if less than 100 bpm hypoxia is probable (Figure 6.10). This can be caused by diminished placental perfusion, cord compression

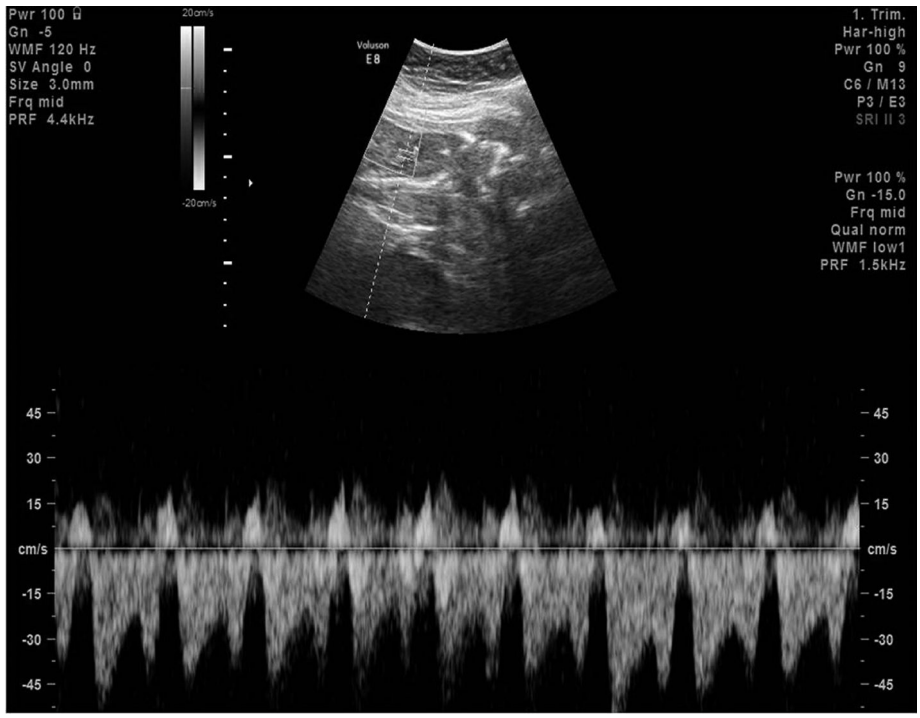

**Figure 6.7** Abnormal ductus venosus flow pattern with reversed a-wave.

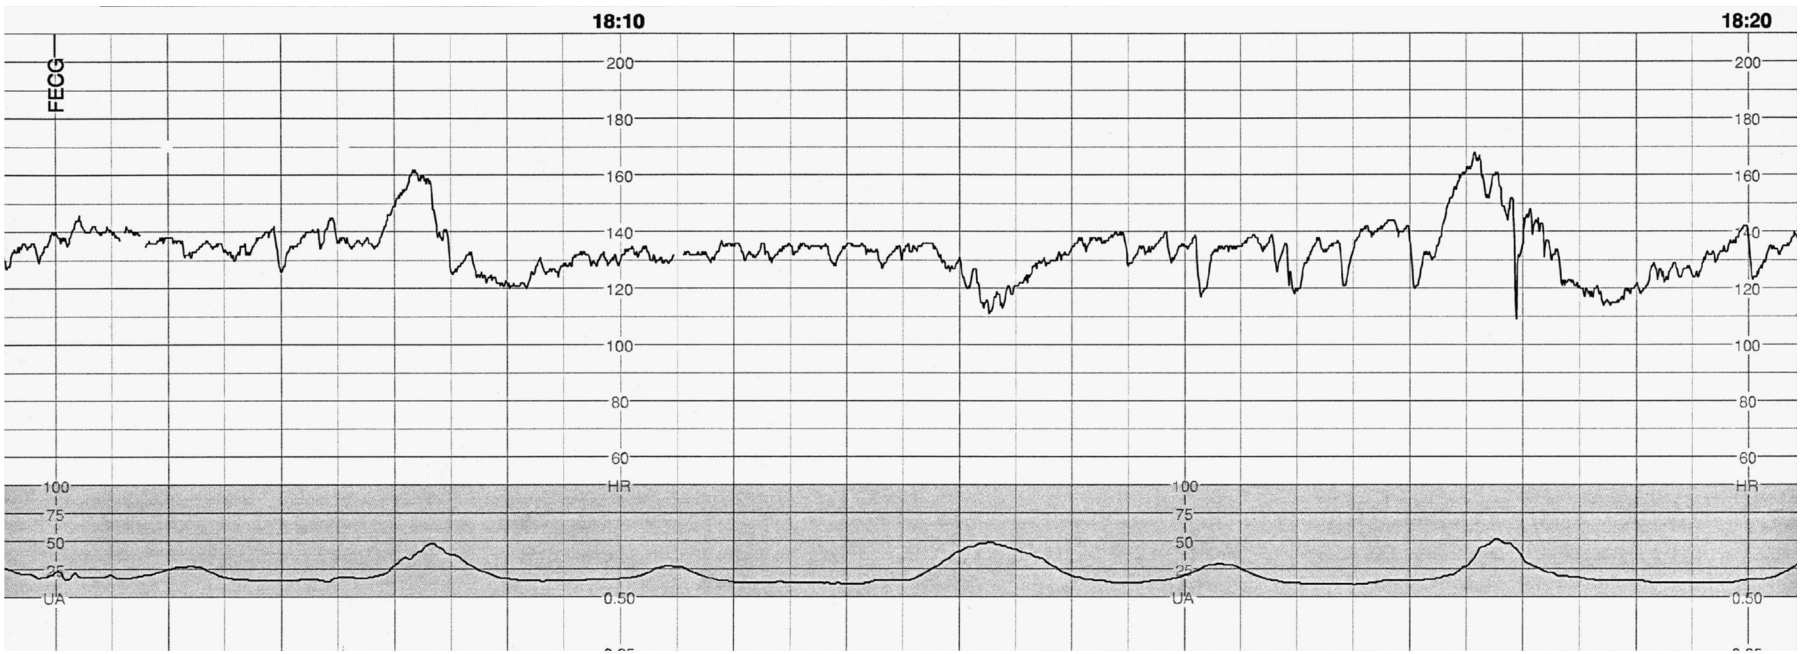

**Figure 6.8** Normal cardiotocography.

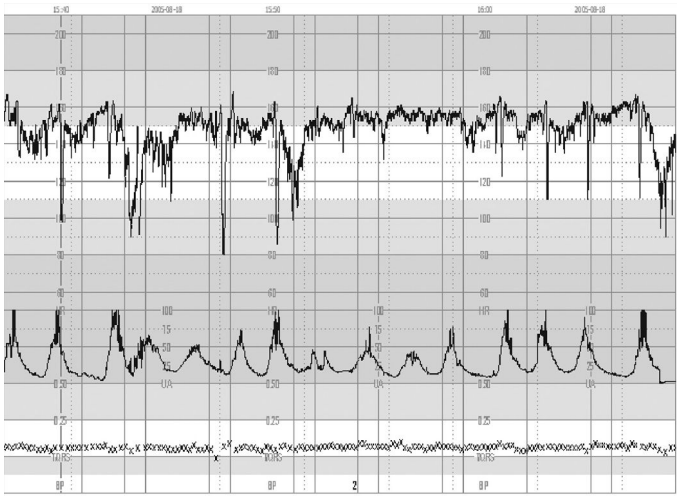

**Figure 6.9** Fetal tachycardia.

(as in oligohydramnios), or maternal hypotension, the most explicit and benign demonstration of this being the aortocaval compression syndrome with the mother in dorsal decubitus. Fetal atrioventricular heart block, as can be caused by maternal systemic lupus disease, can also result in fetal bradycardia that can be further elucidated by fetal cardiac ultrasound.

FHR variability is the variation of the heart rate during 1 minute, without accelerations or decelerations. Short-term or beat-to-beat variation is the difference in interval between consecutive heart beats (expressed in milliseconds and only to be measured by computer-aided systems, see 'Computer-Aided Fetal Heart Rate Analysis'), long-term variability is presented by the bandwidth on the trace (see Figure 6.11) and is expressed in bpm. Bandwidth is normally round 6 bpm at 24 weeks and 10 bpm at 36 weeks; normal variability is considered to be between 5 and 25 bpm. Low, or minimal, variability below 5 bpm suggests fetal hypoxia but is also present in fetal sleeping behavioural states, explaining why a recording of sufficient time is necessary. Persistent low variability is the best predictor to be derived from the CTG for fetal hypoxia/metabolic acidosis. Other reasons for diminished variability include maternal medication such as hypnotics, beta-blocking agents, and fetal central nervous system disorders. Administration of betamethasone and dexamethasone to promote fetal lung maturity in the preterm fetus also results in transient (2–3 days) lowering of FHR variability.

Complete absence of variability is called a preterminal trace and is almost invariably a sign of serious fetal hypoxia or brain damage.

When bandwidth is more than 25 bpm this is called marked variability or a saltatory trace. This can represent acute fetal hypoxia due to an acute imbalance between sympathetic and parasympathetic innervations, but it can also be benign due to fetal thumb sucking or very active moving.

The sinusoidal trace is mostly a slightly tachycardic trace with an oscillating pattern demonstrating 3–5 cycles per minute for at least 20 minutes and a bandwidth of 5–15 bpm. It is seen in case of fetal anaemia but is sometimes due to medication such as meperidine and morphine. The pathophysiology behind this kind of recording is unknown, as most even severely anaemic fetuses do not develop it. In case of forceful fetal thumbsucking, a pseudosinusoidal trace can be seen.

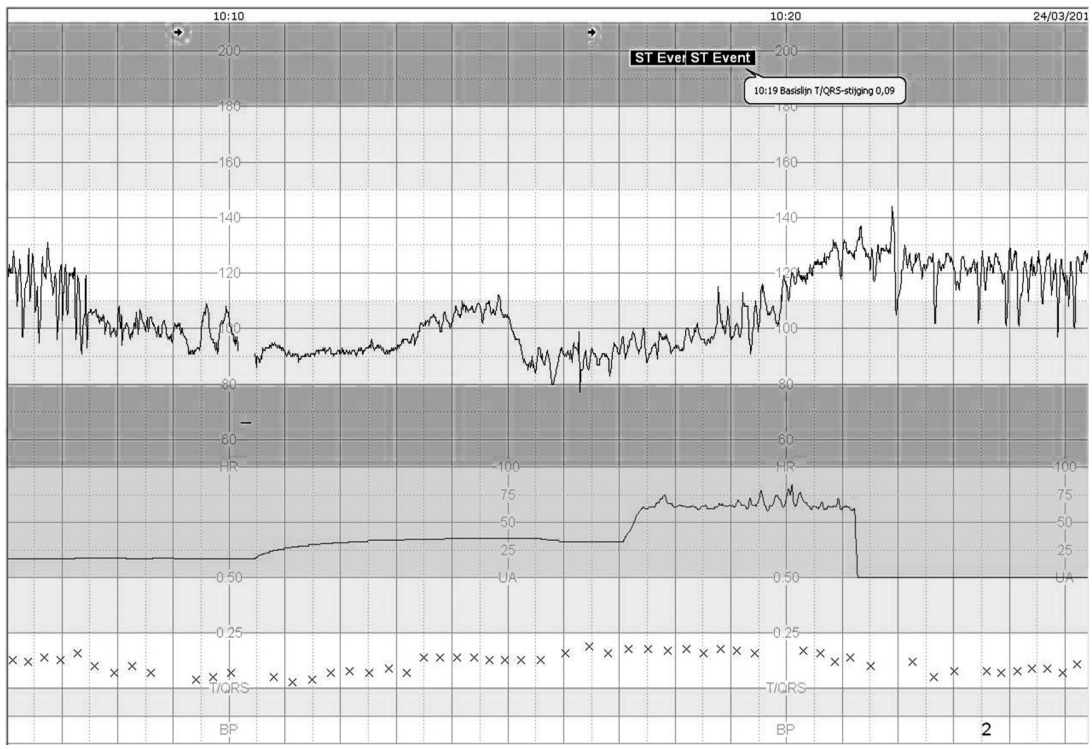

**Figure 6.10** Fetal bradycardia.

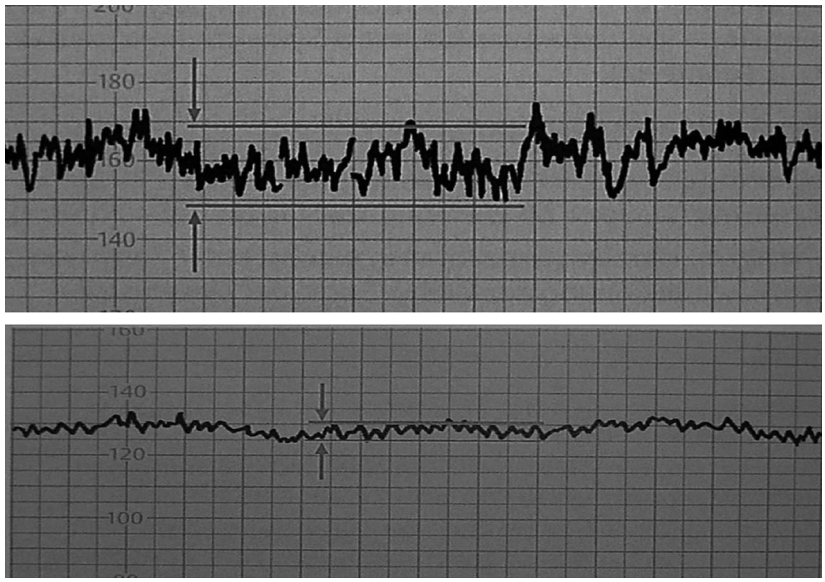

**Figure 6.11** Long-term variability; variability is expressed as the bandwidth of the envelope surrounding the fetal heart rate pattern. The upper panel shows normal variability, the lower panel reduced variability.

Accelerations are defined as (from 32 weeks' gestational age) a rise in FHR for at least 15 bpm compared to the basal FHR during at least 15 seconds. These are mostly associated with fetal movements. Before 32 weeks, 10 bpm and 10 seconds are used. At least two accelerations in a 20-minute period is called a reactive stress test and almost completely excludes fetal acidosis and is related to a risk for fetal demise in the next 7 days of less than 2 per 1000. A trace without accelerations is called non-reactive.

Decelerations constitute a decrease in FHR with at least 15 bpm for at least 15 seconds. Decelerations are subdivided in uniform (early and late), variable (complicated and uncomplicated), and long decelerations.

Uniform decelerations demonstrate a rather 'rounded' pattern; if they are multiple they do have a uniform aspect. Usually the loss of heart rate is not very remarkable nor very sudden (Figure 6.6). Variable decelerations on the contrary show a steep and significant lowering. When looking at a series of variable decelerations they demonstrate changes in form, which is where the denomination 'variable' comes from. Long decelerations by definition mean less than 80 bpm for at least 2 minutes or less than 100 bpm for at least 3 minutes. When decelerations last more than 5 minutes they are called bradycardic.

Early uniform decelerations coincide with contractions (Figure 6.12); a late uniform deceleration shows the lowest point

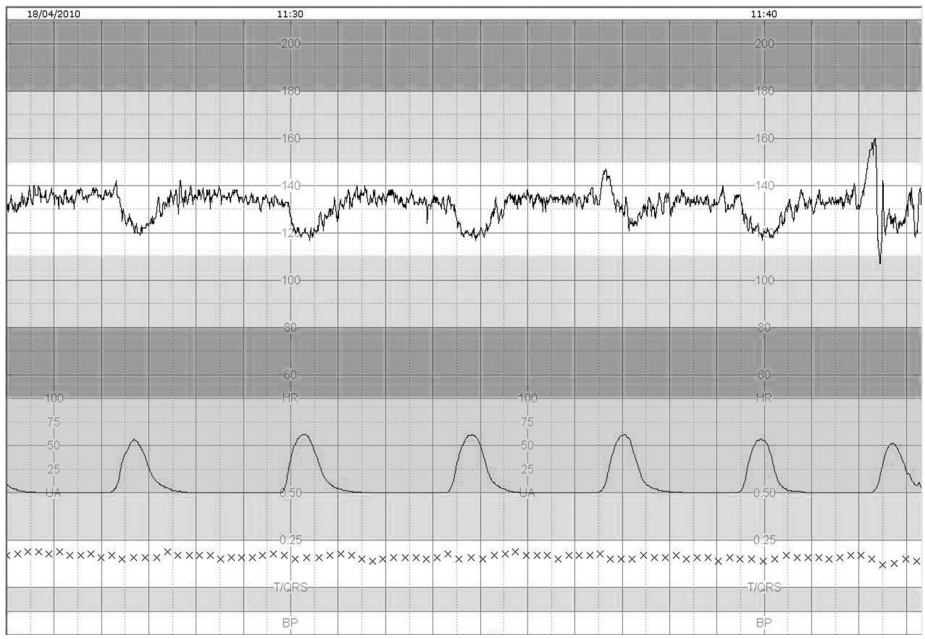

**Figure 6.12** Early uniform decelerations.

**Figure 6.13** Late uniform decelerations.

after the height point (acme) of the contraction (Figure 6.13). Early uniform decelerations are not a sign of fetal hypoxia and are related to increasing pressure on the fetal skin; late uniform decelerations are due to diminished oxygen supply.

An uncomplicated variable deceleration takes less than 60 seconds (Figure 6.14) and complicated ones more than 60 seconds (Figure 6.15). Variable decelerations are mostly due to diminished blood flow to the fetus such as during a contraction or when the umbilical cord is compressed. An overview of the different deceleration types is given in Figure 6.16.

Before 30 weeks, short decelerations (<30 seconds) are frequently seen (the so-called spikes as already mentioned) and should be considered physiological.

Other influences changing the CTG pattern are discussed further later in this chapter.[36]

To aid in diagnosing fetal problems different classification systems have been developed. The system adopted by the Federation Internationale des Gynécologues et des Obstétriciens (FIGO) is most often used and is illustrated in Table 6.3.[37,38]

The system was originally developed for intrapartum monitoring but can also be used antepartum. Other systems have been and still are being proposed, but these have neither been validated nor are they used in Europe.[37]

No good data are available to guide the clinician on the interval of repeat testing.[39] Older studies have demonstrated that the rate of stillbirth after a reactive stress test within 1 week is 1.9 per 1000 compared to 26 per 1000 for a non-reactive test, increasing the rate from once to twice weekly still decreases the rate of stillbirth specifically in case of fetal growth restriction.[40,41] It should be noted that CTG is very good at ruling out fetal compromise (the negative

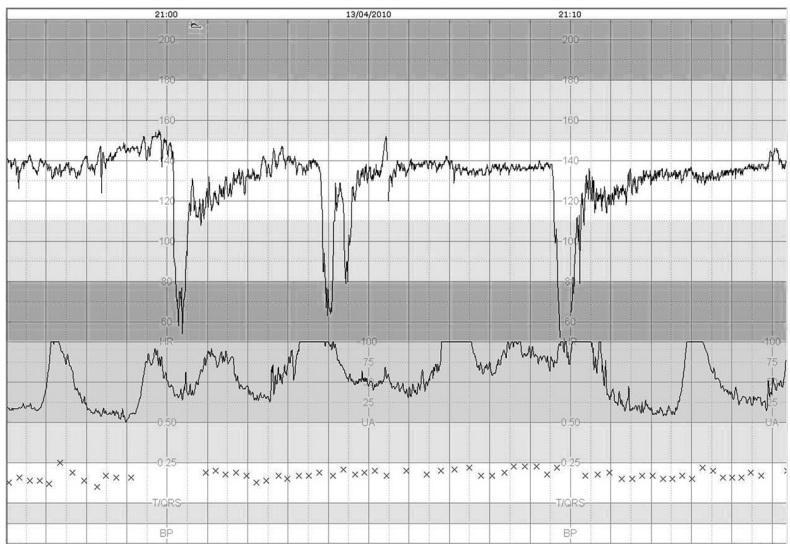

**Figure 6.14** Uncomplicated variable decelerations.

**Figure 6.15** Complicated variable decelerations.

predictive value of a normal trace is higher than 90% in most studies, false negative between 0.19 and 1%) but not so good in ruling in fetal compromise (the positive predictive value is <50%, false positives ~55%). This means that most fetuses diagnosed antenatally with fetal compromise are normal. A meta-analysis of RCTs, only involving women considered at increased risk of pregnancy complications, failed to demonstrate any significant effect on perinatal mortality, low Apgar scores, admission to neonatal intensive care units, gestational age at birth, or neonatal seizures; [42,43] this means that there is no benefit of CTG used in isolation. Many factors such as fetal movements, fetal growth restriction, maternal disease, and so on guide clinical decision-making in this complex area but experience and clinical intuition also play a significant role in this imprecise situation. Studies on intuition and how to train it and on the physiology behind pattern recognition are emerging.

The contraction stress test, when uterine contractions are induced by some method to evaluate the fetal response, has little or no place in modern obstetrics. Contractions can be elicited by administration of oxytocin or by maternal nipple stimulation.

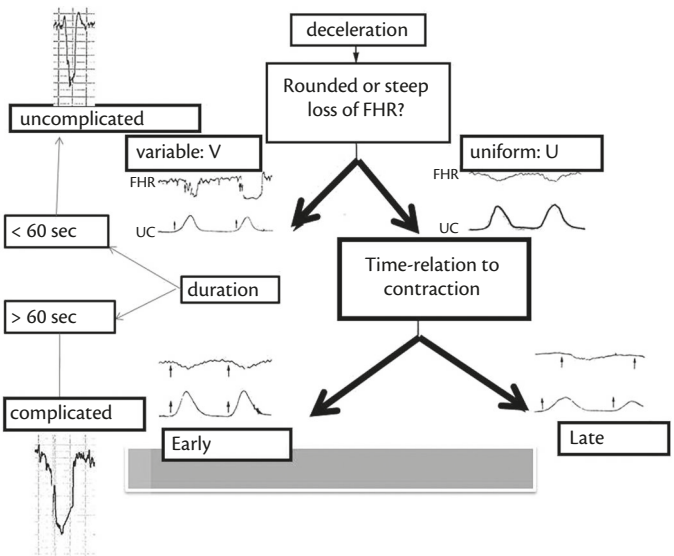

**Figure 6.16** Overview of decelerations.

### *Computer-aided FHR analysis*

Objective computerized FHR analysis taking into account gestational age can identify lower-amplitude FHR variability and accelerations. The systems depict variability as a continuous output variable analysing real beat-to-beat variability, also called short-term variability, but also includes accelerations, decelerations, periods of high variation, and periods of low variation using complicated algorithms. Such systems are able to correlate findings with the normal evolution related to gestational age.[45] No RCT is available comparing computerized CTG with no CTG. Comparing computerized CTG with non-computerized 'traditional' CTG interpretation demonstrated significant reduction in perinatal mortality in favour of the computerized CTG (relative risk (RR) 0.20; 95% CI 0.04–0.88).[44]

## Intrapartum fetal monitoring

### Introduction

In this section, an overview is presented of different techniques that are actually used in the delivery suite to monitor the fetus. CTG

**Table 6.3** FIGO classification of CTG

| CTG classification | Baseline of fetal heart rate | Baseline variability/accelerations | Decelerations | Contractions |
|---|---|---|---|---|
| Normal | 110–150 bpm | 5–25 bpm<br>>2 accelerations/60 min | No decelerations<br>Uniform, early decelerations<br>Variable, uncomplicated decelerations with a duration <30 s and amplitude <60 bpm | 5 or less contractions/10 min |
| Suspicious | 100–110 bpm<br>150–170 bpm<br><100 bpm for ≤3 min | <5 bpm >40 min without accelerations<br>>25 bpm<br>(saltatory pattern/increased variability)<br><2 accelerations/60 min | Variable uncomplicated decelerations with duration 30–60 min and/or amplitude >60 bpm | >5 contractions/10 min |
| | With a combination of 2 or more suspicious/abnormal factors the CTG is classified as suspect pathological | | | |
| Pathological | >170 bpm<br><100 bpm for min | <5 bpm for 60 min without accelerations<br>Sinusoidal pattern | Variable complicated decelerations with duration >60 s<br>Uniform late decelerations<br>Combined decelerations | |
| Preterminal | No variability (<2 bpm) without accelerations regardless of decelerations/heartbeat | | | |

is used both antenatally and during labour, but the evaluation of its effectiveness is different in both situations and adjunctive techniques can be employed during labour that are not available antenatally. In the past decade we have witnessed the rise and fall of fetal pulse oximetry; this technique will not be further discussed as it has been proven not to make any difference in terms of maternal (caesarean delivery rate) or fetal/neonatal (metabolic acidosis) outcome and is no longer commercially available.[46]

## Auscultation

IA is a systematic method of listening to the fetal heart tones with an acoustic (a pinard or fetal stethoscope) device or a hand-held Doppler device. IA during labour is an accepted practice in low-risk labours in many countries. Attention is paid to rate and rhythm and eventually variability. A normal FHR is between 110 and 150 bpm at term, regular, with variation around the baseline FHR, especially an increase during fetal movements. The aim of IA is to detect late or variable decelerations and baseline bradycardia or tachycardia. The presence of any of these abnormalities is a reason to continue with CTG.

No studies have been done comparing IA with no fetal monitoring at all, and for obvious ethical reasons such studies are not expected to be realized in the future. Meta-analyses of the results of randomized clinical trials, comparing IA with CTG have failed to show any significant benefit of CTG over IA in low-risk pregnancies. Moreover, caesarean delivery rates were significantly lower in the IA arm compared with the CTG arm. This is discussed in more detail in the following 'Cardiotocography' section. It has to be mentioned that in the IA arm, IA was mostly performed every 15 minutes in the first stage and after every contraction in the second stage. The current recommendations of IA every 15 minutes in the first stage of labour is rather labour intensive for midwives and doctors and is associated with poor compliance.

## Cardiotocography

In the antepartum period, only external CTG can be used. For this a Doppler device with computerized logic to interpret and count the Doppler signals is used. During labour a more direct reading from the fetal heart activity becomes possible with internal CTG, using a fetal electrode, with a spiral wire directly placed on the fetal scalp or other presenting part. The R–R interval of the extracted fetal ECG is used to calculate FHR. The recording of the contractions can also be monitored externally or internally with an intrauterine pressure catheter. There are several aspects which have to be taken into account when classifying and interpreting the CTG pattern: contractions, baseline FHR, variability, and presence of accelerations and decelerations.

Regional anaesthesia carries the potential to reduce intervillous space blood flow due to maternal hypotension as a result of sympathetic blockade. This has long been suggested as an explanation for the fetal decelerations or short periods of bradycardia noted after epidural or spinal anaesthesia. Conversely, Doppler flow measurements have actually demonstrated an increase in flow in the arcuate uterine vessels in prehydrated patients following epidural anaesthesia.

A variety of classification systems is used worldwide, an example is shown in Table 6.3 (modified FIGO classification, which is also used in the ST-analyser (STAN®) clinical guidelines). Most of them use a classification of normal CTG pattern, intermediate or suspicious CTG, abnormal or pathological CTG, and preterminal CTG pattern, based on the above-mentioned variables.

For women at low risk of intrapartum fetal hypoxia and of developing complications in labour, CTG versus IA on admission to the delivery suite demonstrated no difference in fetal/neonatal outcome, a statistically non-significant trend to more caesarean deliveries in the CTG group was noted (RR 1.20; 95% CI 1.00–1.44) and

marginally more instrumental vaginal deliveries (RR 1.15; 95% CI 1.01–1.33).[40a] For women in established labour, the data from 13 randomized trials on the effectiveness of the CTG were presented in a 2013 Cochrane meta-analysis.[5] Fetal CTG monitoring, whether in combination with FBS (see later 'Fetal Blood Sampling' section) or not, was compared with IA. Continuous monitoring by means of the CTG without FBS leads to a significant increase in the number of caesarean deliveries (RR 1.63; 95% CI 1.29–2.07) and a halving of neonatal seizures (RR 0.50; 95% CI 0.31–0.80), without an effect on other neonatal outcomes including cerebral palsy and infant mortality. It has to be mentioned that IA was performed every 15 minutes during the first stage of labour and after every contraction in the second stage. Furthermore, one has to realize that these trials were mostly performed before 1980, when the caesarean delivery rate was much lower than today. Training in CTG interpretation was mostly not extensive and not uniform and classification and interpretation differs from current insights in CTG patterns. Fetal surveillance with CTG was introduced in the 1960s. Although a positive effect of CTG on neonatal outcome has never been shown, CTG is widely applied.

It is known that classification and interpretation of the CTG is difficult with large interobserver variation. For a substantial part, these problems may be solved by strict adherence to guidelines regarding classification and interpretation of the CTG, obtaining additional fetal information, and subsequent recommendations for obstetric interventions.

## Fetal blood sampling

One of the techniques used to obtain additional fetal information with an abnormal CTG is FBS. FBS was introduced in the 1960s by Bretscher and Saling. Blood is obtained by means of a small incision in the skin of the fetal scalp, from which the pH, the $PCO_2$, and the base excess can be determined (Figure 6.17). In general, for a pH lower than 7.20 it is advised to deliver the baby within a short period of time by means of an assisted vaginal delivery or caesarean delivery. It thus offers information on the acid–base balance in the fetal blood and is regarded as the reference or 'gold standard' methodology to identify fetal distress during labour. However, FBS is inconsistently applied and not used on a large scale worldwide.[47,48] Although it is more specific than CTG alone and thus decreases the intervention rate, prevention of asphyxia is still not guaranteed.[5] Also, the technique is invasive and considered difficult, with a failure rate of at least 10%. Furthermore, the procedure has to be repeated when the CTG remains abnormal and complications have been described. FBS is never used without CTG.

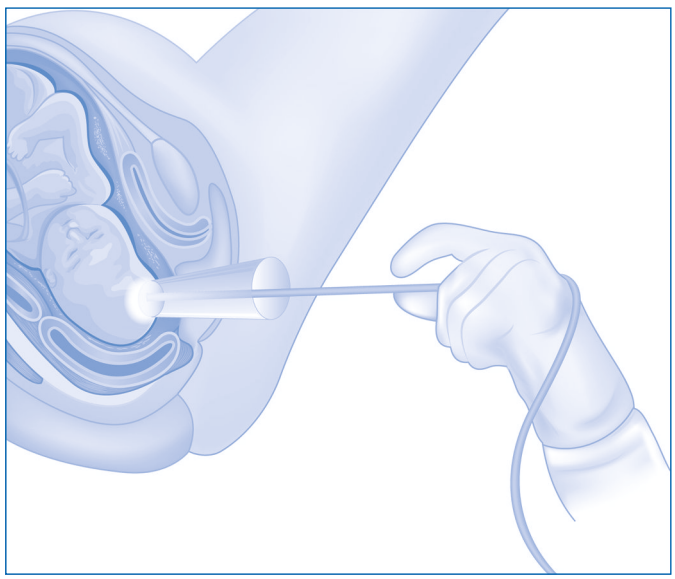

**Figure 6.17** Technique of fetal blood sampling during labour.
Reproduced with permission from BRENNER MEDICAL GMBH.

Complications due to FBS occur rarely, with a reported incidence ranging from 0.4% to 6%. The most frequent is excessive fetal bleeding mostly associated with an underlying coagulopathy.[49]

In 2008, the data from 13 randomized trials on the effectiveness of the CTG with or without CTG were presented in a Cochrane meta-analysis.[5] Fetal monitoring, whether in combination with FBS or not, was compared with IA. Continuous monitoring by means of the CTG without FBS leads to a significant increase in the number of caesarean deliveries (odds ratio (OR) 1.96; 95% CI 1.24–3.09), without a positive effect on neonatal outcome. If, however, FBS was performed alongside the CTG, a less prominent increase in the number of caesarean deliveries was found (OR 1.50; 95% CI 1.10–2.06) with a 50% reduction of neonatal convulsions (OR 0.49; 95% CI 0.29–0.84).

The results on the effectiveness of monitoring by means of the CTG combined with FBS originate from six of the trials that were performed in the period 1976 to 1989. This therefore concerns results of relatively old trials in which the frequency of caesarean deliveries varies from 2.3% to 35%.

Long-term follow-up of these trials is restricted to one study, which revealed that the lower incidence of neonatal convulsions was not associated with an improved outcome over time.[7] There are no studies in which continuous CTG monitoring without FBS is compared to monitoring with FBS.

Performance of FBS has an added value compared to monitoring by CTG only and offers a solution to the large number of false-positive CTG recordings when it is compared with IA. However, in many countries it has disappeared from delivery suites. A significant reason for this is that this investigation only gives a result at a specific point in time and with a persistent anomalous CTG it must be repeated. In addition, FBS is invasive, technically difficult, and patient unfriendly. In at least 10% of attempts, performing FBS is unsuccessful and it can thus be a time-consuming procedure.[50] In addition, the training in performing FBS appears to be inadequate in many hospitals and proper logistics for determining the same are lacking.[48] The relatively large quantity of blood that is required to determine the pH is also stated as a disadvantage of FBS.

A possible alternative to the pH measurement of the FBS sample is determination of lactate concentration. For the latter, less blood is required (5 µL) than the 30–50 µL needed for the determination of the pH. A lower percentage of unsuccessful attempts for lactate determination than for pH determination has repeatedly been reported, but without this having an effect on the neonatal outcome or the number of assisted deliveries.[51] Significant differences between measurement devices have been reported and the use of intrapartum fetal scalp lactate needs more

standardization and the definition of clear cut-off values before its use can be endorsed in clinical practice, until then it should only be used within a research protocol.[52,53,54]

More recently the level of lactate in amniotic fluid has been proposed to detect fetal deterioration. No prospective randomized studies have been conducted to evaluate this method.[55]

## STAN® of the fetal ECG

### *Technique and complications*

Since 2000, it has been possible via a scalp electrode not only to register the FHR but also the rest of the fetal ECG. The fetal heart and the fetal brain appear to be equally sensitive to a shortage of oxygen and thus information on myocardial function also indirectly provides information on the oxygenation of the fetal brain.

It has been shown from experimental animal research that changes in the ST segment of the ECG correlate with fetal hypoxia that occurs or worsens during labour.[14,56] The ST analyser (STAN® monitor; Neoventa Medical, Goteborg, Sweden) was developed in order to be able to combine the CTG with the analysis of the ST segment of the ECG. Changes in the shape of the ST segment are noted automatically and for a significant ST change an alarm is generated, a so-called ST event. The associated STAN® guidelines then state whether intervention is required.[57] The STAN® concept is based on the association between changes of the ST-interval of the fetal ECG and the function of the fetal myocardium during hypoxia. The changes in fetal ECG associated with fetal distress are either an increase in T-wave, quantified by the ratio T-wave to QRS-amplitude (T/QRS ratio), or a biphasic ST segment (Figure 6.18). An increase in T-wave and subsequently in T/QRS-ratio has been associated with a catecholamine surge, activation of beta-adrenoreceptors, myocardial glycogenolysis, and metabolic acidosis. A biphasic shape of the ST segment is related to two situations. First, it may occur when the fetal heart is exposed to acute hypoxic stress whereby it has had no time to respond to hypoxia or second, when the fetal heart has a reduced capacity to respond due to (chronic) stress situations and lack of or already utilized resources. Biphasic ST changes of the fetal ECG have been associated with disturbances in heart muscle function, infection, or malformations.

The STAN® concept is based on a combined interpretation of CTG and ST changes (Table 6.4). The relevance of an ST change depends on the visual assessment of the CTG that, according to FIGO criteria, is classified as 'normal', 'intermediary' (or 'suspicious'), 'abnormal' (or 'pathological'), or '(pre)terminal'.[36] If a CTG is normal, any ST change on the STAN® monitor can be ignored. When a CTG is (pre)terminal, immediate intervention is advised, irrespective of ST changes. In case of an intermediary or abnormal CTG, the STAN® guidelines indicate for what ST changes intervention is advised (Figure 6.19). This intervention may consist of solving a cause of fetal distress, such as hypertonia or hyperstimulation, or proceeding to delivery. The STAN® guidelines can be used from a gestational age of 36 weeks onwards.

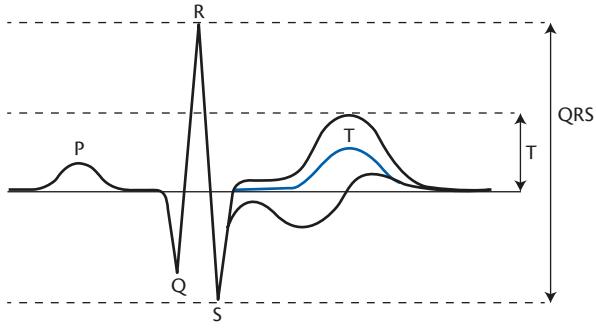

**Figure 6.18** ST-segment changes during hypoxia.

Five RCTs, which included 15,352 patients, have been performed since 1993. Westgate et al. were the first to conduct a RCT on the effect of intrapartum fetal ECG and used absolute values of T/QRS, rather than automatically detected T/QRS changes, as described in the current STAN® clinical guidelines.[58,59,60,61,62] All five RCTs were inconclusive with four studies showing no statistically significant effect on the primary outcome, metabolic acidosis in the umbilical artery. In one study, STAN® significantly reduced the incidence of metabolic acidosis.[59]

Four meta-analyses including these five RCTs have been performed.[63–66] Compared with conventional CTG, STAN® showed no difference in metabolic acidosis (1.12% in CTG alone, 0.81% in STAN group, RR 0.80; 95% CI 0.44–1.47). STAN® significantly reduced the incidence of additional FBS, operative vaginal deliveries, and total operative deliveries with less need for neonatal intensive care. For other outcomes, no differences in effect were seen between STAN® and conventional CTG, or data were not suitable for meta-analysis. An individual patient data meta-analysis including four of the five RCTs did confirm that addition of STAN® to CTG reduces the need for instrumental vaginal delivery without changing the risk of metabolic acidosis or caesarean delivery.[67] The meta-analyses show that additional use of STAN® for intrapartum monitoring does not reduce the incidence of metabolic acidosis, but it does reduce the incidence of operative vaginal deliveries and the need for FBS. Cost-effectiveness studies are scarce but seem to provide some evidence that STAN® is a cost-effective method of intrapartum monitoring when compared with conventional CTG, when looking at both short- and long-term outcomes.[68,69] Implementation of the STAN® methodology, just like any new technology, should be performed carefully, taking into consideration that a learning curve is needed. Recent observational studies investigating the effects of long term use of STAN® have shown a decrease in incidence of metabolic acidosis$_{BDecf}$ over time.[70] Furthermore the cases of adverse neonatal outcome described in literature are mainly due to problems with the interpretation of the CTG or violation of guidelines.[71] Repeated training is crucial in the implementation of the STAN® methodology. Several studies have demonstrated that non-adherence to the clinical guidelines is the major reason for unnecessary interventions without reducing metabolic acidosis.[72–74] Nowadays, the use of the STAN® methodology is increasing and in some countries it is common practice. Fetal STAN®, scalp pH and fetal scalp stimulation are generally accepted adjunctive methods to CTG.[75]

Intrapartum maternal fever results in fetal tachycardia and an accelerated metabolism, possibly resulting in a faster development of metabolic acidosis, CTG alone can be difficult to interpret in these cases, it has been demonstrated that intrapartum fever is not associated with ST segment changes of the fetal ECG and can still

**Table 6.4** The intended use of this CTG classification system is to suggest clinical conditions in which adjunctive use of ST waveform changes may aid the interpretation of specific CTG patterns

| Classification of CTG | Baseline heart frequency | Variability Reactivity | Decelerations |
|---|---|---|---|
| Normal CTG | • 110–150 bpm | • Accelerations<br>• 5–25 bpm | • Early uniform decelerations<br>• Uncomplicated variable decelerations with a duration of <60 sec and loss of <60 beats |
| Intermediary CTG | • 100–110 bpm<br>• 150–170 bpm<br>• Short bradycardia episode (<100 bpm for ≤3 min) | • >25 bpm (saltatory pattern)<br>• <5 bpm >40 min with absence of accelerations | • Uncomplicated variable decelerations with a duration <60 sec and loss of >60 beats |
| | A combination of several intermediary observations will result in an abnormal CTG | | |
| Abnormal CTG | • 150–170 bpm and reduced variability<br>• >170 bpm<br>• Persistent bradycardia (<100 bpm for >3 min) | • <5 bpm for >60 min<br>• Sinusoidal pattern | • Complicated variable decelerations with a duration of >60 sec<br>• Repeated late uniform decelerations |
| Preterminal CTG | • Total lack of variability (<2 bpm) and reactivity with or without decelerations or bradycardia | | |
| **ST Analysis** | | | |
| These guidelines may indicate situations in which obstetric intervention[1] is required. | | | |
| **ST Events** | **Episodic T/QRS rise** | **Baseline T/QRS rise** | **Biphasic ST** |
| Normal CTG | • Expectant management and continued observation | | |
| Intermediary CTG | • >0.15 | • >0.10 | • 3 Biphasic log messages[2] |

be used in these circumstances.[76] Epidural analgesia has no effect on the number or types of ST events.[77]

## Fetal biometry and tests for fetal congenital anomalies relevant to the anaesthetist

Fetal growth is determined both by genetics (maternal and paternal) and by environmental factors influencing maternal nutrition and the function of the uteroplacental unit. IUGR can affect the management of the pregnant woman.

In case of pre-eclampsia, a disorder affecting all maternal organ systems based on a generalized endothelial dysfunction, IUGR is caused by a restricted perfusion of the placenta, resulting in chronic malnutrition and hypoxaemia of the fetus. The spiral arteries, perfusing the placenta, do not remodel their muscular wall in case of pre-eclampsia and remain reactive to vasoconstrictive agents. Maternal hypertension is necessary to compensate for the reduced flow through narrowed vessels. When IUGR based on uteroplacental vascular pathology has been prenatally diagnosed, care should be taken not to lower maternal blood pressure below 140 mmHg systolic and 80 mmHg diastolic as this will result in FHR decelerations due to insufficient placental perfusion.[78] In such case correcting maternal blood pressure should be aimed at first, before proceeding to an emergency delivery.

Ultrasound and, more recently, magnetic resonance imaging have facilitated the detection of a majority of placental and fetal congenital structural anomalies. In most circumstances this will not influence the management of the mother during labour and vaginal or caesarean delivery. Some exceptions should be mentioned, including a prenatally detected placenta increta, in which case one should be prepared for major haemorrhage, or if an EXIT procedure (*ex utero* intrapartum treatment) such as tracheal obstruction is planned, the immediate administration of an uterotonic agent (oxytocin, carbetocin) should be postponed in these cases.

The role of intrapartum ultrasound has been recently emerging. Traditionally the position and descent of the fetal head during labour have been determined digitally. This has been proven to be extremely inaccurate, causing up to 30% of clinically relevant missed diagnosis. Occiput posterior position, asynclytism (the oblique presentation of the fetal head to the pelvic curve), and fetal descent can be reliably diagnosed by transabdominal, transperineal, and transvaginal ultrasound during labour, clearly superior to the digital method.[79–81] It is to be expected that ultrasound will be used more frequently in the delivery suite.

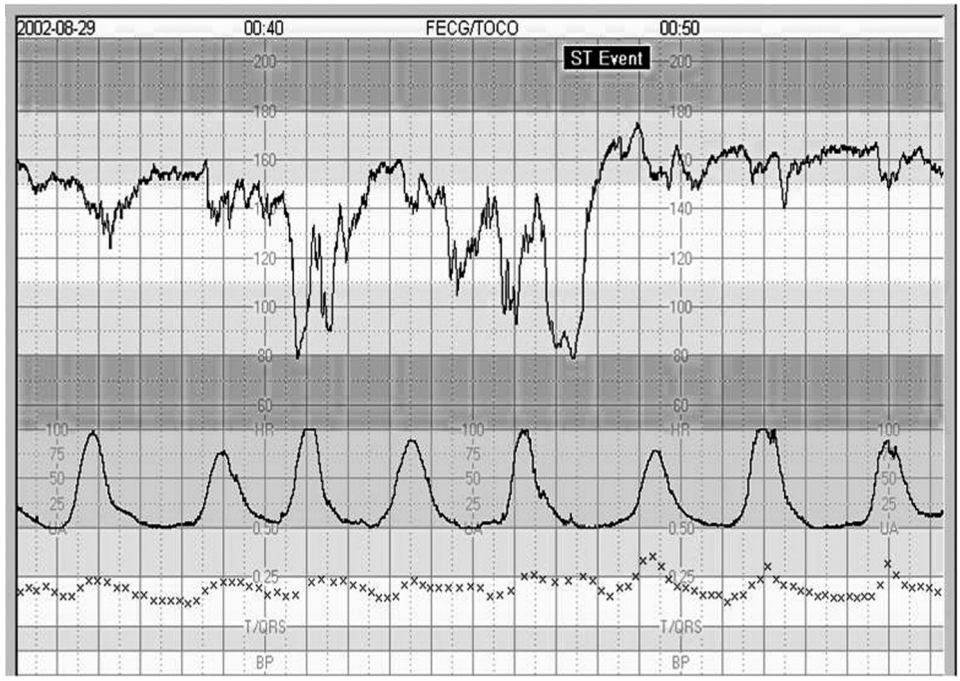

**Figure 6.19** Example of STAN® recording. From top to bottom: the FHR, uterus activity and T/QRS ratio indicated as crosses. The FHR shows complicated variable decelerations resulting in classification of the CTG as abnormal. The T/QRS ratio shows a variable pattern, leading to two significant T/QRS rises indicated by the black horizontal bars stating 'ST Event'. Per ST-event exact time, type and quantification of the T/QRS rise are explained below the recording. According to the STAN® guidelines (see Appendix 1) there is an indication to intervene based on the combined presence of an abnormal CTG and significant ST-events (baseline T/QRS rise of 0.06 and 0.09).

## Conclusion

In antenatal fetal monitoring, CTG and umbilical artery Doppler represent the main techniques that determine management. During labour in low-risk pregnancies, IA and CTG can be equally considered as standard; when CTG signals possible fetal hypoxia, adjunctive techniques are needed such as FBS or STAN®.

# CHAPTER 7

# Fetal medicine, fetal anaesthesia, and fetal surgery

Francesca Russo, Tim Van Mieghem, and Jan Deprest

## Fetal medicine

The main aim of prenatal care is to promote, protect, and maintain the health of the pregnant woman and her future child. The concept of structured prenatal surveillance to reduce maternal and perinatal mortality has been adopted in developed countries since 1920. Until recently this followed a strict schedule with monthly visits from 16 weeks, and a high number of visits in the third trimester ('pyramid of care'; Figure 7.1).[1] In the last two decades, however, several randomized trials[2–4] demonstrated that antenatal care for *low-risk* women can be effectively provided with a lower number of visits.

In contrast, the current concept of modern fetal medicine is that the risk factors for most pregnancy complications, like pre-eclampsia, gestational diabetes mellitus, fetal demise, preterm birth, fetal structural and chromosomal anomalies, fetal growth restriction, and macrosomia, are already present in the first trimester.[5–11] An early estimation of patient-specific risks is done by a combination of ultrasound, maternal biophysical parameters, maternal history, and biochemical markers. The first prenatal examination also provides an opportunity for cervical cancer screening in women who have not been screened recently, assessment of gestational age and calculation of estimated date of delivery, and education on lifestyle (tobacco smoking, food-acquired infections, physical activity, alcohol and recreational as well as medical drug use, vaccination, and food supplementation). This new strategy for pregnancy management may improve perinatal outcome by offering a more individualized care and a disease-specific approach.

At 11–13 weeks, only few women will be selected as being at high risk. In the low-risk group, the number of visits could be reduced to an additional three: one at 20–22 weeks, to evaluate fetal anatomy and growth, and reassess the individual risk for pregnancy complications; one at 37–38 weeks, to check maternal and fetal well-being and determine the timing and mode of delivery; and one at 41weeks, in case the woman has not delivered yet (Figure 7.1B).[12] High-risk patients should be referred to specialist clinics, in order to receive closer, individualized, *disease-specific* pregnancy monitoring. In the course of subsequent visits, a number of women may move between risk categories.[12]

### Screening for fetal chromosomal abnormalities

In most developed countries, genetic screening tests are offered to all women in the first trimester—regardless of maternal age or other identified risk factor. In case of increased risk, a definitive diagnosis is made through further invasive testing, such as mid-trimester amniocentesis or first-trimester chorionic villus sampling (CVS) (Figure 7.2).[13,14] Usually the procedure-related risk of 0.5–1.5% for miscarriage or other pregnancy complications is taken as a guidance for the cut-off of what is considered as 'at increased risk'.[15]

Several studies demonstrated that effective screening for chromosomal abnormalities can be achieved by maternal serum free beta-human chorionic gonadotropin[16] and pregnancy-associated plasma protein-A (PAPP-A)[17] combined with ultrasound measurement of fetal nuchal translucency (NT) thickness.[18] NT is the maximum thickness of the subcutaneous translucency between the skin and the soft tissue overlying the cervical spine of the fetus. A computer algorithm integrates this information with biometry (crown–rump length[19]) and maternal characteristics, including age,[20] weight, height, the presence of type 1 diabetes, and previous history of chromosomal abnormalities.[21] The combined test has a detection rate of 93% and a false-positive rate of 5% for trisomy 21, and a slightly lower detection rate for trisomy 18, 13, or other chromosomal abnormalities.[22] For comparison, the detection rates achieved by selection of at-risk patients by maternal age alone or second-trimester maternal serum testing are 30% and 65%, respectively.[23]

Other first-trimester ultrasound markers, such as hypoplasia or absence of the nasal bone, tricuspid regurgitation, and flow in the ductus venosus and in the hepatic artery, may be added to improve the performance of the first-trimester screening, but their clinical usefulness currently remains uncertain (Figure 7.3).

Offering the first-trimester combined tests can reduce the number of women undergoing invasive diagnostic procedures,[24,25] leading to fewer losses of normal pregnancies.[26]

In the immediate future, this strategy may be revised again, when non-invasive prenatal testing via the analysis of free fetal DNA circulating in maternal blood will be routinely introduced. The technology today is ready, but cost is a limiting factor.

### Screening for other fetal anomalies

Congenital malformations occur in 2–4% of all births. Despite their relatively low prevalence, fetal malformations are responsible for approximately 30% of perinatal deaths and considerable infant morbidity.[27,28] In this respect, the purpose of their prenatal diagnosis is to optimize the management of the pregnancy in terms of antenatal care, referral for planned birth at the required

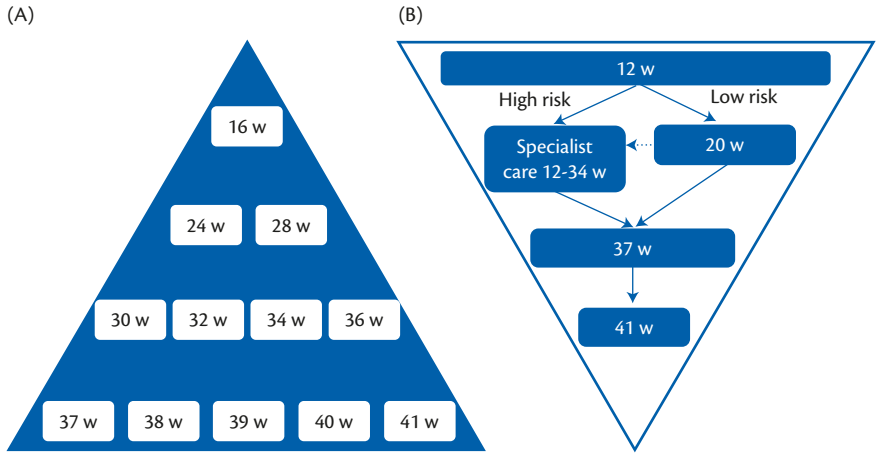

**Figure 7.1** Pyramid of care. (A) Conventional follow-up scheme. (B) Inverted pyramid of care aiming at identifying the at-risk patient.
w, weeks.
Reproduced with permission from Kypros H. Nicolaides, A model for a new pyramid of prenatal care based on the 11 to 13 weeks' assessment, *Prenatal Diagnosis*, Volume 31, Issue 1, pp. 3–6, Copyright © 2011 John Wiley and Sons.

specialist level, and planning of postnatal treatment of the baby. In most European countries, parents are also given the option for termination when severe anomalies are diagnosed.

Whereas in the past these anomalies were typically diagnosed in the second trimester,[29] current resolution and skills often allow for first-trimester diagnosis. When patients opt for risk assessment, they are offered NT measurement, which will include anatomical assessment. This test has indeed been shown to pick up a whole series of gross anomalies, such as skeletal dysplasias, diaphragmatic hernia, and major cardiac defects (Table 7.1). Because a number of malformations may only develop or become visible later in pregnancy, the second-trimester '18–22-week' scan should still be offered in case of a negative first-trimester scan, in both low-risk and high-risk pregnancies.[30] When the first-trimester risk assessment is showing increased risk, yet the invasive genetic test is normal, these patients will be considered as at increased risk for structural anomalies, and will have their second-trimester anomaly scan with an expert. The risk for cardiac defects, for example, increases with fetal NT thickness and the presence of abnormal venous or cardiac Doppler in the first trimester.[31–34]

**Table 7.1** Summary of the most common fetal conditions amenable for therapy and outcome of interventions[a]

| Pathology | Untreated leads to | Therapy | Gestational age at birth | Common complications | Outcome after therapy |
|---|---|---|---|---|---|
| Rhesus disease | High output cardiac failure and decreased tissue oxygenation | Intrauterine transfusion | 36 weeks | IUFD 1.7% per procedure | Survival hydrops 74%, no hydrops 91%, CP 2.1%, developmental delay 4.8% |
| HLHS | Postnatal demise, univentricular circulation | Balloon valvuloplasty | 88% > 36 weeks | Intrauterine resuscitation 30%, IUFD 10% | 33–67% biventricular repair |
| Posterior urethral valves | Renal failure, pulmonary hypoplasia | Vesico-amniotic shunting | 34–35 weeks | Shunt dislodgment 34% | 50–90% survival, 30–40% end-stage renal failure |
| Pleural effusion | Cardiac failure, pulmonary hypoplasia | Thoraco-amniotic shunting | 34–35 weeks | Shunt dislodgment 10–20% | Survival hydrops 55%, no hydrops 85% |
| CDH | Pulmonary hypoplasia | Tracheal occlusion | 35 weeks | Balloon deflation 8% | 50% survival |
| TTTS | IUFD and preterm birth | Laser ablation of anastomoses | 33–34 weeks | IUFD one fetus 15%, TAPS 10% | 70% double survival, 80–90% survival ≥ 1 fetus, CP 6%, mental delay 7%, motor delay 12% |
| Selective reduction | Neurological damage or IUFD | RFA/cord occlusion | 34–35 weeks | Demise non-target fetus 15% | 85% survival non-target fetus |
| Myelomeningocele repair | Hydrocephaly, hindbrain herniation, nerve function loss beyond lesion, cognitive and motoric impairment dependent on level of lesion | Fetal surgical closure | 34 weeks | PPROM 34%, 10% uterine dehiscence | Shunt rate drops from 98% to 68%, improved Bailey score at 30 months; walking improved from 21% to 42% |

CDH, congenital diaphragmatic hernia; CP, cerebral palsy; HLHS, hypoplastic left heart syndrome; IUFD, intrauterine fetal demise; PPROM, preterm premature rupture of membranes; RFA: radiofrequency ablation; TAPS, twin anaemia-polycythemia sequence; TTTS, twin-to-twin transfusion syndrome.

Similarly, open spina bifida is associated with caudal displacement of the brain already detectable at 11–13 weeks.[35]

### Early screening for miscarriage and stillbirth

Increased risk of miscarriage and stillbirth is associated with certain maternal characteristics, including advanced maternal age, maternal weight, previous miscarriages, cigarette smoking, chronic hypertension, and African racial origin.[36–38] Analogous to aneuploidy screening, maternal characteristics are combined with biophysical measurements and biochemical testing at 11–13 weeks to allow an individualized risk estimation. However, the detection rate remains low (30%). This points to the heterogeneous aetiology of miscarriage and stillbirth. Furthermore, while early identification of the group at risk for stillbirth could lead to closer monitoring of fetal growth, well-being, and appropriate timing of delivery, no preventive interventions are known so far, so its value can be questioned.[5]

## Maternal medicine

### Screening for maternal diseases

Hypertensive disease occurs in 12–22% of all pregnancies and is responsible for approximately 11% of maternal deaths in developed countries. Pre-eclampsia is defined as gestational hypertension combined with proteinuria after 20 weeks' gestation.[39] It affects 5–8% of pregnancies and remains a substantial contributor to perinatal morbidity and mortality worldwide. Furthermore, it is one of the three leading causes of maternal mortality.[40] Blood pressure screening is therefore recommended at the first visit and at all subsequent visits though obviously this identifies the patient only at the onset of problems. Risk factors for pre-eclampsia should therefore be investigated during the first visit. This allows intensive maternal and fetal monitoring, leading to a timely diagnosis of pre-eclampsia, and the prompt initiation of prophylactic treatment, such as aspirin.[12] Risk calculation is based on maternal characteristics, such as age, body mass index, the presence of chronic hypertension, previous or family history of pre-eclampsia, as well as first-trimester biochemical and ultrasound parameters, which aim at measuring the degree of invasion of the placental trophoblast—which is believed to be abnormal in pre-eclampsia. Uterine artery Doppler studies can detect increased placental vascular resistance, but its sensitivity ranges from 7% to 80%.[41,42] Measurement of PAPP-A[43–45] a-disintegrin and metalloprotease 12 (ADAM12), soluble endoglin (sEng), inhibin-A, activin-A, pentraxin-3 (PTX3), P-selectin placental growth factor (PLGF), and placental protein-13 (PP13)[6,46–49] have all been associated with pre-eclampsia. Again, algorithms combining maternal characteristics, Doppler findings, and biochemical tests at 11–13 weeks can identify patients at risk for pre-eclampsia, and stratify this condition according to gestational age at onset, which correlates to the severity of the disease.[6] (See Chapter 36 for further details on pre-eclampsia.)

A similar integrated algorithm has been proposed for the first-trimester screening of gestational diabetes. Gestational diabetes is defined as a glucose intolerance occurring during pregnancy, with an incidence of about 2–3%.[50] This condition is associated with adverse perinatal outcomes (death, shoulder dystocia with or without fracture, and nerve palsy). It makes sense to diagnose diabetes, because adequate intervention, by dietary advice, blood glucose monitoring, and, if needed, metformin or insulin therapy, lowers morbidity. In low-risk patients, screening for gestational diabetes mellitus is performed at 24 to 28 weeks' gestation through an oral glucose tolerance test.[39] However, first-trimester algorithms combining maternal characteristics (body mass index, racial origin, family history, and previous macrosomic baby) and biochemical tests (serum levels of adiponectin, sex hormone-binding globulin, or visfatin) may identify about 75% of pregnancies subsequently complicated by gestational diabetes, with a false-positive rate of 20%.[51] (See chapter 47.)

### Screening for preterm delivery

Infants born preterm have an increased risk of mortality and severe comorbidities, despite improved neonatal care. The risk of preterm birth has been rising in most developed countries during the past decades.[52,53] Considerable effort has been spent to investigate the pathogenesis of preterm birth and preventive measures that reduce its consequences.[54,55]

Transvaginal ultrasound of the cervix objectively measures cervical length in a standardized way, and has been shown to enable risk estimation of preterm delivery when performed at 18–22 weeks (which coincides with the anomaly scan) (Figure 7.4).[56,57] Preventive measures (e.g. by administration of progesterone) have been shown to significantly reduce the risk of delivery at less than 37 weeks.[58,59] An alternative treatment for women with a short cervix is cervical cerclage, which reduces the risk of spontaneous early preterm delivery by about 40% in women who had a previous preterm birth or second-trimester loss, but not in those without such history.[60] (See Chapter 33.)

Measuring cervical length only at 20 weeks, however, cannot prevent miscarriages due to cervical incompetence before that gestation and delays prophylactic measures. First-trimester assessment is therefore desirable. Again, it is the combination of maternal characteristics such as ethnicity, age, and socioeconomic status, previous preterm birth as well as pregnancy characteristics such as multiple pregnancy, conception after artificial reproductive technologies, and presence of urogenital tract infections which predict poor outcome.[61,62] This can be combined by measurement of endocervical length at 11–13 weeks, which has been shown to be predictive.[63] A recent study suggests that combination with PP-13, PAPP-A, and uterine artery pulsatility index are useful markers for identifying pregnancies at increased risk for early premature birth.[64]

Fetal therapy became a clinical reality after the introduction of high-resolution ultrasound. It has been boosted by the implementation of systematic pregnancy screening programmes which have led to the early detection and better understanding of the natural history of fetal anomalies. Only a limited numbers of fetal anomalies are progressive in nature, so that when left untreated, they lead to fetal and neonatal demise, or severe morbidity. Prenatal intervention aims at halting or reversing the progression of these diseases and improving the postnatal outcome. Where some fetal conditions such as open neural tube defects,[65] large solid lung masses, or sacrococcygeal teratomas[66] are still treated through maternal laparotomy and hysterotomy, we have witnessed an increased introduction of minimally invasive fetal therapeutic procedures over the last two decades. The aim of the current chapter is to present an overview of the rationale for, the technical aspects of, and outcomes of the most common minimally invasive prenatal therapeutic procedures. These are reserved for well-selected fetuses, at

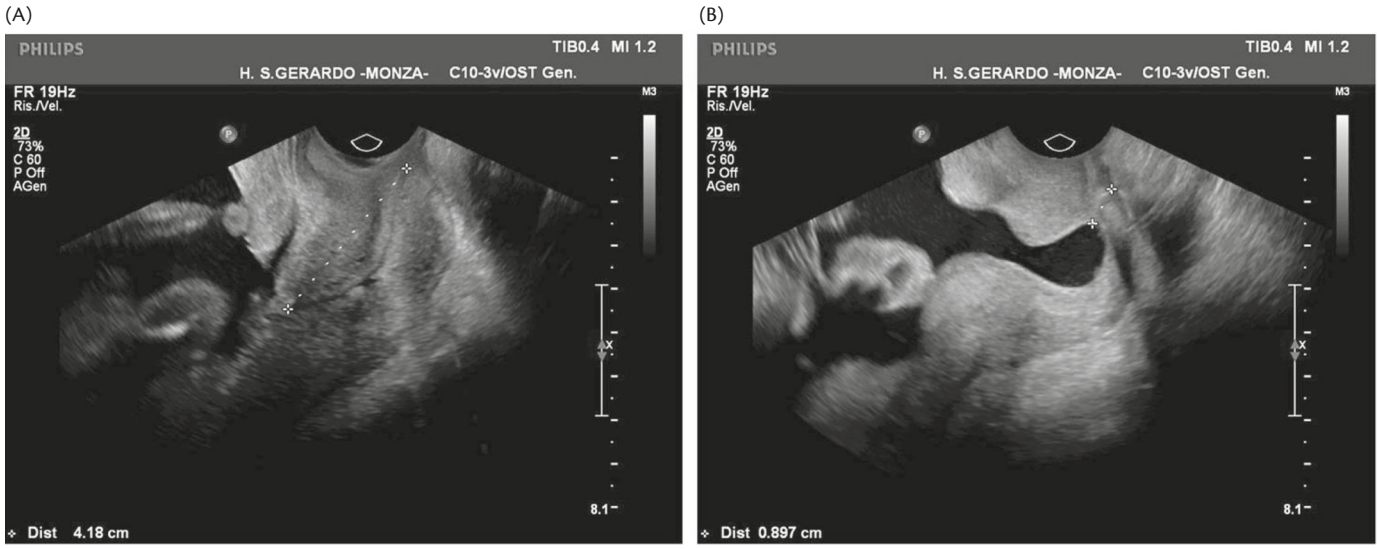

**Figure 7.4** Cervical sonography for the prediction of preterm birth. (A) Normal findings. (B) Patient at high risk because of cervical incompetence.
Reproduced with permission from the University Hospitals San Gerardo, Monza, Italy.

the most severe end of the spectrum, and are only offered in a limited number of centres. Optimal patient selection, expert counselling, rigorous clinical protocols and experienced multidisciplinary teams are strict criteria for fetal therapy programmes.[67,68]

## Fetal therapy

The implementation of systematic ultrasound screening leads to earlier detection of fetal anomalies. Whereas most fetal conditions are adequately treatable after birth, some disorders progress during fetal life and can lead to severe morbidity or fetal and neonatal demise. This inherently raises the question of prenatal therapy. Some fetal conditions are amenable to fetal surgical intervention, some of them by minimal access. Below we provide an overview of the rationale for, the technical aspects of, and (if available) the outcomes of the most common prenatal therapies (Table 7.1).

### Intrauterine transfusion

Intrauterine transfusions are performed for severe fetal anaemia and thrombocytopenia. Technical aspects of the procedure are identical for both conditions. Fetal thrombocytopenia is very rare and for that we refer readers to the excellent recent review by Kamphuis et al.[69] This section will therefore discuss only fetal anaemia. The incidence of rhesus D (RhD) haemolytic disease has decreased dramatically since the routine administration of anti-D immunoglobulins. As a consequence, other causes of fetal anaemia, such as fetomaternal haemorrhage, twin anaemia polycythaemia sequence, parvovirus B19 infections, and haemolytic disease due to other than RhD red blood cell antigens have gained in relative importance. The severity of anaemia in a fetus at risk can be assessed by non-invasive measurement of peak systolic velocity in the middle cerebral artery. Severe anaemia, mandating antenatal intervention, is present when the peak systolic velocity is over 1.5 multiples of the median and shows an increasing trend.[70]

Intrauterine transfusions are usually performed under local anaesthesia in an outpatient setting, or when rescue delivery is anticipated under spinal or combined spinal and epidural[71] (Figure 7.5). Typically, the umbilical vein is punctured under ultrasound guidance either in its intrahepatic portion or at the placental cord root. At the start of the transfusion a blood sample is drawn for haemoglobin and haematocrit measurement and the required volume calculated to reach around 45%.[72] Pancuronium can be administered to immobilize the fetus for intrahepatic transfusions; intrahepatic vein puncture justifies the use of fetal pain relief. O rhesus-negative blood with a haematocrit of 80%, that has been screened for the most common infectious diseases, and irradiated to prevent graft-versus-host reaction, is transfused. Extremely anaemic fetuses are treated with multiple transfusions with a few days' interval. In case of persistent haemolysis, the fetal haematocrit drops around 1% per day. Therefore, repeated transfusions at 2–3-week intervals are required in rhesus disease. The last transfusion is usually given around 34 weeks of gestation to allow for a timed delivery around 36–37 weeks.

In experienced hands, intrauterine transfusions are successful in over 97% of cases.[73] The rate of severe complications is 3% per procedure in rhesus disease and the procedure-related fetal loss rate is 1.6%.[74,75] The latter increases to 10% in transfusions done before 22 weeks of gestation.[76] Overall survival after intrauterine transfusions for rhesus disease is 75% when the fetus is hydropic at the first transfusion, and over 90% in non-hydropic fetuses.[73] A large follow-up study on neurological outcomes after intrauterine transfusions for rhesus disease shows a cerebral palsy rate of 2.1% and an overall risk for developmental delay of 4.8%.[77] Neurological impairment is more likely if hydrops was present.

### Fetoscopic laser coagulation of chorionic plate vessels

Twin-to-twin transfusion syndrome (TTTS) affects 9% of monochorionic twins and fetal therapy is considered when presenting between 16 and 28 weeks of gestation.[78,79] A review on the pathophysiology can be found in a recent review by Fisk et al.[80] Imbalances in vasoactive hormones and fluid shifts lead to one fetus being hypertensive and volume overloaded (the recipient fetus) and the other being volume depleted (the donor fetus). The diagnostic criteria for TTTS rely on the presence of polyuric

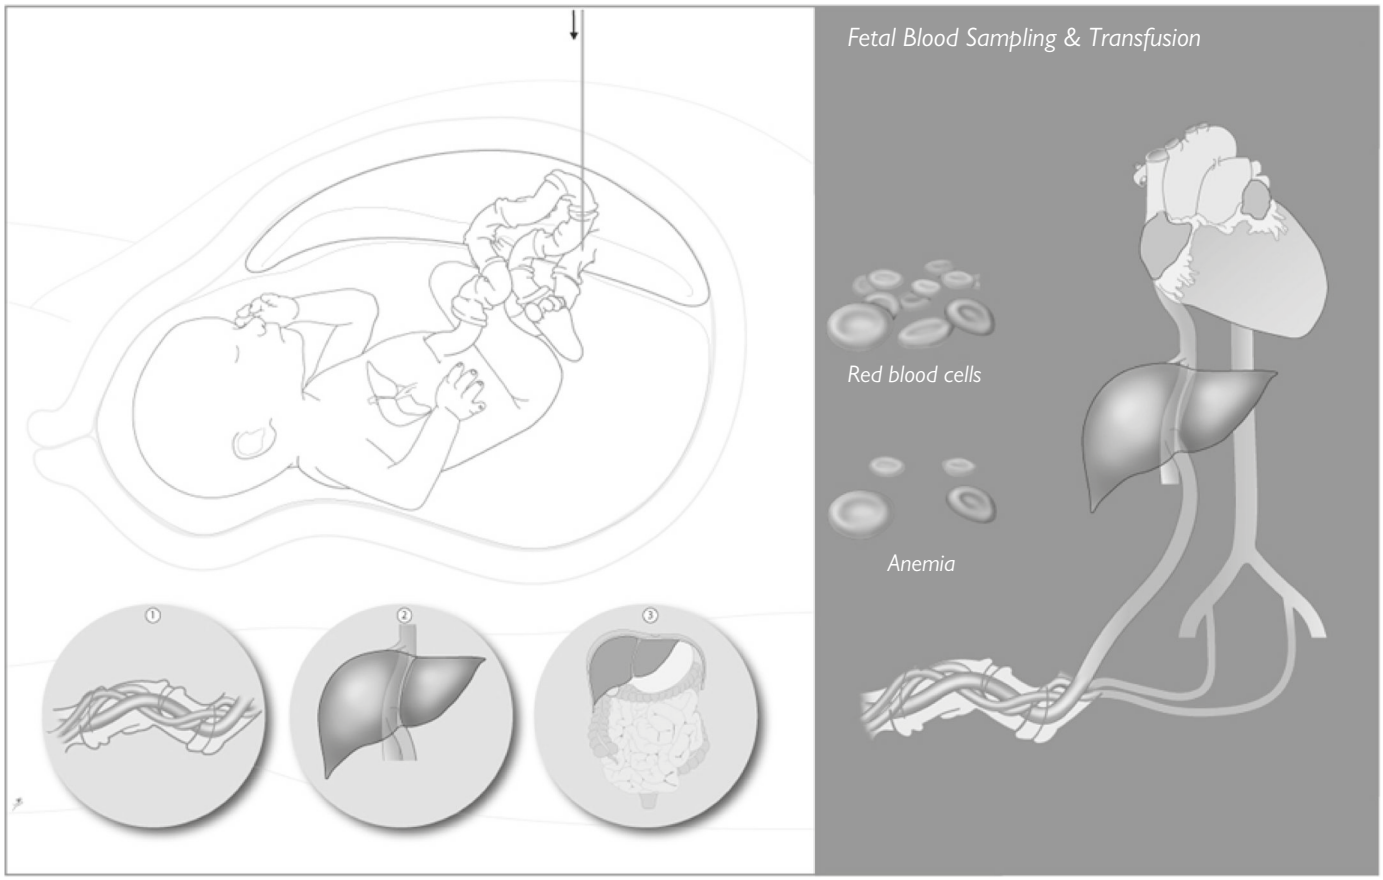

**Figure 7.5** Schematic representation of an intrauterine transfusion. The fetal circulation is typically accessed at the level of the cord insertion (1), or the intra-hepatic vein (2).
Reproduced with permission from the University Hospitals Leuven, Belgium.

polyhydramnios in the recipient fetus and oliguric oligohydramnios in the donor. TTTS is further staged according to Quintero et al.[81] based on the presence (stage I) or absence (stage II) of bladder filling in the donor fetus, Doppler changes in one or both fetuses (stage III) and the presence of hydrops (stage IV), or fetal death (stage V). In a randomized controlled trial, it was shown that causative therapy, by fetoscopic laser coagulation of inter-twin anastomosis, yields better outcome than serial amniodrainages of excessive fluid.[82] Fetoscopic laser is performed under local or locoregional maternal anaesthesia (Figure 7.6). A 2–3.5 mm fetoscope with a working channel for a laser fibre[83] is introduced into the recipient's sac and all anastomosing vessels are coagulated under direct vision. The procedure is completed by amniodrainage. Recurrent TTTS and twin anaemia-polycythaemia syndrome are relatively rare complications but are amenable for therapy. Intrauterine fetal demise of one fetus, which is only partially predictable, occurs in about 15% of cases. Whereas in the earlier large series overall neonatal survival was around 55% and survival of at least one fetus around 70%,[84] these numbers increased to 70% and 80–90% respectively with increasing experience.[85,86] Mean gestational age at delivery is 33–34 weeks. In terms of long-term neurological outcome, a recent, large, multicentre follow-up study (N = 287 TTTS survivors) demonstrated that the risk for cerebral palsy in survivors is 6%.[87] Severe mental delay is observed in 7% and psychomotor impairment in 12%. This compares to the background risk of neurodevelopmental impairment (7%) and cerebral palsy (0.6%) in uncomplicated monochorionic twin pregnancies.[88] The major determinant of these adverse outcomes is prematurity[83] and the stage at the time of intervention, with poorer outcomes at an advanced stage.[89] In a very recent randomized trial, it was shown that complete separation of the placenta along the vascular equator reduces recurrence rate and improves neonatal outcome (Solomon technique—Figure 7.6B).[90]

## Selective reduction in monochorionic twin gestations

In some monochorionic twin pairs, the condition of one fetus may pose a threat to the well-being of the other due to the presence of the placental anastomoses. Examples are impending demise of one fetus by selective (in one twin) intrauterine growth restriction, end-stage TTTS or after its failed therapy, and a number of discordant congenital anomalies, including twin reversed arterial perfusion (TRAP). In these circumstances, controlled fetocide of the affected fetus including obliteration of intrafetal or cord vessels can be performed to protect the healthy twin. Simultaneous arterial and venous occlusion can be achieved by cord occlusion. Bipolar cord coagulation using a 3.0 mm forceps is performed under local anaesthesia with ultrasound guidance (Figure 7.7A).[83] Thermoablation of intrafetal vessels using laser, monopolar energy, or radiofrequency needles has more recently been propagated. A straight needle or a needle equipped

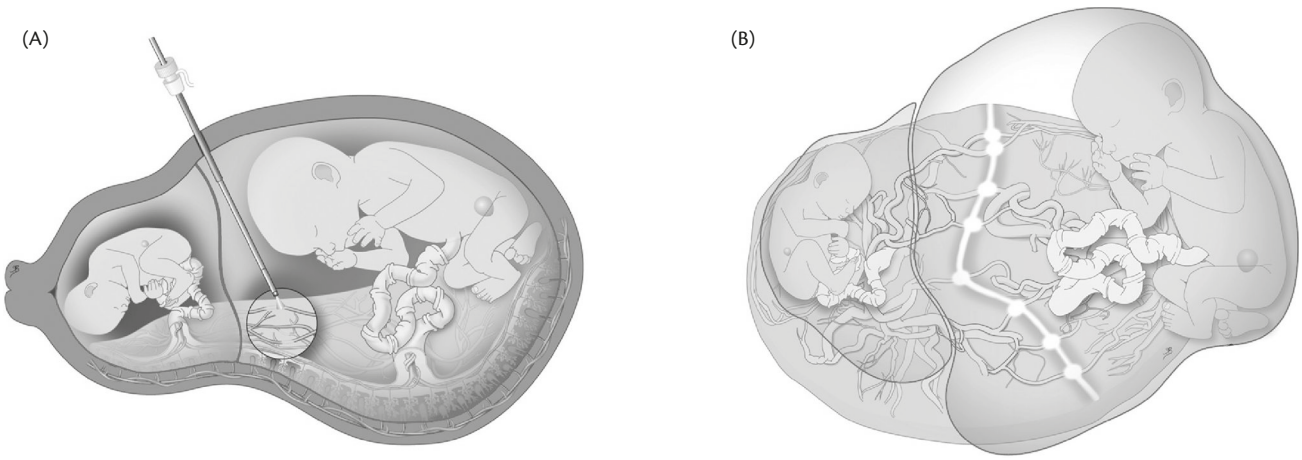

**Figure 7.6** Fetoscopic laser coagulation of chorionic plate vessels for twin-to-twin transfusion syndrome, along the vascular equator (A) and completed by separation (B).
Reproduced with permission from the University Hospitals Leuven, Belgium.

with umbrella-shaped tines is inserted into the abdomen of the target fetus, close to where the cord vessels branch at the level of the umbilicus (Figure 7.7B).[91] Cord coagulation and radiofrequency ablation are equally successful in 97% of cases,[92] but survival of the non-target twin is around 80–85% because of post-procedural losses. Cases operated after 18 weeks do better than early cases.[93,94] Mean gestational age at delivery is 34–35 weeks and neurological outcome in survivors is good, with neurodevelopmental impairment in 2% of cases.[93,95]

## Interventions for lower urinary tract obstruction

Fetal lower urinary tract obstruction (LUTO) occurs in about 2–3/10,000 pregnancies.[96] Many are due to isolated posterior urethral valves or urethral atresia, but associated structural or chromosomal anomalies are present in 25%.[96] Untreated, the perinatal mortality of isolated LUTO is high, primarily due to pulmonary hypoplasia secondary to the oligohydramnios, adding to the problem of severe renal failure. Survivors have a high incidence of chronic renal failure and up to 17% reach end-stage renal disease within 10 years.[97] Vesico-amniotic shunting has been proposed to improve the outcome of fetuses with severe oligohydramnios, that still have acceptable fetal renal function, based on a variety of diagnostic criteria.[98] Vesico-amniotic shunting is a percutaneous procedure using a purpose-designed cannula and trocar with echogenic tip. The instrument is advanced through the fetal abdominal wall into the bladder to deploy a catheter allowing bladder drainage into the amniotic cavity (Figure 7.8A).[83] The most frequent complication of vesico-amniotic shunting is preterm rupture of the membranes leading to a mean gestational age at delivery of 34–35 weeks.[99] Shunt dislodgment, which occurs in 34%,[99] and obstruction may mandate a repeat procedure.[100] There is evidence that vesico-amniotic shunting improves neonatal survival, especially in fetuses with poor renal function.[101] Overall survival ranges between 50% and 90% and one in three chance survivors has end-stage renal disease at a mean follow-up of 5 years.[102] Survivors may also have other respiratory and growth problems, but their self-reported quality of life falls within the normal range.

More recently intrauterine fetal cystoscopy has been proposed (Figure 7.8B).[103] The procedure, which can be done as early as 16 weeks of gestation, allows a more robust diagnosis, and in case of urethral valves, definitive treatment by laser fulguration may be attempted. A recent systematic review of four fetal cystoscopy studies[104] demonstrated that the initial diagnosis of posterior urethral valves changed in 32% (6/19) typically towards urethral

atresia. In terms of postnatal survival, cystoscopic ablation of the valves was superior to expectant management yet comparable to shunting.[36]

## Interventions for fetal thoracic pathology

### Pleural effusions

Fetal pleural effusions can either be isolated (primary hydrothorax or chylothorax) or secondary to other conditions such as diaphragmatic hernia, bronchopulmonary sequestration, cardiac anomalies, fetal infections, and metabolic, chromosomal, or syndromal disorders. Mild to moderate primary hydrothorax, which does not lead to functional cardiac impairment, mediastinal shift, or severe lung compression, has a good outcome and hence can be managed conservatively.[105] Hydrops and association with severe pulmonary hypoplasia reduce survival rate to 25%.[105] Drainage of the effusion should theoretically alleviate intrathoracic compression and hence yield a better outcome. Such drainage can be achieved either by repeated thoracocentesis or pleuroamniotic shunting. A recent systematic review showed that outcomes of thoracocentesis and shunting were similar,[106] yet shunting is often preferred when more distant from term (Figure 7.9). The procedure is comparable to vesico-amniotic shunting. The lateral or posterior chest wall of the fetus is preferred for shunt insertion to avoid lesions to mammary gland and nipple. Shunt migration or obstruction leads to the need for repeated procedures in 10–20% of cases. Preterm premature rupture of membranes and preterm delivery are common, leading to an average gestational age at delivery of 34–35 weeks. In a recent large case series, neonatal survival was 55% in hydropic fetuses and 85% in non-hydropic fetuses.[107] Gestational age at birth and duration of shunting are both important predictors of outcome.[108]

### Pulmonary parenchymal lesions

Congenital cystic adenomatoid malformation (CCAM) of the lung arises from an overgrowth of the terminal respiratory bronchioles. Bronchopulmonary sequestration (BPS) is non-functional pulmonary parenchyma that is separated from the normal lung and receives its blood supply from the systemic circulation. CCAMs are classified as microcystic, macrocystic, or mixed based on their appearance on ultrasound. Most commonly, CCAMs are small and about 50% regress in the third trimester of pregnancy.[109] Limited lesions do not compromise cardiac function or lung development and have very favourable outcomes with conservative prenatal management. Some can even be managed conservatively postnatally.[110]

More rare are the masses that grow very large and lead to pulmonary hypoplasia or hydrops, the latter being almost invariably fatal.[111] In large macrocystic CCAMs, therapeutic size reduction can be obtained by thoraco-amniotic shunting of the larger cyst. Non-hydropic fetuses with masses causing mediastinal shift that are shunted have a postnatal survival rate of 87% (gestational age at birth 37 weeks).[109] For hydropic cases, survival was only 66%. Large microcystic CCAMs are considered not to be amenable for thoraco-amniotic shunting as they are mainly solid. First, maternal administration of glucocorticoids should be attempted.[112–114] If not, surgery can be contemplated. Several minimally invasive techniques have been described but are experimental. There is more information about open fetal surgical lobectomy, which has a survival rate of 50%, yet at the cost of higher maternal morbidity.[66,115]

In view of the potential of identifying a (systemic) feeding vessel to a BPS, vascular occlusion techniques comparable to those used in twins can be used, with a greater than 90% survival rate.[109,116–121]

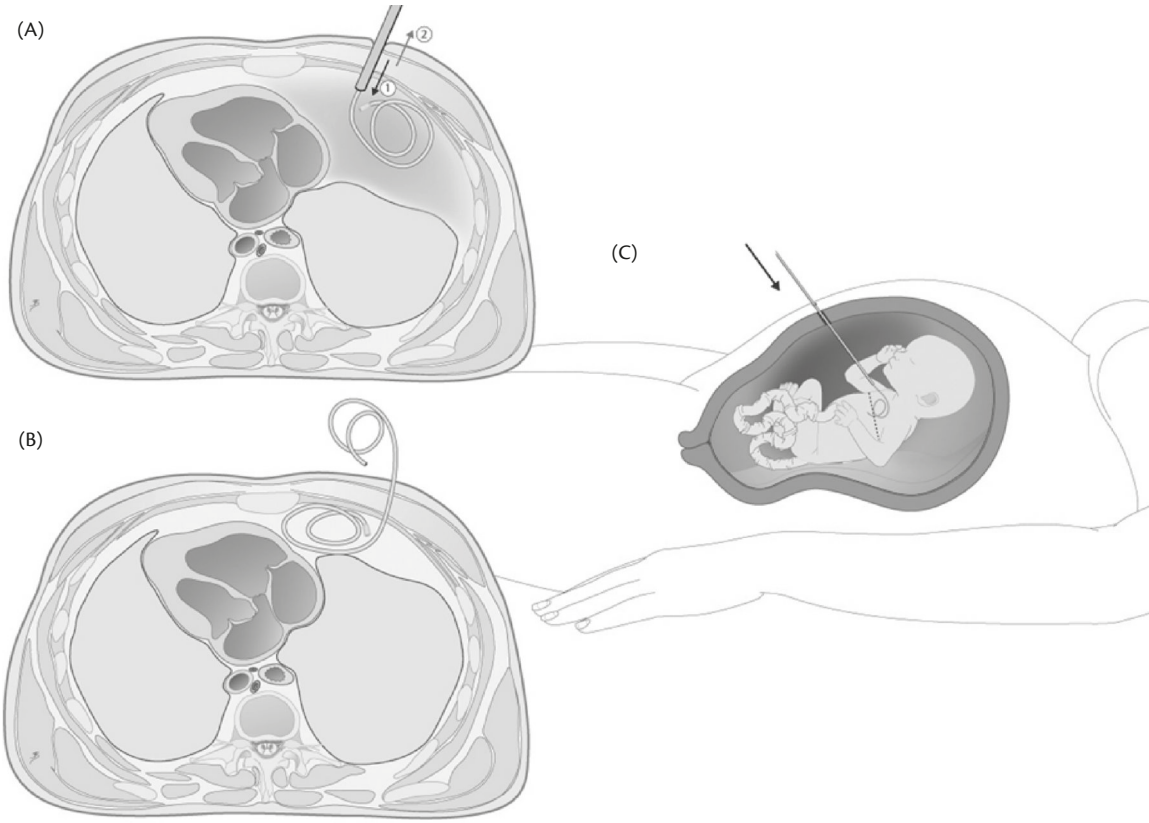

**Figure 7.9** Schematic representation of a thoracic shunt being inserted (A, B) and deployed (C).

### Pulmonary hypoplasia due to congenital diaphragmatic hernia

Congenital diaphragmatic hernia occurs in 1/3000 pregnancies. Even when isolated (i.e. in the absence of other structural defects or chromosomal anomalies) this condition has a high neonatal mortality and morbidity due to pulmonary hypertension and hypoplasia. The prognosis of an individual fetus can be predicted prenatally based on assessment of fetal lung size and liver position.[122,123] Although the overall neonatal survival of fetuses with isolated left-sided diaphragmatic hernia approaches 70–80% in high-volume centres, fetuses with liver herniation and a contralateral lung area less than 25% of the expected area for gestational age on ultrasound have a neonatal survival of less than 25%.[124,125] Fetal lung growth can be stimulated *in utero* by tracheal occlusion (FETO). This procedure prevents the outflow of fluid produced by the lungs. As a consequence, the lungs are inflated and stretched, which is a proven strong stimulus for lung growth. Tracheal occlusion can be done fetoscopically under local anaesthesia within 10 minutes. After the fetus is anaesthetized and immobilized, a fetoscope[83] is introduced percutaneously and the fetal trachea is accessed through the mouth (as for an intubation) (Figure 7.10). A vascular occlusion balloon is delivered in the trachea, just below the vocal cords. As long as the tracheal balloon is *in situ*, the fetal airways are occluded, meaning that normal respiration cannot take place at birth. We have proposed *in utero* reversal at 34 weeks, which in animal experiments has been shown to promote lung maturation, but also allows vaginal birth and referral to a centre not familiar with FETO. Others remove the balloon at birth on placental circulation (Ex Utero Intrapartum Treatment—EXIT). The combined experience of three European centres offering FETO exceeds 200 cases.[126] The most important complications of FETO are preterm prelabour rupture of membranes and preterm delivery which occurs on average at 35 weeks. Compared to an expectantly managed historical cohort, FETO improves survival of cases with severe isolated left-sided diaphragmatic hernia from 25% to 50% and decreases neonatal morbidity.[126–128] This procedure is currently being investigated in a randomized trial (http://www.totaltrial.eu).

## Fetal cardiac procedures

Despite improvements in neonatal (surgical) care and the development of dedicated follow-up programmes for infants with congenital heart disease, the outcome of fetuses with hypoplastic left heart syndrome (HLHS) remains poor. Postnatal surgery, which results in a far from optimal single-ventricle Fontan-type circulation,[129] has a considerable mortality rate leading to a total survival of less than 65%.[130] Moreover, half the long-term survivors have poor neurodevelopmental outcome[131] which may in part have an antenatal origin. Indeed, a preferential return of oxygenated blood towards the right ventricle and lower body rather than towards the left ventricle and the brain may lead to suboptimal brain oxygenation *in utero*.[132,133]

A hypoplastic heart can already be present in early pregnancy,[134] but about 5% develop in the second trimester and are progressive.[130] In these cases, which are often due to outlet valve obstruction, fetal balloon valvuloplasties may allow for intrauterine ventricular recovery and growth, and increase the chance

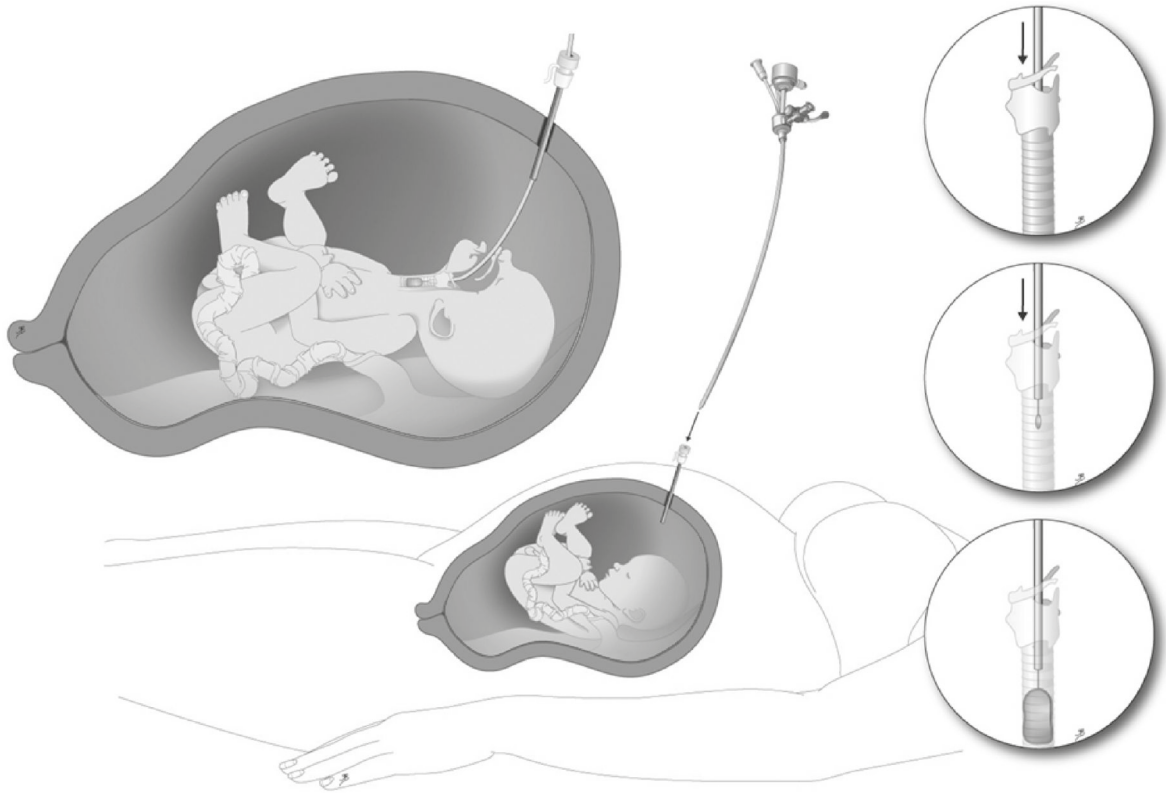

**Figure 7.10** Percutaneous insertion of a balloon into the fetal trachea. Inserts show the steps for positioning a detachable balloon.
Reproduced with permission from the University Hospitals Leuven, Belgium.

of a postnatal biventricular repair. Proper patient selection and optimized techniques for needle-based access to the fetal heart have led to reasonable outcomes.[135–137] For HLHS, an 18- or 19-gauge needle is inserted into the fetal left ventricle at the level of the apex and in alignment with the left ventricular outflow tract (Figure 7.11). A guidewire and a catheter with a coronary dilatation balloon are advanced through the aortic valve, which is dilated to 120% of the valve annulus. Technical success defined as successful inflation and dilatation is achieved in 70% of cases. Perioperative complications are common. These include bradycardia necessitating fetal resuscitation (17–38%), haemopericardium (13%), ventricular thrombosis (15–20%), as well as fetal demise (8–13%).[138] Significant left ventricular growth may be observed *in utero*, yet only 33–67% of the technically successful procedures end up in a postnatal biventricular repair. Similar percutaneous cardiac balloon procedures have been proposed for HLHS with a highly restrictive foramen ovale[139] and pulmonary atresia with intact ventricular septum.[140]

## Myelomeningocoele

The prevalence of neural tube defects in Europe is around 9/10,000 births making it one of the most frequent congenital anomalies affecting the central nervous system.[141] Myelomeningocele (MMC) is the most common distal closure defect and is characterized by extrusion of the meninges and the spinal cord. *In utero* exposure of the developing spinal cord and nerves causes progressive damage, whereas leakage of cerebrospinal fluid leads to hydrocephaly and downward displacement of the cerebellum and brain (Chiari malformation). This in turn affects neurocognitive prognosis and late morbidity. Over 80% of children require lifelong shunting and 50% of them will have shunt complications in the first year of life.[142] The functional impact is highly dependent on the level and extension of the lesion.[143,144]

Fetal intervention essentially aims at *isolating the defect from the toxic and traumatic intrauterine environment*. Following experimental and early clinical evaluation, the Management of Myelomeningocele Study (MOMS) demonstrated benefit of fetal rather than postnatal closure through maternal laparotomy and hysterotomy. Eligible are fetuses with lesions above S1 between 19 and 25 completed weeks of gestation.[65] This results in the *in utero* reversal of the Chiari malformation. Postnatally the need for shunting dropped by a third, and at 30 months of age, 40% of children were able to walk (control: 20%). This is in line with earlier case series that also showed that outcomes after fetal surgery are about two vertebral levels functionally better than anatomically present.

The procedure requires maternal general anaesthesia for adequate fetal anaesthesia and uterine relaxation for fetal surgery and uterine exposure. The fetus is manually positioned such that the MMC sac is in the centre of the future hysterotomy, which is made with specifically designed uterine staplers (Figure 7.12). The fetus is given an intramuscular injection of fentanyl and muscle relaxant. The actual MMC repair is not different from what is typically done after birth. The uterus is closed in two layers with prior restoration of amniotic fluid and antibiotic administration and covered with an omental patch. Prophylactic tocolytics includes magnesium sulphate (24 hours), indomethacin (48 hours), and oral nifedipine after discontinuation of magnesium sulphate until

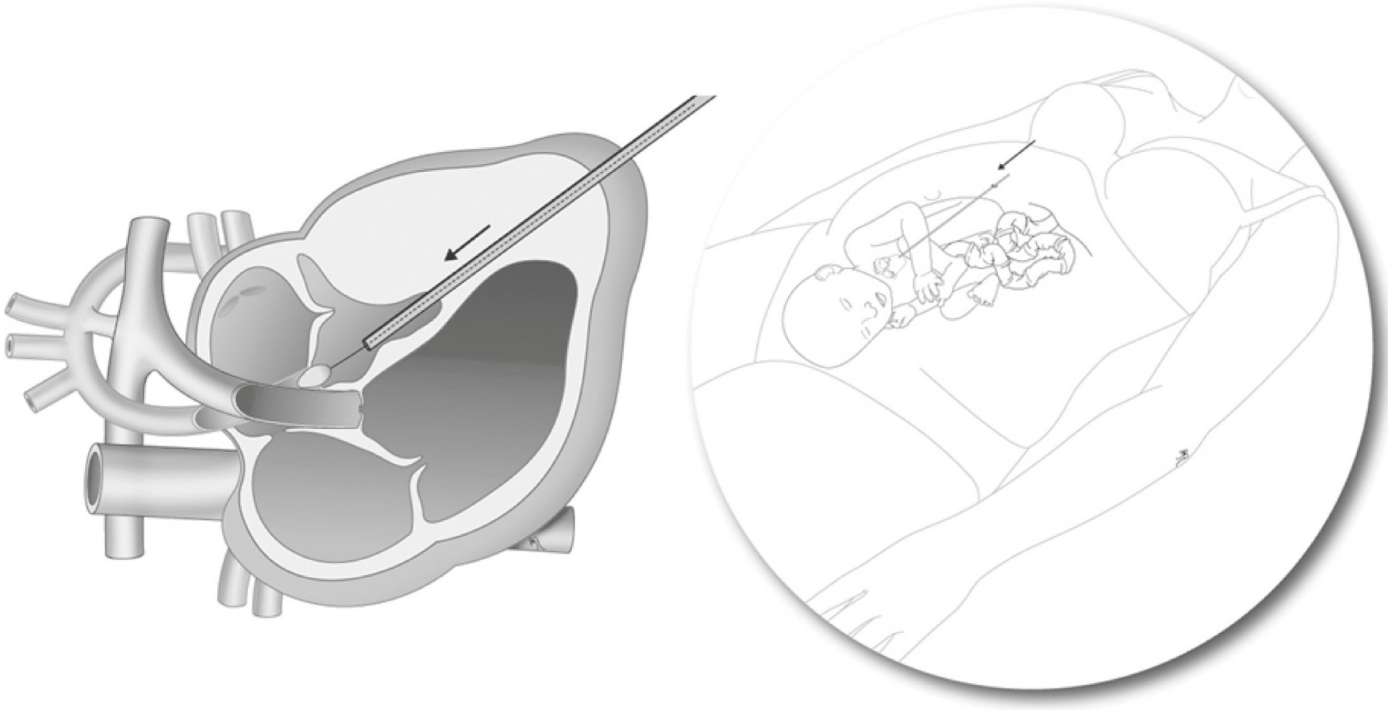

**Figure 7.11** Schematic representation of a percutaneous valvuloplasty, in this case of the left ventricular outlet tract.

37 weeks. Typical hospital stay is 4 days. Elective caesarean delivery by lower uterine incision is at 37 weeks.

## Fetal pain

Pain is a subjective experience occurring in response to impending or actual tissue damage. The subjective experience of pain requires nociception and an emotional reaction. Nociception requires an intact sensory system, and an emotional reaction requires some form of consciousness. It is difficult to know the extent to which the fetus experiences pain. However, several indirect methods have suggested that the fetus at least *can* feel pain. Robinson and Gregory suggested the importance of providing analgesia in preterm neonates.[145] Anand et al.,[146–148] Fisk et al.,[149] and

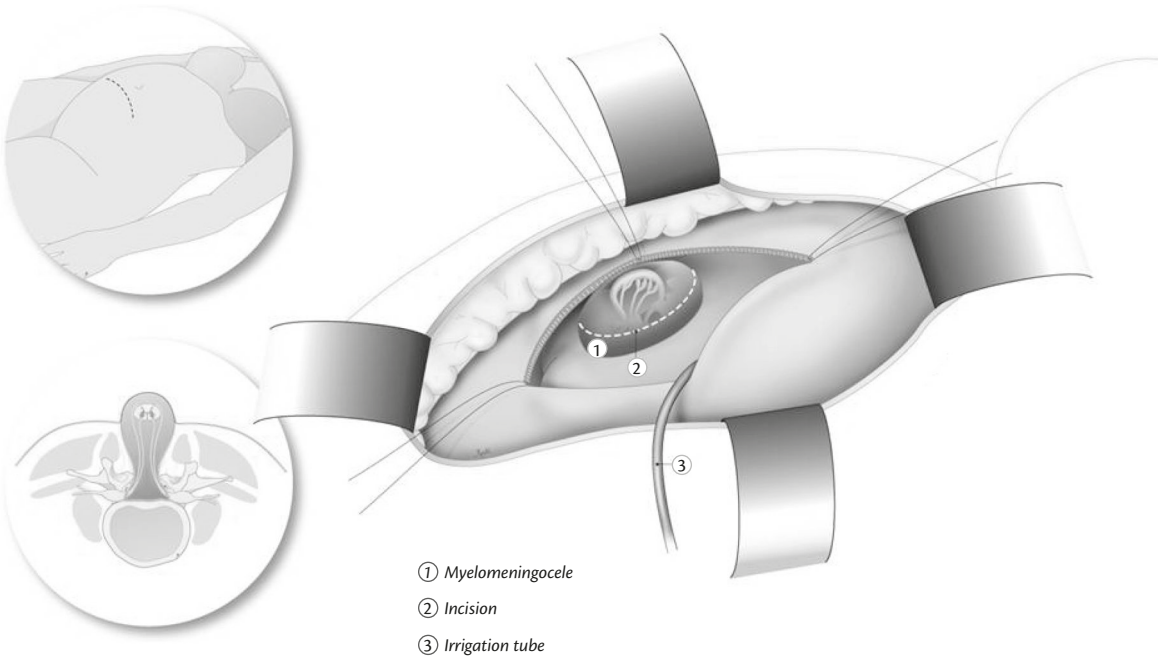

**Figure 7.12** Schematic representation of a fetal myelomeningocele repair; insert: incision (top) and schematic representation of the lesion (bottom).
Reproduced with permission from the University Hospitals Leuven, Belgium.

Giannakoulopoulos et al.[150] demonstrated that premature infants and fetuses display several humoral stress responses during invasive procedures. These data indicate that the mid-gestational fetus responds to noxious stimuli by mounting a distinct stress response, as evidenced by an outpouring of catecholamines and other stress hormones as well as haemodynamic changes. And, analogous to what has been documented in neonates, prenatal stress can be expected to affect later neurodevelopment. Theoretically, *in utero* experienced pain may be 'remembered' by the fetus, which could in turn lead to altered sensory patterns or abnormal behavioural patterns in postnatal life. Consequently, management of fetal pain and associated stress response *in utero* during invasive fetal interventions is important.[149] Even if it remains unproven whether this results in improved neurodevelopment and improved long-term outcome, it is prudent to take pre-emptive action and manage potentially painful procedures accordingly.

Several treatment protocols have been proposed[151] and, in general, a policy of administration of fetal analgesics for any invasive procedures where the fetus might experience pain should be adopted, certainly from 18 to 20 weeks onward. Sufentanil (1–2 mcg/kg) or fentanyl (10 mcg/kg) can be given intramuscularly or intravenously to the fetus. Should the mother undergo general anaesthesia, the fetus should be sufficiently anaesthetized through transplacental passage.[152]

## Conclusion

Advances in prenatal imaging and the introduction of screening policies enable identification of high-risk pregnancies and early diagnosis of fetal anomalies. Some of these are amenable to fetal therapy, in case treatment cannot wait until birth. Over the last two decades, fetal surgery has become a clinical reality, which was boosted by instrument development and successful clinical trials. More recently, open fetal surgery has become more widely reintroduced for *in utero* repair of neural tube defects, which remarkably is not a lethal condition. Performing prenatal surgical interventions requires adequate fetal pain relief.

# CHAPTER 8

# Neonatal assessment and therapy

Ewen D. Johnston and Julie-Clare Becher

## Introduction

The transition from fetal to neonatal life involves significant changes in physiology. *In utero,* life is characterized by a relatively hypoxic environment, with the lungs playing no part in gas exchange and the placenta functioning as the organ of fetal respiration. The physical effects of labour help prepare the fetus for life outside the womb, and an understanding of the processes involved in normal adaptation is essential in assessing and supporting the newborn who may not make this transition unaided.

Worldwide, neonatal mortality rates vary tenfold between developed and developing countries. The World Health Organization estimates a rate of 3/1000 live-births (high-income countries), and 32/1000 live-births (low-income countries) for this statistic.[1] Of those deaths, approximately 30% are thought to be related to birth asphyxia. It is important to appreciate that mortality alone underestimates the impact of problems at delivery on families, with around two-thirds of survivors of untreated moderate/severe hypoxic-ischaemic encephalopathy developing significant neurodisability at 18 months.[2,3]

Our training as physicians focuses on adult physiology and pathology and these concepts and considerations do not generally include the principles of newborn resuscitation and stabilization. As a consequence, even the most skilled adult (or paediatric) practitioners will naturally feel some anxiety when presented with an infant who is apnoeic and bradycardic at delivery. This need not be the case. The underlying tenets of newborn resuscitation—enabling lung aeration and optimizing temperature control—have been recognized for centuries and can be delivered with the most basic of equipment.[4] There are situations where the need for resuscitation at birth can be predicted. However, this is not always the case,[5,6] or it may not be possible to safely transfer the mother to a large unit with neonatal intensive care support before delivery. It is therefore vital that all practitioners who may be called upon to attend a delivery have the skills to provide basic newborn life support.

Delivery suite management of the newborn, once the realm of folklore and fad,[7] is now a rapidly advancing field with the International Liaison Committee on Resuscitation (ILCOR) regularly reviewing the evidence base and providing guidance on both practice and directions for future research.[8]

In this chapter, the fundamental differences between newborn infants at birth and those who have already adapted to life outside the womb will be discussed. The physiology of asphyxia will be described, and how this knowledge leads us to the development of a structured approach towards assessment and intervention when required. Delivery at preterm gestation will be covered separately, along with a number of other specific conditions requiring special consideration.

## Normal physiology and transition

The fetus develops within a tightly regulated environment. Surrounded by amniotic fluid, nourished with a constant supply of glucose and oxygen through the umbilical vein, the lungs are filled with fetal lung fluid. The pulmonary vascular resistance is high, and systemic resistance low, enabling a pattern of circulation unique to this period of life where the lungs receive only 25% of the total cardiac output (at term).[9]

De-oxygenated blood returns from the fetus to the placenta through the umbilical arteries which arise from the external iliacs. (See Figure 4.1 in chapter on Fetal and Neonatal Physiology for diagram of fetal circulation) Fetal red blood cells extract oxygen from the maternal circulation at the chorionic villi, enabled by the high oxygen affinity of fetal haemoglobin. This oxygenated blood enters the umbilical vein with a saturation of approximately 85%, and travels to the ductus venosus and then the right atrium where it travels to the left side of the heart via the foramen ovale. After reaching the left side of the heart, blood follows the same course as in adult life until it returns to the umbilical arteries—the striking difference is that the healthy fetus has a $PaO_2$ of only 4 kPa (30 mmHg; ~60–65% saturation in the descending aorta).

Deoxygenated blood from the superior vena cava is directed from right atrium to right ventricle undergoing some mixing with the well-oxygenated flow. In the pulmonary trunk, the high pulmonary vascular resistance ensures that this blood is predominantly directed through the ductus arteriosus to join the main systemic flow.

During labour, the fetus is exposed to physical and hormonal factors which prepare them for the transition to neonatal life. Uterine contractions result in transient hypoxia as placental gas exchange is interrupted. Studies examining fetal $SpO_2$ during labour have demonstrated levels of 30–40% during late second stage in a group of deliveries where no additional support was required at birth.[10] These normal stresses stimulate a catecholamine response in the fetus which, coupled with the release of thyrotropin-releasing hormone in the mother, serves to stop the production of fetal lung fluid and promote its resorption prior to delivery.[11,12]

At delivery, the fetus must undergo a profound physiological change to successfully adapt to life outside the womb. Central to this are the first breaths which inflate the lungs, allowing the arteriolar bed to dilate, and deliver oxygen to the pulmonary vasculature promoting further vasodilation. The resultant drop in pulmonary vascular resistance allows blood from the right

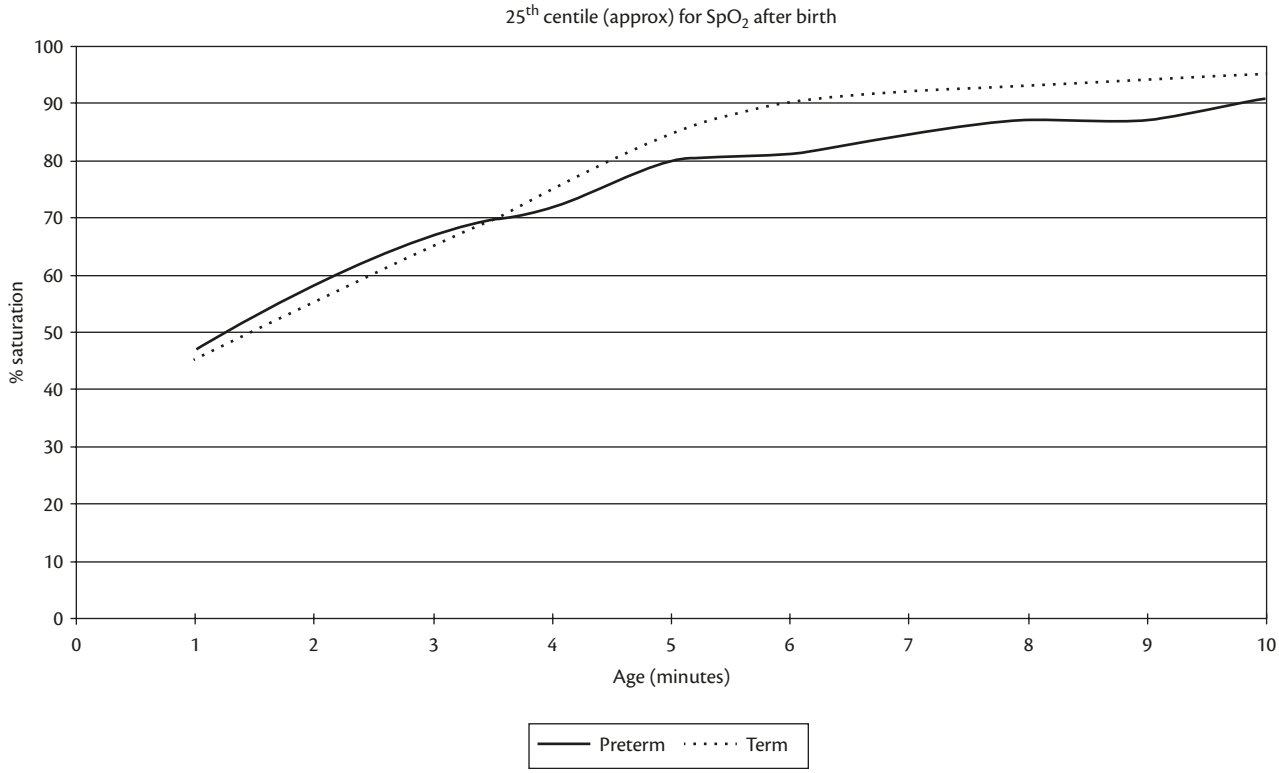

**Figure 8.1** Newborn oxygen centiles.

ventricle to flow to the pulmonary arteries. The increased volume returning to the left atrium closes the foramen ovale, and with the low-pressure placental circuit no longer available, increased pressure in the left ventricular outflow tract now shunts oxygenated blood from left to right through the ductus arteriosus promoting constriction and closure over the coming hours to days.

From the description above it is clear that lung aeration is the key to this transition. The first breath will occur within 60 seconds in most term newborns,[13] stimulated by cold, cessation of placental circulation, and physical stimuli. Newborns must first establish and then maintain a functional residual capacity (FRC). Initial breaths are deep and long, thereafter the infant can be observed to prolong the expiratory phase after a short, deep inspiration. This 'expiratory braking', is achieved by crying and promotes an FRC when the lungs are still partially filled with fluid.[14,15]

If the heart rate has slowed, it will rapidly increase and most well infants will have a pulse of over 100 by 2 minutes.[16] Oxygen saturation will climb steadily but more slowly. It is now recognized that 'low' pre-ductal $SpO_2$ during this time is normal and should be tolerated without interference in an otherwise well infant. More than 25% of well term infants will take longer than 5 minutes to achieve saturations in the 90s[17] (Figure 8.1).

Almost all newborns will make this transition without any additional help—the exact numbers are unclear, but a large Swedish study from the late 1980s found that only 1.7% of infants required resuscitation.[5]

In the next section, the physiology and effects of intrauterine hypoxia will be discussed and the central role of these processes in the approach to resuscitation.

## The physiology of hypoxia

The work of Dawes and Cross,[18,19] published in the 1950s and 1960s, provides the clearest description of the effects of intrauterine asphyxia.

The fetus is well adapted to tolerate the hypoxic process of delivery, and can survive periods of total asphyxia which would result in the death of an adult. This resilience is likely due to the high concentration of glycogen stored in the fetal myocardium. This reserve serves as fuel for metabolism upon which the healthy newborn relies during the first day whilst feeding is established. This glycogen can be mobilized when oxygen is not available, to sustain the fetus.[20] The process is inefficient producing only two ATP molecules for each glucose molecule entering the cycle (in comparison with aerobic respiration which produces 36 ATP per glucose) but is sufficient to maintain cardiac output and cerebral metabolism. The fetus and newborn demonstrate an enhanced ability to utilize alternate substrates for energy, particularly lactate, which may also be protective.[21]

A mammalian fetus starts breathing around 30 seconds after the placental circulation ceases (Figure 8.2). If these efforts fail to establish lung aeration and oxygenation, tachycardia and tachypnoea ensue. Blood pressure is maintained, and may rise slightly. Oxygen stores are rapidly depleted (around 2 minutes) and the fetus becomes unconscious. Breathing efforts cease after a few minutes, and the heart rate falls to about 60–80 beats per minute (bpm). This period is known as *primary apnoea*. The drop in heart rate is a chemoreflex,[9] resulting in vagal stimulation, and thereafter adrenergic vasoconstriction which redistributes the circulation

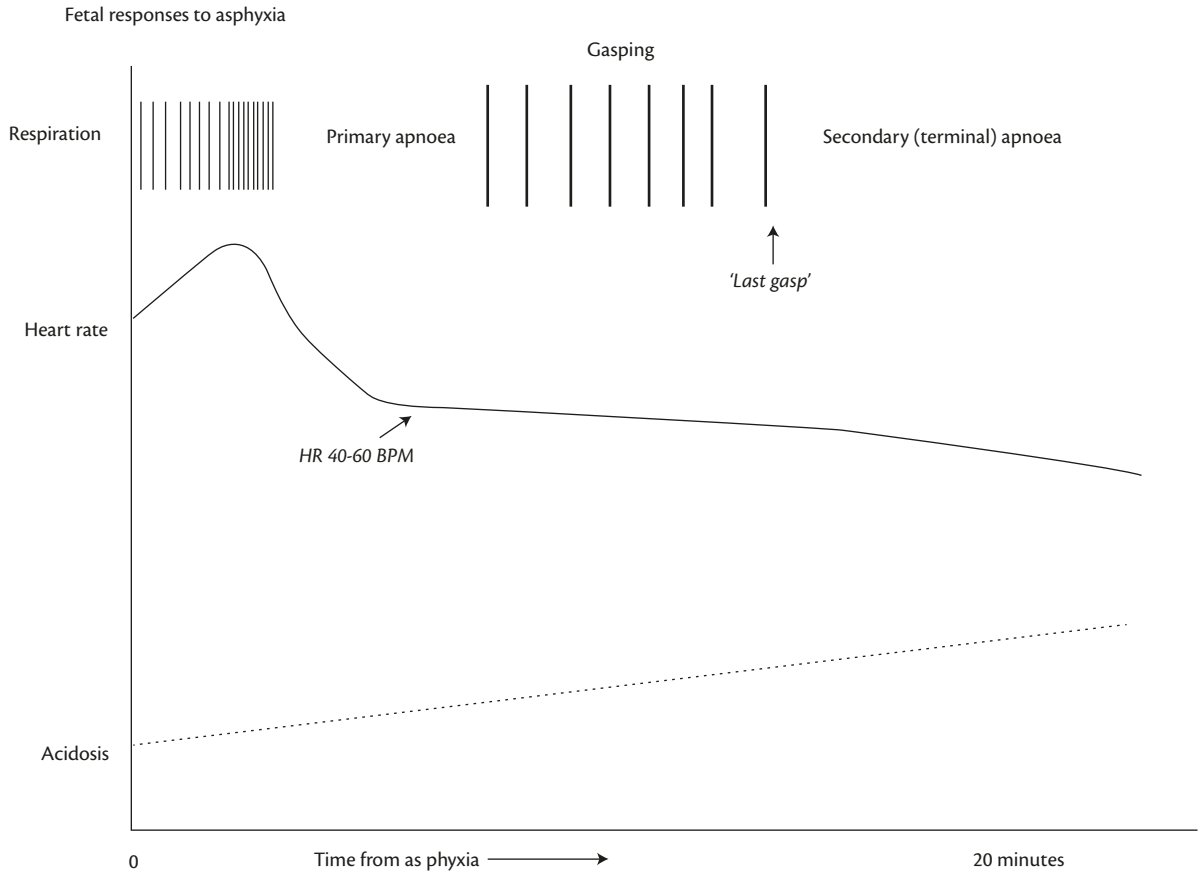

**Figure 8.2** Fetal response to asphyxia.
Data from Geoffrey S. Dawes, Foetal and neonatal physiology; a comparative study of the changes at birth [by] Geoffrey S. Dawes, Chicago, US, Year Book Medical Publishers © 1968.

centrally. If oxygenation is not restored, there is a steady rise in $PaCO_2$, and lactic acid. Cyanosis is replaced by pallor as the vasoconstriction evolves, circulation to the essential organs is maintained, but in the context of increasing acidosis. *Gasping* will now ensue. Gasps are a primitive spinal reflex which are characteristic of the newborn following hypoxia. They occur when the higher cortical suppression fails, and are slow, large volume 'whole-body' breaths—it is difficult to mistake these for normal respiration.

If the asphyxia continues, gasps will become shallower, and weaker. Lactate and $CO_2$ accrue further and increase acidosis. Glycogen stores are exhausted and the circulation begins to fail, with a further drop in heart rate and cardiac output. Around 20 minutes after the initial insult, gasping will cease, this is *terminal apnoea*. The heart beats for around 10 minutes after this but slows steadily and is unable to sustain perfusion. Twenty to thirty minutes after complete total asphyxia, the heart stops, the fetus has a profound mixed acidosis and unless delivery with resuscitation is immediate, death is inevitable. Even if this is the case, resuscitation may not be successful, and significant brain damage may have already occurred.

There are limitations in the application of this animal model to human practice—the timing of each phase is not known with certainty, asphyxia is assumed to be constant and humans have a greater store of glycogen than rhesus monkeys. The model simulates acute, total asphyxia, which is rare, and prior to the event the experimental subjects were healthy, with no previous exposure to either partial asphyxia, or labour.

At delivery, an infant who is not breathing could be in primary or terminal apnoea, or 'between' gasps. It will be difficult to distinguish between them initially, mandating that our approach to resuscitation should be the same for all:

- The infant in *primary apnoea* will have a slow heart rate, some tone, and with gentle stimulation (e.g. drying with a warm towel), is likely to start breathing/crying and their heart rate will rapidly increase. Alternatively they will take one or two gasps which (provided the airway is clear) will inflate the lungs, followed by a rapid increase in heart rate and regular respiration.
- The infant delivered during the *gasping phase of asphyxia* will present similarly, but will be more hypotonic and pale. Gasping will be apparent, and if the airway is clear these may be sufficient to enable lung aeration and delivery of oxygen to the myocardium producing an increase in heart rate. Gasps following more prolonged asphyxia may be too weak to inflate the lungs, and a brief period of artificial ventilation may be required. However, when aeration is achieved, the heart rate will again increase rapidly (Figure 8.3). The gasps will gradually be replaced by regular respirations, over a timescale proportional to the duration of the preceding insult (the longer the asphyxia, the longer the gasping persists for after resuscitation).

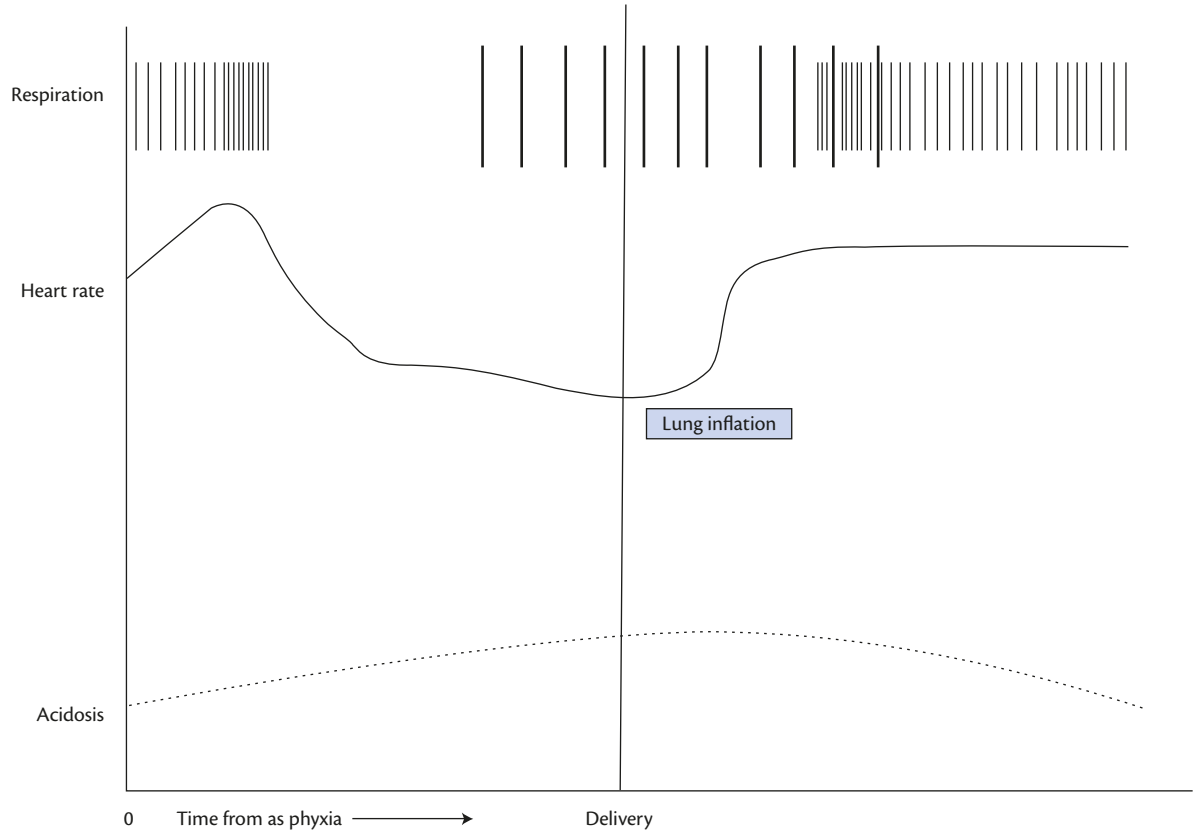

**Figure 8.3** The response of an asphyxiated newborn to lung inflation.
Data from Cross KW, Resuscitation of the asphyxiated infant, *British Medical Bulletin*, Volume 22, Issue 1, pp. 73–8, Copyright © 1966 Oxford University Press.

- The infant delivered in *terminal apnoea* is pale, floppy, and bradycardic (heart rate <60 bpm). If resuscitation is not commenced, death will follow. Artificial ventilation is required to inflate the lungs, and if gasping has only just ceased, this may lead to an increase in the heart rate. Until the infant's own respiratory effort is adequate, artificial ventilation should be provided.

If the insult has continued for longer, the degree of acidosis and circulatory compromise is likely to be so great that lung aeration alone will not result in an increased heart rate—in these circumstances a brief period of cardiac compressions may be required.

Rarely it may be necessary to administer drugs (epinephrine, glucose, sodium bicarbonate) before a response in heart rate is observed. These infants will require cardiac compressions for longer before return of spontaneous circulation. These infants have experienced the greatest degree of hypoxia and acidosis, and have the highest mortality, as well as being at greatest risk of long-term neurological damage.

## Equipment

Although one could provide adequate resuscitation in most cases with no more than a firm surface and a towel, in hospital, most newborn resuscitation will be undertaken on a resuscitaire (Figure 8.4), with additional equipment available. This will be situated either in the delivery suite, obstetric theatre, or a dedicated location nearby. As far as possible, equipment and layout should be standardized within each area (Table 8.1). An example of standard neonatal resuscitation equipment is shown in Figure 8.5.

Increasingly, additional monitoring ($SpO_2$, heart rate, temperature, exhaled $CO_2$) is available to support decision-making and help maintain stability, although one must recognize the potential dangers of using arbitrary, unresearched targets to guide practice.

In this section, we will discuss some considerations regarding equipment for newborn resuscitation in broad terms. However, it is best practice for clinicians to familiarize themselves with what is available within their own unit.

### Resuscitaire

When stripped back to basics, the resuscitaire is simply a firm surface with a source of heat, light, and gas (Figure 8.4). Most are designed to be mobile, and are height adjustable, although they can also be fixed to the wall. Mobile models have the advantage of being able to be used for transfer between the labour suite and the neonatal unit; however, as the overhead heater will lose power when unplugged, care must be taken to ensure that the infant does not become cold. Necessary equipment on a resuscitaire is seen in Figure 8.5.

### Gas supply and blender

Resuscitaires should be connected to the wall gas supply whenever possible, with cylinders kept in reserve for emergencies or transport.

Resuscitation of babies at birth should begin in air,[8,13] and if oxygen is used it should be titrated with the response monitored

**Figure 8.4** An example of a newborn resuscitaire.
Reproduced with kind permission from Laerdal Medical™.

by pulse oximetry. There is no evidence to support the targeting of oxygen saturations to any particular level or centile in any group of infants after delivery. The potential toxicity of oxygen is well recognized[22–25] and any adverse effects are likely to be greater in the two groups of newborns most likely to be given additional oxygen; those born prematurely, and those who have been asphyxiated. One should aim to avoid both hyperoxia and prolonged hypoxia.

Commonly resuscitaires in routine use do not incorporate an air/oxygen blender as standard. If a blender is not available, resuscitation with air can be provided either with a self-inflating bag, or through a T-piece connected to an appropriate air supply.

**Table 8.1** Considerations and key features for a newborn resuscitation area

| Considerations for a newborn resuscitation area | Key features of neonatal resuscitaire |
|---|---|
| Warm, no draughts | Built in over-head heater, light and timer/stopwatch |
| Good lighting | Firm, flat work surface |
| Means of summoning help | Access to the baby from three sides (head/left/right) |
| Adequate space around resuscitaire for three people | Pressure limited gas supply to T-piece ventilation circuit |
| Ease of access (transport incubator, emergency trolley etc.) | Air/oxygen blender (not standard, but strongly recommended) |
| Gas supply (air and oxygen) | Own gas supply (2 × E cylinders—1 × air/1 × $O_2$, or 2 × $O_2$) |
| Resuscitation algorithms easily visible (drug doses etc.) | Suction (usually gas driven—will drain cylinders quickly) |

## T-piece and positive end-expiratory pressure

A pressure-limited T-piece circuit with an adjustable positive end-expiratory pressure (PEEP) valve should be used to provide lung aeration and ventilation.

This system has a number of advantages over a self-inflating bag, principally:

- Can provide PEEP (or continuous positive airway pressure (CPAP))
- Operator sets peak pressure
- Easy to adjust pressure based on infant's response
- Easy to deliver timed aeration breath to set pressure.

Disadvantages:

- Gas supply needed
- Flow dependant (alterations of flow will alter previously set positive inspiratory pressure (PIP)/PEEP).

Connecting a T-piece circuit directly to a gas supply will generate dangerous pressures and must not be done. Similarly, high flow rates can overcome the safety blow-off in the resuscitaire and should be avoided. Flow rates of 8–10 L/min are acceptable.[26]

CPAP can be delivered either by mask or single- or bi-nasal prongs and is an effective way of stabilizing even the most preterm infants.[27–30]

The use of CPAP in the term infant requiring resuscitation has not been studied in humans, but there is compelling animal work suggesting a more rapid attainment of FRC after delivery with PEEP (Box 8.1).[31]

## Self-inflating bags

Every resuscitation area should have a 500 mL self-inflating bag. These will allow resuscitation to continue should the gas supply fail. The bags have a pop-off valve which must be tested before every use by occluding the outflow and giving the bag a sharp squeeze. Most bags have a reservoir, but unless connected to a blended air/oxygen supply they are limited in the concentration of oxygen which can be delivered.[32] It is not possible to provide the sustained breaths required with smaller-volume bags.[33,34] There is a degree of skill required to administer a sustained aeration breath using a bag and mask, more so than using a T-piece and staff should ensure that they are familiar with both devices.

The use of larger bags in the newborn carries the risk of over-inflation (or delivery of excessive pressure); a 3 kg neonate would usually be ventilated with a tidal volume of 12–18 mL in intensive care. Vigorous squeezing of the bag can easily overcome the pop-off valve and peak pressures of greater than 60 $cmH_2O$ can be generated relatively easily.[32,35]

**Figure 8.5** Standard neonatal resuscitation equipment.

## Flow-inflating bags

These are popular in the United States,[36] and to a lesser degree in Australia and New Zealand. In experienced hands, and with a manometer attached, these are effective devices for resuscitation[35]—however, their use is not taught on the Newborn Life Support course[13] and within the United Kingdom it is unlikely that they will be available on the labour suite for neonatal use.

## Masks

Most newborns do not require intubation at birth for resuscitation. The difficulties in maintaining an adequate seal with the masks available in the early days of the speciality[37] led to a perception that intubation was the preferred method of airway management for all but the most vigorous of infants.[38,39] Most facemasks for neonatal use are circular (Figure 8.6). Anatomical versions do exist, and are popular with some resuscitators. There is no evidence to support one type of modern mask over the other.[40,41] What is clear is that one must be familiar with one's own equipment. Good technique is required to minimize leak and practitioners need to use an appropriate hold, which has been shown to differ between designs (Figure 8.7 and Figure 8.8).[42]

**Box 8.1** Beneficial effects of PEEP in the newborn

- Assists lung expansion
- Helps establish functional residual capacity
- Prevents collapse in end expiration
- Improves oxygenation.

## Laryngoscope and blades

Intubation provides a secure airway during prolonged resuscitation and allows administration of surfactant in preterm infants. Direct visualization of the vocal cords enables suctioning of

**Figure 8.6** Two common newborn resuscitation masks. (left Fisher & Paykel Healthcare™, right Laerdal™).

**Figure 8.7** The encircling "Rim Hold" provides an optimum seal with a Fisher & Paykel Healthcare™ mask.
Reproduced with kind permission from Fisher & Paykel Healthcare™.

particulate matter (e.g. meconium), which can impede lung aeration.

Miller blades are preferred; sizes 1, 0, and 00 are used for term, preterm, and extreme preterm infants. In the smallest preterm infants (~500g), even the 00 blade may take up a large amount of space in the mouth making visualization difficult.

## Endotracheal tubes

A selection of uncuffed, non-shouldered endotracheal tubes (ETTs) should be available. Routine stylet use may be associated with complications such as tracheal and pharyngeal perforation. Cold ETTs may provide sufficient rigidity should intubation prove difficult. Methods of securing tubes vary, although direct application of tape to a newborn's skin should be avoided.

**Figure 8.8** The "2-point top-hold" is recommended when a Laerdal™ mask is used.
Reproduced with kind permission from Laerdal Medical™.

**Table 8.2** Suction catheters and uses for neonatal resuscitation

| Device | Usage |
|---|---|
| Paediatric Yankauer | Clearing particulate matter obstructing airway |
| Soft French size 8–10 | Removing oropharyngeal secretions/suction below cords under direct vision |
| Soft French size 2–3 | Suctioning ETT |
| Meconium aspirator | Clearing particulate matter from below cords through ETT |

## Suction devices

A means of clearing the airway of secretions or other material is required. Most resuscitaires will incorporate their own system which is flow driven and relies on anadequate gas supply (wall or cylinder). Pressures should not exceed 200 mmHg (264 $cmH_2O$) but 100 mmHg should be sufficient for routine use.[43] A selection of devices should be available to enable the resuscitator to deal with different circumstances (Table 8.2).

## Airway adjuncts (Guedel/laryngeal mask airway)

Oropharyngeal airways (Guedel) can be useful if the airway is difficult to maintain with other measures, and may be beneficial if there is a congenital airway abnormality (e.g. Pierre Robin sequence). A correctly sized airway will reach the angle of the jaw when the flange is positioned in the middle of the chin (Figure 8.9). Sizes 4, 5, and 6 cm are available for neonatal use, as neonates may range in size from 450 g to over 4500 g and an appropriately sized airway may not always be available. A wrongly sized or inserted Guedel will cause airway obstruction.

Insertion is best practised on a mannequin—the technique is *not* the same as in adult practice—with the airway being inserted following the curvature of the airway (rather than 'upside down' then turning, as in adults) to avoid damage to the delicate soft palate (Figure 8.10).

**Figure 8.9** Sizing a Guedel oropharyngeal airway in relation to mandible (angle of jaw, to centre of chin).

**Figure 8.10** Inserting a Guedel airway in a neonate.

Laryngeal mask airways (LMAs) have been available for neonatal resuscitation since the 1990s.[44,45] Size 1 LMAs are appropriate for infants heavier than 1500 g. There is no evidence to support or reject their use over either mask ventilation or endotracheal intubation. Effective lung aeration can be provided with an LMA, however their role as a primary mode of ventilation has not been established, and is not recommended. Nevertheless the LMA may have a role in the management of an abnormal airway or when ventilation has not been possible by other means.[46]

## Exhaled $CO_2$ detector

Disposable 'colorimetric' $CO_2$ detectors are now established as a means of confirming ETT position,[47–49] and are recommended by ILCOR.[8] These insert into the circuit between the ETT (or mask) and ventilation device, and cycle from purple (no $CO_2$ detected) to yellow ($CO_2$ present). There are limitations with false positive and false negatives possible (Table 8.3).[50] The detectors also prove useful in monitoring airway patency and ventilation in the non-intubated neonates receiving mask ventilation or CPAP in the delivery suite.[51,52]

## Temperature monitoring

The importance of thermal control is discussed in 'Thermal Environment and Care'.

## Oxygen saturation monitor

Oxygen saturation monitoring has become an established tool in the delivery suite (Box 8.2).[53] If supplemental oxygen is used, one should be guided by a preductal (right wrist) $SpO_2$ recording rather than the subjective assessment of colour. Postductal measurements from the feet will be lower for 10–15 minutes after delivery.[54] Obtaining a recording rapidly and reliably in the delivery suite is more challenging than in other hospital environments, but speed/accuracy are improved by practice and adhering to the following sequence of events (Figure 8.11):[55]

1. Turn monitor on, silence alarms, set pulse/tone modulation to desired level.
2. Dry wrist, wrap sensor around and secure (cover from light).
3. Connect sensor to monitoring cable.

Monitoring must never take priority over the basic principles of providing warmth and inflating the lungs, but the constant feedback of heart rate and saturation provides a practical and useful adjunct to clinical assessment alone during resuscitation—although there are no trials comparing outcome after resuscitation with or without monitoring. The UK Resuscitation Council suggests administering oxygen when the saturation of an infant is below the 25th centile,[13] whereas the American Heart Association has opted for values closer to the 50th centile.[56] These centiles are derived from observations in well infants who are spontaneously breathing, and who have not required any resuscitation. There remains little data on the preterm or asphyxiated infant and none on the effect of targeting saturations to any particular centile.[17]

**Box 8.2** Pulse oximeter characteristics for use in neonatal resuscitation

- Ability to obtain reading in low perfusion state/motion resistance
- Averaging time set as short as possible (≤2 seconds)
- Alarms silenced
- Pulse tone modulation
- Battery backup (can use on transfer).

**Table 8.3** False-positive and false-negative results using a colorimetric $CO_2$ detector

| False negative[a] | False positive |
|---|---|
| Inadequate cardiac output | Intratracheal epinephrine |
| Inadequate CPR | Droplet contamination by other drugs |
| Failure to inflate lungs | |
| Obstructed ETT | |

[a]Detector does not change colour despite correctly sited ETT.

## Future directions

The use of a respiratory function monitor (displaying flow, volume, and pressure) has been described,[57] and there are units which have established multiparameter recording of resuscitation data including video of the resuscitation,[58] which serves a training and quality improvement function, as well as enabling research.

Direct and indirect video laryngoscopy blades have been developed in neonatal sizes (0, 1) and are being used successfully in the delivery suite for training and difficult airway management.

Any advance in technology or equipment must be accompanied by research to prove its value if well-intentioned harm is to be avoided, and research in the delivery suite is subject to particular challenges.[59,60]

# Team organization

The majority of newborns need no resuscitation, or lung aeration only, which can be delivered by one person. Where resuscitation is

**Figure 8.11** Application of a saturation monitor at delivery.

prolonged, or complex support is required (e.g. preterm, asphyxiated), additional help will be needed, and the team should be assembled in advance wherever possible.

Figure 8.12 and Figure 8.13 present one approach to team organization for newborn resuscitation, resources, and personnel. Space and experience will vary and individual units should develop their own protocols.

Anaesthetists may be called upon to support newborn resuscitation in the following scenarios:

1. No other resuscitator available
2. Need for additional help
3. Difficult airway management.

## Thermal environment and care

The thermal environment of a newborn infant is key to optimal transition and stabilization. Thermal care is the first priority in the

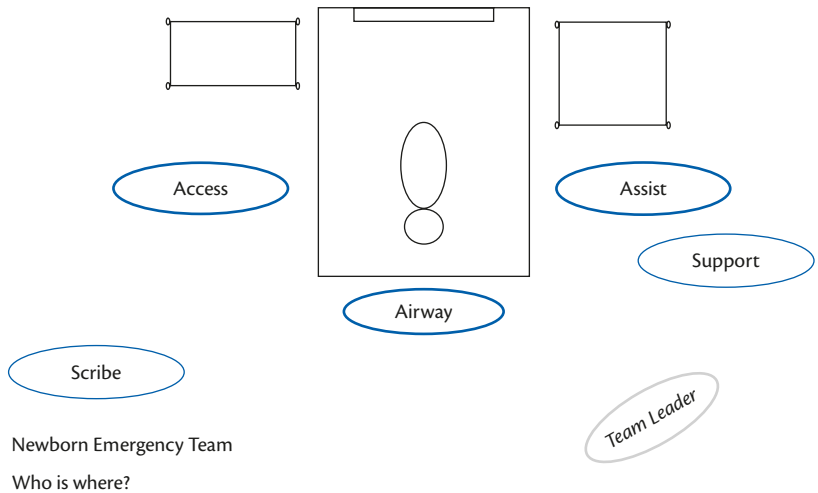

**Figure 8.12** Positions of team during resuscitation.

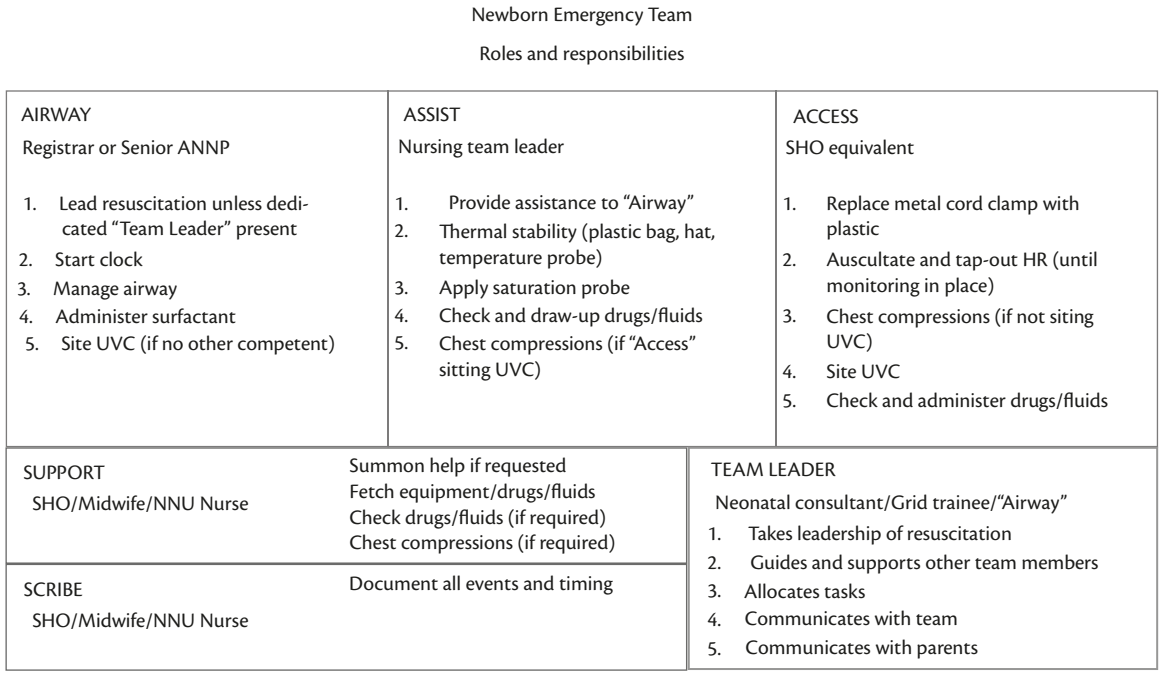

**Figure 8.13** Roles of team during resuscitation.

approach to newborn resuscitation (Figure 8.14). Newborn infants are wet, small, and have a large surface area. They may quickly lose heat through evaporation, conduction, convection, and radiation.

Hypothermia results in exhaustion of glucose reserves leading to hypoglycaemia particularly in the preterm or growth-restricted infant who has low stores of glycogen and impaired mechanisms for glucose homeostasis. Hypothermic stress can result in hypoxia and acidosis and there is evidence from animal models that this impairs surfactant production.[61,62] Hypothermia following delivery in hospital is in most cases preventable, and where infants do become cold they are more likely to require admission to the neonatal unit which results in maternal separation, parental stress, impaired bonding and establishment of lactation, as well as increasing neonatal unit workload.[63,64]

For all infants, the resuscitation environment should be thermoneutral, that is, within a temperature range that allows the infant to maintain a normal temperature with the least amount of energy expended. A room temperature of around 25°C should be comfortable for all present at the delivery and closing doors and windows will minimize draughts and reduce convective heat loss.[65] Sufficient warm, dry towels should be available for drying and wrapping the infant as well as hats of different sizes to prevent radiant heat loss.

Infants who are well at birth should be dried and given to their mother for skin-to-skin contact. This involves placing the infant naked and prone on the mother's chest, covered with a warm blanket and hat, and is associated with improved breastfeeding and temperature homeostasis.[66] It is important to ensure that parents or staff are vigilant that the infant's mouth is able to be visualized, that breathing and colour can be easily observed, and that airway obstruction does not occur.[67]

On resuscitaires, radiant heat is provided by an overhead heater, which should be switched on in advance of birth where resuscitation is anticipated. The infant should be dried and then wrapped in a clean towel. If resuscitation is prolonged, temperature should be monitored using a probe placed between the infant's skin and the mattress. This shows good correlation with core temperature. External heat can then be titrated either manually or by servo methods to maintain normothermia.

## Therapeutic hypothermia

The role of therapeutic hypothermia to 33.5°C in asphyxiated infants who develop moderate to severe hypoxic-ischaemic encephalopathy is now well established.[3]

In infants who require resuscitation for presumed intrapartum asphyxia, passive cooling may be initiated from birth. Passive cooling involves the removal of external heat sources (i.e. turning off the overhead heater) and ideally should occur in conjunction with temperature monitoring. The use of fans or gel or ice packs constitutes active cooling and should not be instituted in the delivery suite as such adjuncts can lead to rapid overcooling, which is associated with arrhythmias, cold shock, and coagulopathy.[68] Passive cooling may be continued in the neonatal unit pending a formal decision to embark on active cooling and in such cases, core temperature monitoring with a rectal probe is essential.[69,70]

Therapeutic hypothermia should only be undertaken in cooling centres which have sufficient expertise and experience to manage these critically ill infants.[71] Early liaison with neonatal transport teams[72] and the regional cooling centre may be required.

Hyperthermia should be avoided in any infant with suspected perinatal brain injury as it potentiates damage and is associated with an increased risk of adverse outcome.[73] Hyperthermia may result from external heat sources such as maximal radiant heat during a prolonged resuscitation but is also seen in maternal pyrexia secondary to infection and an association with epidural use has been reported.[74]

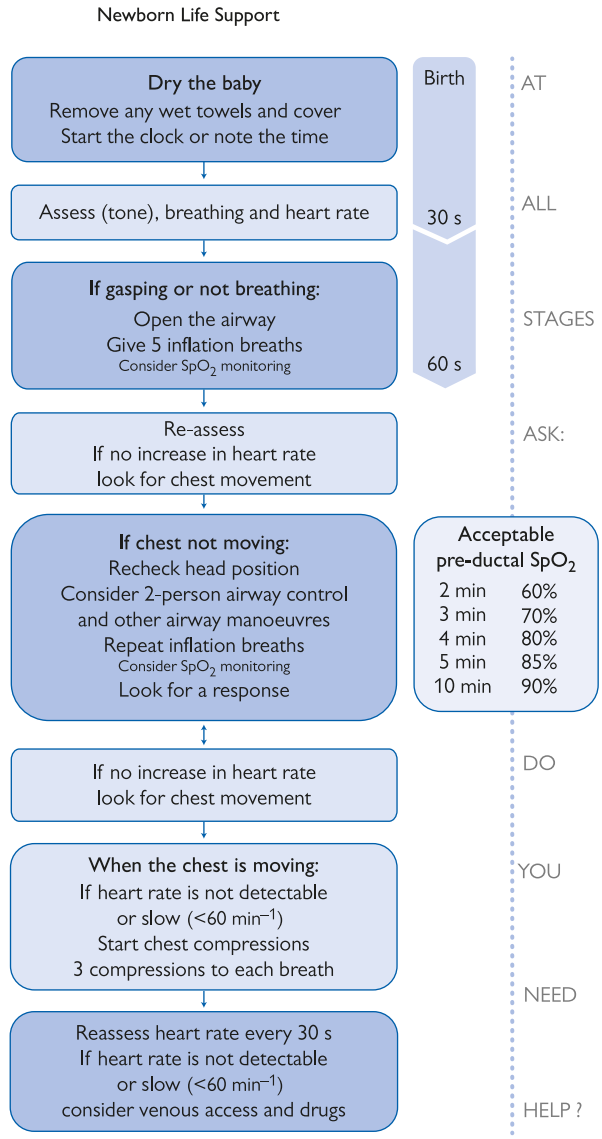

**Figure 8.14** Newborn life support algorithm.
Reproduced with the kind permission of the Resuscitation Council (UK).

## Preterm infants

Preterm infants (<37 completed weeks of gestation) are at increased risk from hypothermia and maintaining normothermia is challenging. They are smaller and have a larger surface area to volume ratio. The preterm skin is thin and poorly keratinized, and transepidermal water and heat loss is high. In addition to the problems described above, hypothermia on admission to the neonatal unit is associated with adverse outcomes including death and intraventricular haemorrhage.[75]

The environmental temperature should be increased to 26°C where possible. A hat is essential. In infants less than 32 weeks, use of polythene bags or film reduces the incidence of hypothermia on admission to the neonatal unit.[76] The infant is placed in a bag feet-first without drying and the bag is tucked around the neck (Figure 8.15). The infant is not covered with towels, allowing the radiant heater to warm the infant directly. Evaporative heat loss is reduced, as the humidity within the bag is high.

Auscultation of the chest and saturation monitoring can be performed through the bag without exposing the chest or limbs. The polythene bag should remain on the infant following admission until the temperature of the infant and the environment are both optimal. Chemical warming mattresses may be a useful adjunct to polythene bags.[77]

## Delayed cord clamping

The practice of umbilical cord clamping within 20 seconds of delivery is widely practised as an element of active management of the third stage of labour. However, in the term infant, immediate cord clamping deprives the infant of 20–30 mg/kg of iron but delaying clamping for at least 2 minutes results

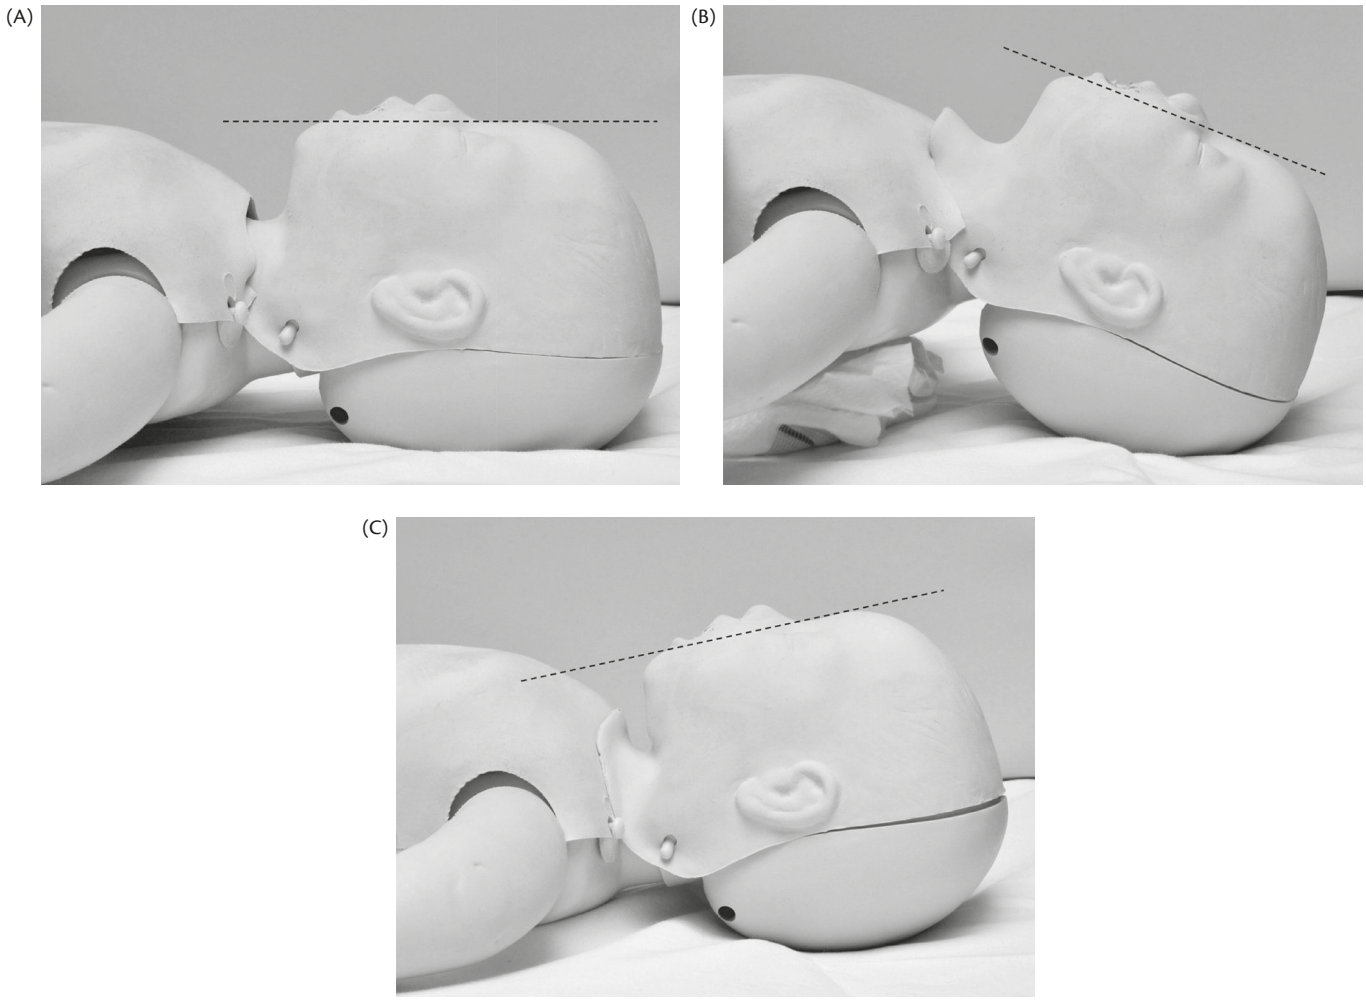

**Figure 8.15** The neutral position (A) provides an open airway in the newborn. Extended (B) and flexed (C) positions will cause airway obstruction.

in increased iron stores and a reduction in iron deficiency in infancy.[78]

Preterm infants are at increased risk of risk of anaemia secondary to iatrogenic bloodletting, reduced red cell lifespan, and relatively low concentrations of erythropoietin. Blood transfusion is common in the first few weeks of life.[79] When cord clamping is delayed by 30 seconds after birth an additional 10–15 mL/kg of blood is received by the preterm infant.[80] Systematic reviews have demonstrated that a delay in cord clamping of 30–60 seconds in the preterm infant results in a reduction in the need for blood transfusion, intraventricular haemorrhage, necrotizing enterocolitis,[81,82] and results in improved cardiovascular stability in the first week of life.

There appear to be no significant adverse effects of delayed cord clamping (DCC) either to the infant (e.g. Apgar, pH, and respiratory symptoms secondary to polycythaemia), or to the mother (postpartum haemorrhage). A 2% increase in neonatal jaundice requiring phototherapy has been observed in term infants.[82]

DCC is recommended by ILCOR and the Newborn Life Support guidelines[8] for all infants not requiring resuscitation. Although professional organizations also support a delay of 30–60 seconds before clamping the cord in preterm birth,[83,84] there may be reason to be cautious in any situation where delaying resuscitation would be disadvantageous (e.g. in those infants with a heart rate of less than 60 bpm at birth or asphyxia), where placental perfusion is significantly impaired (e.g. abruption) or in monochorionic twins where placental blood supply is shared.

In all births while DCC is being undertaken, attention should be given to thermal care and airway patency.

## Assessment after delivery

A structured, objective approach to newborn assessment is essential.

When presented with an infant at delivery, those who require additional support must be rapidly identified, whilst ensuring that over-zealous intervention does not compromise the infant who is spontaneously making the transition from the womb. Our knowledge of normal newborn physiology is important in this assessment.

It will not surprise readers to learn that the name most associated with neonatal resuscitation, Virginia Apgar, was an anaesthetist. Apgar's score (Table 8.4) was initially published in 1953 as a method of assessing an infant's well-being at 1 minute.[85] The '5'- and '10'-minute scores are later additions.

**Table 8.4** The Apgar score

| | 0 | 1 | 2 |
|---|---|---|---|
| Heart rate | Absent | <100 bpm | ≥100 bpm |
| Respiratory effort | Apnoeic | Gaping/irregular | Breathing well/ crying |
| Colour | White/ blue | Pink centrally, blue peripheries | Pink |
| Reflex irritability | No response | Weak response/grimace only | Cry/withdrawal to stimuli |
| Muscle tone | Flaccid | Decreased tone | Good tone |

The usefulness of the summed score assumes that each component is of equal importance, and is always evaluated consistently—this is an incorrect assumption. An infant in asystole at delivery has been subjected to a significant insult (Apgar score '0' for heart rate). This is in contrast to apnoea at delivery, which can occur after a relatively short period of anoxia, and may resolve spontaneously. Colour and heart rate are difficult to assess accurately,[86,87] and it is therefore unsurprising that although correlation is seen between poor outcome (death, disability, acidotic cord pH) and a low Apgar score, the predictive value is poor, with a high percentage of infants with low scores surviving with no impairment. Even when birth asphyxia leads to a clinical encephalopathy, the predictive value of the Apgar score is poor[88] until around 10 minutes.

It is now recognized that even experienced neonatologists are unable to predict outcome with any degree of accuracy based upon their assessment at delivery in the majority of circumstances.[89] The exception to this is the infant born with an obvious lethal abnormality, or those who fail to respond, and remain asystolic after 10 minutes of good quality resuscitation—in those circumstances it would be justifiable not to continue resuscitative efforts and to offer compassionate care.[8]

Apgar's achievement was in convincing those attending a delivery to focus on (and record) objective signs of well-being. Although the score consists of five components (Table 8.4), in practice it is the continued assessment of three vital signs—colour, respiratory effort, and heart rate (Table 8.5)—which provides us with the most useful information and guides our approach. Using these parameters it is possible to divide infants at delivery into three broad groups:

1. Blue, but rapidly becoming pink, with a fast heart rate, breathing well (crying) or who start breathing within 30 seconds of assessment
2. Blue, with a slow heart rate, and inadequate respiration or gasping
3. White, with a slow or very slow heart rate and no respiratory effort.

**Table 8.5** Simplified assessment of the newborn at birth

| Sign | Observation |
|---|---|
| Colour | Pink/blue/white |
| Respiratory effort | Regular(or crying)/gasping/absent |
| Heart rate | Fast/slow/very slow (or absent) |

On the infant's arrival the clock is started and observations begin (Box 8.3). The wet towels are removed and the infant is dried while continuously assessing muscular tone and response to this stimulation. A well infant who has not cried before this time will now usually do so. Colour and respiratory effort are immediately obvious. The crying infant has an open airway, and will have a fast heart rate.

Heart rate is now assessed; auscultation over the apex is preferred as palpation can be unreliable. It will be apparent whether the rate is fast (>100 bpm), slow (60–100 bpm), or very slow (<60 bpm). It is good practice to tap this beat out so that others attending the delivery/resuscitation are immediately informed. This will have taken between 30 and 60 seconds, and you will have the information to decide whether this infant is going to require more support.

Two of the signs described above, colour and heart rate (assessed by brief auscultation or palpation), are subjective and prone to much inter-observer variability. This did not escape Apgar, who commented on colour that it was 'by far the most unsatisfactory sign and caused the most discussion among the observers'.[85] The ability of those attending a delivery to relate 'colour' to oxygen saturation is almost non-existent, with observers reporting infants to be 'pink' when saturations were generally between 60% and 80%.[86] Accurate determination of the heart rate[87] has been shown to be similarly unreliable and has no bearing on seniority or experience of the observer. Interesting though those observations are, it must be accepted that for the most part, it does not matter if an infant has a heart rate of 85 bpm which is assessed as 'fast', if they are well in all other aspects. Most newborns will not derive any benefit from improving the precision of these observations, but when resuscitation is prolonged, or in the context of a preterm infant, more accurate monitoring of heart rate and saturation (preductal pulse oximetry) can be of benefit—providing any response to the numbers displayed is tempered by an understanding that low oxygen saturations can be normal during transition.[17]

One other piece of information is often available shortly after delivery. The umbilical arterial and venous blood gas results, taken from a double-clamped section of cord will provide supportive information, particularly when there is concern about *in utero* hypoxia.

Most term babies, even those for whom neonatal support is requested, will transition without any assistance; however, a small

**Box 8.3** Other observations at delivery

- Obstetric/midwifery anxiety
- Trauma/bruising
- Muscle tone
- Meconium staining (skin/cord/nails)
- Size (smaller/larger than expected)
- Obvious congenital lesions (gastroschisis, neural tube defect)
- Maturity (preterm/post-dates).

number of infants may be identified as being likely to require intervention antenatally (e.g. preterm, known anomaly), and provision must also be made to manage the infant who unexpectedly requires resuscitation at delivery. A standardized approach towards assessment enables practitioners to approach these scenarios with confidence.

## Resuscitation at birth

Training in newborn resuscitation is best learned on a recognized training course, the UK Resuscitation Council's Newborn Life Support and to a lesser extent the American Heart Association's Newborn Resuscitation Program are both taught within the United Kingdom. The differences are principally around the approach to initial lung aeration and the use of oxygen. Both are valid, and reflect the relative lack of evidence of one over the other.

### Preparation

When called to attend a delivery (Box 8.4), make use of the time available. Obtain as much history as possible; three key points should be elucidated:

1. Gestation
2. Presence of meconium
3. Presence of fetal distress (e.g. decelerations, bradycardia, loss of fetal heart, acidotic).

#### Fetal blood sample

Ensure that any windows or doors are closed to minimize heat loss. Request help if you think you may require it, and check your equipment is working and clean. Wash your hands (or use alcohol gel) and put on gloves.

- Turn on resuscitaire, turn on light, turn heater to maximum
- Towels (warm)
- Check gases (wall supply, cylinders)
- Stethoscope
- Masks—appropriate sizes
- Self-inflating bag—check pop-off
- T-piece—set pressures, 6–8 L/min flow, start in air (if possible):
  - PIP 30, PEEP 5 term
  - PIP 20, PEEP 5 preterm

**Box 8.4** Situations where the need for neonatal support may be anticipated

- Preterm gestation
- Meconium staining of the liquor
- Placental abruption
- Cord prolapse
- Shoulder dystocia
- Emergency delivery for fetal distress
- Multiples (twins, triplets, etc.).

**Table 8.6** Guide to ETT diameter and length of insertion by gestation and weight

| Gestation | Weight in kg (50th centile) | ETT diameter (mm) | Length at lips (cm) |
|---|---|---|---|
| 23–24 | 0.5 | 2.5 | 6 |
| 26 | 0.75 | 2.5 | 6.5 |
| 27 | 1 | 2.5 | 7 |
| 30 | 1.5 | 2.5 | 7.5 |
| 33 | 2 | 2.5–3.0 | 8 |
| 35 | 2.5 | 3.0 | 8.5 |
| 37 | 3 | 3.0–3.5 | 9 |
| 40 | 3.5 | 3.5 | 9.5 |
|  | 4 | 3.5–4.0 | 10 |

- Suction working, and catheters/Yankauer suction available
- Check laryngoscope light source, and blades appropriate (Miller 1, 0, 00)
- ETT (3.5 = term, 3.0 = ~33–37 weeks, 2.5 = <33 weeks) (Table 8.6)
- Other equipment (depending on environment/situation/experience):
  - saturation monitor + probes
  - vascular access kit
  - emergency drugs/fluids/blood.

As the infant is delivered, note the time (or start timer) and dry. Assess the infant looking at *colour, breathing*, and *heart rate*. The majority of infants will not require more than warmth and provision of an open airway. If the heart rate is acceptable (>100 bpm, 'fast') there is no reason to cut the cord immediately, and 1 minute of placental transfusion (see below) should be allowed.

Resuscitation follows an ABC approach, with modifications to take the newborn physiology into account. Before effective ventilation can be delivered, the lungs must be inflated. Cardiac compressions if required may only be necessary for a short period. Preterm infants usually do not need 'resuscitation' (they have not experienced *in utero* hypoxia), but do need support to effectively transition to an *ex utero* environment which they are not well equipped to cope with.

The structured approach can be summarized as follows (see Figure 8.16):

- Thermal stability (dry and wrap)—all infants
- Lung aeration—if not breathing
- Ventilation breaths—if still not breathing after the lungs have been inflated
- Cardiac compressions—if the heart rate does not respond to lung aeration
- Drugs—if the heart rate does not respond to a short period of chest compressions.

Progression from each step is determined by ongoing assessment of the infant (colour/heart rate/breathing); an increasing heart

**Figure 8.16** A correctly sized mask will cover the mouth and nose, without placing pressure on the eyes.

**Figure 8.17** Rolling on a mask minimises leak and improves subsequent airway positioning.

rate is the first sign of improvement. Whilst all newborns will require thermal stability, very few need chest compressions and drugs.[5]

## Provide warmth and a neutral airway position

On arrival at the resuscitaire, start the clock, remove any wet towels, and replace with warm dry ones. If available, put a woollen hat on the infant. Leave the chest uncovered to assess breathing whilst maintaining the airway in a neutral position (Figure 8.15). Applying 'head tilt' to a newborn will overextend the neck and cause airway obstruction. Assess the infant. If the heart rate is fast and the infant is breathing then no further intervention is required. If the heart rate is slow, or the infant does not start breathing adequately, then further support is required. Most well infants will begin breathing within 60 seconds.

## Inflate the lungs

Lung aeration (also described as 'lung inflation') is the most essential manoeuvre in newborn resuscitation. No other measures will be successful if this is not achieved. Good airway positioning and minimal mask leak are key.[42,51] A hypotonic infant will obstruct their airway due to loss of pharyngeal tone, and this is overcome by maintaining a neutral position and applying a jaw thrust if required. Once an appropriately sized mask (Figure 8.16) has been chosen, it should be 'rolled' onto the face from the chin[42] using an appropriate grip (Figure 8.17). Now re-check the airway position and inflate the lungs. In Newborn Life Support practice this is done by delivering *5 breaths, each lasting 3 seconds* at a *PIP of 30 cm$H_2O$*. This technique derives from observations that shorter breaths established a lower FRC in newborns,[90] and is supported by recent animal work.[91] Watch for chest wall rise, although this may be subtle,[92] and as the initial breaths replace lung fluid with gas then one may not observe any change with the first breaths.

Reassess the infant—if the lungs have been aerated, the heart should respond. When there is no response in heart rate the most common reason is that the lungs have not been inflated. If no chest wall movement was observed, reposition the airway and try again with jaw thrust (Figure 8.18). A persistent bradycardia with no observed chest wall movement mandates optimization of airway management (Box 8.5) and help should be summoned if not done so already.

**Figure 8.18** The "2 person technique" of providing mask ventilation is shown here, one person manages the airway with a jaw-thrust, the other provides ventilation. It is useful when a newborn's airway is difficult to maintain.

**Box 8.5** Manoeuvres to alleviate newborn airway obstruction

- Optimize airway position (shoulder pad/towel)
- Two-person jaw thrust
- Oropharyngeal airway
- Suction under direct vision.

## Meconium

The majority of infants born through meconium-stained liquor do not aspirate meconium, and routine suctioning of all infants provides no benefit, nor does suctioning on the perineum.[93] Where meconium aspiration syndrome develops after birth, meconium has already been inhaled during *in utero* gasping. Thick particulate meconium, however, may physically obstruct the trachea and prevent lung inflation causing a serious situation. If an infant with meconium staining is not immediately vigorous, inspect the oropharynx before attempting to stimulate the infant. Suction any meconium seen with a wide-bore suction catheter, then visualize the cords and suction the trachea. After suctioning, proceed to resuscitate in the usual manner, drying the infant and providing aeration breaths if required.

Suction should also be considered if no chest wall movement is seen in the absence of meconium as blood clot and vernix may also obstruct the trachea.

## Ventilation breaths

Once the lungs are inflated (i.e. chest wall movement seen), in most cases the heart rate will rapidly respond and ventilation breaths are given until the infant establishes adequate respirations. In the rare event of persistent bradycardia despite good chest wall movement, ventilation breaths (Table 8.7) should be continued and cardiac compressions commenced. Ventilation breaths are delivered at a rate of 30/min (1 second in, 1 second out), lower pressures may be used now that an FRC is established (20–25 $cmH_2O$). Loss of ventilation due to loss of airway position or increased mask leak during resuscitation will manifest as a fall in heart rate. A colorimetric $CO_2$ detector can be useful during prolonged resuscitation and supplements observation of chest wall movement.[51]

## Cardiac compressions

Chest compression is useless if the lungs have not been aerated.[13]

**Table 8.7** Comparison of inflation and ventilation breaths

| | Inflation breaths | Ventilation breaths |
|---|---|---|
| Indication | Establish lung aeration | Ventilation after lungs inflated |
| Duration | 3-second inflation | 1-second inflation |
| Pressure | PIP 30 $cmH_2O$ | PIP 20–30 $cmH_2O$ (chest movement) |
| Rate | Sets of 5 (e.g. 5 × 3 second breaths) | 30/minute |

**Box 8.6** Considerations prior to initiation of chest compressions

- Ask 'Am I getting chest wall movement?'
- Check mask, minimize leak
- Check gases, check flow
- Consider increasing PIP and inflation time
- Check airway position
- Consider tracheal obstruction
- Confirm ETT position (if using).

If the heart rate remains undetectable or very slow (<60 bpm) and chest wall movement is seen then chest compressions should be started (Box 8.6).[8,13,56]

Cardiac compressions in the newborn may be more likely to elicit an improvement than in an adult. The infant has been subjected to an acute stress, but was in optimal physiological condition prior to this, with a physiology primed to deal with hypoxia. If oxygenated blood is delivered from the pulmonary vasculature to the coronary circulation the heart should respond and function well thereafter. The compression phase empties the chest of blood, and the relaxation phase is of paramount importance to allow refilling[94] and coronary perfusion.

Compression should be on the lower third of the sternum,[95–97] this is located by positioning one's thumbs or fingers either just below the nipple line, or a finger's breadth above the xiphisternum. Two methods are recognized (Box 8.7); the two-thumb (encircling) method and the two-finger method. The encircling method is preferred (Figure 8.19)—producing greater blood flow and pressure in experimental models when compared to two-finger compressions.[98–101] It is also less likely to cause fatigue in the resuscitator. The two-finger method is useful if one has small hands, or if access to site an umbilical venous catheter is required (Figure 8.20).

A ratio of 3:1 (compressions:breaths) should be delivered to a depth of approximately one-third of the chest's anteroposterior diameter,[102] aiming for 90 compressions and 30 breaths in 1 minute. This ratio has been demonstrated to provide more consistent compressions,[103] it allows enough time for refilling, and is supported by animal models.[104,105]

Re-assess every 30 seconds, and continue to pay close attention to airway positioning, which can become compromised during compressions. If the heart rate does not respond to a short period of compressions with adequate ventilation, the myocardium has been impaired by the degree of acidosis and exhaustion of its glycogen stores. Drugs must now be considered.

**Box 8.7** Chest compressions in the newborn

- 3:1 ratio
- 30 breaths/minute (90 compressions)
- Lower third of sternum
- Two-thumb (or two-finger) technique
- Compress anteroposterior diameter by one-third
- Re-assess every 30 seconds (15 breaths).

**Figure 8.19** Hand position for chest compressions using the "encircling" method.

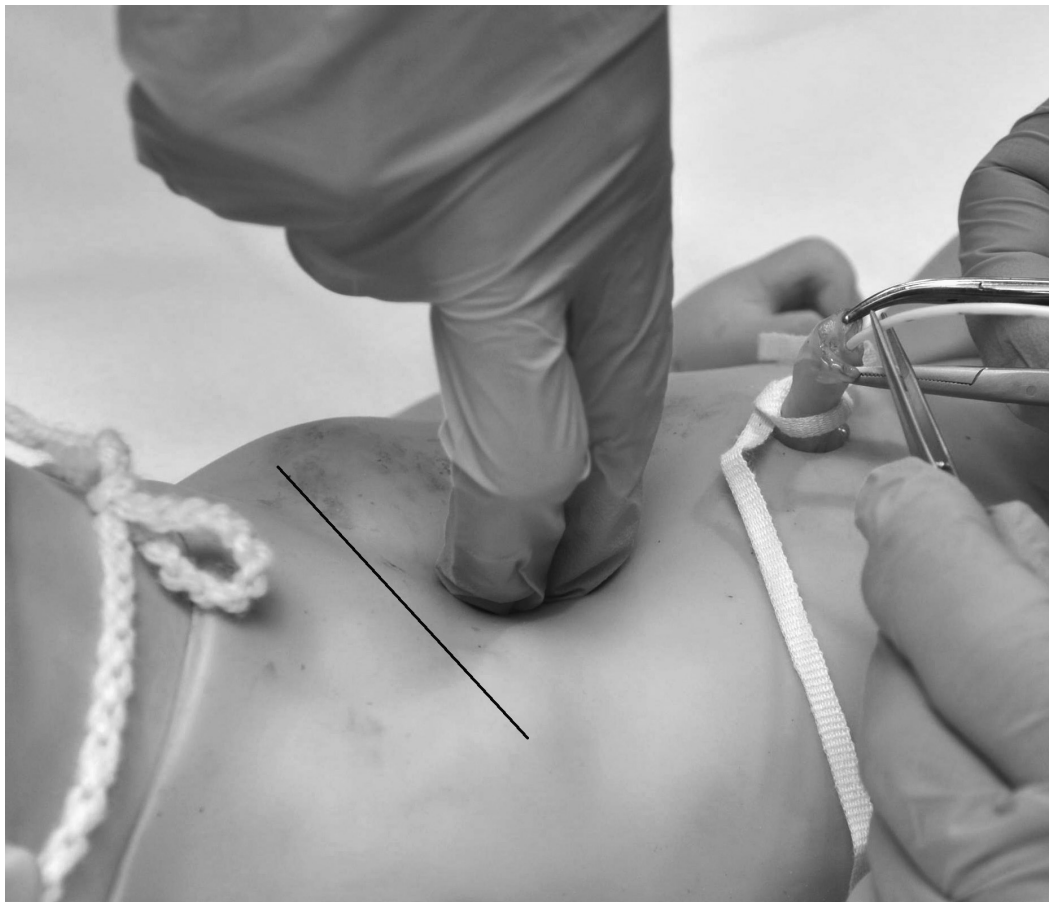

**Figure 8.20** Chest compressions delivered by the "2-finger" technique are useful whilst umbilical access is being obtained.

**Table 8.8** Drugs, doses and routes of administration during newborn resuscitation

| Drug | Preparation | Dose | Route | Repeat? |
|---|---|---|---|---|
| Sodium bicarbonate | 4.2% Minijet® | 2–4 mL/kg | UVC | No |
| Epinephrine | 1:10,000 (100 mcg/mL) Minijet® | 0.1 mL/kg | UVC/ tracheal[a] | Yes |
| Glucose ('dextrose') | 10% bags (10 g/100 mL) | 2.5 mL/kg | UVC | No |
| Volume | 0.9% sodium chloride, O –ve Blood | 10 mL/kg | UVC | Once |

[a]If the tracheal route is used a higher dose will be required (50–100 mcg/kg).

UVC, umbilical vein catheter.

## Drugs

No drug can aerate the lungs, and no newborn will recover without the lungs being aerated. Failure to respond to resuscitation is almost always an airway problem, but on occasion the circulation may be so impaired that it cannot respond to lung aeration and chest compressions.

If there has been no response to 30 seconds of chest compressions, an umbilical vein catheter should be sited. Pragmatically, we would advise not to waste time trying to obtain peripheral access. The drugs used in resuscitation are shown in Table 8.8. This is an infrequent event and it is recommended that these doses are easily visible in all resuscitation areas. Measuring small doses from a Minijet® can be achieved using a three-way tap, and 1 mL syringe (Figure 8.21).

There is little evidence to support the use or sequence of any drugs during newborn resuscitation; however, epinephrine may be less effective if profound acidosis is present, and thus bicarbonate may be given concurrently. Glucose should be given too as myocardial stores will have been depleted, and volume (as saline, or blood) should be given cautiously unless there is a clear reason to suspect hypovolaemia. Although a moderate increase in filling pressure generally improves cardiac output, excess volume may overload an already compromised myocardium.

Note the time all drugs are given and follow each with a small-volume saline flush (e.g. 2 mL). Continue a cycle (30 seconds, 15 breaths) of chest compressions after each drug, and reassess response.

## Stopping resuscitation

If no heart rate is detectable after 10 minutes of good quality cardiopulmonary resuscitation, the outlook is bleak and care should be reoriented.[8,106] There is little data to guide us when an infant remains persistently bradycardic, and advice should be sought from the local tertiary neonatologist.

# Special considerations

## Prematurity

Six to ten per cent of all births are premature—delivered before 37 completed weeks of gestation. Around 1% of infants are born at a gestation less than 28 weeks. In the developed world, the

**Figure 8.21** The preferred method of measuring small doses of epinephrine during resuscitation.

incidence of prematurity is rising, as is the incidence of multiple births.

Premature birth may occur following spontaneous onset of labour precipitated by maternal infection, multiple gestations, congenital anomalies in the fetus, or structural uterine abnormalities. Delivery may also be expedited in non-labouring women because of concerns about maternal health (e.g. pregnancy-induced hypertension or cardiac disease) or because of concern about fetal well-being, for example, growth restriction, maternal cholestasis, or blood group incompatibility.

## Mortality

Survival is directly proportional to gestational age as are both short-term complications, such as respiratory distress syndrome, intraventricular haemorrhage, and necrotizing enterocolitis, and longer-term sequelae, such as bronchopulmonary dysplasia and neurodisability including cerebral palsy, cognitive and behavioural impairment.[107,108] Improvements in both antenatal and neonatal care in the last 20 years have resulted in improved survival such that around 90% of infants born with a birthweight less than 1500 g now survive. At extremely premature gestations, survival is less good with only 20% of infants born at 23 weeks surviving, around half suffering moderate or severe disability.[109]

## Neurological morbidity

At the time of delivery and in the weeks that follow, the extreme preterm brain is undergoing a rapidly developing process of growth. The vasculature is fragile and the cellular components are vulnerable to ischaemic and inflammatory injury. Impaired cerebrovascular autoregulation means that cerebral blood flow is susceptible to swings in blood pressure including those resulting from ventilation, and changes in oxygen and carbon dioxide tension. Hallmarks of preterm brain injury therefore include periventricular haemorrhage and white matter ischaemic damage, also known as periventricular leucomalacia,[110] both of which may result in long-term cognitive and motor neurodisability.

## Improving outcomes in the delivery suite

### *Antenatal corticosteroids*

Recommendations from professional organizations state that treatment should be considered for all women at risk of preterm delivery between 24 and 36 weeks.[111,112] A course of dexamethasone or betamethasone initiated between 24 and 168 hours prior to delivery is associated with reductions in mortality (relative risk (RR) 0.69; 95% confidence interval (CI) 0.58–0.81), respiratory distress syndrome (RR 0.66; 95% CI 0.59–0.73), intraventricular haemorrhage (RR 0.48; 95% CI 0.29–0.79), pneumothorax, and necrotizing enterocolitis.[113,114]

### *Antenatal magnesium sulphate*

Cerebral palsy develops in 15% of preterm infants with a gestational age less than 28 weeks.[108,109] Administration of antenatal magnesium sulphate shortly before preterm delivery has been shown to reduce cerebral palsy with a RR of 0.68 (95% CI 0.54–0.87[115] and is recommended by the Royal College of Obstetricians and Gynaecologists.[116] There are no associated adverse long-term fetal or maternal outcomes although some mothers may experience minor adverse symptoms associated with administration.

### *Delaying cord clamping*

DCC reduces adverse outcomes in preterm infants (see 'Delayed cord clamping').

**Table 8.9** Goals of preterm respiratory management

| Aim | Rationale |
|---|---|
| Optimize early alveolar recruitment | Maximize gas exchange surface area |
| Avoid collapse during expiration | Prevent atelectotrauma |
| Avoid intubation if possible | Prevent endotrauma |
| Avoid excessive tidal volume | Prevent volutrauma |
| Avoid excess inspiratory pressure | Prevent barotrauma |

### *Maintaining normothermia*

Low temperature on admission to the neonatal unit is associated with adverse outcome in preterm infants (see 'Thermal Environment and Care').

## Respiratory support of the preterm Infant

Most preterm infants regardless of gestation age require stabilization rather than resuscitation. Gentle lung recruitment rather than aggressive intervention is important in aiding transition and avoiding lung injury (Table 8.9). Following birth, infants of 32 weeks or more are generally vigorous. More immature infants may require respiratory support with or without surfactant.

Preterm infants have fragile lungs which are less compliant and therefore less able to maintain an FRC. The lung can be easily injured by over-distension and repeated re-expansion from a collapsed state. Tracheal intubation may introduce bacteria. Lung damage leads quickly to inflammation which can inhibit surfactant function and can lead ultimately to bronchopulmonary dysplasia, a chronic lung condition associated with prolonged hospital stay, reduced pulmonary function in childhood, and neurodevelopmental impairment.

### *Continuous positive airway pressure*

CPAP reduces work of breathing by recruiting alveoli and preventing end-expiratory collapse. This aids oxygenation and prevents atelectrauma. Evidence suggests that intubation can be avoided in around 50% of infants (<750g) who can instead be managed on CPAP alone from birth with intubation for surfactant administration only if respiratory distress syndrome (RDS) develops.[37,38,126,127] Care should be taken when adopting this 'wait and watch' approach in the delivery suite that positioning of the airway is optimal and that CPAP is continuously applied, as breaks in CPAP pressure rapidly lead to alveolar de-recruitment. CPAP may be applied using a standard facemask or bi-nasal (Argyle) prongs.

### *Surfactant*

Surfactant is a mixture of phospholipids and proteins produced by alveolar cells in increasing quantities from around 20 weeks onwards. A deficiency in surfactant results in poor lung compliance, alveolar collapse, and increased work of breathing manifest clinically as RDS. The incidence of RDS is inversely proportional to gestational age but is also more common in male infants, those of Caucasian race, and infants of diabetic mothers. Surfactant production and function is inhibited by hypothermia, infection, asphyxia, and the presence of meconium in the alveoli. Lung maturation and surfactant synthesis can be accelerated by antenatal corticosteroids.

Exogenous surfactant can be administered after birth either prophylactically or as 'rescue' treatment for RDS. Surfactant

improves outcomes in infants with established RDS, resulting in a reduction in pneumothorax, mortality, and the combined outcome of mortality and bronchopulmonary dysplasia.[118]

Surfactant is normally administered to those infants most at risk of developing RDS, and may be given prophylactically in the most immature infants who require intubation in the delivery suite. More mature infants may be managed without surfactant in the delivery suite with early application of CPAP, and intervention when signs of RDS become significant in the first hours of life. Prophylactic surfactant may reduce the incidence of RDS compared to a 'rescue' therapy but results in overtreatment of infants who would not otherwise go on to develop RDS.

### *Oxygen*

As described earlier, there is increasing evidence that a high concentration of oxygen at resuscitation is harmful to newborn infants. Preterm infants in particular have low antioxidant reserves to neutralize free radicals[119] and oxygen injury is implicated in a range of neonatal morbidities including retinopathy of prematurity, bronchopulmonary dysplasia, necrotizing enterocolitis, and brain injury. On the other hand, it has recently been shown that infants nursed at lower oxygen saturations have a higher mortality than those nursed in a higher range and this has fuelled the debate about what constitutes an appropriate saturation target range in preterm infants.[120] As with term infants, reference ranges for preterm infants have been published to guide oxygen management in the delivery suite.[17] Avoidance of both hyperoxia and hypoxia should be the goal—whilst recognizing that saturation may take 10 minutes to approach 'normal'.

## The principles of stabilization of preterm infants

1. Maintenance of normothermia (see 'Thermal Environment and Care')
2. Facilitation of spontaneous respiration and supporting it with CPAP or IPPV
3. Monitoring of oxygen saturations and avoidance of hyperoxia
4. Maintenance of stability and avoidance of episodes of acute hypoxia or bradycardia.

## Equipment

- Standard resuscitation equipment including appropriately sized mask, endotracheal tubes, airways, and saturation monitor
- Plastic bag or wrap
- Hats of different sizes.

## Approach to resuscitation and stabilization

The approach to resuscitation/stabilization is the same as for term infants (Figure 8.14) with the following key differences:

1. Alert the neonatal unit in advance of delivery.
2. Infants under 32 weeks should be placed in a plastic bag under a radiant heater, and a hat put on them (Figure 8.22).
3. A saturation monitor and temperature probe should be applied if available.
4. Infants may have an immature respiratory drive and support of respiration is increasingly required as gestation decreases:

**Figure 8.22** Thermal stabilisation using a clear plastic bag.

a. Preterm infants require careful positioning of their airway as they exhibit reduced tone compared to term infants with small changes in position affecting airway patency.

b. Work of breathing may be increased because of poor lung compliance secondary to surfactant deficiency, and a compliant chest wall.

5. Spontaneous breathing may be adequate to maintain a heart rate above 100 bpm and optimal saturations with minimal work of breathing, but if not, ease of respiration and alveolar recruitment is best supported by:

a. CPAP at 5 $cmH_2O$ delivered by nasal prongs or mask through a T-piece

b. IPPV that can be delivered through a mask at starting pressures of 20/5 $cmH_2O$. T-piece ventilation is preferable to bag and mask ventilation as PEEP can be delivered and pressures measured and controlled:

i. Aeration and ventilation breaths should be given until spontaneous respiration is sufficient.

ii. Inspiratory pressure may need to be gradually increased if chest wall movement is not seen and there is no response in heart rate. Colorimeteric $CO_2$ detectors inserted into the circuit provide useful information about the patency of the airway and ability to ventilate.

iii. If manual ventilation continues to be required, intubation should be considered.

c. Intubation with an appropriate-sized ETT and IPPV delivered at initial pressures of 20/5 $cmH_2O$. Secure the tube carefully as accidental extubation predisposes to cardiorespiratory instability with resultant fluctuations in cerebral blood flow and this may precipitate intraventricular haemorrhage

i. Colorimetric $CO_2$ detectors are recommended to ensure correct tube placement.

ii. As with mask-ventilated infants, the PIP may need to be titrated to observe a response in heart rate and chest movement. Evidence of 'excellent' chest wall movement with a fast heart rate may indicate very high tidal volumes. PIP should be reduced where able to avoid lung injury.[57]

iii. Once adequate ventilation is achieved and the heart rate is stable above 100 bpm, there may be a decision to administer surfactant in the delivery suite. Surfactant is not a resuscitation drug but aids stabilization and reduces injury in the surfactant-deficient lung where positive pressure ventilation is required.[118]

### Cardiac compressions

Cardiac compressions and drugs are very rarely required in the resuscitation of asphyxiated preterm infants who do not respond to ventilation and oxygenation alone. The need for these advanced resuscitation measures are associated with a high rate of mortality and neurodevelopmental impairment especially in infants with a birthweight less than 1000 g.[121] There is no evidence to support the use of chest compressions or epinephrine by any route during resuscitation in the extreme preterm infant of gestational age less than 26 weeks.[122]

### Infants at the borderline of viability

Ethical concerns about the appropriateness of resuscitation of infants born at the extremes of prematurity (22–25 weeks of gestation) have led to the issue of professional guidance from the Nuffield Council of Bioethics and from the British Association of Perinatal Medicine.[122,123]

Infants born between 22 and 25 weeks of gestation have a high risk of mortality and may endure many challenging weeks of intensive care with significant morbidities both in the short term,[124] in infancy, and later in childhood when almost half of survivors born at 25 weeks or less exhibit moderate or severe impairment (Table 8.10).[109]

Current recommendations state that where infants are expected to be born at the limits of viability and if time allows, a discussion between the parents and a senior neonatologist will be had in which the risks of mortality and morbidity are discussed.

- Current evidence does not support resuscitation of infants born at 22 weeks or less of gestation, as the chances of survival are very low and the majority of survivors are likely to be seriously disabled. These infants should be offered palliative care with attention to alleviating pain and distress.
- Given the uncertainty of death and neurological sequelae in any individual infant born at 23 weeks, resuscitation should be guided by the wishes of the parents following informed and thorough discussion with a senior paediatrician. A decision not to offer resuscitation may be appropriate. Assessment of the condition of the infant at birth is not useful in predicting outcome and these decisions should be made prior to delivery where possible.[89] Active care should only be provided if parents are in clear agreement.
- Resuscitation of infants at 24 and 25 weeks is accepted neonatal practice in the United Kingdom, despite a high likelihood of some degree of disability, particularly at 24 weeks' gestation. However some parents may have views about the appropriateness of intensive care which are important to discuss.

Where an extremely premature infant of uncertain gestation delivers unexpectedly without time for parental discussion, the infant's maturity, size, and condition should be assessed by a senior paediatrician. Where only junior or non-paediatric staff are in attendance, the default position should be to proceed with resuscitation until senior advice can be sought and a more detailed discussion with parents can take place.

**Table 8.10** Outcomes of delivery at extreme preterm gestation

| | Gestation (completed weeks) | | | |
|---|---|---|---|---|
| | **23** | **24** | **25** | **26** |
| Mortality | 81% | 60% | 44% | 33% |
| Disability amongst survivors[a] | 47% | 35% | 28% | 20% |

## The difficult neonatal airway

The neonatal airway is prone to obstruction even under standard physiological conditions. Predisposing factors include the following:

- Small anatomical structures including diameter of larynx (typically 4–5 mm diameter compared to 12–15 mm in adults) mean that small changes in diameter lead to significant reductions in airway calibre.
- A relatively large tongue obstructs passage of air through mouth and makes infants preferential nasal breathers.
- Large occiput favours head flexion and airway obstruction.
- Limited range of neck rotation through which the airway remains patent.
- There may be low muscular tone secondary to maternal sedation or hypoxia.
- Presence of fluid and particulate matter in the airway at birth.

Other anatomical features may make management of the airway more difficult than in older children or adults:

- High position of the larynx at C3–4 increases airway resistance and necessitates straight blade rather than curved.
- Epiglottis larger and angled over the laryngeal inlet.
- Funnel shaped airway with narrowest portion at the cricoid cartilage meaning uncuffed tubes can be successfully used to seal and protect the airway.

Structural abnormalities may further threaten airway patency and are often unexpected (Box 8.8). Large masses such as cystic hygroma or haemangiomas may be diagnosed antenatally by ultrasound scan and may be accompanied by polyhydramnios. Detailed information about the airway may be obtained by magnetic resonance imaging scan and a plan made for management at birth that may include an EXIT (*ex utero* intrapartum treatment) procedure[125] or necessitate the presence of paediatric surgical and ENT teams. Abnormalities in which cleft palate or micrognathia are prominent may also be evident antenatally (e.g. Pierre Robin sequence). Pharyngeal and laryngeal abnormalities may not be apparent until birth.

**Box 8.8** Conditions which may cause airway obstruction at birth

- Beckwith–Wiedemann syndrome
- Choanal atresia
- Cleft palate
- Craniofacial dysostosis
- Cystic hygroma
- Goldenhar syndrome
- Laryngeal/tracheal webs, clefts etc.
- Mandibulofacial dysostosis
- Pierre Robin sequence
- Treacher–Collins syndrome
- Trisomy 21
- Vascular malformation.

Airway difficulties may also present following birth. Laryngomalacia classically presents in the first postnatal days with stridor and infants who have been intubated over prolonged periods of time may develop subglottic stenosis or post-extubation oedema.

Clinical signs of airway obstruction include stridor, respiratory distress with significant suprasternal tug and intercostal recession, and snorting respiration with inability to breathe through the nose. There may be an associated cleft lip or palate, a small receding chin, or an obvious neck or oral mass. On inspection of the larynx, the cords may or may not appear normal and there may be difficulty passing an ETT (laryngeal or subglottic stenosis, laryngeal or tracheal atresia), or difficulty keeping it *in situ* (laryngeal cleft). Even if the tracheal tube inserts, difficulty in ventilating may be seen with tracheal anomalies.

There is no standard protocol in the United Kingdom for the management of a difficult neonatal airway and many neonatal intensive-care units will not stock the equipment required for advanced airway techniques nor have a paediatric anaesthetist on site to offer expert support.[126]

### Equipment

An easily accessible, well-maintained trolley specific to the difficult airway is central to the management of a difficult airway. Recommended contents include:

1. Oropharyngeal airways (Guedel size 000, 00, and 0)
2. Nasopharyngeal airways (size 2.0, 2.5, 3.0, 3.5)
3. Laryngeal mask airway (size 1)
4. ETTs (size 2.0, 2.5, 3.0, 3.5, 4.0)
5. Laryngoscope with straight and curved blades (size 000, 00, 0)
6. Face masks (size 00, 0/1, 2)
7. Neonatal self-inflating bag
8. Stylets
9. Sutures
10. Video laryngoscope where available (direct or indirect)
11. Algorithm and urgent referral pathway with contact list (e.g. see Figure 8.23).

## Congenital diaphragmatic hernia

Congenital diaphragmatic hernia (CDH) arises from herniation of the abdominal contents into the thoracic cavity secondary to a defect in the diaphragm. The site of the defect is on the left side posteriorly in 80% (Bochdalek hernia) and more rarely may be on the right side anteriorly (Morgagni).

The prevalence of CDH in live-born (Figure 8.23) infants is between 1/2000 to 1/5000 births. With fetal anomaly screening, the majority of cases are diagnosed antenatally but some infants remain undiagnosed until birth or even into childhood. CDH may be associated with other anomalies such as aneuploidy and structural cardiac and genitourinary abnormalities. A number of different antenatal and postnatal features have been studied in an attempt to determine specific predictors of outcome although prognosis remains somewhat unpredictable. Associated abnormalities are indicative of a poor outcome.

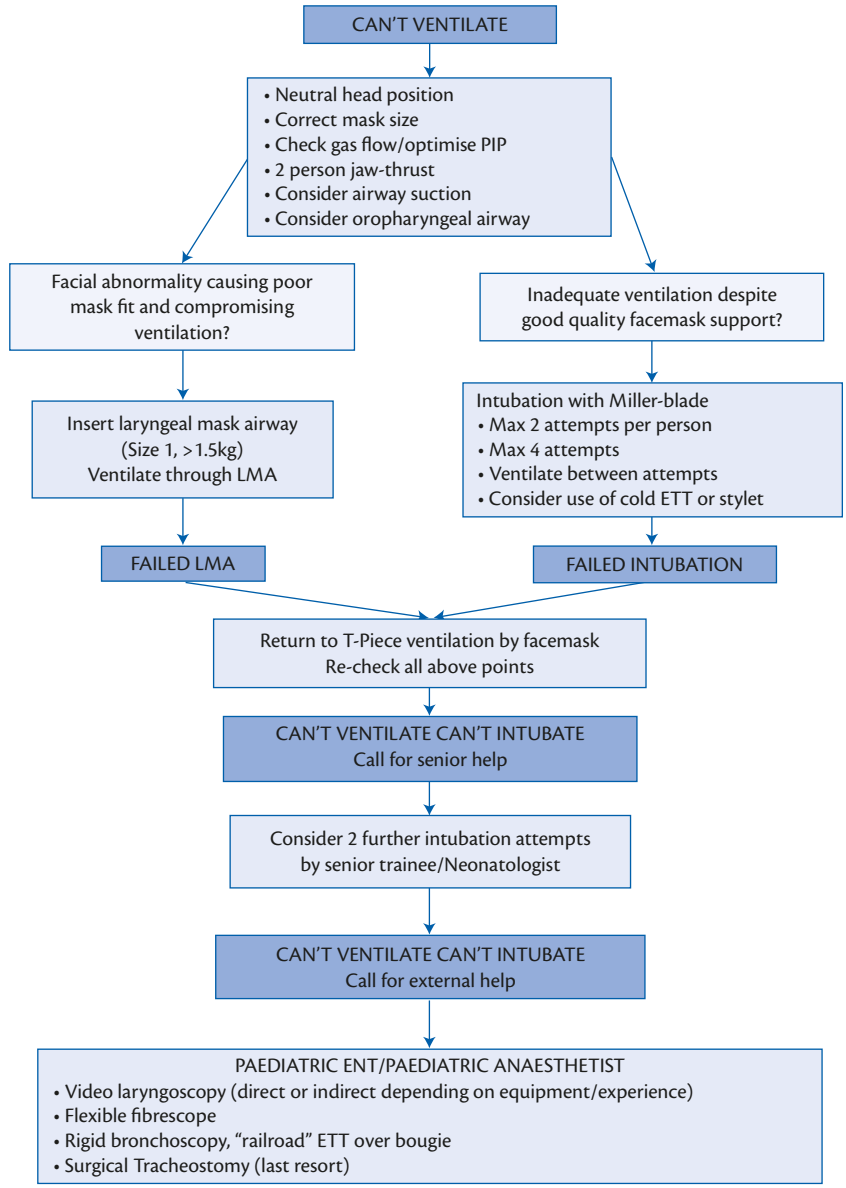

**Figure 8.23** Flowchart for managing a neonatal 'Can't ventilate, can't intubate' scenar.[126]

The hernia is a space-occupying lesion which impairs lung growth and may cause mediastinal shift. There is reduction not only in lung weight and volume but also in the number of bronchial branches and alveoli. Pulmonary vessels are reduced in number and contain a high content of smooth muscle which exhibits an exaggerated response to hypoxia, acidosis, and hypercarbia and leads to pulmonary hypertension.

Internationally it has been shown that a protocol approach to management can improve some aspects of outcome with CDH.[127] Professional guidelines have recently been published in Scotland to support management decisions at birth and in the early neonatal period.[128]

## The principles of resuscitation and stabilization

1. Achieve oxygenation while avoiding volutrauma/barotrauma of the existing lung tissue
2. Restore cardiac output
3. Minimize gaseous distension of the bowel

A strategy of 'gentle ventilation' with permissive hypercapnia is now standard practice, with high-frequency oscillatory ventilation (HFOV) and paralysis often required. Pulmonary hypertension is commonly treated after admission with inhaled nitric oxide. This approach, with delayed surgery may result in survival in 60–70% of cases.[129,130]

## The approach to resuscitation

1. Ensure a senior paediatrician and neonatal team of appropriate skill mix are present.
2. Dry and wrap the infant.
3. Monitor $SpO_2$, heart rate, and temperature.

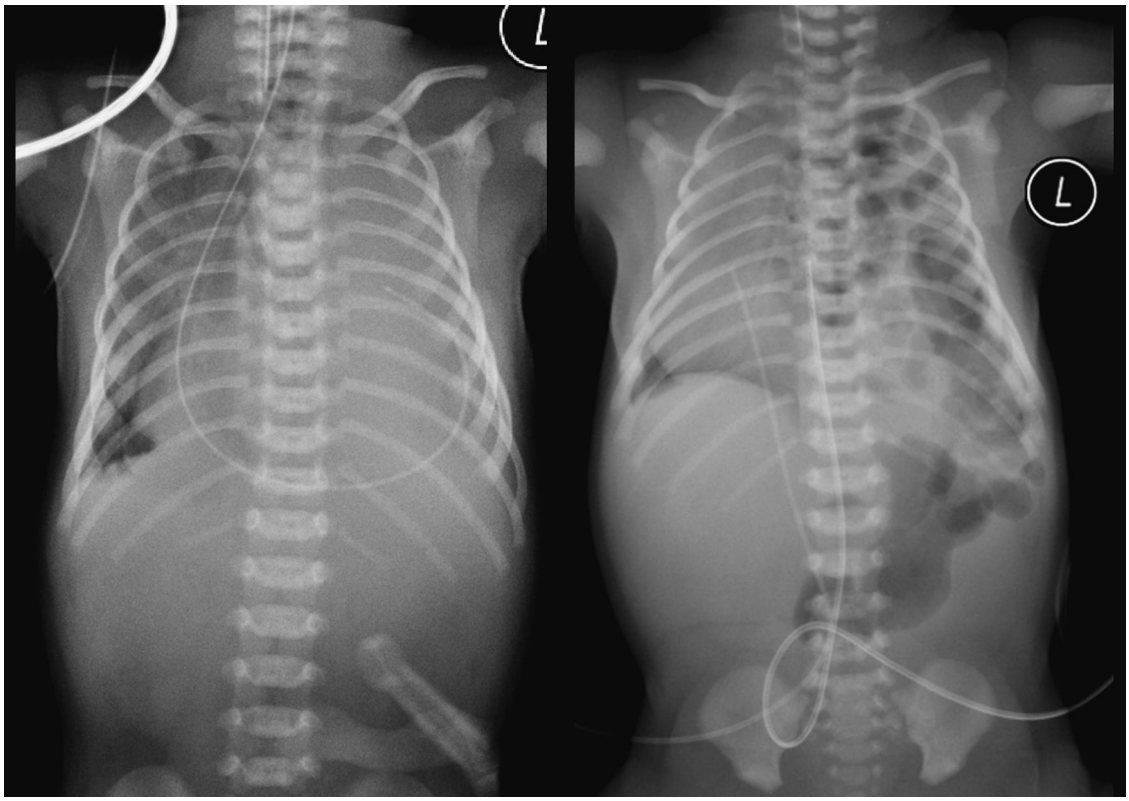

**Figure 8.24** Two X-rays of infants with a congenital diaphragmatic hernia. The X-ray on the left demonstrates an infant with a left-sided diaphragmatic hernia who was intubated and paralysed from shortly after delivery. The ETT is at T1. The NGT can be seen in the intrathoracic stomach, and there is no gas in the gut. Contrast with the infant on the right, who has no gastric tube *in situ*, and a large amount of gas in the gut.

4. Intubate immediately using an appropriately sized ETT and secure.
5. Insert a large-bore (10 F) gastric tube, orally or nasally, secure, aspirate, and leave on free drainage.
6. Inflate the lungs. PIP should be limited to pressures of 25 $cmH_2O$ or less. Higher pressures may be required initially to achieve chest wall expansion and an adequate heart rate.
7. Aim for preductal $SpO_2$ of 80–95%, with lower saturations acceptable if improving and the heart rate is stable.
8. Secure peripheral intravenous access and administer muscle relaxant and sedation to avoid swallowing of air and minimize respiratory asynchrony.
9. A fluid bolus of 10–20 mL/kg of intravenous 0.9% sodium chloride may be administered to improve perfusion and systemic pressure.
10. Alert the neonatal unit of delivery and transfer for admission.
11. Alert the surgical team of the birth and the condition of the infant.

## Abdominal wall defects

Abdominal wall defects generally comprise two conditions: exomphalos and gastroschisis. Though such infants are usually vigorous at birth, such defects require additional care and early, if not urgent, liaison with a paediatric surgical team. As such, delivery is usually planned either in or near a surgical centre with a neonatal team in attendance at delivery.

Exomphalos results from herniation of the bowel into the umbilical cord and may range from a small cord hernia to a large defect containing bowel and liver. The prevalence is 1/5000 births. The bowel is usually covered but the exomphalos sac may sometimes rupture exposing the bowel. Exomphalos is important to distinguish from gastroschisis clinically as the former is associated with other abnormalities in around 50% of cases including structural cardiac malformations, aneuploidies and conditions such as Beckwith–Wiedemann syndrome.

The pathogenesis of gastroschisis is less clear. It is commoner in younger mothers.[131] The prevalence ranges from 1/2000 to 1/10,000 births.[132] The abdominal wall defect typically lies to the right of the umbilical cord through which small and large bowel, and gonads may prolapse.

The principles of stabilization in abdominal wall defects include:

- facilitating normal cardiorespiratory transition
- avoiding distension of the bowel with air
- avoiding ischaemic damage to the gut secondary to vascular compression at the sides of the defect
- minimizing heat and fluid loss from the gut.

The following equipment should be available in advance:

- Standard resuscitation equipment, including blankets and hat

- Plastic bag
- Equipment for venous cannulation and blood tests including blood group and save
- Wide-bore nasogastric tube (NGT) (size 10)
- Fluid bolus for use if required.

The approach to stabilization at birth:

1. Have a neonatal team in attendance with appropriate skill mix.
2. Alert the paediatric surgical team in advance of birth where possible.
3. Deliver the infant feet-first into a plastic bag secured under their arms.
4. Dry their head and arms and put a hat on them.
5. Inspect the bowel without handling it unnecessarily as this may cause vasospasm. The bowel may appear normal or thickened and covered with a fibrin peel. Poorly perfused black bowel indicates ischaemia and requires urgent discussion with the paediatric surgical team.
6. Maintain the airway in a neutral position. If resuscitation permits, it is recommended that the infant is placed in a right lateral position to avoid traction on the mesenteric vasculature or compression of the bowel beneath the body.
7. In gastroschisis, a towel over the plastic bag may protect exposed bowel from overhead radiant heating, once a satisfactory position is established. If used the towel must be periodically removed to assess gut perfusion.
8. Place a large-bore (10 F) NGT, secure and on free drainage. Regularly aspirate.
9. If the infant requires manual breaths to support respiration, mask ventilation should be avoided as this may result in gaseous bowel distension. Intubation is preferred.
10. Monitor heart rate and $SpO_2$.
11. Secure intravenous access in the upper limbs and replace losses as estimated by aspiration of the intestinal exudate accumulating within the bag.
    a. Assess perfusion clinically, including colour of the gut.
    b. Volume expansion may be required to optimize perfusion of the bowel and it is not unusual for infants with gastroschisis to require 20–60 mL/kg of volume in the first 6 hours of life.
12. Prophylactic systemic antibiotics may be recommended by local protocol.
13. Infants should be considered at high risk of hypoglycaemia:
    a. Increased metabolic losses
    b. Association of exomphalos with Beckwith–Wiedemann syndrome (infants may have hyperinsulinism)
14. Allow parents time to be with their baby following initial resuscitation.

Surgical repair depends on the nature and the size of the defect. For both exomphalos and gastroschisis, options include primary repair or staged silo reduction for large lesions and primary reduction of small defects. A further option in exomphalos is to promote epithelialization of the sac with a delayed ventral hernia repair.

### Infants who do not respond

The commonest reason for non-response to standard resuscitative measures is inadequate airway management. Measures to optimize airway patency and ventilation are discussed in previous sections.

#### Cyanosis

Where infants remain blue with a good heart rate, the oxygen saturation should be checked. Many babies will only achieve saturations above 90% by 10 minutes after birth. Causes of continued low saturations include respiratory (e.g. pneumonia, pneumothorax, congenital diaphragmatic hernia) or cardiac pathology (usually mixing conditions such as atrioventricular septal defect or truncus arteriosus). Occasionally cyanosis may be due to persistence of high pulmonary artery pressure following birth, persistent pulmonary hypertension of the newborn.

Adequacy of ventilation should be assessed and optimized where necessary, oxygen should be administered to improve saturations, and the infant admitted to the neonatal unit for further assessment.

#### Inadequate respiratory drive

Continued poor respiratory effort following lung aeration/oxygenation may result from prolonged asphyxia, infection, prematurity, or opiate depression. Any infant who has required prolonged respiratory support in the delivery suite should be admitted to the neonatal unit for further evaluation and monitoring, and ventilatory support. Naloxone may be rarely required to reverse the effects of maternal opiates.

#### Prolonged asystole

The long-term outcome in surviving infants with an Apgar score of zero at 10 minutes of age is generally extremely poor and historically over 95% of such infants die or suffer severe disability.[106] The influence of therapeutic hypothermia on outcome in these infants is not clear but in one large multicentre trial, a quarter of infants who survived to receive cooling treatment in the neonatal unit were alive and well at follow-up.[133] ILCOR considers that it may be justifiable to stop resuscitation if there are no signs of life after 10 minutes of continuous and adequate resuscitation.[8] It should be appreciated that 10 minutes of age and 10 minutes of effective resuscitation are not necessarily equivalent.

## Communication and record-keeping

### Communication

#### Resuscitation

Gathering key facts about the mother and the fetus before delivery will aid the approach to resuscitation and help plan the composition of your team. Communication tools such as SBAR (Situation, Background, Assessment, and Recommendation) are increasingly used to improve timely and effective communication, a key factor in reducing risk and near miss within hospital settings (Table 8.11).[134]

**Table 8.11** Example of SBAR communication

| | |
|---|---|
| **Situation**<br>Who are you? Where are you? What is happening? | 'I am the senior midwife on labour ward, we have a 33-year-old woman admitted to labour ward in labour at 28 weeks' gestation' |
| **Background**<br>Key features of the mother, pregnancy, labour or baby to date? | 'The woman was discharged yesterday after presenting with ruptured membranes at 27 weeks. She received a full course of steroids, we have not had time to give magnesium' |
| **Assessment**<br>What is the current assessment of the mother, fetus, labour, baby? | 'The woman is fully dilated and starting to push. There are no fetal heart rate concerns and there is no meconium. Mum has a temperature and has had antibiotics. The resuscitaire is set up and being warmed' |
| **Recommendation**<br>What do you want and by when? | 'Please attend labour ward immediately with your senior and alert the neonatal unit' |

During resuscitation, one individual, usually the most senior doctor, will take responsibility for leading the process and should ensure that both verbal instructions and responses from the team are clear and unambiguous.

### Parents

It may be possible to meet with parents before the birth and explain the expected chain of events after delivery. This is a good time to discuss their expectations and concerns. Providing information in lay terminology will improve understanding and rapport.

It is increasingly common for resuscitations to take place in the delivery suite and parents may witness events which they will find frightening or which they do not understand. Information about the condition of their child should be communicated to parents as soon as possible after resuscitation. This should be done with both parents present and include the midwife looking after the mother where possible. It is critical not to offer any personal interpretation of the quality of obstetric care, instead give facts not opinions. It is good practice to check the parents' understanding of the information given. Parents may be exhausted and in a heightened state of anxiety, the mother herself may be ill, in pain, or she may have recently received analgesia or sedation—these factors may impair concentration during the discussion and comprehension of the situation.

Parents should be given the opportunity to see and touch their child even where admission to the neonatal unit is planned.

Any conversations should be documented in the infant's notes and include the information provided, questions asked, and the process of any decision-making, particularly where there has been a decision not to continue resuscitation.

If the infant dies, the role of postmortem in establishing death, and excluding other coexistent abnormalities is crucial.[135] A senior obstetrician or paediatrician should discuss postmortem and obtain consent, and in some cases where the cause of death cannot be ascertained, involvement of the relevant authorities will be necessary. Any bereaved parent should be provided with contact information and a meeting should take place with a senior paediatrician at 6 weeks.[136]

### Other health professionals

All health professionals are responsible for ensuring that high-quality information is communicated in an effective way to individual parties. Verbal information should be supported by written documentation of the information shared. Where resuscitation has been difficult or unsuccessful, it is important to be aware that both junior and senior members of the team may need immediate support. It may be beneficial to recall the team at a later time for a formal debrief.

## Record-keeping

All written documentation should occur as contemporaneously with events as possible in a legible form and in black ink. Entries should be signed with name and role given in block capitals (± professional registration number), and dated with the time of entry. Retrospective entries should have the time of entry recorded, as well as the time of events.

Accurate, factual accounts of the infant's condition and response should be provided along with a timeline of events, including the date and time of your summons and attendance (Box 8.9). Subjective terms such as 'Poor condition at delivery' or 'Difficult delivery' should be avoided.

Any scribing of events that has occurred during the resuscitation should be filed in the notes. As with verbal communication, avoid making assumptions about causation and ensure that if opinion is recorded that it is clearly documented as such.

# Procedures

## Neonatal intubation

In the delivery suite, an oral approach to intubation of the trachea is commonly practised. In infants where more long-term ventilation is anticipated, there may be conversion to a nasal tube with premedication in the neonatal unit.

### Equipment

- Appropriately sized face mask
- T-piece or self-inflating bag
- Supply of air and oxygen
- Suction and large-bore catheter
- Stethoscope

**Box 8.9** Key information to record after newborn resuscitation

- Condition of baby on first assessment (colour, tone, heart rate, and respirations)
- What measures of resuscitation were instituted
- When there was first good aeration of the lungs
- When the heart rate first rose above 100 bpm
- When infant made first respiratory effort
- Nature of first respiratory effort (e.g. gasp)
- Dose, route, and timing of any drugs
- Name and designation of staff present
- Cord blood gas results.

- Straight blade laryngoscope with working light and appropriately sized blade
- Range of ETT sizes (uncuffed) (Table 8.11)
- Fixation device for ETT
- Saturation monitor (if available)
- Carbon dioxide colorimeter (if available)
- Stylet introducer (optional).

### Procedure

1. Prepare equipment.
2. Maintain good oxygenation and ventilation by facemask. A saturation monitor should be in place if available.
3. Place the laryngoscope in the mouth, over the tongue, guarding the gums with the thumb and forefinger of the right hand, and advance until the epiglottis is visualized. Avoid overextension of the neck as this will position the larynx very anteriorly.
4. Remove any secretions present that obscure visualization, under direct laryngoscopy. Be careful not to over-stimulate the pharyngeal wall and larynx as this may cause reflex bradycardia and spasm of the vocal cords.
5. Position oneself to ensure a view down the laryngoscope and ultimately the trachea.
6. With the laryngoscope blade in the vallecula, lift the epiglottis upward using a vertical motion of the laryngoscope blade; avoid pivoting around the end of the blade.
7. The larynx and vocal cords should be in view. Downward pressure on the cricoid may facilitate the view of the larynx.
8. With the right hand, bring the ETT in from the right angle of the mouth and not down the central groove of the laryngoscope blade where it will obscure the view.
9. If the cords are adducted, wait for them to relax, rather than forcing the tube through. Insert the tracheal tube through the cords advancing only 1–2 cm.
10. Withdraw the blade while fixing the tube against the superior alveolar ridge of the gum with the left forefinger.
11. Connect to the ventilation device and assess chest expansion. A colorimetric $CO_2$ detector is recommended to confirm ETT placement.
12. Auscultate for equality of air entry and heart rate. The end of the tube should be mid trachea.
13. Ensure the tube remains *in situ* while being secured.

## Conclusion

In this chapter, the physiology of fetal–neonatal transition has been described, and this understanding applied to the structured approach to the newborn who does not breathe after delivery. The skills of newborn resuscitation are best learned on a recognized course, followed by a period of practice. It is hoped that this chapter has provided a useful and interesting adjunct to these courses enabling the interested reader to further explore a fascinating area of medicine.

PART 4

# Fertility treatment, anaesthesia for non-obstetric surgery, and drugs in pregnancy and lactation

# CHAPTER 9

# Fertility treatment in the modern age: possibilities and anaesthesia

Diane De Neubourg and Sarah Devroe

## Introduction

Assisted reproductive technology (ART) is part of medically assisted reproduction and comprises all treatments or procedures that include the *in vitro* handling of both human oocytes and sperm or of embryos for the purpose of establishing a pregnancy. This includes, but is not limited to, *in vitro* fertilization (IVF) and embryo transfer, gamete intrafallopian transfer, zygote intrafallopian transfer, tubal embryo transfer, gamete and embryo cryopreservation, oocyte and embryo donation, and gestational surrogacy.[1,2] ART does not include assisted insemination (artificial insemination) using sperm from either a woman's partner or a sperm donor or surgery.

ART is becoming increasingly important and is responsible for up to 4% of all pregnancies in Europe in 2009.[3]

In 2004, 2184 clinics from 52 countries and regions worldwide have reported their outcomes of ART to the International Committee for Monitoring Assisted Reproductive Technologies (ICMART) and are reporting on types of cycles and procedures, pregnancy, delivery and multiple birth rates, and perinatal outcomes.[4] A total of 954,743 initiated cycles resulted in an estimated 237,809 babies born. The availability of ART varied by country and ranged from 14 to 3844 treatment cycles per million inhabitants. Of all cycles, 60.6% were intracytoplasmic sperm injection (ICSI). Frozen embryo transfers (FETs) represented 31% of the initiated cycles. The overall delivery rate per fresh aspiration for IVF and ICSI was 20.2% compared with 16.6% per FET. The average number of embryos transferred was 2.35. Single (16.3%) and double embryo transfers accounted for 73.2% of cycles.

The 13th European IVF monitoring report[3] presents the results of treatments using ART initiated in Europe during 2009. From 34 countries, 1005 clinics reported 537,463 treatment cycles including IVF (135,621), ICSI (266,084), frozen embryo replacements (FERs, 104,153), egg donation (21,604), *in vitro* maturation (1334), preimplantation genetic diagnosis/screening (4389), and frozen/warmed oocyte replacements (4278). In 21 countries where all clinics reported to the ART register, a total of 399,020 ART cycles were performed in a population of 373.8 million, corresponding to 1067 cycles per million inhabitants. For IVF, the clinical pregnancy rates per aspiration and per transfer were 28.5% and 32.5%, respectively, and for ICSI the corresponding rates were 28.9% and 32.9%. In FER cycles, the pregnancy rate per thawing was 20.9%. In IVF and ICSI cycles, one, two, three, and four or more embryos were transferred in 24.2%, 57.7%, 16.9%, and 1.2%, respectively. The proportions of singleton, twin, and triplet deliveries after IVF and ICSI (combined) were 79.8%, 19.4%, and 0.8%, respectively, resulting in a total multiple delivery rate of 20.2%, compared with 21.7% in 2008, 22.3% in 2007, 20.8% in 2006, and 21.8% in 2005.

The most important complication of ART are the multiple pregnancies which have been tackled in some European countries by limiting the number of embryos for transfer, particularly in the twin-prone patient population while maintaining acceptable pregnancy rates. In Belgium, a legally enforced reduction of the number of embryos for transfer resulted in a 50% reduction of the multiple pregnancy rate from 27% to 11% since the introduction of this law in 2003 to the last assessment in 2010, without reduction of the pregnancy rate per cycle (Figure 9.1).[5]

## Overview of an assisted reproductive technology procedure

An ART cycle is composed of five phases, namely controlled ovarian hyperstimulation (COH), oocyte retrieval, fertilization, embryo transfer, and luteal phase support.

### Controlled ovarian hyperstimulation

Ovarian hyperstimulation has become an essential part of ART treatment. We are aiming to achieve 10–15 oocytes as this has been proven to give the highest success rates.[6] Different treatment schedules are used depending on how a premature luteinizing hormone (LH) surge is inhibited. When a gonadotropin-releasing hormone (GnRH) agonist is used, it can be done in a long down-regulation protocol or short flare-up protocol. In the long down-regulation protocol, LH and follicle-stimulating hormone (FSH) secretion are suppressed after 10–14 days after an initial flare-up. In the short flare-up protocol, gonadotropin stimulation is started during the initial flare-up of LH and FSH secretion. With GnRH antagonists, prevention of premature LH surge occurs fast and therefore no preparation in advance needs to be done. The actual stimulation of the ovaries is with gonadotrophins extracted from urine and highly purified or produced by recombinant technology. Starting doses may vary between 75 and 300 IU/day depending on age of the patient, menstrual cycle regularity, ovarian reserve testing (anti-Mullerian hormone, antral follicle count, basal FSH) and previous response to COH. The most important complication of COH is ovarian hyperstimulation syndrome (OHSS) which is a potentially very severe disease that can affect young infertile

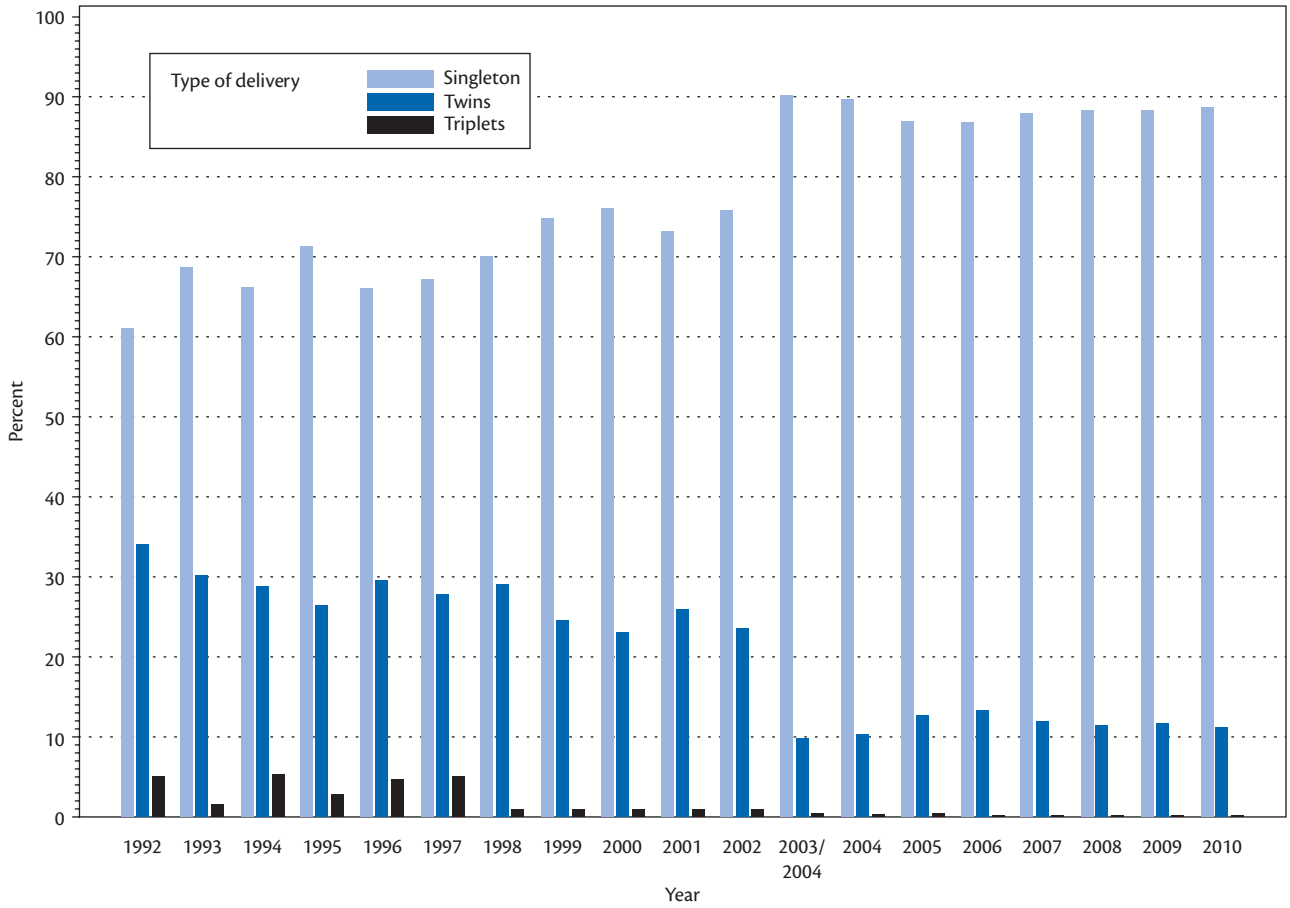

**Figure 9.1** Evolution of the number of single and multiple deliveries after ART between 1992 and 2010.
http://www.Belrap.be © The College of Physicians Reproductive Medicine.

women and is characterized by enlargement of the ovaries and signs and symptoms of a fluid shift to the third space with ascites, hydrothorax, and haemoconcentration with oliguria and thromboembolic disease as a consequence.

The incidence of severe OHSS is 2% and although stimulation schedules have been adjusted and dose of gonadotrophins have been reduced, it can never be fully excluded. Therapy is usually observational and supportive. Occasionally, ascites or pleura drainage are needed for the patient's comfort and in case of severe dyspnoea.

## Oocyte retrieval

Thirty-four to thirty-six hours after administration of human chorionic gonadotropin (hCG), the oocyte aspiration is planned. This interval aims at achieving maximal cytoplasmic and nuclear maturation of the oocyte to metaphase II and at being just in time before ovulation occurs. Therefore, timely initiation of the oocyte retrieval procedure is mandatory as patients may lose the whole cycle by not doing so. This will then inevitably lead to a tremendous disappointment for the couple as well as an important financial burden for the lost cycle. Nowadays, nearly all egg retrievals are performed vaginally under ultrasound guidance. A single- or double-lumen needle is introduced through a guide that is fixed on the vaginal probe of the ultrasound that is wrapped in a sterile cover. The ovaries can be reached through the lateral fornices of the vagina. Depending on the patient's characteristics, the procedure may vary from straightforward access and oocyte retrieval to a more risky intervention in some patients. This is the case in patients with obesity or prior extensive surgery in the pelvis for endometriosis or inflammatory disease of the intestine, a history of pelvic inflammatory disease, or any other event leading to an adhesive status of the ovaries. Apart from the wishes of the patient, the type of analgesia will also be dependent on the patient's history as already mentioned. Therefore, ultrasound-guided oocyte retrieval can be performed under local or locoregional anaesthesia, conscious sedation, or general anaesthesia. Gynaecological complications related to the oocyte retrieval procedure are the occurrence of bleeding and infection. In cases where a difficult procedure is anticipated or in patients with a history of important pelvic surgery or disease, antibiotics are usually given prophylactically.

Laparoscopic oocyte retrieval is rarely performed. It is used in cases where it is difficult to reach the ovaries, for example, in obese patients. However, performing a laparoscopy in this patient population is subject to an increased risk for complications as well. Therefore, in many clinics, invasive procedures such as oocyte retrieval and diagnostic and therapeutic laparoscopy will only be executed in patients with a body mass index below 35. Laparoscopic oocyte retrieval can also be part of the gamete intrafallopian transfer procedure where gametes are transferred

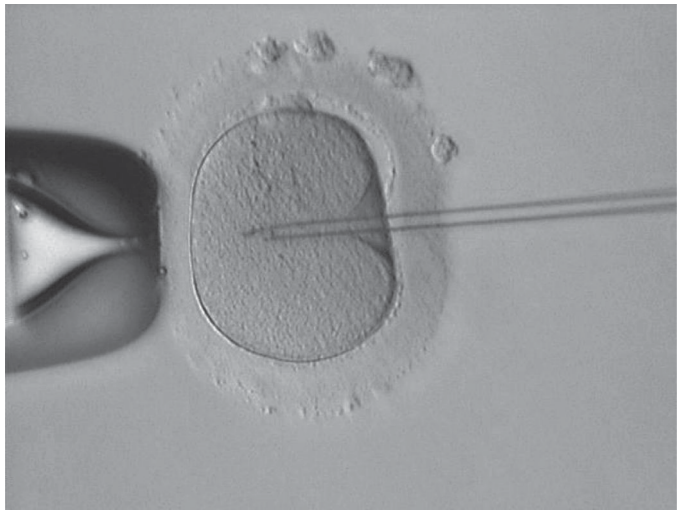

**Figure 9.2** Intracytoplasmic sperm injection (ICSI) procedure: a spermatozoon is injected with a glass pipette in the cytoplasm of an oocyte under the microscope.
© the laboratory of the Leuven University Infertility Center.

in the tubes via laparoscopy. However, this procedure is rarely performed in Europe nowadays as transcervical transfers are very easy and non-invasive to perform.

### Fertilization

Immediately after the oocytes have been retrieved, they are placed in the incubator under ideal culture conditions. Thereafter oocytes are inseminated with approximately 20,000 spermatozoa per oocyte in the 'classical' IVF procedure or the oocytes are denudated from the cumulus cells and injected under the microscope with one sperm cell during the ICSI procedure (Figure 9.2).

### Embryo culture and embryo transfer

The embryo transfer (ET) occurs at day 2, 3, 5, or 6 after oocyte aspiration yielding a cleavage stage embryo (D2, D3) or a blastocyst (D5, D6) (Figure 9.3). The timing of the transfer depends on the experience of the laboratory and the patient's characteristics. The goal is to find the best balance between selection of the embryo with the highest implantation potential and providing optimal culture conditions. The embryo transfer is usually performed transcervically after the installation of a speculum with a soft catheter loaded with one or two embryos. Quite often the embryo transfer is executed under abdominal ultrasound guidance for excellent positioning of the embryo(s). This is a minimally invasive and a nearly painless procedure and therefore no analgesia is administered. However, in a very few cases, ET is performed with analgesia for example, in patients with a history of surgery (exconization) at the cervix.

ET can be done directly in the Fallopian tube via laparoscopy. When the embryo is in the zygote stage it is named 'zygote intrafallopian transfer' (ZIFT) and when a cleavage stage embryo is transferred it is called 'embryo intrafallopian transfer' (EIFT).

### Luteal phase support

The luteal phase is shortened after ART and therefore, supplementation with progesterone administered vaginally or intramuscularly or with hCG is mandatory.

The cost of an ART cycle is around €4000 in most European countries.

## Anaesthetic management of the oocyte retrieval procedure

### General considerations

The ideal anaesthetic method should be safe and comfortable for the patient undergoing the procedure, should not compromise the quantity or quality of the oocytes, and should have no effect on fertilization, embryo development, and pregnancy rate. It should be easy to administer and monitor, short-acting, and with few side effects.

Oocyte retrieval can be performed transvaginally or laparoscopically. Only in very few cases is a laparoscopy needed to reach the ovaries and general anaesthesia with intubation is required in these cases.

During transvaginal oocyte retrieval, the aspirating needle puncturing the vaginal fornix and the ovarian capsule, as well as the manipulation within the ovary during the procedure causes pain. It is essential to provide adequate pain relief, to immobilize the patient, and eliminate the dangers of piercing any vessel during the process of oocyte retrieval.

Since some women require high doses of sedatives and analgesics to obtain adequate pain relief while others do not, various pain-relieving methods are in use. There is currently no evidence for superiority of one procedure over another.[7,8]

Controversy exists regarding the effects of all these drugs on conception rates. In many studies, anaesthetics have been detected in follicular fluid and reported to interfere with the outcome of fertility treatment.[9] In a study published in 2012, significant differences were revealed between different anaesthetic methods for the total number of oocytes retrieved per patient, percentage

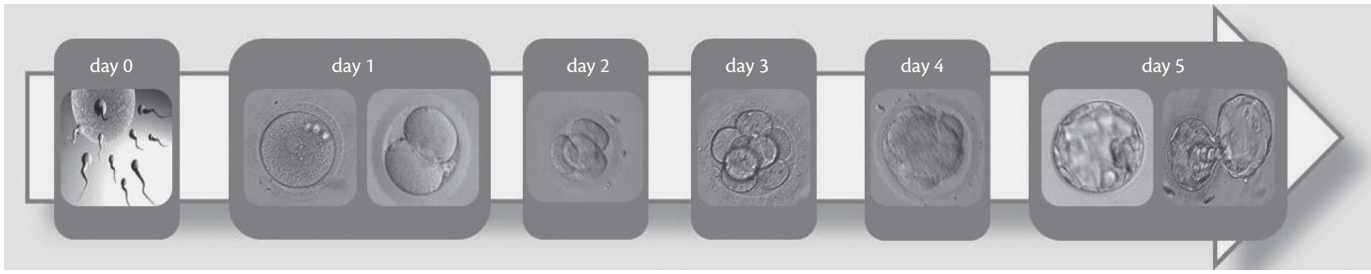

**Figure 9.3** Evolution from a fertilized oocyte to a cleavage stage embryo (D2, D3) and to the blastocyst stage (D5, D6).

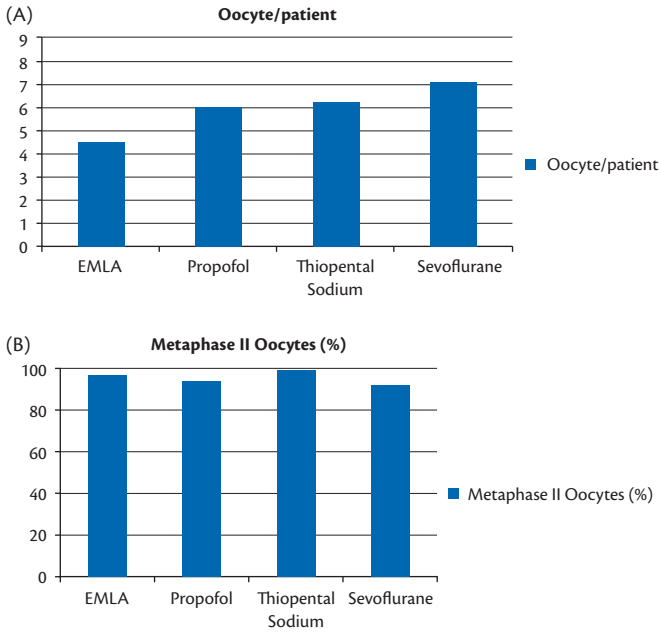

**Figure 9.4** Biological parameters: number of oocytes retrieved per patient (A) and rate of metaphase II oocytes (B). In the EMLA® group they observed a lower number of retrieved oocytes when compared to the other groups. In the thiopental and sevoflurane groups, they found the highest oocytes retrieval. In the EMLA® and thiopental groups they observed more metaphase II oocytes. Reprinted from Comparison of different anaesthetic methodologies for sedation during in vitro fertilization procedures: effects on patient physiology and oocyte competence, Alba Piroli, Roberto Marci, Franco Marinangeli, *et al*, *GYNECOLOGICAL ENDOCRINOLOGY*, volume 28, issue 10, pp. 796–9, 2012, reprinted by permission of the publisher (Taylor & Francis Ltd, http://www.tandfonline.com).

of mature oocytes in metaphase II stage, fertilization rate, and embryo development (Figure 9.4).[10]

A Cochrane analysis reviewed 21 controlled trials and concluded that there was no evidence of a significant difference in pregnancy rate or in quality of analgesia between the different methods of pain relief during oocyte pick-up. The simultaneous use of more than one method of sedation and pain relief (e.g. sedation in combination with paracervical block) resulted in better pain relief. All reviewed approaches seemed to be acceptable and were associated with a high degree of satisfaction.[8]

## Different analgesia/anaesthesia techniques

Analgesia techniques that may be used for the transvaginal follicular aspiration are local anaesthesia (paracervical block or topical anaesthesia), neuraxial anaesthesia (spinal, epidural or combined), conscious sedation and general anaesthesia, or any combination of the above.

### Local anaesthesia

Local paracervical anaesthesia can provide adequate pain relief for the transvaginal puncture but will not affect pain sensation when puncturing the ovaries. In a 2012 Italian study, a eutectic mixture of local anaesthetic (EMLA®) cream, a eutectic topical mixture of lidocaine and prilocaine incorporated in cream base, was administered on the vaginal fornices 1 hour before the procedure. This was compared with sedation using either propofol, sevoflurane, or thiopental. In comparison with sedation using propofol, sevoflurane, or thiopental, the authors retrieved a significantly lower number of oocytes per patient in the EMLA® cream group.[10] It was assumed that the gynaecologist performed the oocyte retrieval faster by puncturing only the largest follicles because the patients were awake during the procedure and this resulted in a high rate of mature (metaphase II) oocytes. The EMLA® cream group showed the highest fertilization rate. Anaesthesia with EMLA® cream is a possible and an acceptable alternative for anaesthesia during transvaginal oocyte retrieval in well-motivated patients.[10,11] In animal models, local anaesthetic agents seem to have an influence on the development of the early embryo. This is of minimal clinical significance because of the extreme low concentrations used in human practice.

### Neuraxial anaesthesia

Neuraxial analgesia has been shown to be an effective form of pain relief during transvaginal oocyte retrieval. A spinal technique involves an injection of drugs into the cerebrospinal fluid. Epidural analgesia provides analgesia by injecting drugs into the epidural space. Both techniques have the advantage of limited absorption of the anaesthetic agent into the systemic circulation and will be associated with minimal accumulation into the follicular fluid. Of these two, spinal anaesthesia would be the advised method because a lower dose of local anaesthetic is needed, a faster onset of pain relief and recovery occurs, and there is a reduced failure rate. Hyperbaric lidocaine and bupivacaine in low dose in combination with an opioid have been successfully used in these procedures. Hyperbaric lidocaine is no longer used in current practice due to the high incidence of transient radicular irritation, but hyperbaric prilocaine could be an acceptable alternative. In addition, the risks associated with the neuraxial anaesthesia techniques must not be overlooked. Postdural puncture headache will occur in 0.5% of cases. Back pain, urinary retention, accidental intravascular injection, and anaesthesia reaching high spinal level can also occur. Apart from other more serious complications (epidural abscess or haematoma) neuraxial anaesthesia remains very time-consuming for a usually very short procedure.

### Sedation and general anaesthesia

We have to differentiate moderate or conscious sedation from deep sedation or monitored anaesthesia care. Conscious sedation is a moderate sedation and defined as 'a method in which the use of drugs produce a minimally depressed level of consciousness enabling treatment to be carried out while the patient maintains an open airway continuously and responds appropriately to verbal commands' (defined by the American Society of Anesthesiologists' website in 2004, http://www.asahq.org/). This method is very popular for oocyte retrieval because it is easy to administer and safe in this mostly young, healthy and well-motivated population.

Deep sedation or monitored anaesthesia care consists of safe administration of a maximal depth of sedation in excess of that provided during conscious sedation. The ability to adjust the sedation level from full consciousness to general anaesthesia during the course of the procedure provides maximal flexibility in matching sedation levels to patients' and procedural needs. In many European countries this needs to be performed by an anaesthetist, while in some countries skilled anaesthetic personnel will take care of these procedures. There is a fine line between sedation with good pain control and general anaesthesia that requires assisted ventilation. Full monitoring of the patient with a pulse-oximeter, end-tidal $CO_2$, electrocardiography, and non-invasive blood

pressure monitoring is necessary to ensure the patient's safety. All drugs and equipment for advanced life support should be available at the site of the procedure. The frequency of severe complications after transvaginal oocyte retrieval is very low but half of the cases with complications were anaesthesia related (bronchospasm).[12]

When selecting a desired agent for sedation, it should be considered whether it is safe for the woman and whether the substance enters the follicular fluid and has negative effects on fertilization and pregnancy rates.

#### *Opioids*

Opioids are used in moderate and deep sedation and in general anaesthesia for their analgesic effects. They should be used in a monitored way because of the dose-dependent depression of respiration. Rapid administration of opioids can also induce rigidity of the thoracic, laryngeal, or pharyngeal muscles. All equipment for respiratory support should be available, especially if a difficult airway access is expected (e.g. in obese patients). Urinary retention, pruritus, and postoperative nausea and vomiting (PONV) are also side effects of opioids.

When given during the procedure, opioids are detected in extremely low concentrations in the follicular fluid. Any potential influence on fertilization and implantation rates in these concentrations has never been substantiated.[9,13]

Remifentanil has an ultra-fast onset, organ-independent metabolism, and a very short elimination time, making it an ideal opioid for short procedures. There has been no report on negative interference with pregnancy rates or numbers and quality of retrieved oocytes using remifentanil.[14]

Alfentanil is another fast-acting opioid and is the narcotic agent most commonly used during oocyte retrieval. It has been detected in the follicular fluid but does not influence pregnancy rates even in high concentrations. It is more important to give an adequate, individualized dose of alfentanil than reducing the dose because of a potential harmful effect on the embryo.[9,15]

#### *Benzodiazepines*

Patients presenting for IVF treatment are under a high degree of stress and anxiolysis is another challenge for the anaesthetist. Benzodiazepines are used because of their sedative, anxiolytic, and amnesic effects. Additional properties of benzodiazepines include muscle relaxation and anticonvulsive effects. Midazolam is the most commonly used benzodiazepine. Although midazolam is found in the follicular fluid after a single intravenous (IV) dose, no detrimental effects have been shown.[9,15–17] Accurate respiratory monitoring is advised when these are used in combination with opioids since concurrent use may increase the incidence of apnoea and respiratory depression.

#### *Propofol*

Propofol is a short-acting anaesthetic agent for IV administration, suitable for induction and maintenance of anaesthesia and for sedation. It has a rapid onset of action and recovery and reduces PONV. An unpleasant effect for patients during intravenous administration of propofol is pain and burning at the site of injection. Propofol causes a dose-dependent decrease in systemic blood pressure and respiratory depression underlining once more the need for the presence of an anaesthetist or at least skilled anaesthetic personnel. Propofol has been reported to accumulate in the follicular fluid and these concentrations increase throughout the procedure.[18,19] At first it was suggested that propofol might have deleterious effects on reproductive outcome following IVF in animal models.[20,21] Ben-Shlomo et al. examined whether exposure to increasing concentrations of propofol had an adverse effect on fertilization and embryo development in humans. They compared oocyte quality between the first and the last oocyte retrieved in a cohort of 130 women and found no difference on fertilization rate, cleavage rate, or embryo cell number. However, they could not rule out the possibility that the short duration of their procedures and the consequent low follicular fluid concentrations contributed to this result.[22]

#### *Ketamine*

Ketamine, introduced in the 1960s, provides all components of anaesthesia necessary for oocyte retrieval: good pain-relief, loss of consciousness, and antegrade amnesia. Ketamine does not suppress the respiratory system, but it may produce unpleasant emergence reactions like vivid dreaming, 'out-of-body' experiences, and illusions within the first hours after awakening. Ketamine in combination with midazolam has been used frequently for oocyte retrieval and no differences in reproductive outcomes were observed.[23,24] To the authors' knowledge, there have been no studies measuring ketamine concentration in the follicular fluid in patients during oocyte retrieval under ketamine sedation.

#### *Sevoflurane*

In modern anaesthesia, sevoflurane is the most popular volatile anaesthetic agent. Not a lot is known about the effect of sevoflurane on the fertilization and early cleavage rate. One study conducted by Piroli et al., observed a decreased number of good quality embryos in the group of patients who received sevoflurane during oocyte retrieval[10] (Figure 9.5). The only evidence of a negative effect of sevoflurane reported in the literature is a study by Eger et al. They found that compound A, a degradation product of sevoflurane, had a genotoxic effect in Chinese hamster ovary cells.[25] A few years later, the same experiments were repeated to test sevoflurane and no genotoxicity could be found.[26] Currently sevoflurane sedation has become largely abandoned since more elegant techniques for sedation are available and the danger of inducing a general anaesthesia is substantial.

## Alternative types of anaesthesia

### Electroacupuncture

Recently a lot has been published in the Chinese literature about the role of electroacupuncture in the outcome of IVF procedures. There is some evidence that acupuncture treatment during ART could improve pregnancy rates in women undergoing IVF. Electroacupuncture probably has a good intraoperative supplementary analgesic effect without any extra adverse reaction and could be an adjuvant in reducing the dose of the anaesthetic drugs.[27]

### Patient-controlled sedation

As the pain associated with ovum pick-up is intermittent rather than continuous, the best form of analgesia is one which allows maximal flexibility and responsiveness to the woman's needs. Patient-controlled anaesthesia could be superior to physician-administered analgesia in this context. Patient-controlled IV analgesia using opioids, propofol, or a mixture of the two has been used successfully, but satisfaction was less than conscious

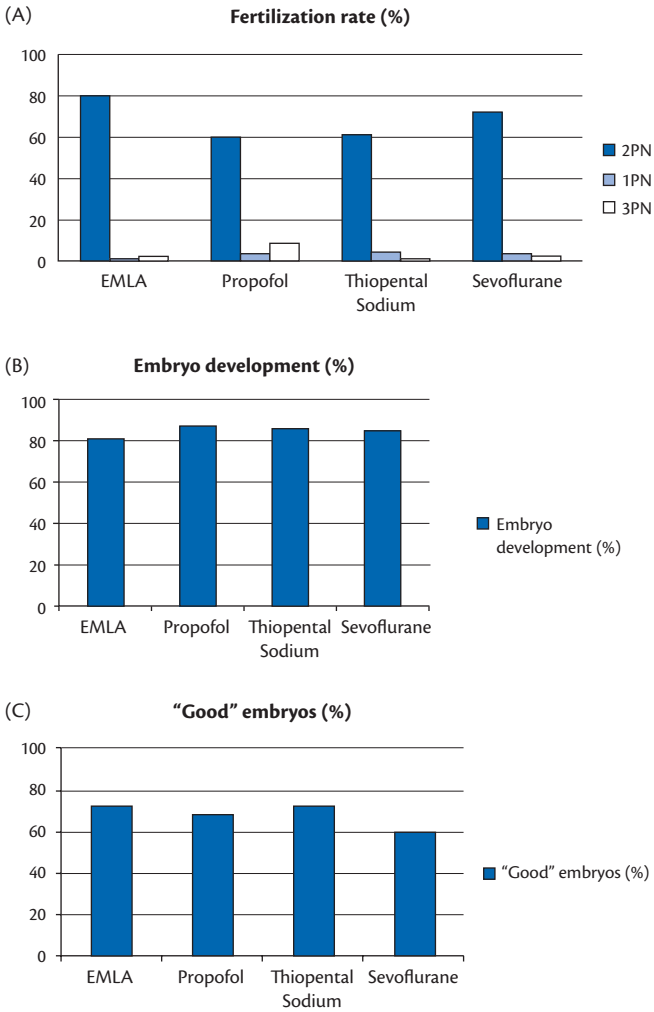

**Figure 9.5** Biological parameters: fertilization rate (A), embryo development (B), and 'good embryo' rate (C). Fertilization rate was similar in EMLA® and sevoflurane groups, but significantly higher than in propofol or thiopental groups. They observed the highest rate of anomalous fertilization (defined as rate of 1PN and 3PN oocytes) in the propofol group. There was no overall difference in embryo development, but the sevoflurane group had a lower rate of 'good' embryos.

Reprinted from Comparison of different anaesthetic methodologies for sedation during in vitro fertilization procedures: effects on patient physiology and oocyte competence, Alba Piroli, Roberto Marci, Franco Marinangeli, *et al*, *GYNECOLOGICAL ENDOCRINOLOGY*, volume 28, issue 10, pp. 796–9, 2012, reprinted by permission of the publisher (Taylor & Francis Ltd, http://www.tandfonline.com).

sedation provided by a physician. A self-administered inhalational analgesic agent, such as isodesox, has potential advantages in terms of safety, ease of administration, short half-life, and minimal effects on the patient and her oocytes. Self-administered inhalation analgesia with isodesox by facemask was also associated with less effective analgesia and less patient satisfaction than physician-administered intravenous analgesia.[28,29]

## Suggested anaesthetic management for transvaginal oocyte retrieval

As mentioned before, the ideal method of pain relief during oocyte retrieval should be safe and comfortable for the woman with minimal side effects, easy to administer and monitor, short acting, easily reversible, and with minimal to no effect on oocytes and embryos. Paracervical block, general anaesthesia, neuraxial anaesthesia or sedation all have advantages and disadvantages. Subsequently anaesthesia practice for IVF procedures varies in different fertility centres. In 1997, Ditkoff et al. published a US survey that demonstrated most programmes utilized anaesthesia, most commonly conscious sedation. Other types of anaesthesia used included general, neuraxial, or local anaesthesia. Anaesthesia personnel performed anaesthesia most of the time, although a significant number of IVF clinics were giving analgesia/anaesthesia without anaesthetists present. The majority of IVF personnel used a combination of meperidine and midazolam while 90% of the anaesthesiologists used midazolam and/or propofol with fentanyl. For both groups, complications were infrequent and no serious life-threatening incidents were reported.[30]

In the United Kingdom, a postal questionnaire audit was performed in 2003 by Elkington et al. which demonstrated a wide variation in personnel present during the procedure, in the drugs used, in the degree of monitoring, and the availability of emergency drugs.[31] A typical IVF procedure room in hospitals is located adjacent to the embryology laboratory and not near the general operating theatre. In the United Kingdom, more than 23% of fertility units are isolated without coverage of a resuscitation team. Remote locations should put in place regulations and protocols to maximize safety. Since the IVF population is usually young and healthy, it differs distinctly from the general population of patients requiring sedation. Serious morbidity is very rare, but women undergoing fertility procedures are increasingly older and have more frequent comorbidities (e.g. obesity, patients post chemotherapy, genetic disorders, or cystic fibrosis). It is unclear how far one should go in safety measures.[32]

The selection of the type of anaesthesia will depend on the IVF centre, and the preference of the surgeon and anaesthetist. As women vary in their experience of pain and in coping mechanisms, the optimal method should be individualized depending on the preference of both the woman and the clinician. Most centres have established protocols but the variety of methods and drugs used for this procedure raises questions about the potential advantages and disadvantages. A 2013 Cochrane review[8] aimed to assess the effectiveness and safety of different methods in terms of pain relief during and after the procedure, pregnancy outcome, patient satisfaction, and postoperative complications. It did not support one particular method or technique over another in providing effective conscious sedation and analgesia. Regardless of the nature of the drug or the dose used, opiates were effective at reducing the perception of pain. Where a second drug or intervention such as paracervical block or electroacupuncture, was associated, the simultaneous use of more than one method resulted in better pain relief than one modality alone. Patient-controlled sedation and analgesia was associated with more intraoperative pain compared with physician-administered sedation and analgesia. There was no evidence of significant difference in pregnancy rate with different methods of pain relief. High levels of satisfaction were reported in all studies. Most centres will use sedation, varying from conscious sedation to monitored anaesthesia care, provided by anaesthetists or by the fertility centre's own team (trained midwifes, nurses, or medical doctors).

A preoperative visit to the sedation team should involve a complete medical history, including patients' medication and allergies,

history of PONV, motion sickness, and a clinical examination. A sedation plan should be explained to the patient and informed consent should be obtained. A good explanation of what can be expected will alleviate some of the anxiety stress associated with the procedure.

On the day of the procedure, nil per os (NPO) state and basic clinical signs should be checked. The patient is placed supine on the operating table and an IV cannula is inserted. Routine monitoring of the patient with a pulse-oximeter, end-tidal $CO_2$, electrocardiography, and non-invasive blood pressure monitoring is necessary to ensure the patient's safety. Oxygen is supplied by mask or nasal cannula. Sedation can be provided by intermittent titrated doses of propofol and alfentanil or fentanyl, but a continuous infusion of propofol and remifentanil is a very elegant alternative that can provide the full range of anaesthesia depth from conscious sedation, over monitored anaesthesia care to full general anaesthesia, according to the patient's need. The latter must, however, be performed by an anaesthetist. Anaesthesia managed in this way could result in higher patient acceptance than conscious sedation due to improved pain relief and less awareness during the procedure. Rarely this type of anaesthesia may require airway support. Mostly chin lift or verbal communication will be enough to encourage the patient to breathe adequately but all equipment and drugs for mask ventilation or emergency endotracheal intubation should be available. Once the desired depth of sedation is achieved, the surgeon starts the procedure. Good communication between the sedation team and the surgeon about the length of the procedure and possible additional painful stimuli will optimize the quality of sedation. At the end of the procedure, the surgeon achieves haemostasis from the vaginal wall and the patient is awakened. Paracetamol is given during the procedure and is usually enough to provide adequate analgesia in the postoperative period. Non-steroidal anti-inflammatory drugs can be added but should be avoided after the embryo transfer because changes in the prostaglandin milieu can affect embryo implantation. For antiemesis, prophylactic treatment with non-dopaminergic agents like cyclizine can be considered.

After the procedure, the patient is transferred to a recovery room and will be discharged once the discharge criteria are fulfilled. The incidence of serious postoperative complications requiring hospital admission is very low.

## Conclusion

ART treatment is becoming increasingly popular to treat infertility disorders with nearly 1 million cycles reported in 2004 worldwide. Oocyte retrieval is an essential part of the *in vitro* procedure. Most oocyte retrievals are performed vaginally under ultrasound guidance. Puncturing the vaginal wall and the stimulated ovary can be painful, therefore some analgesia is usually required. The method used should be safe and comfortable for the woman with minimal side effects, easy to administer and monitor, short acting, easily reversible, and with minimal to no effect on oocytes and embryos. Topical anaesthesia, paracervical block, general anaesthesia, neuraxial anaesthesia, and sedation all have advantages and disadvantages. Most fertility clinics have chosen their method depending on patients' demands, staffing, and available facilities in the hospital or centre.

# CHAPTER 10

# Anaesthesia for non-obstetric surgery

Vegard Dahl and Ulrich J. Spreng

## Introduction

For a pregnant woman, there is always a risk of requiring anaesthesia for non-obstetric reasons. Around 1–2% of all pregnant women will undergo non-obstetric surgery during gestation.[1] A substantial number of anaesthetic procedures and operations will be performed on women in the early stages of pregnancy who are unaware of their pregnant status at the time of intervention. Therefore pregnancy tests should be performed on all women of child-bearing age undergoing surgery. The reason for surgery may be directly related to the pregnancy, such as *in utero* operations on the fetus or cerclage; it may be indirectly related, such as, for instance, an ovarian cystectomy; or it may be coincidental, such as an appendectomy, cholecystectomy, or an injury requiring surgical intervention. In a review published in 2005 by Cohen-Kerem and colleagues including more than 12,000 non-obstetric surgical interventions in pregnancy, the reported rate of miscarriage was 5.8%, premature labour was 3.5%, and maternal deaths were as rare as 0.006%.[2]

Historically, there has been reluctance to anaesthetize pregnant patients due to a fear of jeopardizing the well-being of the fetus and mother. Although the safety of non-obstetric surgery and anaesthesia during pregnancy seems well established, there are several concerns that need to be addressed. The anaesthetist must provide safe anaesthesia for both mother and fetus. Furthermore, the anaesthesiologist must take into consideration the changes that a pregnancy induces on normal maternal physiology, and be aware of the possible hazards that anaesthesia may impose on the fetus. This includes possible teratogenic effects of drugs and diagnostic imaging, risk of preterm delivery or abortion, as well as intraoperative haemodynamic alteration of uteroplacental perfusion.

## Maternal physiological changes: anaesthetic considerations

Pregnancy is associated with profound anatomical and physiological changes. Knowledge and understanding of these changes are crucial for optimal perioperative care in pregnancy.[3,4] Maternal physiological and anatomical changes requiring precautions by the anaesthetist are presented in Table 10.1.

## Anaesthetic principles

Non-obstetric surgery can be carried out with either general or neuraxial anaesthesia techniques and will depend on the site of surgery, the emergency of the situation, and the choice of the anaesthetist and the pregnant patient, if possible. A multidisciplinary team approach with focus on communication and cooperation is necessary in order to minimize the risk and possible harm of the surgical and anaesthetic procedure. The multidisciplinary team should include surgeons, anaesthetists, obstetricians, and radiologists, as well as midwifes and nurses.

If possible, surgery should be performed in the second trimester because in this period the risk for preterm labour seems to be lowest. It is important to inform the patient of possible risks of anaesthesia and surgery to the fetus and pregnancy (e.g. abortion and preterm labour). The goal must, of course, be to minimize the risks of anaesthesia and surgical procedures.

The key issue during anaesthesia, no matter which technique used, is to preserve maternal haemodynamic stability. Neuraxial anaesthesia should be considered whenever possible. Accompanying maternal hypotension will reduce uteroplacental blood flow, and treatment is mandatory.[1,5] Pregnant women undergoing acute abdominal surgery will usually require general anaesthesia,[6] although some procedures like open appendectomy can be done with a regional technique.

### Preoperative period

The use of tranquillizers such as midazolam and weak analgesics such as paracetamol can reduce anxiety and pain and may be beneficial in order to reduce maternal stress, which can decrease uterine blood flow. Anticholinergic medication (e.g. glycopyrrolate) will reduce oral secretions as well as prevent bradycardia during induction of anaesthesia and is recommended.[6]

Pregnancy is associated with a hormonally induced decrease in gastric motility and a cephalad displacement of the stomach. Moreover, the lower oesophagus sphincter tone is decreased in pregnant women.[7] Aspiration prophylaxis (e.g. metoclopramide, oral antacid, or $H_2$-receptor antagonist), especially during the third trimester, may be beneficial.[8–10] However, this is a controversial issue.[11,12] Wong et al. have shown that gastric emptying in obese, non-labouring pregnant woman is not delayed after ingestion of 300 mL of water.[13]

### Intraoperative period

The risk for difficulties during intubation is higher in pregnant patients undergoing general anaesthesia compared with a general population.[4,14–16] An anaesthetist has to be prepared for a difficult airway and training in airway management is mandatory.[4,17–19]

**Table 10.1** Maternal changes in anatomy and physiology and anaesthetic implications and precautions

| Maternal changes | Consequences | Precautions |
|---|---|---|
| Venous engorgement<br>Oedema upper airways<br>Gain in weight<br>Increased breast size | Intubation difficulties | Difficult airway management |
| Functional residual capacity ↓<br>Oxygen consumption ↑ | Early desaturation | Preoxygenation |
| Hyperventilation | Respiratory alkalosis | Normoventilation[a] |
| Aortocaval compression (>12 weeks) | Preload ↓ | Left lateral decubitus position |
| Systemic vascular resistance ↓ | Hypotension | Fluid load<br>Vasoconstrictor |
| Cardiac output ↑ | Oxygen consumption ↑ | $FiO_2$ ↑ |
| Intra-abdominal pressure ↑ | Gastric emptying delayed | Rapid sequence induction |
| Oesophageal sphincter tone ↓ | Gastro-oesophageal reflux | Rapid sequence induction |

[a]Normoventilation in pregnancy, e.g. slight hyperventilation compared with non-pregnant.

Equipment for difficult airway management should be easily accessible.[4,17]

After failed direct laryngoscopy, a device offering a view into the glottis (e.g. video laryngoscope) should be used. Moreover, the anaesthetist should be familiar with the use of an intubation laryngeal mask (e.g. LMA Fastrach™) and gum elastic bougie.[4] The management of a difficult or failed airway is discussed in Chapter 26.

Optimal positioning of the patient is important. A 15° left lateral decubitus position will help to prevent aortocaval compression (reduction in preload). Alignment of the ears with the sternal notch is advisable in order to facilitate mask ventilation, laryngoscopy, and intubation (see Figure 39.3 in Chapter 39).

Pregnancy is associated with a reduction of the functional residual capacity, which leads to a reduction in oxygen reserve. Moreover, oxygen consumption in pregnant women is increased.[3,4] Therefore, desaturation occurs faster during induction of anaesthesia.[20] Effective pre-oxygenation with a tight facemask is crucial. Several techniques can be used for optimal pre-oxygenation. The woman can either breathe with normal tidal volumes for a minimum of 3 minutes or, when time is limited, use the eight deep breaths technique.[20–22] Rapid sequence induction (RSI) is advisable and the airways should be secured with an endotracheal tube. Whether cricoid pressure should be used during RSI is controversial. On the one hand, if applied properly, it may protect against regurgitation during induction. On the other hand it may make viewing of the epiglottis and intubation more difficult. If one chooses to use a cricoid pressure or Sellick's manoeuvre during induction, it is advisable to loosen it if viewing of the epiglottis is compromised.[12,23–25]

When choosing appropriate anaesthetic drugs for pregnant women, there are three main goals:

1. Ensure maternal anaesthesia and analgesia
2. Avoid maternal hypoxia and hypocapnia
3. Avoid maternal hypotension (preserve uterine blood flow).

## Induction of anaesthesia

Thiopental, propofol, etomidate, and ketamine all cause unconsciousness and can be used for induction of anaesthesia in pregnancy. Etomidate has favourable pharmacodynamic properties, causes minimal histamine release, and is suitable in haemodynamically unstable patients, especially in cardiac surgery patients.[26,27] However, etomidate supresses corticosteroid synthesis in the adrenal cortex and should be used with caution in septic patients. There is conflicting evidence whether a single dose, such as would be used for induction in the obstetric patient, is associated with increased 28-day mortality.[28,29] Clinicians should use etomidate with caution because although it may provide haemodynamic stability at induction, the long-term outcome may be worsened.[30,31] Ketamine is best suited for haemodynamically unstable patients in emergency settings and has, in addition, excellent analgesic properties.[32]

Opioids must be used to provide analgesia during intubation and surgery. The use of opioids (e.g. fentanyl, sufentanil, alfentanil, and remifentanil) may induce fetal respiratory depression. However, this is only relevant if the baby is going to be delivered during the current surgery. Moreover, opioids may decrease fetal heart rate variability during anaesthesia, and this should not be considered as a sign of impaired fetal well-being or non-reassuring fetal status.[33] This should be emphasized to the midwives and obstetricians who may assume wrongly that this is a sign of fetal distress.

The conditions for endotracheal intubation will be improved by using muscle relaxants. In RSI, succinylcholine or high-dose rocuronium should be used. Although good intubation conditions have been reported with a standard dose of rocuronium (0.6 mg/kg), 1.0–1.2 mg/kg is recommended for RSI and will give as good intubation conditions after 1 minute as a standard dose of succinylcholine.[34–36] In the rare case of a 'cannot intubate—cannot ventilation' situation[35] the muscle block induced by rocuronium can be reversed by the use of the drug sugammadex.[37] Sugammadex is especially designed to encapsulate the muscle relaxants in the steroid group. A high dose (16 mg/kg) will remove all muscle-relaxing molecules from the circulation within minutes and allows earlier re-establishment of spontaneous breathing compared with succinylcholine.[38] Due to the large molecular size of sugammadex, placental transfer is probably minimal, but data in human fetal transfer are lacking. The potential effects of sugammadex on the fetus are not known. Sugammadex as a reversal of the neuromuscular block should therefore only be used in critical situations.

## Maintenance of anaesthesia

Both intravenous drugs (e.g. propofol) and volatile halogenated agents (e.g. sevoflurane, desflurane, or isoflurane) are frequently used for the maintenance of anaesthesia during pregnancy.[6,39–41] It has recently been shown that high concentrations of sevoflurane

and isoflurane (minimum alveolar concentration 1.5–2.0) may induce haemodynamic instability in both the mother and the fetus[42] and that high concentrations of desflurane can reduce fetal cardiac function.[43] Nitrous oxide can be used during surgery.[37] However, it is controversial as to whether nitrous oxide should be avoided in abdominal surgery because of its ability to cause bowel distention.[44–46]

### Neuraxial anaesthesia for non-obstetric surgery

Locoregional anaesthesia for non-obstetric surgical procedures during pregnancy has many advantages compared to general anaesthesia and should be preferred whenever possible. The fetus will not be exposed to drugs with possible detrimental effect and possible respiratory problems can be evaded. Neuraxial anaesthesia (spinal, epidural, or a combined spinal–epidural technique) is recommended for lower abdominal surgery and surgery in the lower extremities. When choosing neuraxial anaesthesia, posture of the patient during the procedure is important, and aortocaval compression has to be avoided (as previously discussed). The same cautions regarding fasting and preparation with antacid prophylaxis as for a general anaesthesia should be followed. It is essential to avoid hypotension in order to maintain uteroplacental blood flow. Hypotension should be treated with volume co-loading and vasoactive drugs whenever needed. Dosage of local anaesthesia needed for neuraxial anaesthesia in the second and third stages of pregnancy is reduced, and may sometimes be difficult to predict.[47] A combined spinal–epidural technique with a small dose of local anaesthesia combined with a fat-soluble opioid spinally and the possibility to top-up with local anaesthesia epidurally is probably a safe way to perform neuraxial anaesthesia in these patients. Peripheral nerve block is the method of choice for surgery in the upper extremities and surgery below knees, whenever possible.

### Postoperative period

Postoperative pain should be treated adequately as pain may increase catecholamine levels with resultant placental vasoconstriction. There are many options available for treating pain after surgery, including systemic analgesia (i.e. opioid and non-opioid drugs), regional analgesic techniques (i.e. neuraxial and peripheral), local anaesthetic wound infiltration and a combination of these. It is important to assess the risks and benefits of each treatment modality. The goal is an optimized postoperative analgesic regimen for each individual patient.

Drugs used for systemic analgesia can be divided into opioid and non-opioid drugs. All opioids can induce fetal respiratory depression. However, this is only important if the surgical procedure is combined with a caesarean delivery or an immediate vaginal delivery.[6] It has been shown that the daily use of opioids in the first trimester may be associated with cardiac and neurological defects.[48] However, this has never been demonstrated for short time use of opioids in the postoperative period.

Regarding non-opioids, paracetamol (acetaminophen) is the drug of choice during pregnancy. Even in patients who have taken a paracetamol overdose the majority of pregnancies had normal outcomes.[49] Non-steroidal anti-inflammatory drugs (NSAIDs) exert their analgesic effect through inhibition of cyclooxygenase (COX) and synthesis of prostaglandins.[50] There have been several published studies reporting an increased risk for cardiac abnormalities when NSAIDs were taken during the first trimester.[51–53] Moreover, Nielsen and colleagues have recently shown that the prescription of NSAIDs may be associated with higher rates of miscarriage.[54] The use of NSAIDs during late pregnancy may lead to intrauterine constriction of the ductus arteriosus and is not recommended.[55] COX-1-mediated thromboxane facilitates platelet aggregation and haemostasis, and NSAID-derived COX inhibition may increase the risk of postoperative haemorrhage.[56] There are insufficient data regarding the use of selective COX-2 inhibitors in pregnancy.

Pregnant patients have an increased risk for thromboembolism. Therefore, it is important that these patients are mobilized as early as possible. Moreover, thrombosis prophylaxis with anticoagulants is mandatory.

Careful observation of the pregnant woman and fetus may be indicated for several days after surgery. The postoperative care unit team has to be aware of the risks of complications like preterm labour (see 'Miscarriage and Preterm Birth').

## Fetal considerations for anaesthesia during pregnancy

### Early period: teratogenicity of anaesthetics

In spite of fears of possible teratogenetic effects of anaesthesia no such effect has ever been demonstrated in humans in clinically relevant doses. There are, of course, no prospective comparative studies due to ethical and practical concerns. Speculation on possible harmful effects on the fetus comes either from studies on animals or from epidemiological surveys on operating theatre personnel and on outcome in women having undergone surgery during pregnancy. Studies on animals will generally include an exposure to a large dose of a drug during a long time period, and cannot be extrapolated to a short exposure with a limited concentration as in anaesthesia during surgery in humans. Nevertheless, two agents have been controversial in the last 50 years and need to be addressed:

- *Nitrous oxide* reacts with the reduced form of vitamin $B_{12}$, thereby inhibiting methionine synthase, which indirectly supports nucleic acid synthesis. Animal studies in the 1970s and 1980s demonstrated teratogenetic effects of nitrous oxide, which could be reversed by halothane or isoflurane but not by addition of folic acid.[57,58] Thus, from a theoretical point of view, the possible teratogenetic effect of nitrous oxide must also have a different explanation than methionine synthase inhibition. Nitrous oxide could possibly influence uterine blood flow and thus fetal oxygen supply.[59] These effects on reproduction occurred only after prolonged exposure to high concentrations of nitrous oxide and cannot be compared to real life when patients are anaesthetized for surgery in a clinical setting for relatively short periods. Large population studies from Sweden and Hungary have not found any correlation between intrauterine exposure to nitrous oxide during surgery and teratogenicity.[60,61] One may conclude that a short time exposure to nitrous oxide during pregnancy is safe. Whether exposure to nitrous oxide during a period of extensive receptogenesis later in pregnancy or in childhood results in cognitive deficits is yet to be determined (see 'Behavioural Teratogenicity'). Higher rates of spontaneous miscarriages have been observed among workers with occupational exposure to nitrous oxide such as dental

assistants and operating theatre nurses.[62] When adjusted for age, smoking, and working hours, however, this association is no longer statistically significant.

- *Benzodiazepines* have been associated with a higher incidence of cleft lip and palate, pylorostenosis, and alimentary tract atresia, but the results are conflicting.[63–66] Pregnant women who use benzodiazepines long term often have multiple other confounding factors such as psychiatric disorders, social problems, multiple medication use, or epilepsy. The use of a short-acting benzodiazepine like midazolam during anaesthesia has never been associated with teratogenicity.

### Behavioural teratogenicity

Lately, more focus has been set on the possible behavioural teratogenic effect of anaesthetics, defined as the possibility of permanent changes in behaviour without significant structural changes. The pathophysiology seems to include an increase in neuronal death, decreased neural stem cell migration, and a possible altered cytoskeletal structure of glia cells when exposed to anaesthetics in periods with high synaptogenesis. The human brain is developing throughout gestation and for many years after birth. During this period of extensive receptogenesis, an exposure to drugs interacting with GABA (gamma-aminobutyric acid) and NMDA (*N*-methyl D aspartate) receptors has, in animal models, been shown to enhance apoptosis or programmed cell death with persistent learning deficits.[67,68] The anaesthetic drugs that interfere with either the GABA or the NMDA receptors include most widely used anaesthetic drugs like nitrous oxide, midazolam, ketamine, and volatile agents. As an example, isoflurane has been shown to decrease proliferation and inhibit neuron growth in a dose-dependent matter in a cell culture model.[69] These data, although disturbing, must be analysed with caution. It is important to know that the period of extensive receptogenesis is weeks in rats, compared to many years in humans. The average rat brain has 70–200 million neurons, compared to 86,000 billion in the developed human brain. Therefore, these experimental models in rodents cannot be compared to human exposure to anaesthetic drugs. The doses used in the animal models would represent continuous exposure for several weeks without any surgical stimulation in humans, and thus cannot be extrapolated to a short exposure during pregnancy. Some epidemiological studies on humans may, however, support the hypothesis that extensive exposure to anaesthesia has a negative influence on human brain development. A population-based, retrospective cohort study from Minnesota, United States, compared 593 children, who had received general anaesthesia before the age of 4 years to 4764 children without anaesthesia exposure. Results have shown that multiple exposures to anaesthesia revealed an increased risk of learning disabilities.[70] It is impossible to say whether anaesthesia by itself may be harmful or the need for anaesthesia is a marker for other causes. This has been heavily debated during the last decade. One must also take into consideration that painful procedures and stress in itself may influence neurodevelopment in a negative way. Data on exposure to anaesthetic drugs during pregnancy and behavioural teratogenicity in humans are sparse. One other population-based study also from Minnesota found no differences in learning abilities between children who had been exposed to general anaesthesia during a caesarean delivery compared to those who had been delivered vaginally.[71]

One may hope that our future knowledge regarding the influence of anaesthetics on human brain development will enable us to take measures in order to minimize the possible harmful effects. In the meantime, it is advisable to have in mind that general anaesthesia is potentially harmful to the developing fetal brain. Therefore, general anaesthesia should be used with care and prolonged periods of exposure to anaesthetic drugs should be minimized if possible. This is in addition to the risks of general anaesthesia for the pregnant mother herself.

When informing the pregnant woman about possible harmful effects of anaesthesia to the fetus one should emphasize that the risks for damage are very small. There is no evidence for teratogenicity with a single anaesthetic exposure during the first trimester of pregnancy, and no risks for adverse effects during third-trimester exposure. Possible negative effects on learning and behaviour are based on animal data and of little relevance.

## Perioperative fetal monitoring

Interdisciplinary cooperation between anaesthetist, obstetrician, and midwife is important regarding fetal monitoring. The well-being of the fetus should be verified by an obstetric consultation before induction of anaesthesia. Fetal heart rate and uterine activity should be monitored and documented before induction and, if possible, throughout the whole surgical procedure until emergence from anaesthesia. It is important to know that loss of beat-to-beat variability is normal during anaesthesia. However, fetal bradycardia is a serious sign, which must initiate immediate reactions. It is advisable to continue fetal monitoring into the postoperative period in order to document the well-being of the fetus and reassure the mother.

## Miscarriage and preterm birth

Non-obstetric surgery during pregnancy will increase the risk of abortion and preterm delivery. It is still unclear whether the disease itself, the surgery, or the anaesthesia is responsible for the increased risk. In a large systematic review published in 2005 encompassing more than 12,000 pregnant women, Cohen-Kerem and colleagues found the overall percentage of reported miscarriages to be 5.8% of pregnant women undergoing a surgical intervention.[2] The risk was especially high during the first trimester (10.5%). The rate of delivery induced by surgical intervention was 3.5%. A subanalysis indicated that the type of surgery was an important factor. Appendectomy seemed to be associated with the highest risk of miscarriages and preterm labour. The gravity of the disease, as well as early diagnosis and management, will influence on the frequency. There are no major differences between open and laparoscopic surgery related to miscarriage and preterm delivery.[2] From a theoretical point of view one would think that the use of volatile agents, which are known to be uterorelaxant, would be advantageous. This has, however, never been proven. No evidence supports one anaesthetic drug as superior to another in the prevention of preterm labour or miscarriage, and neither is there evidence that one tocolytic drug is better than another. In order to minimize the risk of preterm labour and miscarriage, it is important for the anaesthetist to balance anaesthesia as careful as possible. Measures should be taken in order to maintain uteroplacental blood flow by ensuring a haemodynamically stable woman.

The pregnant patient should be kept normoventilated (for pregnancy) and normovolaemic. Surgery should be done gently with as little manipulation of the uterus as possible. The risk of preterm labour or miscarriage necessitates careful observation of the pregnant woman, also in a prolonged postoperative period. Treatment with a tocolytic agent in this period may be necessary, and the new oxytocin antagonist atosiban is recommended.[72] Tocolysis by prostaglandin inhibition, using an NSAID such as indomethacin, although controversial, is an option during the first trimester.

## Diagnostic imaging in pregnancy

Pregnant women with a condition that requires anaesthesia and surgery are often in need of diagnostic imaging in order to establish a diagnosis.[73] Exposure to radiation has been a source of much speculation and anxiety among patients and healthcare professionals. As an example, the pregnancy website of the American Health Physics Society (http://www.HPS.org) received 1.3 million visits in 2007, most of them concerning risks of environmental xenobiotic exposure during pregnancy.[74] Potential risks include teratogenicity, intrauterine death, genetic damage, and risk of malignancy later in life. Indeed, older studies seemed to confirm that exposure to radiation *in utero* augments the risk of post-exposure malignancies in childhood such as leukaemia and intracerebral tumours.[75,76] However, modern, better-designed studies have failed to replicate these associations, both to X-ray in general and to abdominal and pelvic X-rays.[77]

Radiation can be divided into either ionizing or non-ionizing radiation. Ultrasound imaging and magnetic resonance imaging (MRI) are examples of the latter, while diagnostic X-ray is an example of ionizing radiation. When describing ionizing radiation exposure from medical diagnostic equipment, the amount is described in the SI unit gray (Gy) or milligray (mGy). The use of absorbed dose of radiation (rad) is also common. The possible detrimental effect on the fetus will depend on the radiation dose and the gestational age.[78] Studies on animals seem to indicate that doses of 100–200 mGy (10–20 rad) can be lethal during the first weeks of gestation (3–4 weeks' gestational age). The lethal doses increase rapidly and are similar to the mother at birth (20,000 mGy or 2000 rad). High doses of exposure are also necessary in order to induce malformations, neurobehavioral abnormalities, or cancer.[79]

**Table 10.2** Estimated radiation to the fetus according to imaging procedure

| Imaging procedure | Estimated fetal absorption | |
|---|---|---|
| | mGy | Rad |
| X-ray of the chest | <0.01 | 0.001 |
| CT scan of the chest | 0.06–0.96 | 0.006–0.096 |
| X-ray of the abdomen | 1–4.2 | 0.1–0.42 |
| X-ray lumbar spine | 8–49 | 0.8–4.9 |
| CT-scan of the abdomen | 8–49 | 0.8–4.9 |
| X-ray of the pelvis | 1.1–4 | 0.11–0.4 |
| MRI | Non-ionizing radiation | Non-ionizing radiation |
| Ultrasound | Non-ionizing radiation | Non-ionizing radiation |

Adapted from the *American Journal of Obstetrics and Gynecology*, volume 206, issue 6, Groen RS *et al.*, Fear of the unknown: ionizing radiation exposure during pregnancy, pp. 456–62. Copyright (2012) with permission from Elsevier.

The doses that a fetus is exposed to during diagnostic imaging vary from less than 0.01 mGy for a chest X-ray to 10–50 mGy for an abdominal computed tomography (CT) scan (Table 10.2). Although reassuring, there are controversies regarding the safety limit of radiation exposure. The International Commission on Radiological Protection has estimated that a intrauterine exposure of less than 100 mGy is safe, while the American College of Obstetricians and Gynaecologists has set the limit, particularly regarding the risk of congenital malformations, to 50 mGy.[80] Taking these safety limits into consideration, one should be cautious with repeated CT scans and/or fluoroscopically guided procedures during pregnancy. With the exception of the above-mentioned procedures, women should be reassured that the hazards of diagnostic imaging during pregnancy are far outweighed by the benefit of an accurate diagnosis,[73,81] for example, in thromboembolic disease (see Chapter 37).

Diagnostic ultrasound has, during the last five decades, become an essential tool in obstetrics. The original analogue imaging devices have developed to digital two-dimensional (2D) imagers, and subsequently into 3D (4D with motion). Safety limits for thermal and mechanical exposures have been gradually relaxed during the last decades. Considering the huge amount of ultrasound imaging that has been performed without ever demonstrating any harm to the mother or fetus, it seems safe to assume that ultrasound can be used in any medical examination of the pregnant woman.[82] Ultrasound is a very useful tool in diagnosis of the acute abdomen in pregnancy,[83] and is now considered the modality of choice for a suspected appendicitis in pregnancy.[84]

As radiologists gain more knowledge, the use of MRI in diagnosing abdominal pathology in pregnancy is growing. MRI without intravenous contrast is safe for mother and child, and provides excellent anatomical resolution.[85–87] If contrast enhancing is indicated, gadolinium-containing contrast media are contraindicated and should only be used if absolutely essential. Iodine-containing contrast media may lead to a transient hypothyroidism in the newborn.[88]

In summary, there is no evidence of any major risk to the developing fetus from a single exposure to any diagnostic imaging modality.

## Laparoscopic surgery during pregnancy

Pregnancy used to be considered as an absolute contraindication to laparoscopic procedures. This has been challenged during the last decades, and laparoscopy is now considered as a safe alternative to open surgery in pregnant women. The possible benefits include better intraoperative visualization, less surgical trauma, less uterine manipulation, and faster recovery.[89,90] Laparoscopic procedures are safest when performed in the second trimester, when the uterus is smaller and less susceptible to trauma from the instruments.[90]

The access to the abdomen should be performed with an open technique as suggested by the Society of American Gastrointestinal Endoscopic Surgeons (SAGES),[91] thus avoiding direct injury to

the gravid uterus. The use of $CO_2$ to achieve pneumoperitoneum will lead to possible ventilation problems, and is a potential risk for acidosis in the fetus. The pressure should therefore be as low as possible (10–12 mmHg).[91] Great care should be taken in order to minimize manipulation of the uterus. Intraoperative and postoperative preventive measures should be followed in order to avoid thromboembolic complications.[90]

## Electroconvulsive therapy during pregnancy

Serious mental disorders requiring treatment may occur during pregnancy. Postpartum depression is a common disorder, and studies indicate that in women who experienced postpartum depression, more than 50% were also depressed during the pregnancy itself.[92] Treatment of serious mental illness during pregnancy represents a special challenge since the well-being of at least two individuals has to be taken into consideration. Pharmacological treatment of the mother may pose a threat to the fetus, especially during the first trimester. In this context, electroconvulsive therapy (ECT) seems to have a role in the treatment of serious conditions of perinatal depression. ECT does not generate electric current directly through the uterus. Possible harm to the fetus may occur due to hypertension and/or hypoxia during seizure. There are no randomized controlled studies comparing ECT with other treatment modalities for mental disorders in pregnancy. In a review article published in 2007 encompassing 339 pregnant women who underwent ECT series, remission or partial remission was reported in 78% of the cases. There were 25 fetal and neonatal complications, but only 11 of these were possibly related to the ECT treatment and only one was believed to be the direct result of the ECT.[93] Anaesthesia during ECT is normally induced by propofol or thiopentone. Motor activity is limited by the use of low-dose succinylcholine (0.5–1 mg/kg), thus preventing the patient harming herself or the fetus by vigorous muscle contractions. None of above-mentioned drugs are considered harmful to the neonate as long as they are administered before delivery. Theoretically, the risk of pulmonary aspiration during the procedure is higher in pregnant patients than in a non-pregnant population. However, in the review there were no reports of pulmonary aspiration among the 339 cases. This review, however, does not state whether the patients had cricoid pressure applied or indeed were intubated. In conclusion, ECT for serious mental disorders during pregnancy is often the preferred method of treatment. It does not seem to have any harmful effect on the fetus.

## Electric cardioversion during pregnancy

Arrhythmias during pregnancy are not uncommon.[94] Often, arrhythmias are diagnosed for the first time in pregnancy. Although some cases are due to underlying cardiac diseases, most cases are benign and do not need medical intervention. However, sustained arrhythmias with symptoms may require treatment. The treatment of arrhythmias in the pregnant population is similar to the treatment in non-pregnant people, and when medical treatment fails or the situation becomes life-threatening, electric cardioversion should be considered.[95] It is recommended to use a smaller dose of energy, 50–100 joules at least as the first application of current.[96] A review of the literature seems to indicate that the success rate of cardioversion is greater (>90%) in pregnancy compared to a non-pregnant population (success rate of 40–90%).[95] Very little current reaches the uterus, and the small size of the fetal heart implies a high fibrillation threshold.[97,98]

As for the non-pregnant population requiring cardioversion, anaesthesia is induced with small to medium doses of propofol or thiopentone. Due to the physiological changes during pregnancy, preoxygenation should be performed.[20] Endotracheal intubation is recommended after the first trimester.

## Cardiac surgery during pregnancy

Cardiac disorders may complicate pregnancy. However, the prevalence of clinically significant cardiac disease in pregnancy is low (<1%).[99] Women with pre-existing cardiac disease can develop acute heart failure during pregnancy.[100] Medical therapy is the first-line treatment. However, rarely, cardiac surgery is necessary. A multidisciplinary approach including the obstetrician, the cardiologist, cardiac surgeon, and anaesthetist, with close communication is necessary. Cardiac valve disease is the most frequent pathology and mitral valve disease is most prevalent.[101] Pregnancy is associated with profound physiological changes (as earlier described; Table 10.1). Both cardiac output and maternal blood volume are significantly increased. It is essential to maintain adequate preload and systemic vascular resistance. Aortocaval compression must be avoided. Moreover, hypoxaemia and myocardial depression during general anaesthesia should be avoided.

Cardiac surgery requiring cardiopulmonary bypass increases both maternal and fetal mortality.[100] The use of hypothermia decreases oxygen exchange through the placenta and may result in fetal bradycardia. It is important to maintain adequate uteroplacental flow and the pump flow should be increased by up to 50% during cardiopulmonary bypass. Moreover, the mean arterial pressure should be above 60 mmHg.

The use of perioperative fetal monitoring is advisable during cardiac surgery.

## Neurosurgery during pregnancy

Cerebrovascular disease such as haemorrhage, arterial infarction, and venous thrombosis can occur during pregnancy. It is unclear if the incidence of intracerebral haemorrhage is increased in pregnancy. Bateman and colleagues found a frequency of 7.1/100,000 person-years in pregnant woman compared to 5/100,000 person-years in non-pregnant woman.[102] In contrast to this, Kim and colleagues recently have shown that the risk of rupture of cerebral aneurysms is not increased during pregnancy.[103] Intracerebral haemorrhage is the cause for about 7% of all pregnancy-related mortality.[102]

Anaesthetic management in patients undergoing neurosurgical procedures should be similar to that described for other obstetric patients. Maintenance of uteroplacental flow is essential. Pregnant women with untreated aneurysms should be managed in such a way that haemodynamic stability is maintained. Hypertension should be avoided. Many have their surgery/interventional radiology postponed till after delivery.

## Anaesthetic management of the traumatized pregnant woman

Trauma is one of the most common causes of non-obstetric maternal morbidity and mortality during pregnancy. In some

reports, as many as 40–50% of maternal deaths are related to trauma and it represents one of the leading causes of death due to non-obstetric reasons in pregnant women.[104] The incidence of major trauma varies in the literature between 2% and 7% of all pregnancies,[105,106] and is highest in the last trimester. Motor vehicle accidents, domestic violence, and/or intimate partner violence are the leading causes. Injuries from falls are also common. As in the non-pregnant population, socioeconomic status, level of education, and the use of toxic substances are strongly correlated to incidents of domestic violence.

When exposed to trauma, the risk for the fetus may result from direct force or by the changes imposed on the mother. In motor vehicle accidents, incorrect use of a safety belt may expose the fetus to coup/contre-coup forces leading to high intrauterine pressure and the risk of uterine rupture, bleeding, and abruption. Complications for the fetus encompass spontaneous abortion, placental abruption, premature birth, uterine rupture, fetal-maternal haemorrhage, and stillbirth. The risk of intrauterine death is correlated to the severity of the trauma. High maternal injury severity score, severe haemorrhage and hypovolaemia, an established abruption placenta, and maternal disseminated intravascular coagulation are all strong predictors of intrauterine death.[107–109]

Trauma management should primarily focus on stabilizing the mother, as the fetus is highly dependent on the mother's haemodynamic stability. The trauma team should initially follow a standard, well-established algorithm like the advanced trauma life support (ATLS).[110] When following the ABCDE of advanced life support, one should remember the many physiological changes that a pregnancy induces. Left lateral tilt should be established in order to avoid aortocaval compression if the woman is more than 20 weeks pregnant. If a chest tube is indicated it should be placed one or two intercostal areas higher than normal in order to avoid intra-abdominal placement, and guidance by ultrasound is advisable. As for all anaesthesia inductions in the pregnant woman, one should be prepared for a difficult intubation. An obstetrician should be part of the initial trauma team, and if the fetus is viable (>24 weeks), a neonatologist should also be present whenever possible. Fetal monitoring must be established as quickly as possible after the initial stabilization of the mother. An early ultrasound is indicated in order to establish the state of the fetus. If the pregnancy by itself makes resuscitation and stabilization of the woman difficult, especially during emergency intra-abdominal procedures, a termination of the pregnancy or an emergency caesarean delivery must be considered. If the mother is dead one must consider perimortem caesarean delivery as early as possible during resuscitation, preferably within 4 minutes.[111] A possible algorithm for guiding care of the pregnant trauma victim, including the letter F for Fetus, is shown in Table 10.3.

**Table 10.3** Algorithm for guiding care of the pregnant trauma victim

| Advanced trauma life support | | Management |
|---|---|---|
| A | Airway | Secure airway<br>Protect cervical spine<br>Prepare for a difficult airway |
| B | Breathing | Check respiration<br>Avoid maternal hypoxia<br>Avoid maternal hypocapnia |
| C | Circulation | Identify and control bleeding<br>Maintain adequate blood pressure (systolic blood pressure > 100 mmHg)<br>Left lateral tilt (on backboard)<br>Consider emergency caesarean delivery to save the mother |
| D | Disability | Examine neurology<br>Glasgow Coma Scale score |
| E | Exposure | Undress patient<br>Prevent hypothermia |
| F | Fetus | Establish fetal monitoring as quickly as possible<br>Perform early ultrasound<br>Carry out emergency caesarean delivery if necessary |

## Conclusion

Surgery for non-obstetric reasons will be performed in 1–2% of all pregnant women. A careful evaluation of these patients and a good multidisciplinary preparation will reduce the risks for preterm labour, miscarriage, or abortions. Preventive measures should encompass a thorough evaluation of the airways, aspiration prophylaxis, and aortocaval displacement in order to prevent hypotension. The anaesthetic management should focus on maintenance of maternal haemodynamic stability and normoventilation. Locoregional anaesthetic techniques should be preferred whenever possible.

# CHAPTER 11

# Drugs in pregnancy and lactation

Oliver Kraemer and Timothée Fraisse

## Drugs during pregnancy

Whereas during normal, uncomplicated pregnancy few drugs are usually required, a wide range of drugs might be necessary during high-risk or complicated pregnancies. This can lead to complex or controversial decisions.[1,2] Besides herbal and over-the-counter drugs, it is estimated that more than half of pregnancies in developed countries are exposed to one or more prescribed drugs, with 7–10% of exposed pregnancies being exposed to drugs labelled D or X, based on the US Food and Drug Administration (FDA) classification (Figure 11.1).[3] However, drug safety classification gives a very crude estimation of risks and should only be used as a general guideline when planning treatment.[4] This chapter will provide the basis for understanding the principles of reproductive and developmental toxicology and elaborate on strategies for use of some of the most common drugs in obstetric anaesthesia. It should neither be considered as an exhaustive description of the potential side effects nor as a prescription guide for specific situations.

Scientific knowledge evolves continuously with the emergence of new drugs and reports of newly observed side effects based on pharmacovigilance follow-up. One should always refer to up-to-date international references when administering drugs to pregnant women, especially with newly marketed compounds. Literature references typically include Schaefer et al.'s *Drugs During Pregnancy and Lactation*[5] and Briggs and Freeman's *Drugs in Pregnancy and Lactation*[2], also available as an iPhone app. Web-based public sources include the Organization of Teratology Information Specialists (http://www.otispregnancy.org/), the Drugs and Lactation Database (LactMed; http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm), the Toxnet Toxicology data network (http://toxnet.nlm.nih.gov), and the European Network of Teratology Information Services (ENTIS; http://www.entisorg.org) which provide useful guidelines for most common prescription drugs, herbals, and other chemicals (e.g. drugs of abuse).

Additionally, specialized units in most university hospitals and poison control centres will provide useful recommendations in cases of atypical situations.

## Basic principles of reproductive and developmental toxicology

A drug's ability to induce developmental or fetotoxic disorders depends upon four fundamental variables:

- Developmental stage of the embryo/fetus
- Genetic susceptibility (as for codeine metabolism)
- Dose
- Mechanism of action.

The complex interaction of all four variables leads to a great variability in the observed effects of a given drug. Hence it is difficult to extrapolate the data obtained in toxicological animals experiments to humans. Moreover, because of the ethical limitations to conduct clinical trials in the pregnant population, most relevant evidence is obtained following clinical monitoring of drugs inadvertently administered to women at various pregnancy stages. In order to assess the potential reproductive and developmental toxicity of a drug in humans, all available data sets should be taken into account prior to a decision (animal reprotoxicological studies as well as epidemiological data).[6] Epidemiological observations such as case registries are essentially limited in number and subject to various biases. Cohort studies and case–control cohort studies have been commonly used since the 1980s to establish statistical associations between drug exposure and various pregnancy outcomes.[7–11]

### Pharmacokinetic changes during pregnancy

During pregnancy, several ADME parameters are modified that can lead to different risks for the embryo/fetus (i.e. absorption, distribution, metabolism, and excretion). The final concentration of a given drug in the embryo is therefore affected by four main consecutive factors: drug distribution in the mother, maternal drug metabolism and passage through the placental barrier (Chapter 3 has more detailed information on drug passage through the placenta), drug distribution in the embryo/fetus, and reabsorption from the amniotic fluid. Dosages must therefore be carefully adapted (often increased) during pregnancy in order to meet the therapeutic range required for the mother. However, when increasing dosages of drugs easily crossing the placental barrier, the prescribing physician should be particularly cautious regarding potential embryo- or fetotoxicity and always favour drugs that are known to be the safest:

- Drug distribution in the mother is affected by physiological changes which can be summarized by an increase in resorption (decrease in peristalsis of the intestines and increase in skin and lung blood flow), an increase in volume of distribution (plasma, total body water increases up to 8 L at the end of pregnancy, and fat deposition), a decrease in plasma proteins concentration to which drugs are non-covalently linked (especially albumin that decreases up to 10 g/L), changes in metabolism (the different liver metabolic pathways are activated when increasing the female hormone production), and an enhanced excretion through glomerular filtration (almost double the renal plasma flow).[12]

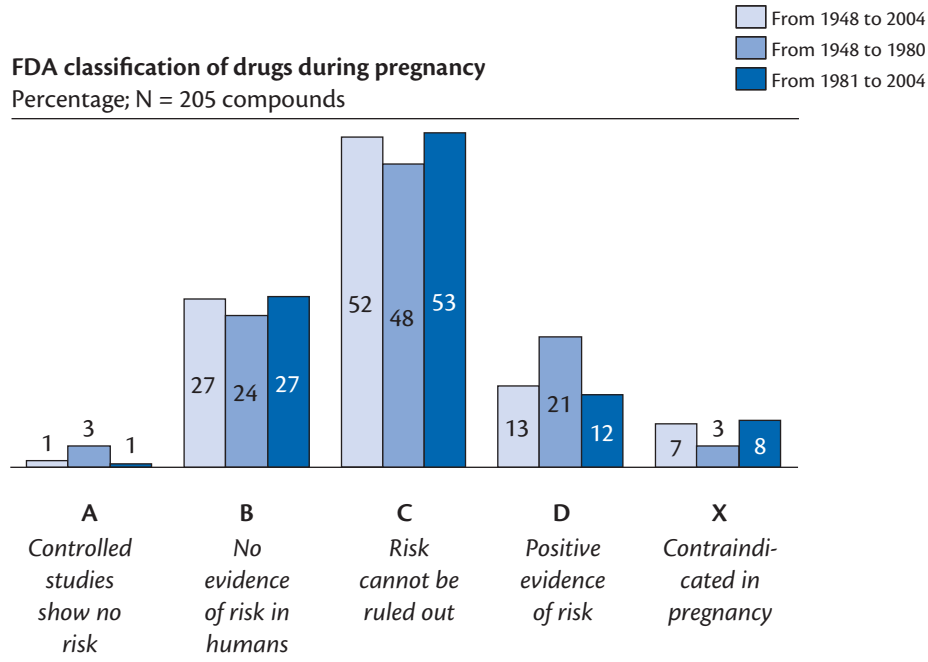

**Figure 11.1** The sole FDA classification of drugs does not provide sufficient information to support informed prescription in most cases.
Data from the U.S. Food and Drug Administration.

- The passage to the placenta has been extensively studied at the time of delivery. The maternal/placental blood–blood barrier allows selective diffusion of drugs. One should consider that most molecules will achieve equilibrium on both sides of the placenta over time and that transfer of most drugs to the fetus is certain. Small (molecular weight < 600–800 Da), lipophilic, non-ionized molecules tend to cross the placenta more easily than others. Larger molecules with molecular weight around 5000 Da (such as insulin), hydrophilic, ionized, or linked to plasma proteins will cross the barrier to a lesser extent. Therefore, most anaesthetics will easily cross the placental barrier due to their high hydrophobic/lipophilic profile. Some other drugs cross through specific transport mechanisms (e.g. immunoglobulins). Little is known regarding *in vivo* drug transport through the yolk sac and the placenta at earlier stages of pregnancy. Most early-stage studies have been performed with *in vitro* models allowing a better understanding of single-dose transfer but not capturing the complexity of multiple-dose administration, and potential accumulation (depending on biodistribution and pharmacokinetics of the drugs in mother).[5,13]
- Accumulation of the parent drug or its metabolites is likely to occur in the fetal compartment (embryo/fetus and the amniotic fluid) because of the limited fetal metabolism.[14] While this is in most cases detrimental to the fetus, it is considered beneficial in the prevention of mother-to-child infections transfer (e.g. with certain antiretrovirals or antibiotics).

## Anaesthetic drugs: local anaesthetics, hypnotics, and muscle relaxants

Major stages of fetal brain development occur during the last trimester of intrauterine life, with the human brain being not fully developed at birth and continuing to grow over the first few years of postnatal life.[15] There is a current debate on whether general anaesthesia can cause cognitive and mild neurocognitive effects due to neuronal apoptosis in newborns during their neonatal period.[16] Few epidemiological studies have specifically focused on individual anaesthetic drugs. However, several studies did not exert negative outcomes after a range of surgical procedures, which used a variety of anaesthetic agents.[8,10,17,18] The potential impact of surgery on neurodevelopment is not the purpose of this chapter.[19]

None of the commonly used anaesthetics induce an increase in congenital malformations. However, particular attention should be paid to avoid otherwise common anaesthesia-related side effects occurring in the mother that might be detrimental to the fetus (e.g. hypoventilation and malignant hyperthermia):

- Widely used local anaesthetics (ropivacaine, bupivacaine, levobupivacaine, lidocaine, and chloroprocaine) are generally considered safe during pregnancy and labour. Both ropivacaine and bupivacaine are highly bound to plasma proteins (94–95%) which leads to low placental transfer (equilibrium in the fetus occurs at roughly one-third of the mother's blood concentration). Both drugs exert extended half-lives in neonates.
- Bupivacaine's half-life in adults and neonates is 2.7 and 8.1 hours, respectively. Ropivacaine's milk transfer is very low and probably lower than that of bupivacaine and lidocaine.[20] Lidocaine has been widely studied in humans and rats at various pregnancy stages and does not demonstrate higher teratogenic risks in humans.[21,22] However, because of its lower protein binding (60–80%), lidocaine (FDA Pregnancy Category B) easily transfers through the placenta and achieves high concentration equilibrium in the fetus. Several side effects have been observed, all occurring at a very low frequency (e.g. transient neurobehavioral or cardiopulmonary impairments in the neonates). However, the total amount needed should be as little as possible when procedures (e.g. dental) are required in pregnant women, and should be postponed if not required.

- Most intravenous hypnotics may be used during pregnancy and labour, with particular caution for specific molecules:
  - Propofol (molecular weight 179 Da) can be administered during the entire pregnancy (from oocyte retrieval in the fertility laboratory to labour and delivery). It is highly bound to plasma protein (95–99%) but highly lipophilic/hydrophobic (3.842) and therefore reaches fairly high levels in the fetus at all stages of pregnancy (~70% of the mother's blood concentration). When used during the period of delivery, and because of its respiratory depressant effects, specific care should be given to monitoring of the neonate.[23–25]
  - Thiopental is considered safe for use at all stages of pregnancy. There is, however, less epidemiological data available regarding its use at early pregnancy stages. Thiopental achieves a fast equilibrium (1:1) between maternal and fetal blood as it binds to a lesser extend with plasma proteins (80%). Similarly to propofol, specific attention should be paid to monitoring the neonate when administered around the time of delivery.[22]
  - Etomidate is generally considered safe during pregnancy despite the fact that there is only limited epidemiological data available. When administered at the time of delivery, main adverse effects are a transient decrease in newborn cortisol levels (with no clinical impact) and possible respiratory distress.[26]
  - Ketamine should, when possible, be avoided during pregnancy (limited epidemiological data) and labour, as several adverse effects can occur, such as increased uterine tone and neonatal behavioural impairment. Additionally, ketamine should be clearly contraindicated in the following occurrences: maternal hypertension and/or (pre-)eclampsia, uterine hypertonicity, and intermediate to pathological fetal cardiotocography patterns.
- Halogenated agents are commonly used during pregnancy and delivery. These agents may be considered safe at any time during pregnancy. However, a careful monitoring of the newborn should be done when used at the time of delivery (possible respiratory and circulatory depression). These agents are considered non-teratogenic.[5,27,28] Sevoflurane, desflurane, and halothane have a uterine relaxant effect through activation of ATP-dependent potassium channels, and their ability to reduce uterine tone is well known to obstetricians.[29,30] This may result in a higher risk of blood loss at caesarean delivery. The use of isoflurane may cause an increase in bilirubin levels in the newborn.[31] Limited human data are available on the use of desflurane and sevoflurane during pregnancy, which are nonetheless routinely used at various stages of pregnancy. Sporadic cases of malignant hyperthermia and fetal bradycardia have been reported with the use of desflurane and sevoflurane respectively.[32,33]
- Nitrous oxide is generally a well-tolerated anaesthetic, with a mild effect on the circulatory system or the uterine tone. When used during pregnancy,[22,34] no increase in the incidence of malformations was demonstrated. Nevertheless several anaesthetists do not use it in pregnant patients, as it interacts with vitamin $B_{12}$ resulting in a selective inhibition of methionine synthase, a key enzyme in methionine and folate metabolism. When used at the time of delivery, the newborn should be monitored for possible respiratory distress.
- Most common muscle relaxants (e.g. atracurium, rocuronium, suxamethonium, and vecuronium) may be safely used at various stages of pregnancy, including during delivery. Only limited amounts of these drugs cross the placental barrier, because of their short half-lives and low hydrophobic and high ionization profiles. Concentration in the umbilical cord accounts for 10–20% of maternal plasma concentration.[35–38]

Contrary to what has long been thought, several studies did not demonstrate an association between occupational exposure to volatile anaesthetics and abortion or malformative rates,[39,40] despite workplace concentrations that often exceed legal requirements. On the other hand, occupational exposure to nitrous oxide has been retrospectively associated with increased abortion rates and decreased fertility, both of which may be mitigated by the use of scavenging devices.[41,42] These results may have been biased by several confounding factors and should therefore be considered with all due caution.

## Analgesics and anti-inflammatory drugs

- Paracetamol (acetaminophen) is considered safe at all stages of pregnancy. It is the first-line analgesic and antipyretic treatment in pregnant women.[43–45] Because of its low protein binding (~25%) and small molecular weight (151 Da), paracetamol easily crosses the placental barrier and achieves high concentrations in the fetal compartment. Maternal intake of paracetamol for more than 4 weeks during pregnancy, especially during the first and second trimesters, may moderately increase the occurrence of cryptorchidism.[46]
- Codeine may be used during pregnancy when therapeutic doses of paracetamol do not achieve sufficient pain relief, and also as a third-line treatment (after non-steroidal anti-inflammatory drugs (NSAIDs)). Animal studies have not shown any hazards, but there is inadequate evidence of safety during pregnancy. A few unconfirmed retrospective studies indicated a possible teratogenic effect. These were not confirmed by more recent cohort studies.[47] Administration at the time of delivery may trigger respiratory depression and suckling difficulties in the newborn. Additionally, withdrawal symptoms may appear after chronic *in utero* exposure (e.g. abuse). Recent studies outlined a possible link between codeine intake during pregnancy, caesarean delivery, and postpartum haemorrhage.[47] According to a 2013 update from the UK Medicines & Healthcare products Regulatory Agency (MHRA) (https://www.gov.uk/drug-safety-update), the use of codeine during pregnancy and lactation should be balanced between risks and benefits, and is considered acceptable if there is no safer alternative. Similarly, the MHRA has said that codeine is contraindicated in children under the age of 12 because of an increased risk of serious and life-threatening adverse reactions, including loss of consciousness and respiratory arrest.
- Fentanyl, sufentanil, and alfentanil are commonly used during all pregnancy stages, either through intravenous, spinal, or epidural administration.[5,48] They easily cross the trophoblast membrane and the placenta.[49,50] There is only limited epidemiological data available in humans, especially regarding pregnancy outcome after administration during the first trimester.
- Chronic morphine use should, when possible, be avoided during pregnancy. Developmental studies in mice and hamsters

demonstrated an increased teratogenicity,[48] with increased neurological, soft tissue, and skeletal abnormalities, when used at a maternal toxic dose. Available epidemiological data in humans does not confirm an increase in malformations or in behavioural anomalies in newborns exposed during pregnancy. As for codeine and other opioids, specific attention should be paid when administered chronically *in utero* and at the time of delivery (respiratory depression and psychophysiological effects can occur in neonates, and naloxone and resuscitative equipment should be available).

- Pethidine should not be used as an analgesic during pregnancy because of fetal:maternal concentration ratios greater than 1. It is, however, widely used during labour for pain relief (with no negative effects on labour duration nor on postpartum bleeding). Poorly metabolized by the newborn, it may trigger respiratory depression and breastfeeding difficulties and neonates should be appropriately monitored when pethidine is administered 1–4 hours before delivery, especially after administration of repeated doses (accumulation in the maternal and fetal compartments) or in premature births (for which it should be contraindicated).
- Tramadol use should, when possible, be avoided during conception and early pregnancy. There is no proper evaluation or clear evidence of fetal or neonatal harm, despite sporadic fetal losses being reported. At the time of parturition, and following chronic maternal use, there is a risk of neonatal withdrawal syndrome, with the molecule easily crossing the placental barrier and achieving equilibrium in the fetal compartment.
- Naloxone may be administered at all stages of pregnancy. Animal data does not suggest any teratogenic effect. Human data are sporadic but reassuring.
- Ibuprofen and other commonly used NSAIDs (i.e. diclofenac) may be used for anti-inflammatory or analgesic indications before 24 weeks' gestation.[46,51] After 24 weeks, all NSAIDs are contraindicated whatever the route of administration because of pulmonary and renal vasoconstriction in the fetus that can lead to oligoamnios or fetal death following the closure of the ductus arteriosus. In a recent Norwegian cohort study, use of ibuprofen or diclofenac in the second trimester was significantly associated with low birthweight, and ibuprofen use in the second and third trimesters was significantly associated with asthma in 18-month-old children.[51] This large cohort study assessed infant survival, congenital malformations, structural heart defects, neonatal complications, haemorrhage during pregnancy and postpartum, as well as asthma at the age of 18 months. It did not find any effect on rates of infant survival, congenital malformation, or structural heart defects. There was, however, a significant association between diclofenac and ibuprofen use late in pregnancy, and maternal bleeding and asthma in the child, respectively.
- Aspirin is not considered as the analgesic or antipyretic of choice but may still be used at various stages of pregnancy.[52,53] Large retrospective and prospective studies in humans did not demonstrate an increase in malformation rates, despite evidence of birth defects in the animal models. Aspirin may be used at therapeutic doses during pregnancy with the following restrictions:
  - Doses greater than 500 mg/day are contraindicated after 24 weeks gestation. Special caution should be paid during the last weeks of the pregnancy, since even low-dose administration will decrease platelet adhesiveness and may trigger newborn intracranial bleeding and increased postpartum bleeding.
- Selective cyclooxygenase (COX)-2 inhibitors should be avoided during pregnancy because of the lack of human data to support their use. Use of diclofenac systemic formulations during pregnancy has recently raised concerns in the United Kingdom, despite a reassuring prospective observational cohort study.[54] As for other NSAIDs, administration should be contraindicated after 24 weeks' gestation.

## Anti-infective agents during pregnancy: antibiotics, antimycotics, and antivirals

- Penicillins and other beta-lactam antibiotics are classified as bactericidal. As penicillin interacts with bacterial wall synthesis (this mechanism does not exist in humans) it is the first-line antibiotic treatment for many common infectious problems in pregnancy. There exists sufficient clinical proof that there is neither embryo- nor fetotoxicity even though penicillin has rapid transplacental passage.[55,56] This is also true for combination therapy with clavulanic acid and also beta-lactamase inhibitors, which are considered safe for use during pregnancy.
- Cephalosporins such as penicillin are commonly used during pregnancy. They have a higher clearance during pregnancy and a dosage adaption is needed. Almost a complete transplacental passage occurs for all generations of cephalosporins.[57] However, as second- and third-generation are associated with cases of immunohaemolysis,[58] most clinicians prefer the older cephalexin and cefuroxime. There is no evidence for teratogenicity in the first trimester.[59,60]
- Erythromycin and other macrolide antibiotics are bacteriostatic, and are commonly used in case of known allergy to penicillin. They interact with bacterial protein synthesis. There are reports of maternal hepatotoxicity in the second half of pregnancy for erythromycin estolate or troleandomycin and therefore these two macrolides are to be avoided during the second and third trimester. The placental passage is low (5–20%) during the third trimester for erythromycin, and it is therefore not recommended in the treatment of fetal or amniotic infections. No macrolides have demonstrated teratogenicity,[61,62] and clindamycin and lincomycin do not cause embryo- or fetotoxicity.[63–66] Spiramycin is the treatment of choice for toxoplasmosis in the first trimester. Clindamycin and lincomycin are used second line, because they are less effective in bacterial vaginal infection and should be used only after penicillins, cephalosporins, or other macrolides failures. They do present with high maternal resorption and there is a 50% passage across the placental barrier.
- Tetracyclines are only used in a second intention, as broad-spectrum antibiotics, and can be used, for example, for treating urinary tract infections in the first trimester. They are contraindicated after the 16th week of gestation because of their accretion to teeth and bones that is clearly demonstrated in animals. In the 1950s they were often used, and are associated with

yellow discoloured teeth. They are bacteriostatic, affect protein synthesis, and no teratogenicity has been reported.[2]

- Sulphonamides, trimethoprim, and co-trimoxazole (single or combination use) are also used as a second choice during pregnancy for urinary tract infections. There is no evidence for teratogenicity. Sulphonamides are bacteriostatic and 50–90% accumulates in the fetal compartment. They do suppress bilirubin from their plasma protein binding. Trimethoprim is a folic acid antagonist, and its use can be considered, when combined with folic acid substitution, in specific situations such as *Pneumocystis jirovecii* pneumonia (AIDS setting) during the first trimester.
- Gyrase antagonists (4-quinolones) interact with a bacterial-specific topoisomerase enzyme and therefore have theoretically no interaction in humans. They are used when first-line therapy for enteral bacteria such as pseudomonas fails or when resistance to better agents is identified (e.g. ciprofloxacin and norfloxacin). However, routine use of these agents is not recommended despite reassuring reports. In cases of occasional use in the first trimester, a high-definition ultrasound is recommended to evaluate malformative risk in the embryo/fetus.
- Nitrofurantoin, fosfomycin, and methenamine, used for urinary tract infections, are not recommended except in very specific situations.
- Nitroimidazole antibiotics are indicated in trichomonas or anaerobe infections. Metronidazole reaches higher concentrations in the fetal compartment than in the maternal compartment. As it presents mutagenic and carcinogenic potential, following toxicological *in vitro* and *in vivo* evaluation, a cautious approach is advised when used during pregnancy. Its vaginal use is not indicated.
- Aminoglycosides have bactericidal interaction on (Gram-negative) bacterial protein synthesis. Concentration in the fetal compartment does reach up to 20–40% of maternal concentrations after parenteral administration. No teratogenicity has been reported, but because of ototoxicity, their indications are limited to life-threatening infections or after first-line treatment failure. Maternal plasma concentrations should be regularly monitored.
- Chloramphenicol presents a bacteriostatic action, and is clearly contraindicated in pregnancy because of its known risks of potentially lethal agranulocytosis or Grey syndrome.
- Polypeptides antibiotics are used against Gram-positive bacteria as multiresistant staphylococci, but remain limited to life-threatening infections.
- Tuberculostatics such as isoniazid, rifampicin, and ethambutol are first-line treatment against mycobacteria and are not considered teratogenic. Vitamin $B_6$ must be administered to the mother treated with isoniazid. Vitamin K must be administered to the newborn of mothers treated by rifampicin. Pyrazinamide and dapsone are second-choice treatments.
- Local antimycotics:
  - Nystatin is the first-choice agent for non-systemic, local treatment during pregnancy, with limited feto- or embryotoxicity reported.[67,68] There might be a possible, yet unconfirmed, association between hypospadias and nystatin.
  - Clotrimazole is a good choice in local antimycotic treatment in pregnancy, as there is limited systemic absorption, and with limited feto- or embryotoxic effects reported.[68] Other imidazole derivatives are considered second-choice alternatives in the second and third trimesters.
  - There is only limited human data available regarding the use of other local antimycotics during pregnancy (amorolfine, ciclopirox, naftifine, terbinafine, tolciclate, and tolnaftate), that are hence not recommended as first-line therapies.
- Systemic antimycotics:
  - Conazole antimycotics: in animal models these drugs are described to pass the fetoplacental barrier, but they have shown a limited teratogenic potential in humans (http://www.entisorg.org). Their use can be allowed during the first trimester when systemic treatment cannot be avoided. Regular ultrasound for organogenesis confirmation should be performed by a trained physician.
  - Amphotericin B is only considered for local use. The parenteral route is only used in cases of threatening, generalized mycosis. Regular ultrasound to check organogenesis should be performed by a trained physician.
- Antivirals—antiretroviral drugs/HIV drugs during pregnancy and during labour/postpartum:
  - Aciclovir: there is no data on embryo- or fetotoxicity. Local application is possible.
  - Famciclovir, ganciclovir, valaciclovir, and the prodrugs of these virostatics are inadequately investigated to allow unequivocal statements for use in pregnancy.
  - A more detailed account of antivirals is presented in Chapter 50.

## Other drugs of interest during anaesthesia

- Epinephrine may be used during pregnancy either via epidural administration associated with a local anaesthetic or through intravenous administration. Epidemiological data does not suggest an increased teratogenic risk. However, epinephrine can have significant effects on uteroplacental perfusion. Nevertheless, its administration should not be delayed if life-saving, as in the setting of resuscitation.
- Ephedrine, phenylephrine, pseudoephedrine, and similar drugs should be avoided during pregnancy whatever their administration route, as they induce fetal vascular system abnormalities.[69] Appropriate ultrasound monitoring is suggested after accidental use during the first trimester. Low-dose nasal administration may be considered provided that the treatment is only for a short duration. Using these drugs in a perioperative setting or at the time of delivery to maintain blood pressure is of course acceptable and often required.
- Atropine may be used during pregnancy at the therapeutic recommended doses. Epidemiological data is rare but reassuring regarding embryotoxicity potential. Atropine easily crosses the placenta and reaches concentrations in the fetus that are similar to the mother. Its use should be limited to clear therapeutic indications.

- Glycopyrrolate, on the other hand, does not cross the placenta and is the drug of choice for maternal bradycardia.

## Drugs during lactation

Multiple studies demonstrate that breastfeeding is beneficial for both the mother (reduced blood loss, reduced incidence of postpartum depression, etc.) and the breastfed infant (respiratory, gastrointestinal, meningeal and urinary infection protection, better developmental scores, auditory and visual acuity, etc.). The World Health Organization and the Innocenti Declaration therefore both promote breastfeeding over bottle-feeding.[70] However, medical interventions requiring appropriate sedation and/or analgesia are fairly frequent during the perinatal and immediate postpartum periods and, to a lesser extent, during the late postpartum. It thus becomes the responsibility of the anaesthetist, together with the obstetrician and/or paediatrician, to assess and balance the risks associated with each drug for both the mother and infant. Pharmacological risks to the lactating mother (e.g. linked to pharmacokinetic changes) are quite rare, especially when compared to the risks stemming from not treating or undertreating. Risks to the breastfed infant are most commonly linked to the amount of drug received (i.e. volume ingested multiplied by milk concentration) and drug disposition in the infant (which depends upon the absorption and clearance rates of the specific drug). For some drugs, it may however be totally or partially unrelated to the drug amount. Therefore, any clinical decision should be scientifically supported and appropriately documented in the patient's medical record in order to mitigate legal risk and ensure optimal care is provided.

This section aims at providing the clinician with a better understanding of the underlying mechanisms of blood–milk transportation of drugs as well as a description of the current consensus for most commonly encountered anaesthetics and analgesics. It will not discuss the rational of breastfeeding versus traditional formulas outside the context of the postpartum surgery nor will it be exhaustive in the description of the therapeutic classes. The reader will find mention of Internet and printed references at the beginning of this chapter that may come useful in atypical situations.

### Functional anatomy of the breast during pregnancy and lactation

The mammary gland consists of 10–15 ducts extending from the nipple together with alveolar complexes at the termination of every duct. The areola has multiple physiological roles. It contains sebaceous and sweat glands, serves as the termination point for the fourth intercostal nerve, and regulates oxytocin secretion from the posterior pituitary gland as well as prolactin secretion from the anterior pituitary gland. During pregnancy, alveolar complexes increase in number and intricacy while milk secretion is kept low by sex steroids (primarily by progesterone). At parturition, a series of changes called 'lactogenesis' transforms the cells into the fully secretory state. These include closing of apical tight junctions, increasing blood flow, and so on.

### Five different ways for molecules to cross the milk–blood barrier

As for most blood barriers, there are five mechanisms involved in the transfer of drugs from blood to milk: exocytosis (apical secretion through vesicles), lipidic transport (apical secretion in lipidic vesicles), apical transport (passive diffusion through the cell), transcytosis (active transport mechanisms), and paracellular pathway (diffusion of large molecules through intercellular spaces). While the paracellular pathway is clearly the dominant pathway during pregnancy, a few days after parturition the apical tight junctions close, therefore limiting the drug transfer to apical transport and, to a lesser extent, transcytosis. The paracellular pathway is again involved during involution, at the end of the lactation period, or in the event of mastitis.

### Main physicochemical properties influencing drug transfer during lactation

During lactation, most blood–milk transfer occurs through apical transport, which is a passive diffusion of the drugs through the mammary cells. The extent to which a drug will be transported through the cell is driven by the molecule's physicochemical properties, namely:

- Molecular weight: molecules under 300 Da are likely to cross easily (e.g. ethanol and amphetamines) whereas large molecules simply cannot (e.g. heparin and insulin).
- Lipid solubility: highly lipophilic drugs are likely to achieve a quick equilibrium between blood and milk concentrations. This implies that most anaesthetics and central nervous system (CNS) drugs are likely to easily cross the milk–blood barrier.
- pH ionization: the milk's pH is slightly lower than blood's (pH = 7.2 vs 7.4). Weak bases are likely to be sequestered in the milk (barbiturates, antihistamines, and erythromycin) whereas weak acids are less likely to cross (penicillins).
- Plasma protein binding: highly bound molecules are less likely to cross and therefore milk/plasma (M/P) ratio is likely to decrease sharply as plasmatic protein binding increases. For example: sulphanilamide (protein binding = 8%, M/P ratio = 1), sulfathiazole (protein binding = 50%, M/P ratio = 0.36), and warfarin (protein binding > 90%, M/P ratio = 0.03).

### Physiological co-factors influencing the milk/plasma ratio

Besides the drug's intrinsic ability to cross the milk–blood barrier, several physiological co-factors influence the M/P ratio for any given drug:

- The drug's dose and bioavailability: the level to which any given drug will be found in the mother's blood will influence the milk equilibrium level. Drugs such as aminoglycosides, vancomycin, or cephalosporin are poorly absorbed and therefore less likely to be found in the milk. Additionally, fed or fasted mothers will absorb a given drug at different rates, resulting in different M/P ratios.
- The drug's maternal clearance: the mother's kidney and liver metabolism will influence the rate at which a drug will be cleared from the blood. An altered clearance will trigger a prolonged plasma half-life and hence a potentially higher milk concentration.
- Timing of medication: this is clearly the most complex influencing factor, given the variability in milk composition and production during the postpartum period as well as during the

circadian cycle. However, in most cases, the preferred timing for drug administration is just after breastfeeding.

- Drug administration immediately postpartum: the breastfed infant will only ingest small volumes of milk during the immediate postpartum (which does not imply small concentrations or small quantities of drugs because of the predominance of the paracellular pathway at this stage of the lactation).

Milk secretion increases sharply in the first postpartum days (from 50 mL on day 1 to >600 mL on day 5) and quickly reaches a plateau (usually limited to a maximum of about 1.5 mL of milk per gram of tissue per day). Meanwhile, milk composition varies drastically with lactose concentration increasing sharply and sodium and chloride concentration dropping rapidly.

## Local anaesthetics, hypnotics, and muscle relaxants

Local anaesthetics are widely used and generally considered safe during all stages of breastfeeding, including when added to epinephrine. Lidocaine and bupivacaine have been extensively tested in lactating mothers, including at high intravenous dosages, for example, for cardiac arrhythmia. Despite a rather quick milk:blood equilibrium, relatively small amounts of the drugs are ingested by the suckling infant. Ropivacaine's milk transfer is very low and probably lower than that of bupivacaine and lidocaine.[20,71] Articaine has an even shorter half-life associated with a higher plasmatic binding probably resulting in an even lower milk concentration. Considering the poor absorption patterns of these drugs and their metabolites it is not surprising that clinical observation does not report any serious adverse events.[72–74] The addition of epinephrine to any of the previous drugs should not be considered problematic as it will in any case limit the passage of the drugs from the mother's blood to the milk. Prilocaine is the only local anaesthetic that should be avoided because it may create more methaemoglobin, however its accidental use should not be an indication to breastfeeding interruption.

It is now widely accepted that mothers may breastfeed their infant as soon as they recover from general anaesthesia. Methohexital, thiopental, and halothane are the drugs of choice according to the American Association of Pediatrics (AAP). Because of their physiochemical properties and despite the absence of studies, sevoflurane and isoflurane are believed to be excreted into the milk. However, since there has been no report of adverse effects to the breastfed infant their use might be considered compatible with breastfeeding. Methohexital passes into the milk in negligible amounts, resulting in extremely low infant exposure.[75] Thiopental has a rather long half-life of approximately 10 hours but a M/P ratio of about 0.5 which leads to negligible amounts ingested by the breastfed infant. No toxic effect is expected despite its prolonged half-life in the infant after single-dose administration.[76] Halothane and other volatile agents easily cross the milk–blood barrier but no adverse clinical outcomes have been yet reported after anaesthesia of a lactating mother or after prolonged occupational exposure.[77,78]

Propofol may be safely used for general anaesthesia induction. It has a short half-life and an extremely high plasma binding (95–99%). Despite its small molecular weight, high pKa, and hydrophobicity, the amount ingested by the infant is considered negligible.[25,79]

Most commonly used muscle relaxants (e.g. atracurium, pancuronium, rocuronium, suxamethonium, and vecuronium) may be safely prescribed at various stage of lactation. Only limited amounts of these drugs cross the milk–blood barrier, because of their low hydrophobic and high ionization structures. Moreover, all these drugs demonstrate an extremely limited intestinal absorption profile.

## Analgesics and anti-inflammatory drugs

Paracetamol is the analgesic and antipyretic drug of choice during lactation. It is excreted at a very low rate into the milk, with a peak level occurring 1–2 hours after a single oral dose. A suckling infant will receive 1–2% of the weight-adjusted maternal dose. There has been only one adverse event reported so far (a maculopapular rash which resolved within 24 hours after discontinuation of the treatment and resumed when the treatment was reintroduced).[80–82]

Codeine may only be used as a third-line treatment and for a short duration (up to four times at 60 mg). Specific attention should be taken with children with a risk for apnoea. Breastfeeding should be stopped if the mother or the child demonstrates symptoms of opioid toxicity (sedation, constipation, poor milk intake, or poor body weight gain). There is a clear dose–effect correlation between maternal treatment and CNS depression in the infant. Moreover, it should be contraindicated in known or suspected ultrarapid metabolizers (cytochrome P450 2D6 ultrarapid metabolizers) (high sedation and constipation) as a case report from 2006 shows.[83–85] In 2013, the MHRA issued a recommendation to avoid codeine during lactation and to reserve its use to third-line indications, after use of paracetamol and NSAIDs (https://www.gov.uk/drug-safety-update).

Fentanyl and associated drugs (sufentanil, alfentanil, etc.) are considered safe for use during lactation. Fentanyl easily crosses the milk–blood barrier with a peak concentration occurring 0.75 hours after a single administration and a milk/blood ratio greater than 1. Because of the rapidly decreasing colostrum concentration and its low oral bioavailability, fentanyl is considered compatible with breastfeeding.[86]

Use of morphine should be limited to single administration or short duration treatments, with specific CNS monitoring of the infant. Morphine easily crosses the blood–milk barrier due to its low molecular weight and intermediate plasma binding (30–40%). There is no available clinical data regarding the neurobehavioral and developmental effects over the long term. It is nonetheless considered compatible with breastfeeding by the AAP.[87–89]

Pethidine is widely used at the time of parturition. It triggers higher saliva levels in infants up to 48 hours after birth with no significant adverse effects reported. It is considered compatible with lactation by the AAP. As for all opioid drugs, and because of the very long half-lives of pethidine and its metabolite in neonates (13 and 63 hours, respectively), particular attention should be paid to CNS monitoring when administered 1–4 hours before delivery, especially after repeated doses (accumulation in maternal and fetal compartments). It is contraindicated in preterm infants.[75,89–91]

Tramadol may be used during breastfeeding for short-duration periods and in case of mild to severe pain after delivery, especially in case of poor opioids tolerance. Both tramadol and its active metabolite are excreted into breast milk to a limited extent. There has been no evidence of fetal or neonatal negative outcomes when used during labour (however, the analgesic effect of tramadol is limited during labour).

Naloxone is supposed to be compatible with lactation, despite the fact that there is no human data available. In the absence of consensus, and because of its rather short adult half-life (30–81 minutes), one may consider to avoid breastfeeding for 12–24 hours after single-dose administration.

Ibuprofen and other commonly used NSAIDs (e.g. diclofenac) do not cross easily the milk–blood barrier (M/P ratio < 1). These drugs have very short half-lives, are highly bound to plasma proteins (99%) and are polarized (acidic profiles). Ibuprofen is the NSAID of choice as it is very poorly excreted into milk and widely used with no significant adverse events reported.[92,93] Other common NSAIDs may also be used occasionally but should not be considered as safe as ibuprofen or flurbiprofen. Diclofenac and its numerous metabolites have not been studied in humans. One may want to consider indomethacin as a valid alternative to diclofenac despite one reported seizure case possibly attributed to the drug. Indomethacin is considered compatible with breastfeeding by the AAP and should be preferred over diclofenac[94] despite reported cases of convulsions in newborns associated with its use.[95,96] Accidental exposure to the other NSAIDs does not require weaning but the medication should be adapted.

Acetyl salicylic acid is very poorly excreted into milk but is trapped in this compartment (M/P ratio ~0.05 at plasmatic peak level 3 hours after administration reaches ~0.3 after 12 hours). There has been one reported case of metabolic acidosis in a breastfed infant. The AAP does not ban aspirin but calls for particular caution.[97,98]

Ketorolac has been studied after oral administration in breastfeeding mothers 2–6 days after parturition. It reached extremely small concentrations in milk. It is approved by the AAP.[99]

There are not sufficient data available with selective COX2 inhibitors to support their use during lactation. Because celecoxib and rofecoxib are poorly excreted into milk and are unlikely to pose a significant risk, an accidental single-dose administration does not require any limitation of breastfeeding. It is believed that celecoxib is eliminated from the breast milk 24 hours after a single-dose administration. On the other hand, rofecoxib has a rather long adult serum half-life (~17 hours) and may trigger accumulation in both serum and milk compartments.[100–103]

### Anti-infective agents during lactation: antibiotics, antimycotics, and antivirals

Most antibiotics pass in minimal concentration (< 1% of newborn body weight adjusted dosage during therapeutic use) into the suckling infant. Theoretically side effects to the infant are changes in defaecation, formation of antibiotic resistances, and sensibility. None of them is considered clinically relevant.

- Penicillins and cephalosporins are all considered as first choice in lactation, especially second-generation cephalosporins. Combinations with or single use of clavulanic acid can be used when necessary.
- Erythromycin and roxithromycin are again first choice in lactation. Other macrolide antibiotics remain second choice. It should be used with caution if there is hyperbilirubinaemia of the newborn.
- Tetracyclines remain second-line treatment.
- Sulphonamides and nitrofurantoin cross the milk–blood barrier. Special attention should be paid in case nitrofurantoin use when the infant has a G6PD deficiency, as cases of haemolytic anaemia were reported.
- Dapsone has been associated with one reported case of haemolytic anaemia in a breastfed infant.[104]
- Clindamycin and vancomycin are excreted into the milk but poorly absorbed in the infant bowel. Clindamycin is approved by the AAP. Vancomycin is considered safe but was not reviewed by the AAP. The main side effect for both drugs is a modification of the bowel flora. There was one reported case of haemorrhagic enteritis with clindamycin.
- Chloramphenicol seems to have a bone marrow depressant effect and is therefore not recommended in breastfeeding mothers.[105]
- Metronidazole is considered compatible with breastfeeding.
- Aminoglycosides (e.g. gentamicin) are absorbed by the infant gut and can accumulate.
- Antimycotics in lactation: in general, local therapy is not considered harmful during lactation. Systemic therapy should only be considered if there is a clear clinical indication. In breast skin/nipple mycosis, the germ reservoir is the oral cavity of the suckling infant. Therefore treatment of mother and child is necessary. Nystatin and clotrimazole or miconazole are first choice for local treatment, but depending on the indication other antimycotics might be used temporarily or on small localizations.

### Other drugs of interest during anaesthesia

Epinephrine may be used during lactation when associated with local anaesthetics. There are no human data available regarding its use following intravenous administration in emergency situations but there is a suspected toxicity for the infant. Under these emergency circumstances, one should temporarily avoid breastfeeding.

There are very scarce data regarding human exposure to ephedrine during lactation with only one case report presenting an irritability and disturbed sleeping pattern in a 3-month-old suckling infant.

Atropine is approved for use during lactation by the AAP. Its passage through the milk–blood barrier has not been extensively studied but no clinical adverse effects have been reported so far.

## Conclusion

With drug safety classification only providing a very crude estimation of maternal, fetal, and neonatal risks, physicians, and especially anaesthetists, often face complex or controversial decisions during pregnancy and lactation.

There are a few basic rules applicable to most cases in order to limit risks to the fetus or the suckling infant:

- Limit prescription to what is truly necessary.
- Do not prescribe lower/higher doses than necessary.
- Avoid newly released medications or medications known to be at risk (e.g. cytotoxic agents, radioactive compounds, CNS active drugs, active metabolites of the parent drug, drugs that have long paediatric half-lives such as barbiturates and benzodiazepines, and all drugs of abuse).
- Choose drugs that are poorly excreted into the fetal compartment or into the milk.

- Additionally, during lactation one should:
  - avoid drugs that are poorly eliminated by the infant, especially for premature or sick infants
  - adapt formulation and route of administration so that the plasma concentration is low at the time of breastfeeding and preferably breastfeed just before drug administration
  - advise the paediatrician and nurses in charge of the suckling infant when particular surveillance is needed.

In any case, as scientific knowledge evolves continuously with the emergence of new drugs and reports of newly observed side effects, one should always refer to up-to-date best standard of care and review references, which should be clearly documented in the patient's medical record, especially with respect to newly marketed compounds. Specialized units in most university hospitals and poison control centres will always provide useful recommendations in cases of atypical situations.

PART 5

# Obstetric management of labour and labour analgesia

# CHAPTER 12

# Obstetric management of labour, delivery, and vaginal birth after caesarean delivery

Roland Devlieger and Maria-Elisabeth Smet

## Introduction

Due to Eve's disobedience in the Garden of Eden, God condemned not only her, but all women, to painful labour for many generations. In view of this religious conviction and partly due to the fallacy that it supports bonding between mother and child, one can understand the acceptance with which many women over the centuries gave birth without pain relief. Fortunately, nowadays divine condemnation is considered outdated by most and analgesia in labour is accepted practice in many cultures.

The first anaesthetic used in labour was nitrous oxide. This 'laughing gas' was discovered in 1799 by Sir Humphrey Davy. In 1847, Sir James Young Simpson discovered the anaesthetic possibilities of chloroform. This was given to numb Queen Victoria during the deliveries of her two youngest children. Hence the name, anaesthetic 'à la reine'.

More recently, the paracervical block was introduced. Today, this technique has been largely abandoned even though it is a relatively simple way to relieve pain during the first stage of labour. It is limited in its use mostly because of its short duration of action and the fact that fetal bradycardia has been described after inadvertent intravascular injection, in some cases with fatal outcome. The history of obstetric anaesthesia is detailed in Chapter 1.

With the improvements in efficacy and safety of neuraxial techniques for pain relief during labour, the demands on the obstetric anaesthetist increase. Moreover, the role of the anaesthetist extends beyond pain relief. As labour and delivery can be complicated by many life-threatening emergencies (fetal distress, amniotic fluid embolism, postpartum haemorrhage (PPH), etc.) obstetricians often rely on their anaesthetic colleagues who have become important players in the multidisciplinary obstetric management team. Therefore, an optimal bilateral understanding between obstetrician and anaesthetist is of utmost importance for the well-being of women in labour, and some insight into normal and abnormal labour and delivery is helpful for anaesthetists.

## Normal labour and delivery

Labour is the process where uterine contractions lead to effacement and progressive dilation of the cervix. The cervix dilates until it is fully confluent with the vagina (Figure 12.1). The fetus can then descend through the birth canal. Delivery of the baby is followed by delivery of the placenta.

Labour in humans is typically divided into three phases or stages:[1] during the *first stage* the cervix progressively dilates as a result of regular uterine contractions to full dilatation (referred to as 10 cm). The cervix starts off as closed, firm, posterior, and approximately 3 cm long. This first stage begins with a *latent phase*, which is very variable in duration. It represents the early stage of labour that is characterized by irregular, infrequent, and mild contractions and little or no dilation of the cervix or descent of the fetus. In this phase, the cervix becomes softer, shorter, and more anteriorly situated into the vagina while the fetal head descends. This phase can last for days, may or may not be associated with painful contractions, and ends when the cervix is fully effaced and around 3 cm dilated. There is strong evidence that the first stage of labour is 1 hour shorter when women are stimulated to assume upright positions (standing, sitting, kneeling, walking, etc.) in comparison with a recumbent position.[2] Once the contractions are regular and powerful, resulting in cervical effacement, dilatation of 3 cm and more, the so-called active first phase of labour has been reached. The *active phase* of labour is more predictable in timing and is associated with increasingly powerful contractions. During this active phase, the cervix dilates at a rate of about 1 cm per hour but faster progression is common, especially in multiparous women. The *second stage* of labour is from when the cervix is fully dilated until the baby is born. The *third stage* of labour ends with the delivery of the placenta.

Traditionally labour has three components (the three 'Ps'); the passage (pelvis), the passenger (baby) and the powers (uterine contractions and maternal effort). Each of these can contribute to the labour and delivery, to deviate from the physiological situation, thereby causing a prolonged or obstructed labour (see later sections).

Cervical dilatation and other cardinal maternal and fetal parameters are recorded during labour using a composite graphical representation over time on a sheet of paper: the partogram (Figure 12.2). Relevant measurements might include statistics such as cervical dilatation, fetal heart rate (FHR), duration of labour, and vital signs. It is intended to provide an accurate record

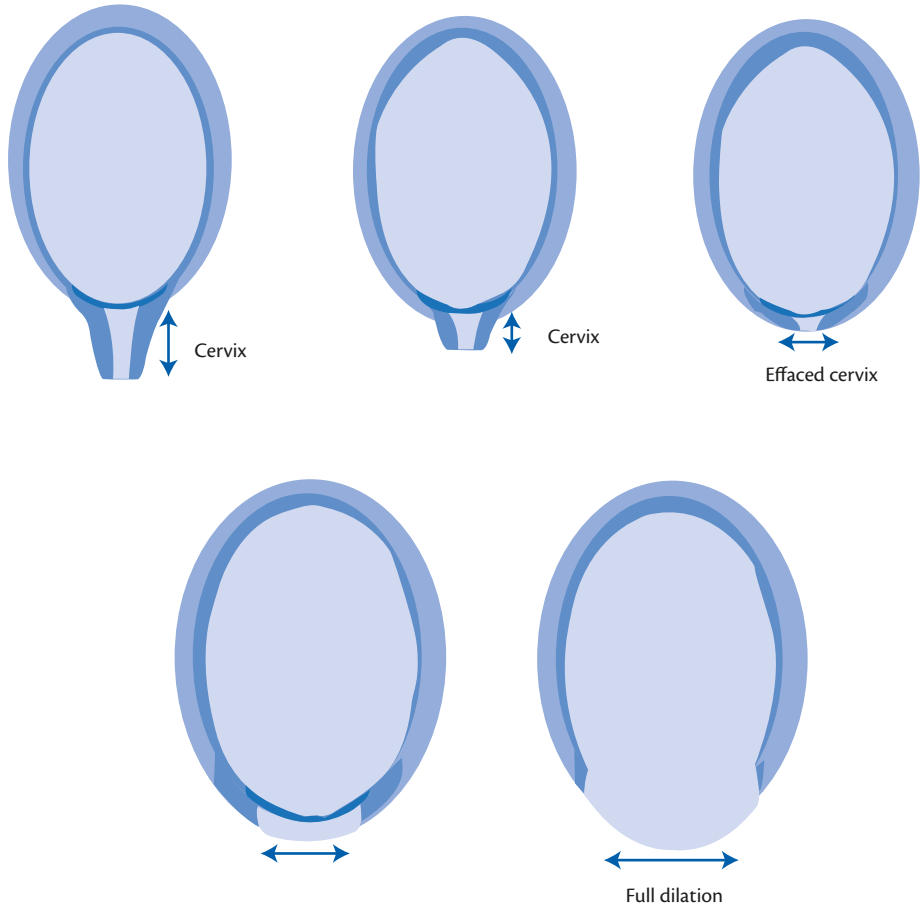

**Figure 12.1** Cervical changes during labour.

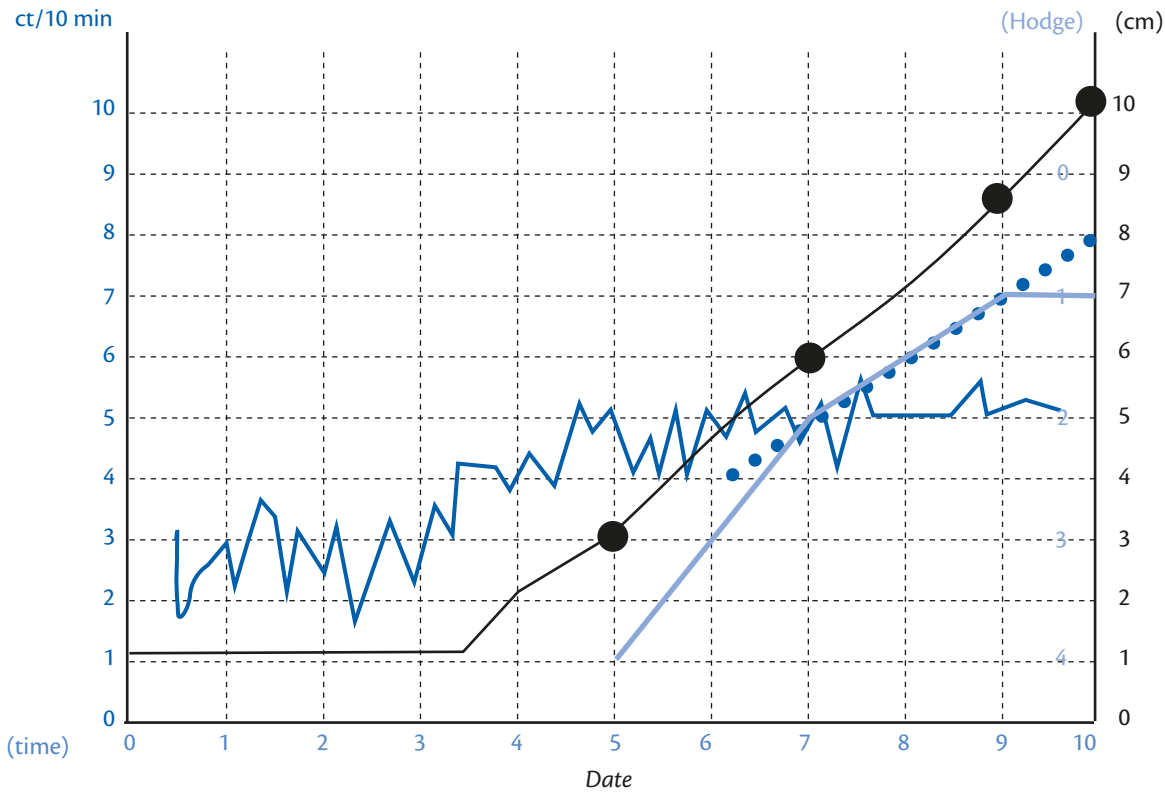

**Figure 12.2** Intrapartum information.

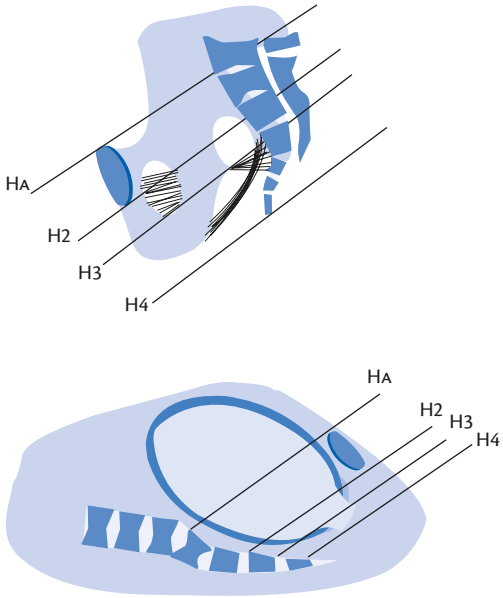

**Figure 12.3** Hodge planes.

of the progress in labour, so that any delay or deviation from normal may be detected quickly and treated accordingly. The use of a partogram in established labour is recommended by the *Intrapartum Care* guideline from the UK National Institute for Health and Care Excellence (NICE).[3]

Nowadays, intrapartum information including maternal parameters and partogram is available electronically in most units (Figure 12.2). During labour, the attendant midwifery or medical staff will evaluate the patient at regular intervals. This will include a vaginal examination during established labour to assess:

- cervical dilatation, softening, effacement, and position (modified Bishop's score)
- presenting fetal part (cephalic, breech, other)
- engagement and descent of the presenting parts in Hodge planes I, II, III, and IV (Figure 12.3)
- position (occiput anterior, occiput posterior, occiput transverse) and flexion (occiput, vertex, brow, face) of the fetal head in the pelvis.

In case of inconclusive vaginal examination, ultrasound is increasingly being utilized to evaluate the position of the fetus. Besides regular vaginal examination, the assessment of progress in labour depends on the assessment of effective contractions. The nature and timing of contractions can be evaluated clinically by abdominal palpation or can be recorded using a tocograph, usually in combination with FHR monitoring: cardiotocography (CTG) (Figure 12.4).

External tocodynamometry or tocography does not, however, provide detailed information on the strength of the contractions. In contrast, internal tocodynamometry using invasive intrauterine pressure sensors is able to detect normal and abnormal intrauterine pressure levels. Monitoring of the frequency of contractions is important especially when intravenous (IV) oxytocin is used as excessive uterine activity (hyperstimulation or tachysystole) can cause fetal distress. As the insertion of an intrauterine catheter has higher costs and also potential risks for mother and child and no benefit was shown in a recent Cochrane review, the use of internal uterine pressure sensors is not advised in routine practice.[4]

The *second stage* of labour starts at full dilation of the cervix, includes the descent of the fetus in the birth canal, and ends with the birth of the newborn. Active pushing is best started when the parturient feels the urge to push due to the pressure of the descending fetal head on the cervix and on the rectum (Ferguson reflex). It is therefore advised to wait for approximately 1 hour, after full dilatation of the cervix is achieved, in order to allow for the spontaneous descent of the fetal head. The latter is especially advised in nulliparous women.[1] In a patient with neuraxial anaesthesia in labour and a term, singleton fetus, the second stage can be prolonged by approximately 1 hour. Delayed pushing (waiting 1–3 hours or until urge to push) is associated with higher incidence of spontaneous vaginal delivery in these patients compared to pushing immediately upon entering the second stage.[5]

Women should be encouraged to give birth in the position they find most comfortable. Care should be taken when positioning a patient in supine or lithotomy positions to avoid maternal hypotension and decreased uterine perfusion compression of the great vessels by the gravid uterus ('aortocaval compression syndrome'). This is best achieved by slightly tilting the parturient towards the left lateral position.

As the fetus descends through the pelvis, initially with the sagittal suture in the transverse direction, it will perform an internal

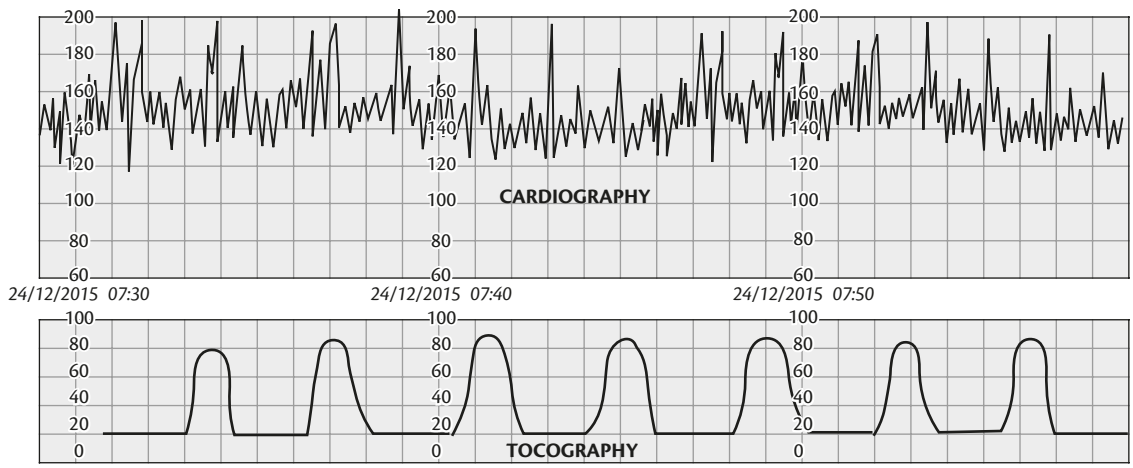

**Figure 12.4** Cardiotocography.

rotation at the level of Hodge III, thereby turning the occiput to an anterior position. The reason for this rotation lies in the anatomy of the human female pelvis offering the largest transverse diameter at the pelvic inlet, and the anteroposterior, vertical diameter at the outlet. As a result, after the delivery of the head, the head will reposition with an external rotational movement to enable the shoulders to pass through the pelvic outlet.[1] There are no clear data on whether an episiotomy influences the fetal outcome.

After the fetal head descends, flexes, and rotates to the occiput anterior position, the labia minora will distend, and crowning will occur. At this time, an opening of approximately 3–4 cm will be seen at the introitus. Should episiotomy be deemed necessary, it should be performed at this stage. The use of episiotomy, however, remains controversial, as it does not appear to protect against sphincter damage in a systematic review by Hartmann et al.[6] The routine use of episiotomy should therefore be avoided.

When the head is delivered, the birth attendant examines the neck of the newborn for the presence of a nuchal cord. If tightly entwined, the cord is cut by the obstetrician at that point. Subsequently, the head is gently pulled towards the sacrum, allowing the anterior shoulder to be born. When moved upwards in the direction of the pubic symphysis, the posterior shoulder follows. In the so-called hands-on method, the perineum is supported by the hand of the birth attendant both during the passage of the head through the perineum, as well as during delivery of the posterior shoulder. Although this method was developed to prevent severe (third- and fourth-degree) perineal tears (Table 12.1), this was not confirmed in comparative studies.[7] In contrast, the use of warm compresses on the perineum is associated with a decreased occurrence of perineal trauma and should be offered to labouring women.[8]

The *third stage* of labour comprises the delivery of the placenta. Although this happens spontaneously in most cases, an active management of the third stage of labour is advisable. This includes:[9]

- prophylactic oxytocin (5–10 units intramuscular (IM) or slowly IV) at delivery of the anterior shoulder
- uterine massage
- controlled cord traction.

**Table 12.1** Degree of perineal tears

| Degree of laceration | Description |
|---|---|
| First degree | Superficial laceration limited to the perineal skin or vaginal mucosa |
| Second degree | First-degree rupture with laceration of the perineal muscles and fascia, with intact anal sphincter |
| Third degree | Second-degree rupture with laceration comprising the anal sphincter |
| 3a | Laceration of the external anal sphincter < 50% |
| 3b | Laceration of the external anal sphincter > 50% |
| 3c | Laceration of the internal anal sphincter |
| Fourth degree | Third-degree rupture with laceration comprising the rectal mucosa |

Active management of the third stage was shown to shorten the third stage, to reduce blood loss and PPH (>1000 mL), and therefore to reduce the incidence of maternal anaemia (haemoglobin <9 g/dL).[9] Randomized trials also have examined the use of oxytocin alone, ergometrine alone, misoprostol alone, and combinations of oxytocin and ergometrine (syntometrine) in active management protocols compared with physiological management where a spontaneous delivery of the placenta is awaited. Trials have also compared the various uterotonics in active management protocols and this has been the subject of a meta-analysis in an extensive recent Cochrane review.[9]

These findings suggest that syntometrine may have a slight advantage in reducing PPH by 500 mL or more (relative risk (RR) 0.74; 95% confidence interval (CI) 0.65–0.85) and possibly by 1000 mL or more (RR 0.79; 95% CI 0.59–1.06), oxytocin alone is also very effective and does not have the adverse effect profile (nausea, vomiting, and hypertension) that is frequently associated with preparations containing ergot.

This review further demonstrates that increasing the IM dose of oxytocin from 5 IU to 10 IU raises the effectiveness of oxytocin. However, no more than 5 IU of oxytocin as a single IV bolus should be given, although it may be repeated after an interval. All IV oxytocin boluses should be administered slowly over several minutes to avoid cardiovascular side effects.

Trials using oxytocin alone showed reduced rates of manual removal of the placenta, whereas those using ergot preparations demonstrated increased rates.

More recently, trials have been performed using a synthetic oxytocin analogue, carbetocin (Pabal®), which has a prolonged action. A review on the subject showed a decreased need for additional uterotonic drugs after a bolus of carbetocin.[10] However, a Cochrane review concluded that carbetocin should not be used as a first-line agent compared to other proven uterotonic agents, in view of the reduced availability and increased costs associated with carbetocin.[11]

Misoprostol is a low-cost, heat-stable uterotonic drug in pill form and therefore potentially an excellent agent for prophylaxis in the third stage of labour. Unfortunately, randomized trials have shown it to be inferior to injectable uterotonics.[12] Adverse effects, such as shivering and fever, are common and in regimens using higher doses, nausea, vomiting, and diarrhoea occur more frequently. The presence of prostaglandin-induced pyrexia and shivering in the postpartum period may lead to confusion in the diagnosis of septic complications.[13]

Cord clamping is best delayed (30–90 seconds, maximum 120 seconds) in preterm neonates as it is associated with fewer neonatal transfusions, less hypotension, and less intraventricular haemorrhages.[14] However, in term deliveries the advantages of delayed cord clamping are less clear. On one hand it results in a higher level of neonatal haemoglobin and iron levels, on the other hand it increases the incidence of jaundice. Therefore, delayed cord clamping in term infants, is not routinely advised and should be individualized.[15]

## Normal and prolonged third stage

The length of the third stage itself is usually 5–15 minutes. However, the absolute time limit for delivery of the placenta, without significant bleeding, remains unclear. Placental retention or

prolonged third stage is defined as a placenta that is not delivered 30 minutes after the birth of the baby.[1] The main complications associated with this condition are uterine atony, maternal PPH, and subsequent hypotension. PPH may cause anaemia and should be corrected with oral or IV iron or by transfusion if appropriate (see Chapter 35 and Chapter 48). The duration of hospitalization may be prolonged if the patient is anaemic, and the establishment of effective breastfeeding may be hampered.[16]

The pregnancy-related (direct) maternal mortality rate in the United States is approximately 7–10 women per 100,000 live births and it is estimated that 8% of these deaths are caused by PPH.[17] In the developing world, several countries have maternal mortality rates in excess of 1000 women per 100,000 live births, and World Health Organization statistics suggest that 25% of maternal deaths are due to PPH. Therefore, an active management of the third stage is advised as discussed previously. Emptying the bladder and actively rubbing the uterus are an integral part of active management. If despite these measures the placenta is not delivered after 1 hour, additional uterotonic drugs (prostaglandins)[18] and operative manual removal of placenta and exploration of the uterine cavity needs to be considered. The clinical management in case of retained placenta is summarized in Box 12.1.

As mentioned earlier in this section, the most common definition for placental retention is non-delivery of the placenta for more than 30 minutes. This is an arbitrary definition, and management is greatly influenced by the clinical assessment of whether significant bleeding is occurring. This bleeding may be visible or may manifest only by the increasing size of the uterus, filled with blood and clots. In the absence of any evidence of placental detachment, one should also consider the diagnosis of complete placenta accreta or a variant. This condition may present with bleeding if only a portion of the placenta is abnormally implanted.

Ensuring that the bladder is empty speeds up the delivery of the placenta and at least aids in the assessment and control of the uterus. Ideally, women should have an empty bladder at the start of the active second stage of labour. This usually occurs naturally because of pressure from the presenting part and maternal expulsive effort. Encouraging the woman to attempt to void late in the second stage or following delivery is not unreasonable, although this may be difficult. Alternatively, a single sterile catheterization can be performed. Emptying the bladder is mandatory before any attempt at assisted vaginal delivery.

A number of trials have evaluated the role of injection drugs and/or fluids into the umbilical cord in the management of retained placenta. This procedure takes time and should only be attempted in women not experiencing significant bleeding. Tested injection fluids into the umbilical cord vein include isotonic sodium chloride solution (normal saline), oxytocin and saline, prostaglandin and saline, misoprostol and saline, and dextran-70. The studies comparing injection of oxytocin (commonly, 10 IU) and saline (commonly, 20 mL) with expectant management (odds ratio (OR) 0.7; 95% CI 0.48–1.02) or saline injection alone (OR 0.59; 95% CI 0.43–0.82 and number needed to treat 8; 95% CI 5–20) suggest that this practice indeed reduces the need for manual removal of the placenta. However, misoprostol (oral or rectal) could be at least as effective in this setting and the effect of injecting oxytocin in the umbilical vein showed little or no effect in the high-quality trials.[19,20] This intervention seems therefore only reasonable in stable women with minimal bleeding while preparations for a manual removal are being made.

Manual removal of the placenta (Figure 12.5) is warranted if the above manoeuvers have failed to deliver the placenta or if significant bleeding occurs. The retained or partially detached placenta interferes with uterine contraction and retraction and leads to bleeding. The risk of significant PPH increases the longer the placenta remains *in situ* and is increased sixfold if the placenta remains undelivered after 30 minutes.

To safely perform a manual placental removal, it is mandatory to perform this in an operation theatre. The choice of type of anaesthesia (neuraxial or general) that is required should depend upon the clinical urgency of the situation and the presence of

**Box 12.1** Management summary for retained placenta

1. Empty bladder and massage uterus
2. Consider umbilical vein injection of oxytocin (10 IU in 1–2 mL saline) in stable women
3. Consider alternative uterotonics (sulprostone, Hemabate®, misoprostol)
4. Insert IV line (2 large-bore cannula if bleeding actively) and take blood samples for haemoglobin, clotting and cross match)
5. Provide adequate anaesthesia in theatre
6. Attempt manual removal
7. Check the uterine cavity using ultrasound to ascertain that all placenta and fetal membranes have been removed
8. Palpate and massage uterus until firm, continue uterotonic drugs
9. Proceed to curettage, preferably under direct ultrasound visualization if incomplete manual removal
10. Consider diagnosis of placenta accreta
11. Administer antibiotics
12. Quantify fetomaternal transfusion in Rhesus D-negative patients before anti-D administration
13. Monitor patient for increased risk of PPH.

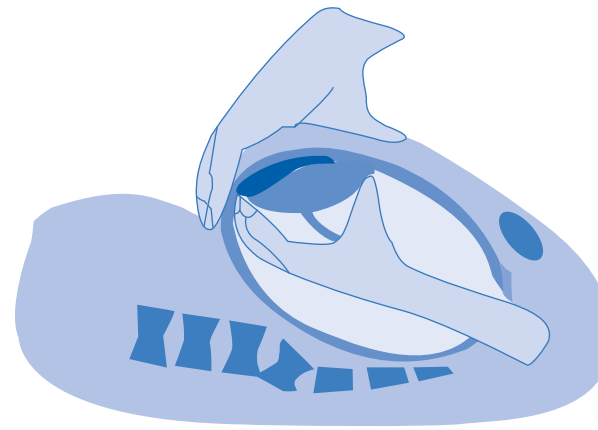

**Figure 12.5** Manuel removal of the placenta (manoeuvre of Credé).

contraindications to neuraxial anaesthesia such as hypovolaemia or coagulation abnormalities. If spinal anaesthesia is chosen, inexperienced anaesthetists often block too low, thinking that only uterine anaesthesia is required. The block should be high enough for the patient to tolerate the hand in the fundus (e.g. 2.4 mL 0.5% bupivacaine). The cessation of an oxytocin infusion or the administration of uterine relaxants to promote uterine exploration and manual removal is of questionable value and may lead to increased bleeding. Ultrasonography is useful in many cases in order to evaluate the uterine cavity, to instrument the uterus without the risk of perforation, and to assess the completeness of the removal after the procedure.

When possible, an elbow-length glove is worn and attention is paid to asepsis. Antibiotic prophylaxis (cefazolin 2 g IV) is best administered in the absence of contraindications. The perineum and vagina must be prepared and disinfected. The vaginal hand may be immersed in povidone-iodine solution (Proviodine®) or in a chlorhexidine crème (Hibitane®) to facilitate entry. The hand is passed into the vagina through the cervix and into the lower segment following the umbilical cord. Care is taken to minimize the profile of the hand as it enters, keeping the thumb and fingers together in the shape of a cone to avoid damage to the soft tissues, especially the cervix.

The non-vaginal hand is used to hold the uterus at its fundal part. If the placenta is encountered in the lower segment, it is removed. If the placenta is not encountered, the placental edge is sought. Once found, the fingers gently expand the space between the placenta and uterus and shear off the placenta. The placenta is pushed to the palmar aspect of the hand and wrist; and when it is entirely separated, the hand is withdrawn. Ensure that an oxytocin infusion (e.g. 40 IU/1 L Ringers' lactate at 125 mL/unit) is running rapidly as the hand is withdrawn in order to encourage strong uterine contraction and subsequently perform uterine massage. Care must be taken to remove all the fetal membranes. Once uterine contraction is established, the placenta and membranes are examined by the operator to determine whether further exploration or curettage is necessary.

## Obstructed labour and delivery

Obstructed labour is a first- or second-stage phenomenon in women whose labour is prolonged. A prolonged first stage exists when no progression in dilatation and descent occurs during 2–4 hours.[1] The reason why labour becomes prolonged or obstructed may be due to one of the 'Ps' referred to earlier—passenger, passage, and powers—and is summarized in Table 12.2:

- *Passenger*: the fetus is the 'passenger' travelling down the birth canal. Prolonged labour may occur if the fetal head is too large to pass through the mother's pelvis, or the fetal presentation is abnormal.
- *Passage*: the birth canal is the 'passage', so labour may be prolonged if the mother's pelvis is too small for the baby to pass through or if the pelvis has an abnormal shape, or in case there is a tumour (e.g. fibroids) or other physical obstruction in the pelvis.
- *Powers*: inadequate 'power', due to poor or uncoordinated uterine contractions, is a major cause of prolonged labour. Either the uterine contractions are not strong enough to efface and dilate the cervix in the first stage of labour, or the muscular effort of the uterus is insufficient to push the baby down the birth canal during the second stage. Another important component of the 'power' is the active maternal 'pushing' effort during the active second stage. This can be reduced due to maternal exhaustion or interfering muscular, respiratory, or cardiovascular conditions.

**Table 12.2** Causes of prolonged or obstructed labour

| Passenger | Passage | Powers |
|---|---|---|
| Large head (cephalopelvic disproportion):<br>◆ Macrosomia<br>◆ Macrocephaly<br>◆ Hydrocephaly | Bony pelvis abnormalities:<br>◆ Malnutrition<br>◆ Deformation (trauma, poliomyelitis, etc.) | Inadequate contractions:<br>◆ Regional anaesthesia<br>◆ Induced labour (less effective contractions) |
| Malpresentation, malpositioning, multiple pregnancies:<br>◆ Brow, face, shoulder<br>◆ Persistent malposition<br>◆ Locked twins<br>◆ Conjoined twins | Soft tissue abnormalities:<br>◆ Tumour (fibroids)<br>◆ Infections<br>◆ Scars (genital mutilation) | Insufficient/ineffective maternal effort:<br>◆ Maternal exhaustion,<br>◆ Maternal respiratory, neuromuscular or cardiovascular condition |

A cardinal clinical sign for the diagnosis of obstructed labour is when the widest diameter of the fetal skull remains *stationary* above the pelvic brim because it is unable to descend. This can be clinically detected by careful palpation of the mother's abdomen as the uterus relaxes and softens between contractions, but an internal examination is usually required to confirm the diagnosis and determine the cause of the arrest.

Uterine contractions are considered adequate when they occur every couple of minutes and last for at least 30 seconds. Insufficiently frequent or strong uterine contractions are more often seen in a patient with neuraxial analgesia containing opioids.[21] The contractions can then be optimized either by artificially rupturing the fetal membranes (AROM; see 'Induction of Labour') (Figure 12.6) if the membranes are still intact, or by exogenous administration of oxytocin according to local institutional protocols.

Oxytocin (derived from the Greek word *oxys tocos*, meaning 'fast birth') is a mammalian neuropituitary hormone that acts primarily as a neuromodulator in the brain but also plays roles in sexual reproduction, in particular during and after childbirth. It is released in large amounts after distention of the cervix and uterus during labour, facilitating birth, maternal bonding, and, after stimulation of the nipples, breastfeeding. Oxytocin effects are regulated by complex positive feedback mechanisms (Figure 12.7).[22]

Cephalo-pelvic disproportion (CPD) is present when there is a disproportion between the head of the fetus and the birth canal. CPD means it is difficult or impossible for the fetus to pass safely through the mother's pelvis due either to a maternal pelvis that is too narrow for that fetal head, or due to a fetal head that is relatively too large for the mother's pelvis. Small (or contracted) pelvises are more frequent in developing countries, on one the hand due to malnutrition in childhood persisting into adult life, and on the other hand due to underage sex and marriage. CPD causes

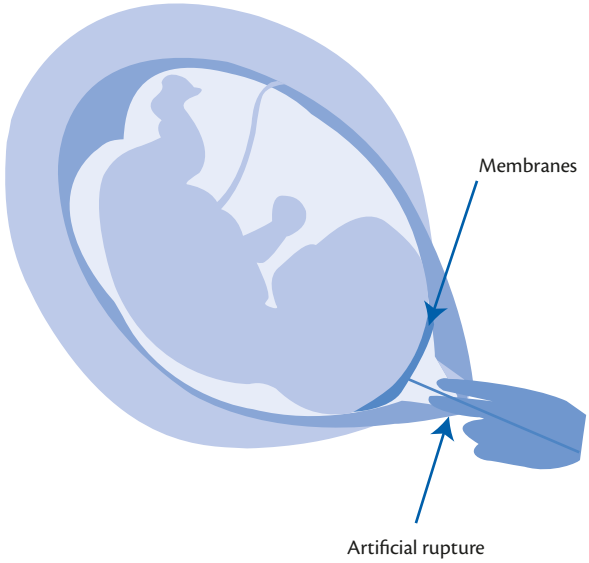

**Figure 12.6** Artificial rupture of membranes (AROM).
Courtesy of S. De Bisschop.

a prolonged first and second stage, which yields an increased risk for fetal and maternal complications. A longer second stage is accompanied by increased occurrence of fetal asphyxia, PPH, perineal laceration, infection of mother and fetus, and is a good predictor for shoulder dystocia (see 'Shoulder Dystocia').

Therefore, if despite adequate stimulation no progression in the partogram is obtained and labour is obstructed during the first stage, the safest management plan is to perform a caesarean delivery (CD). In case of arrest of labour during the second stage, the physician needs to evaluate the possibility of performing an operative or instrumental vaginal delivery as an alternative for CD.

## Induction of labour

Overall, induction of labour should be restricted to medical conditions in which the prolongation of pregnancy yields significant risks for mother or fetus (e.g. post-term pregnancies pursuing 10 days beyond the due date). If induction of labour is performed solely for non-obstetric reasons (e.g. for the convenience of the patient or the caregiver) it will result in increased rates of failures, complications, and morbidity.

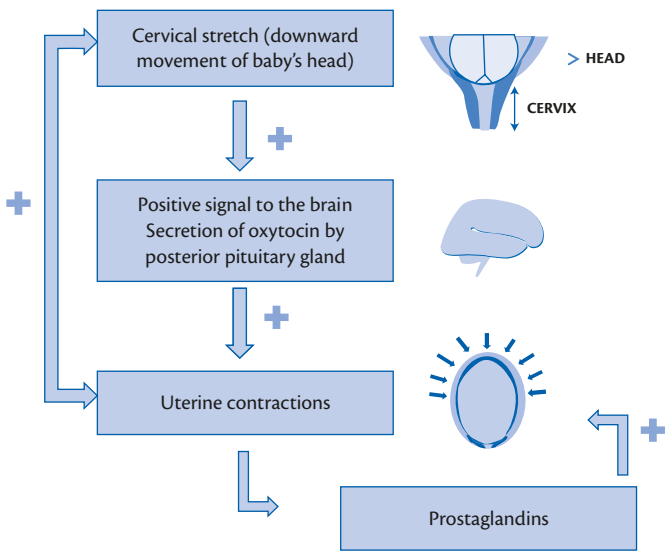

**Figure 12.7** Positive feedback mechanism oxytocin.

If the cervix is unfavourable, labour can be induced by exogenous administration of prostaglandin $E_2$ ($PGE_2$), the synthetic form of the natural hormone involved in the normal initiation of labour.

If, however, the cervix is already partially dilated (2–3 cm) and effaced, labour can be induced by membrane sweeping or amniotomy (Figure 12.6) alone. In many cases, contractions will follow AROM.

If contractions are poor or the cervix fails to dilate, IV oxytocin can augment the induced contractions. This is best preceded by AROM as the uterus responds poorly to exogenous oxytocin in the presence of intact membranes.[23]

There is currently insufficient evidence to assess how to best use oxytocin for augmentation of labour. Based mostly on physiological studies, an oxytocin dilution of 10 mU/mL, initial dose of 2 mU/min (12 mL/h) with incremental increase of 2 mU/min (12 mL every 30–45 minutes until adequate labour) and maximum dose of 16 mU/min have been proposed.[24]

There is significant debate about the ideal setting and timing of induction of labour. Limited information is available on the safety of outpatient management of induction of labour, and larger controlled studies are needed to establish an effective and safe dose and vehicle for $PGE_2$ before use on an outpatient basis can be recommended.

### Membrane sweeping

Membrane sweeping or 'stripping' is commonly practised to induce labour. According to the American College of Obstetricians and Gynecologists (ACOG), stripping membranes increases the likelihood of spontaneous labour within 48 hours and reduces the incidence of induction with other methods.[25] NICE notes that membrane sweeping should be regarded as an adjunct to induction of labour rather than an actual method of induction.[26] It recommends membrane sweeping be offered to all women prior to formal induction of labour, to nulliparous women at 40 weeks of gestational age, and to all women at 41 weeks of gestational age.

### Amniotomy

Amniotomy (Figure 12.6) alone for labour induction is not recommended in most leading guidelines on the subject. According to ACOG, amniotomy used alone for inducing labour can be associated with unpredictable and sometimes long intervals before the onset of contractions.[25] There is therefore insufficient evidence on the efficacy and safety of amniotomy alone for labour induction. Amniotomy combined with early oxytocin infusion compared with amniotomy alone reduces the induction-to-delivery interval significantly. Amniotomy should be postponed if the baby's head is high and the physician/midwife should palpate for the umbilical cord and vasa previa and avoid dislodging the fetal head when performing amniotomy. If amniotomy has to be performed with a high fetal head, this is best done in theatre where there are all the facilities for immediate delivery if cord prolapse occurs.

## Induction in women with ruptured membranes

For women with premature rupture of membranes (PROM) at term, labour is usually induced at the time of presentation, or within 48 hours of presentation, to reduce the risk of chorioamnionitis. Oxytocin is the method of choice, especially if the Bishop score is favourable. Vaginal $PGE_2$ is globally regarded as an appropriate, safe, and effective induction method for women with PROM. In a randomized study of labour induction in women with PROM at term, a single dose of intravaginal misoprostol was necessary for successful labour induction in 86% of the patients.[27] The same precautions should be exercised when prostaglandins are used for induction of labour with ruptured membranes as for intact membranes.

For women with preterm pre-labour rupture of membranes (PPROM), induction should not be carried out before 34 weeks unless there are additional obstetric indications (like infection or fetal compromise). After 34 weeks, the maternity team and mother should discuss risks to both woman and baby, as well as local availability of neonatal intensive care facilities, before a decision is made about whether to induce labour, using vaginal $PGE_2$.[25] (See also Chapter 33.)

## Mechanical methods

Although they are debated in some countries like the United Kingdom,[26] mechanical dilation methods are effective in ripening the cervix and include hygroscopic dilators, osmotic dilators (*Laminaria japonicum*), Foley catheters, and double-balloon devices. In women undergoing induction with an unfavourable cervix, mechanical methods are associated with a decreased CD rate when compared with oxytocin alone. Multiple studies have demonstrated the efficacy of mechanical cervical dilators but there is insufficient evidence to assess how effective (vaginal delivery within 24 hours) mechanical methods are compared with prostaglandins. Potential advantages of a mechanical method like the Foley bladder catheter include low cost compared with prostaglandins, stability at room temperature, and reduced risk of uterine hyperstimulation with or without FHR changes.[25]

### Prostaglandins

Recommendations for pharmacological induction of labour with prostaglandins also differ. Both prostaglandin analogues (misoprostol and dinoprostone) are regarded as effective for cervical ripening and induction of labour according to ACOG. ACOG states that there is extensive clinical experience with misoprostol and a large body of published reports supporting its safety and efficacy when used appropriately.[25] The US Food and Drug Administration in 2002 approved a new label on the use of misoprostol during pregnancy for cervical ripening and for the induction of labour. In contrast, the UK NICE, states that vaginal $PGE_2$ (dinoprostone) is the preferred method of induction of labour and that misoprostol should only be offered as a method of induction of labour to women who have intrauterine fetal death or in the context of a clinical trial. While, extensively used in clinical practice, Misoprostol is not officially licensed for use in pregnancy in the United Kingdom, because of marketing reasons.[26]

# Intrapartum fetal monitoring

Monitoring of fetuses in labour aims to identify hypoxia before it is sufficient to lead to damaging acidosis and long-term neurological adverse outcome for the baby.[1] The limitations of the different tests available mean that, in order to avoid significant hypoxia, interventions such as caesarean or instrumental vaginal delivery are undertaken when there is concern regarding the fetal condition. Fetal monitoring thus leads to higher rates of interventions. (For greater detail, refer to Chapter 6.)

The assessment of the fetus during labour therefore depends on a careful consideration of the antenatal course of the pregnancy, the liquor or amniotic fluid (meconium staining), and the heart rate changes of the fetus during labour (reassuring versus non-reassuring or abnormal). Typically, once a woman in labour presents herself at the delivery ward in established labour, the FHR and uterine contractions will be monitored by CTG for at least 30 minutes, and then intermittently. Most accepted lists of indications for *continuous* electronic fetal monitoring during labour include neuraxial analgesia and are listed in Table 12.3.[27]

A normal FHR at term should be between 110 and 150 beats per minute (bpm). A reassuring FHR (Figure 12.4) trace shows normal variability and the presence of accelerations. Variability (Figure 12.8) is defined as a short term ('beat-to-beat') change in FHR and should normally be between 5 and 25 bpm.[28] An acceleration (Figure 12.8) is defined as an increase of the FHR from baseline with 15 bpm lasting for at least 15 seconds. A deceleration is defined as a decrease of the FHR with 15 bpm during at least 15 seconds. A baseline greater than 160 bpm during 10 minutes is defined as tachycardia (Figure 12.9). A baseline beneath 110 bpm during at least 5 minutes or a decline in FHR of 40 bpm, is defined as a bradycardia (Figure 12.10). Decreased variability and so-called late decelerations (Figure 12.11), with a nadir after the contraction has passed, have the strongest relationship with fetal acidosis and

**Table 12.3** Indications for continuous electronic fetal monitoring during labour

| Risk factor | Example |
|---|---|
| High-risk pregnancy identified before labour | Intrauterine growth restriction, preterm labour, post-term pregnancy (>42 weeks), poly/oligohydramnios, multiple gestation, suspicion of (partial) abruption (more than average vaginal blood loss, sonographical presumption, non-reassuring intermittent auscultation) |
| Induced or augmented labour | |
| Obstructed labour | |
| Abnormal fetal presentation | Breech |
| Neuraxial analgesia | Epidural, combined spinal–epidural analgesia |
| Significant maternal condition | Renal disease, diabetes, cardiovascular disease, pre-eclampsia, HELLP syndrome |
| Previous caesarean delivery | |
| Threatened fetal condition | Non-reassuring intermittent auscultation, meconial amniotic fluid, increasing blood loss |

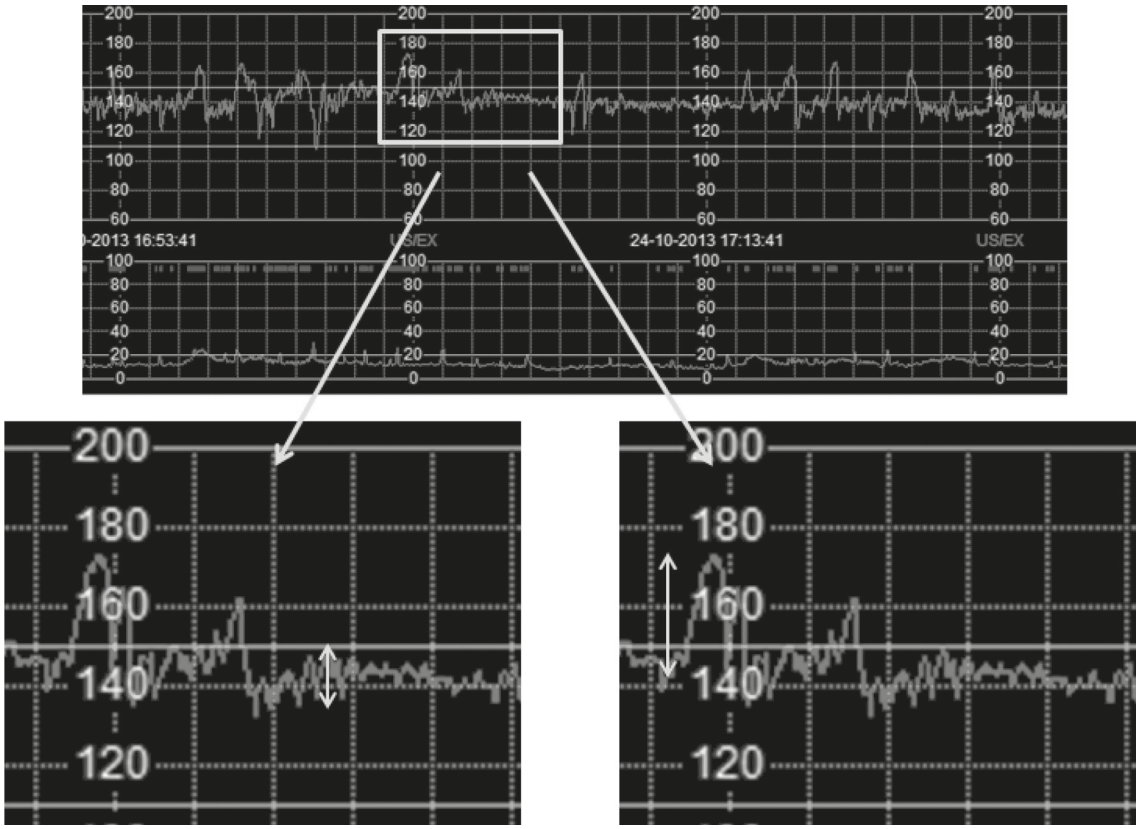

**Figure 12.8** (Lower left) Beat-to-beat variability (5–25 bpm) and (lower right) acceleration.

hypoxia.[28] In case there is no variability or reactivity left, the CTG has become pre-terminal and immediate delivery is mandatory (Figure 12.12).

In case of non-reassuring CTG, fetal scalp sampling for determination of the fetal acid–base state, or more recently fetal electrocardiography with ST analysis (STAN®) can help to identify compromised fetuses at risk for perinatal asphyxia. A normal ST waveform demonstrates a sufficient fetal oxygen supply. During hypoxia the T-wave amplitude of the ECG increases and the STAN® monitor displays an automatic 'ST Event' alert (Figure 12.13).

The STAN® method is a combination of standard CTG parameters and ST analysis. If there is a significant change in the ST interval and a 'ST event' alert is displayed, actions are recommended according to clinical guidelines. A recent Swedish meta-analysis comparing CTG plus ST analysis with CTG alone concluded that there is currently no evidence that STAN® reduces the incidence

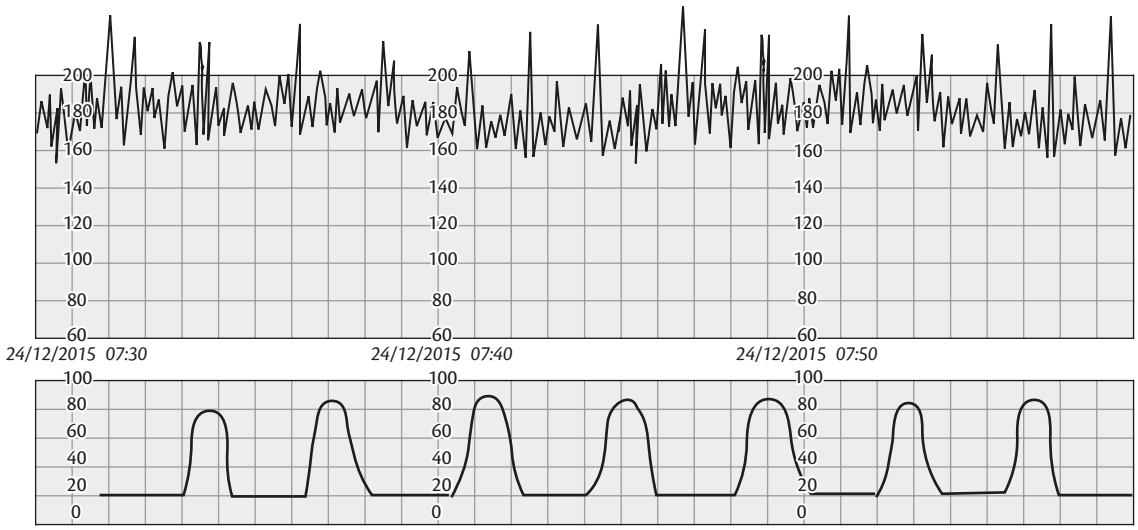

**Figure 12.9** Fetal tachycardia.

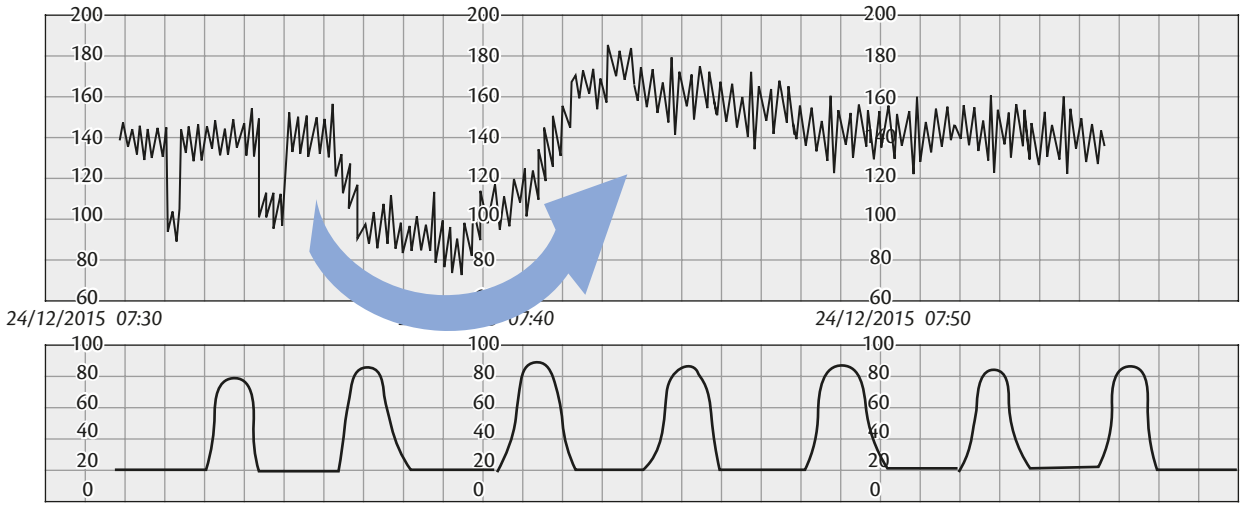

**Figure 12.10** Fetal bradycardia.

of metabolic acidosis (RR 0.96; 95% CI 0.49–1.88). Caesarean and instrumental vaginal deliveries due to fetal distress or other indications were also comparable in both groups but STAN® reduced the number of instances which require scalp blood sampling.[29]

## Shoulder dystocia

Shoulder dystocia is a specific case of dystocia. It occurs when after delivery of the head, the anterior shoulder cannot pass or requires significant manipulation to pass below the pubic symphysis (Figure 12.14), prolonging the head-to-shoulder interval. It occurs in approximately 1% (range 0.6–1.4%) of deliveries.[1] Clinically, shoulder dystocia is recognized by non-emergence of the anterior shoulder during a routine delivery and is sometimes preceded by the so-called turtle sign (the 'bobbing' or appearance and immediate retraction of the fetal head during maternal effort and expulsion).

In shoulder dystocia, it is the chin that presses against the walls of the perineum of the parturient due to the shoulder being impacted behind the pubic symphysis, causing the so-called turtle sign (Figure 12.14).

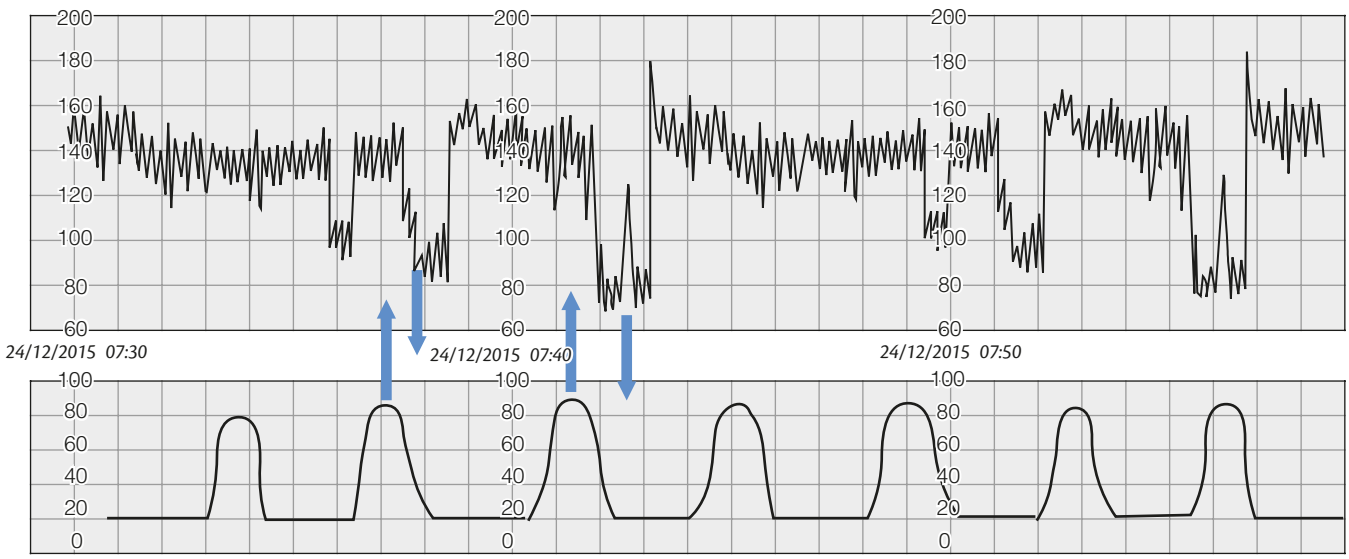

**Figure 12.11** Late deceleration.

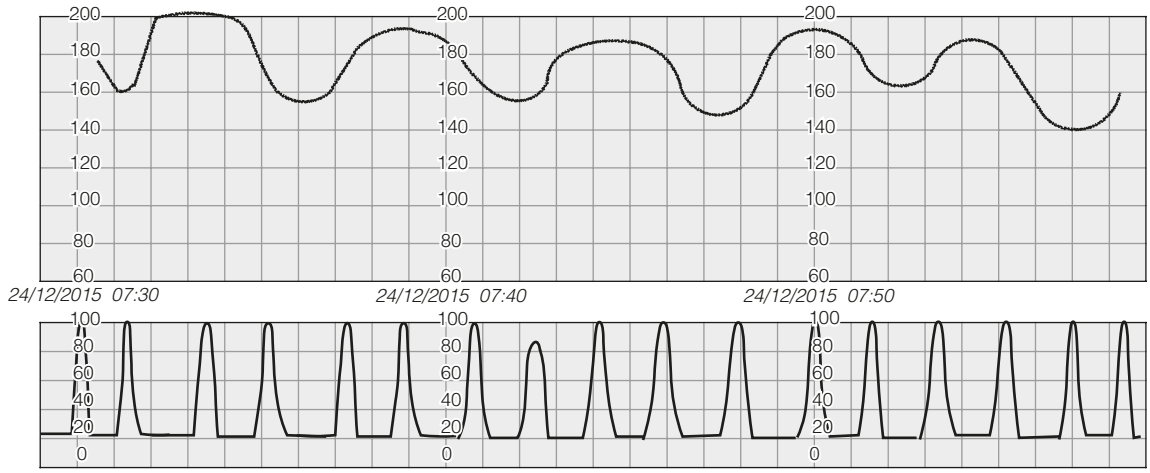

**Figure 12.12** Preterminal cardiotocography.

Shoulder dystocia is an obstetric emergency, and fetal demise can occur if the infant is not delivered within minutes. Indeed, once the head is born, the umbilical cord is being compressed within the birth canal with almost complete cessation of blood flow. As a result, the cord blood pH declines by approximately 0.04 units/min. On the one hand this means the obstetrician has time to resolve the dystocia, on the other hand it means that if the interval is prolonged, severe damage to the fetus can occur as a result of decreased umbilical blood flow. Additional morbidity can be the result of inadvertent excessive pulling on the fetal head, or result from the manipulation and manoeuvers required to deliver the shoulder and complete the delivery (Box 12.2).

The major concern of shoulder dystocia is damage to the upper brachial plexus supplying the sensory and motor components of the shoulder, arm, and hands. The ventral roots (motor pathway) are most prone to injury, as they are in the plane of greatest tension (anterior, sensory nerves are somewhat protected due to the usual inward movement of the shoulder).

The major risk factors for shoulder dystocia are summarized in Table 12.4.[30] Shoulder dystocia often (50%) occurs in the absence of any risk factor. Therefore, it is advised that all personnel assisting childbirth should be trained in managing cases of shoulder dystocia and that at least one clinician experienced in the management of shoulder dystocia is available at every delivery.

The most studied risk factors for shoulder dystocia are maternal diabetes and fetal macrosomia. If the birth weight of the infant was between 4250 and 4500 g, the frequency of shoulder dystocia

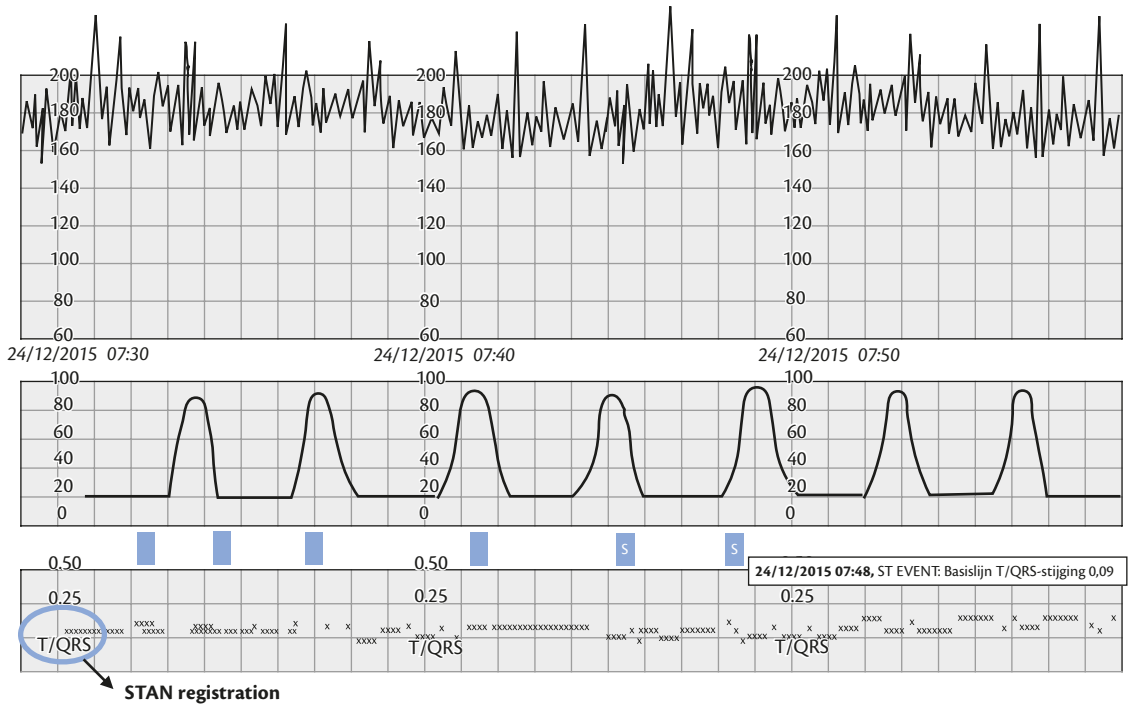

**Figure 12.13** ST event.

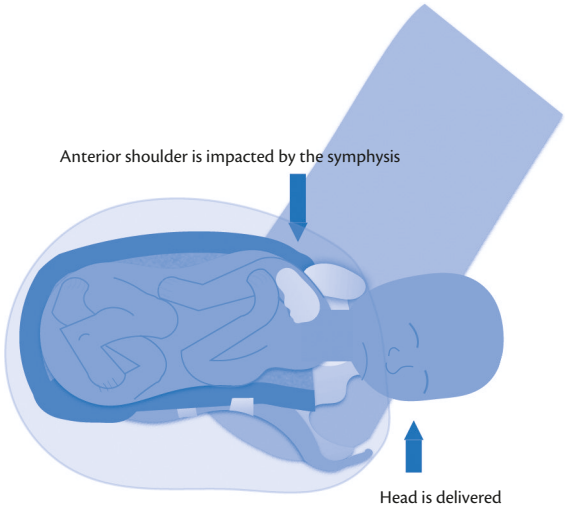

**Figure 12.14** Turtle sign.

was 9.1% if the mother was not diabetic and 16.7% in diabetic mothers in a large Californian cohort.[31]

Many manoeuvers have been developed and modified to facilitate the delivery of the anterior shoulder in cases of shoulder dystocia including:

- *Episiotomy*: although the problem of shoulder dystocia is related to the bony pelvis and not the soft tissues, the space created with an episiotomy (Figure 12.15) may facilitate further internal manoeuvers. An episiotomy can be difficult to perform in these cases due to the impaction of the fetal head tightly to the perineum. In these cases, a scalpel may be helpful.
- *McRoberts' manoeuver*: this manoeuver involves hyperflexion and exorotation of the maternal legs, placing the mother's legs tightly to her abdomen with flexed knees (Figure 12.16). This manoeuver widens the pelvis, and flattens the spine in the lower back (lumbar spine level).[32]
- *Suprapubic pressure* (or Rubin I manoeuvre): if McRoberts' manoeuver does not succeed, an assistant applies pressure on the lower abdomen (Figure 12.17, external suprapubic pressure) while the delivered head is gently pulled. The pressure should be applied from the side of the fetal back to move the shoulder of the baby ventrally. The combination of McRoberts and suprapubic pressure are considered first-line manoeuvers in the management of shoulder dystocia and these will resolve the shoulder dystocia in more than 50% of cases.[34,35]

**Box 12.2** Complications associated with shoulder dystocia

- Injury of the brachial plexus: Erb's palsy (affecting C5/6), Klumpke's palsy (affecting C8/T1).
- Fracture of the clavicle/humerus
- Cerebral palsy
- Fetal hypoxia
- Fetal demise
- Maternal vaginal lacerations
- Postpartum haemorrhage.

**Table 12.4** Risk factors for shoulder dystocia

| Antepartum | Intrapartum |
|---|---|
| History of shoulder dystocia | Labour induction/augmentation |
| Prior macrosomic baby | Dysfunctional labour |
| Excessive weight gain | Prolonged first stage |
| Maternal obesity | Prolonged second stage |
| Maternal diabetes | Neuraxial analgesia |
| Fetal macrosomia | Operative vaginal delivery |

If not successful, it is advised to proceed to second-line manoeuvres:

- *Rubin II manoeuvre*: in this manoeuvre (Figure 12.18) the operator will enter vaginally from the back of the delivered head and posterior pressure is applied on the anterior shoulder, which brings the fetus in an oblique position with the head somewhat towards the vagina.
- *Woods' screw manoeuver*: in this manoeuvre the operator enters and applies pressure to the dorsal part of the posterior shoulder, which leads to turning the anterior shoulder to the posterior and vice versa (somewhat the opposite of Rubin II manoeuvre).
- *Removal of the posterior arm* (Jacquemier's or Barnum's manoeuvre): this manoeuvre implies delivery of the posterior shoulder first (Figure 12.19). This is realized by entering the operator's hand and ventrally from the baby, identifying the forearm and hand in the birth canal and gently pulling the posterior arm ventrally over the face of the baby. Once the posterior shoulder is delivered, the anterior shoulder is usually disimpacted easily.

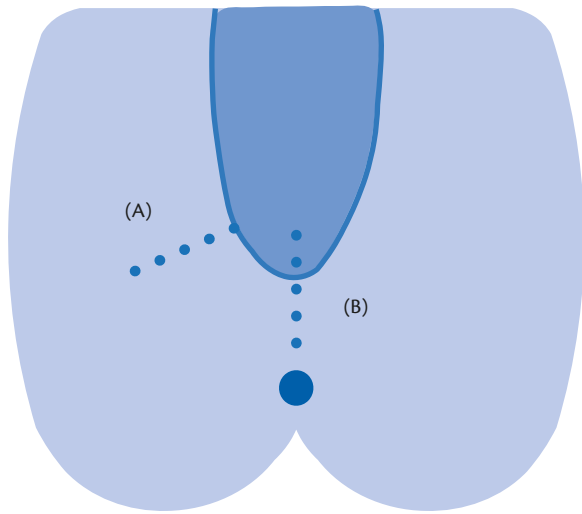

**Figure 12.15** Episiotomy. The dotted line indicates the possible routes of an episiotomy. (A) Mediolateral episiotomy (preferable). (B) Median episiotomy.

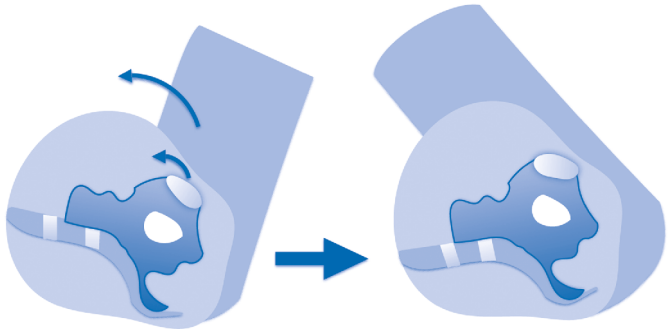

**Figure 12.16** McRoberts manoeuver.
Reproduced From Jacquemyn Y. *Procedureboek Verloskunde. Praktische richtlijnen bij verloskundige problemen.* Leuven: Acco; 2007.

- *Positioning on 'all fours'* (Gaskin's manoeuvre): this manoeuver is named after a midwife, Ina May Gaskin. It involves moving the mother to an all-fours position with the back arched, widening the pelvic outlet. The realization of this measure requires sufficient mobility of the patient and is not always feasible in most patients with neuraxial analgesia.

If the baby is still not delivered despite attempting the second-line manoeuvres described above and after considering repeating the prior steps, more aggressive third-line manoeuvers can be attempted:

- *Zavanelli's manoeuver*: this involves internal cephalic replacement followed by CD. It is realized by flexing the fetal delivered head and correcting the external rotation. Uterine relaxation is usually required.[36]

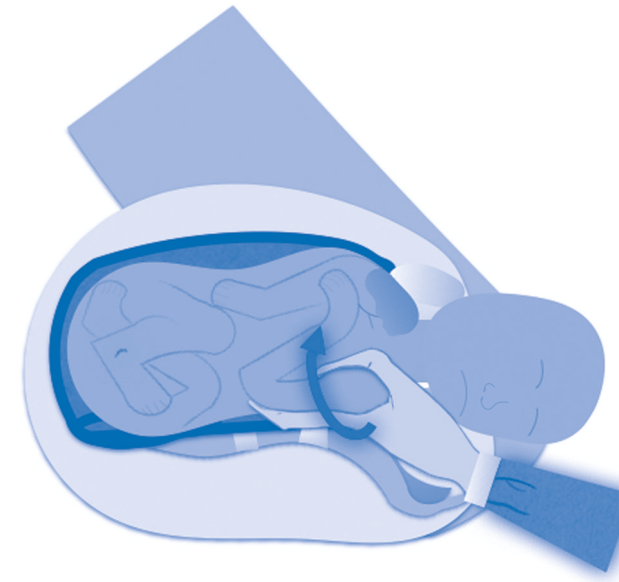

**Figure 12.18** Rubin II manoeuver.
Reproduced From Jacquemyn Y. *Procedureboek Verloskunde. Praktische richtlijnen bij verloskundige problemen.* Leuven: Acco; 2007.

- *Intentional fetal clavicular fracture*: this manoeuver involves applying pressure on the fetal anterior clavicle in order to fracture it. This reduces the diameter of the shoulder girdle, required for passage through the birth canal.[37]
- *Maternal symphysiotomy*: this manoeuvre involves surgical or traumatic separation of the pubis symphysis which makes the opening of the birth canal laxer by breaking the connective tissue between the two pubic bones and facilitates the disimpaction of the fetal shoulders.

HELPERR © ALSO (Advanced Life Support in Obstetrics).

- *Abdominal rescue*, described by O'Shaughnessy:[38] this technique involves performing a hysterotomy to facilitate vaginal delivery of the impacted shoulder.

Different mnemonics (Table 12.5) have been developed to facilitate a systematic approach for training and management of shoulder dystocia. The advantage of proceeding in the order of a logical sequence of action like HELPERR (Advanced Life Support in Obstetrics®) is that it goes from least to most invasive, thereby reducing harm to the mother in the event that the infant delivers with one of the earlier manoeuvers. In case these manoeuvers are unsuccessful, a skilled obstetrician may attempt some of the additional third-line procedures listed above. Intentional clavicular fracture is a final attempt at non-operative vaginal delivery prior to Zavanelli's manoeuver or symphysiotomy, both of which are considered extraordinary treatment measures. Finally, detailed and systematic notification of the order and duration of manipulations reduces the risk for litigation, which is high in obstetric trauma. Specific checklist and forms are available in some units to facilitate this.

## Operative vaginal delivery

Operative vaginal delivery or instrumental delivery refers to a vaginal delivery in which the operator uses a forceps or a vacuum device to assist the delivery of the baby.

Decisions regarding use of instrumental delivery are based primarily upon the maternal/fetal/neonatal impact of these procedures and are always weighed against the alternative options such as CD, expectant management (prolonging the second stage), and augmentation of contractions using oxytocin.[1]

In the United States, forceps deliveries account for 1% of vaginal births and vacuum deliveries account for about 4% of vaginal births.[39] In some countries, like the Scandinavian countries, the use of forceps has been largely abandoned at the expense of vacuum (ventouse) delivery.

There are three main *indications* for operative vaginal delivery:[39]

- *Prolonged second stage of labour*: in nulliparous women, this is usually defined as lack of continuing progress for 3 hours with neuraxial analgesia or 2 hours without analgesia. In multiparous women, it refers to lack of continuing progress for 2 hours with neuraxial analgesia or 1 hour without analgesia.
- *Non-reassuring fetal condition*: suspicion of immediate or potential fetal compromise (e.g. non-reassuring FHR pattern, abruption) is an indication for operative vaginal delivery. The condition to proceed to operative vaginal delivery is that expeditious vaginal delivery can be readily accomplished. If this is not the case, CD may be the safer option.
- *Maternal indications to shorten the active phase*: forceps or vacuum can be used to shorten the second stage of labour if the Valsalva manoeuvre is contraindicated because of maternal cardiovascular or neurological disease, or if pushing is ineffective because of exhaustion or a history of maternal neurological or muscular disease.

To safely perform an instrumental delivery, the operator should be experienced in operative vaginal delivery and the following *prerequisites* should be present:[39]

- The fetal position is cephalic, with the vertex presenting (exception: forceps delivery to assist in the delivery of an after-coming head in vaginal breech delivery (see 'Breech Delivery').
- The cervix is fully dilated.
- The fetal membranes are ruptured.
- The head is engaged in the maternal pelvis, meaning that the largest diameter of the fetal head is below the level of the ischial spine (below Hodge II). With abdominal examination, no more than one-fifth of the fetal head should be palpable abdominally if the vertex is engaged.
- The fetal size has been estimated at less than 4500 g and clinical pelvimetry shows adequate mid and outlet pelvic dimensions.
- Maternal analgesia is satisfactory.
- Maternal bladder is empty.
- The patient consents to the procedure.
- The option of performing an immediate CD should be available if complications arise.
- The operator is experienced and ready to stop the procedure if a reasonable number of attempts are not successful.

If the fetal presentation or position is uncertain, intrapartum ultrasound examination should be performed, as it is more accurate than digital examination in this setting. Studies have shown that digital examination incorrectly defined fetal head position in over 25% of cases about to undergo operative vaginal delivery.[40]

Factors associated with an increased risk of failed operative delivery include occiput posterior position (Figure 12.20), one-fifth of the head palpable abdominally, the presenting part only as far as the ischial spines, excessive moulding of the fetal head, protracted labour, maternal obesity, and macrosomia.

The choice of instrument is determined by level of training and experience, availability, and the specific clinical situation. Further factors that might influence this choice are the degree of maternal analgesia and knowledge of the risks and benefits associated with each instrument. Vacuum devices should not be used to assist delivery prior to 34 weeks of gestation because of the risk of fetal intraventricular haemorrhage. Prior fetal scalp blood sampling or multiple attempts at fetal scalp electrode placement are also relative contraindications to vacuum extraction since these procedures may increase the risk of cephalohaematoma or external

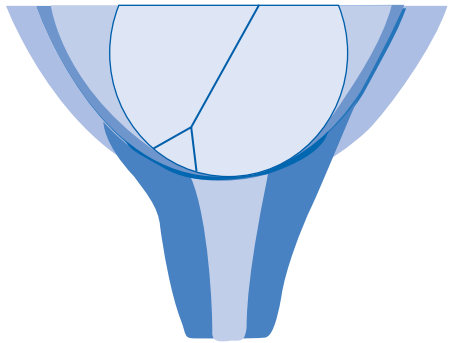

**Figure 12.20** Occiput posterior position.

bleeding from the scalp wound. Overall, vacuum delivery is probably safer than forceps for the mother, while forceps delivery is probably safer than vacuum for the fetus. Vacuum devices are easier to apply, place less force on the fetal head, require less maternal analgesia, result in less maternal soft tissue trauma, and do not affect the diameter of the fetal head compared to forceps. By comparison, the advantages of forceps are that they are unlikely to detach from the head, can be used on premature fetuses, result in less cephalohaematoma and retinal haemorrhage, and do not aggravate bleeding from scalp lacerations (Table 12.6).[39]

There are many different designs for forceps, but all consist of two separate blades that each have the same four components: blade, shank, lock, and handle (Figure 12.21).

There is insufficient evidence to compare different types of forceps.[40] Specific types exist for rotational applications (e.g. Kielland) and forceps application in case of an after-coming head during a vaginal breech delivery (e.g. Piper).

Vacuum devices include soft (silicone, plastic, rubber) and rigid (metal, plastic) cups (Figure 12.22). Smaller disposable hand-pumped devices are also becoming widely available (e.g. Kiwi® omnicup; Figure 12.23).

A meta-analysis of eight trials involving 1076 women compared soft (silicone, plastic, rubber) vacuum extractor cups to rigid (metal, plastic) showed that soft cups were more likely to fail in achieving vaginal delivery (OR 1.63; 95% CI 1.17–2.28).[41] However, there were fewer scalp injuries and cephalohaematomas with the soft cup and no differences between groups with regard to maternal injury.

Trials comparing conventional vacuum devices to the Kiwi Omnicup® showed a statistically significant higher failure rate with the Kiwi Omnicup® compared to conventional vacuum (30.1 versus 19.2% (RR 1.58; 95% CI 1.10–2.24)).[42] It was also associated with a greater number of cup detachments (mean 0.68 compared with 0.28, with 44% compared with 18% having at least one detachment; $P < 0.0001$). There was no difference in the incidence of severe maternal trauma, and there were no cases of serious neonatal injury. Therefore, most obstetricians will only use the elegant but expensive Kiwi Omnicup® device for the 'easier' procedures.

There is paucity of data to assess the benefits and risks of episiotomy in operative vaginal delivery. A large observational study demonstrated that mediolateral episiotomy (Figure 12.15) significantly protected against anal sphincter damage in both vacuum and forceps delivery.[42] Long-term maternal sequelae from operative delivery are primarily related to potential disturbances in urinary and anal function, such as urinary incontinence, faecal

**Table 12.6** Advantages of forceps and vacuum delivery

| Favours vacuum | Favours forceps |
|---|---|
| Less third and fourth degree tears (7.5% vs 14%) | Can be used before 34 weeks |
| Less vaginal wall lacerations (8% vs 26%) | Less cephalohaematoma (5% vs 9%) |
| Less severe postoperative pain (9 vs 15%) | Less retinal bleeding 5% vs 8%) |
| Easier to apply, less training required, less anaesthesia required | Less likely to fail (9% vs 14%) |
| Less facial injury (0.2% vs 1.7%) | Less maternal concern about the babies appearance (see above, cephalohaematoma) |

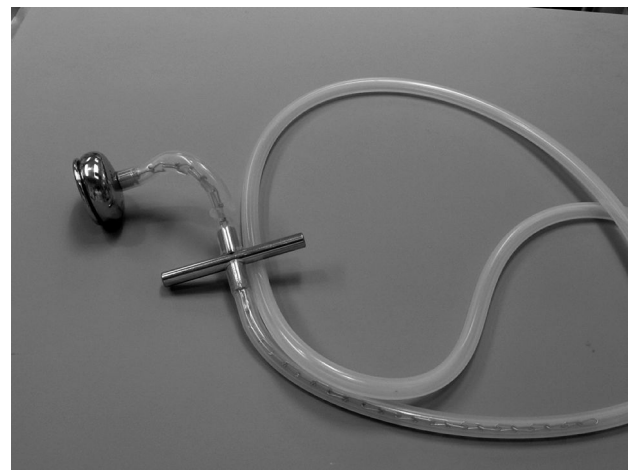

**Figure 12.22** Ventouse.

**Figure 12.23** Kiwi Omnicup® device.

incontinence, pelvic organ prolapse, and, occasionally, fistula formation.

If performed, vacuum application should begin with low suction and be slowly increased to 0.7–0.8 kg/cm$^2$. Traction should only be in the direct line of the vaginal canal and the cup should be positioned correctly to the fetal occiput, at the so-called flexion point. Ideally, vacuum application should not last longer than 5 minutes as the risk for cephalohaematomas increases with increasing duration of application of the vacuum.[42]

After delivery, the neonatal care provider should be informed that the birth was attempted or assisted by vacuum or forceps. Since a serious complication, such as a subgaleal haematoma, can occur within hours of delivery, it is important that the infant care providers be informed by either a reliable charting method or direct notification.

The short-term complications to the fetus from operative vaginal delivery are usually caused by head compression and traction on the fetal intracranial structures, face, and scalp. The most serious complication is intracranial haemorrhage. Virtually all of these complications can also occur in the course of a spontaneous vaginal delivery, but the incidence is lower than with instrumental delivery. The reported incidence of each complication varies widely and depends on a number of factors, such as the equipment used (metal, plastic, vacuum, forceps), fetal station, and the experience of the operator. Developmental outcome appears to be equivalent for both forceps- and vacuum-assisted births.[42]

Recently, next to forceps and vacuum, a new alternative instrument, the Odón device (Figure 12.24), was developed. It is a low-cost device that may be safer and easier to apply than forceps/vacuum extractor for assisted deliveries in developing countries but needs extensive clinical evaluation first.[43]

## Breech delivery

Breech presentation complicates 3–4% of all pregnancies at term (>37 weeks). The problem with vaginal breech delivery is that the head, usually the biggest part of the fetus, has to pass through the pelvis after the body has delivered. The term breech trial[44] has resulted in a change in practice in most countries, and it is now largely recommended that a breech baby is delivered by CD. It is also advised that women presenting with a fetus in breech at 36–37 weeks of gestation should be offered the opportunity to have their baby turned to cephalic near term (external cephalic version).[45] The management summary of breech presentation at term is presented in Box 12.3.

Despite this, vaginal breech deliveries will continue to occur, even in institutions with a policy of routine CDs for breech presentation, because of situations such as precipitous delivery, out-of-hospital delivery, severe fetal anomaly or fetal death, and mother's preference for vaginal birth. Therefore, it is essential for clinicians to maintain the skills of breech delivery. (For greater detail see Chapter 33.)

## Delivery in twins

Twin pregnancies, either monochorionic or dichorionic, are at increased risk of intrapartum complications compared to singletons.[47] The most frequent problems encountered are FHR abnormalities and complications related to dystocia and malpresentation. The delivery of twins therefore requires properly trained staff and a multidisciplinary approach. Globally, the feeling is that twins should be delivered by CD if the presenting twin (twin I) does not have a cephalic presentation.[48] If twin I is cephalic, in the small majority of cases twin II will also be cephalic but the head will be obliquely placed. In other cases, twin II will be breech or transverse. Generally, twin II is the smaller of the twins. Chorionicity is another important determinant of the perinatal risks in twins and should also be taken into account in the decision process of how and when to deliver twins.[49] (See Chapter 33 for more details of the management of twins.)

**Box 12.3** Management of breech presentation at term

- Offer and encourage external cephalic version (ECV) at term.
- There is no simple algorithm for predicting ECV success.
- Tocolysis with a betamimetic drug appears to increase ECV rates.
- If vaginal delivery of breech presentation is chosen, ensure involvement of adequate staff.
- Assisted breech delivery or Bracht manoeuvre may be equally effective.
- Ensure that drill for nuchal arm and entrapped head is in place.
- Maintain competencies through practice at caesarean delivery for breech and through regular manikin training.
- Audit uptake and success rates of ECV.

## Caesarean delivery

A CD is a surgical operative procedure in which one or more incisions are made through the mother's abdomen (laparotomy) and uterus (hysterotomy) to deliver one or more babies, or to remove a dead fetus. The first modern CD was performed by German gynaecologist Ferdinand Adolf Kehrer in 1881.

### Technique

A number of different techniques for CD have been described and compared to each other.

While most CDs are performed under neuraxial blockade, patients should be given a prophylactic histamine 2 receptor antagonist like ranitidine. In some units, oral sodium citrate is given as well. Prior to skin incision, antibiotic prophylaxis should routinely be administered in order to reduce the incidence of endometritis and wound infection (e.g. cefazolin 2 g IV).[50]

The skin incision can be transverse or vertical. In general, a transverse (e.g. Pfannenstiel or Joel–Cohen) incision of approximately 15 cm is preferred for CD. This type of incision results in less postoperative pain, greater wound strength, and better cosmetic results than a vertical incision. On the other hand, vertical incisions sometimes allow faster abdominal entry cause less bleeding and nerve injury, and can be more easily extended if more space is required for access in specific cases (fibroids, abnormal placentation, etc.).

Incision and dissection is performed using the scalpel for sharp dissection or electrocautery device in accordance with the surgeon's preference. The dissection of the subcutaneous tissue layer can be performed blunt (with fingers) of sharp (with knife, dissection scissors of electrocautery). Blunt dissection (Misgav–Ladach technique) is probably the method of choice as it has been associated with shorter operative times and decreased risk of vessel injury.[51]

For the opening of the fascial layer, a small transverse incision is usually made medially with and then extended laterally using blunt digital dissection or surgically using scissors. The rectus muscles are preserved and separated bluntly. Most authors favour using the fingers to bluntly open the peritoneum to minimize the risk of inadvertent injury to bowel, bladder, or other organs that may be adherent to the underlying surface. The abdominal incision should be adequate to allow atraumatic delivery of the fetus. The surgeon and the assistant can manually stretch apart the opening at the angles of the incisions if necessary. Also, sharp additional dissection may be necessary at this point. A routine bladder flap is not required, but some obstetricians choose to perform a bladder flap when a difficult delivery is anticipated (e.g. deeply engaged or large head). In these cases, creation of the bladder flap may help to keep the bladder dome out of the surgical field. In some patients, such as those who are not in labour, it may not be possible to make an incision in the lower uterine segment without first creating a bladder flap. Prior to opening the uterus (hysterotomy), the surgeon should determine the location of the placenta and the fetal lie. A correct estimation of the position can usually be obtained by palpating the uterus. If not, ultrasound (sterile probe) can be

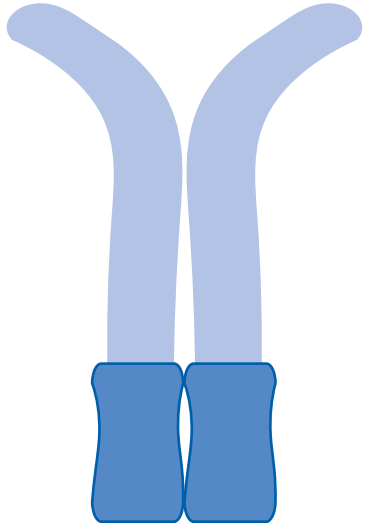

**Figure 12.25** Uterus didelphys.

useful if it is important to avoid lacerating the placenta. The size of the hysterotomy should be large enough to allow atraumatic delivery of the fetus. A transverse lower uterine incision (i.e. Monroe–Kerr or Kerr incision) is generally performed but the type of incision (vertical or horizontal) may vary depending on the position and size of the fetus(es), the location of the placenta, presence of uterine anomalies (didelphys (Figure 12.25), myomata (Figure 12.26)), and the development of the lower uterine segment.

Compared with vertical incisions, transverse incisions result in less blood loss, less need for bladder dissection, easier approximation, and a lower risk of rupture in subsequent pregnancies.[52] If extension of the transverse incision is required, a 'J' or inverted 'T' extension is used as lateral extension is not possible without the risk of laceration of large blood vessels.

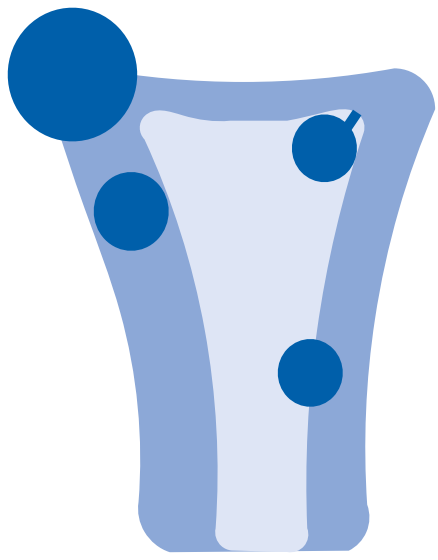

**Figure 12.26** Example of a uterus myomatosus.

A 'classical' incision is a vertical incision that extends into the upper uterine segment/fundus. This type of incision is only rarely performed at or near term because it is associated with more maternal morbidity. In subsequent pregnancies, it is also associated with a higher risk of uterine dehiscence or rupture (4–9%) compared with low vertical (1–7%) and low transverse (0.2–1.5%).

The uterus is opened with a scalpel and care should be taken at that point not to injure the baby or the umbilical cord. Various techniques have been described to perform this safely. The uterine muscle is elevated and carefully thinned, separating the uterine tissue from the fetal membranes or skin. If possible, the fetal membranes are left intact until complete extension of the incision. Once the uterine cavity is entered, the hysterotomy incision can be extended using scissors or blunt expansion with the surgeon's fingers. The latter technique is faster, has less risk of inadvertent trauma to the fetus, and may reduce blood loss and extension of the incision. The use of absorbable staples is not advocated and should be restricted to specific situations (e.g. open fetal surgery and *ex utero* intrapartum treatment (EXIT) procedure).

As a result of impaired uteroplacental blood flow after incision of the uterus, the time lag between the uterine incision and the delivery of the baby influences the blood gases and Apgar scores of the baby and should be kept as short as possible. At the same time, the extraction should be atraumatic for both the mother and baby. Extraction of the baby at CD is usually uncomplicated, but may be made more difficult in cases of oligo- or anhydramnion, extreme prematurity, a deeply impacted or floating fetal head, or an abnormal lie (breech, transverse). For each of these situations, specific techniques have been described, that go beyond the scope of this chapter.

However, in certain circumstances to aid delivery, the obstetrician may request that the anaesthetist relax the uterus. This can be achieved by increasing the volatile agent if a general anaesthetic has been administered. Alternatively, sublingual glyceryl trinitrate two puffs or subcutaneous terbutaline 250 mcg can be given if the patient is awake.

Once the baby is born, the cord is clamped and the baby is handed to a paediatrician or appropriately trained clinician for initial evaluation and stabilization depending on the (expected) condition of the neonate. Especially in premature babies, delayed clamping of the cord could be beneficial.[53]

Once the baby is delivered, IV oxytocin is administered by the anaesthetist to promote uterine contraction. Different regimens have been proposed (Table 12.7), but in order to avoid maternal cardiovascular complications, a slow continuous rather than fast bolus is advocated (5 IU slow IV over 10 minutes).

Manual extraction of the placenta results in more maternal morbidity (bleeding, endometritis, and low haemoglobin) and should be avoided when possible. Instead, gentle cord traction together with massage of the uterus and the use of oxytocin to enhance the contractile expulsion should be used to deliver the placenta. The surgeon then inspects the placenta for abnormalities and completeness. Subsequently, the uterine cavity is explored to ensure that the entire placenta has been removed and no parts of placenta or membranes are left.

Recently, carbetocin (Pabal®) has become available. Its use after CD has been associated with lower need for additional uterotonics

**Table 12.7** Proposed oxytocin regimens after caesarean delivery

| Bolus | Infusion | Combination |
|---|---|---|
| 5 IU slow IV/10 min | Initial dose: 80 IU in 500 mL Ringer's lactate over 30 min<br>Subsequent dose: 20 IU in 1L Ringer's lactate at 125 mL/h | Oxytocin + ergometrine (0.5 mg)<br>No significant reduction in blood loss<br>Oxytocin + misoprostol (200–800 mcg rectal or sublingual). Reduces the need for additional uterotonics<br>Oxytocin + tranexamic acid (10 mg/kg) given before caesarean delivery. Reduces the need for additional uterotonics and the amount of blood loss |

but the higher costs and restricted availability have so far limited the use of this drug.[54]

Closure of the uterus can be performed with or without exteriorizing the uterus based on individual clinical circumstances and personal preference. However, communication between the obstetrician and anaesthetist is important before this manoeuvre is carried out as the peritoneal stretching during exteriorization can cause considerable discomfort if the CD is under epidural and the patient should be warned. Spinal anaesthesia is usually of sufficient density that the patient will not experience painful sensation.

For closure of the uterine incision, a single- or double-layer continuous closure can be opted for. The suture material used is often an absorbable synthetic monofilament (e.g. Monocryl®) or braided (e.g. Vicryl®) suture with sharp or blunt tip needles. The latter type of needle results in less glove perforation incidents, but reduced operative performance. Full thickness suturing, involving the endometrial layer results in less wedge-type healing defects 6 weeks postpartum and may be beneficial. There is significant debate on whether a single- or a double-layer closure of the uterine incision should be performed, and the literature contains conflicting evidence. Single-layer closure results in decreased operation time, but may be associated with increased risk for uterine dehiscence or rupture during a subsequent pregnancy. In a recent systematic review, a locked single-layer closure was associated with a significantly increased risk for uterine rupture compared to a double-layer closure (OR 4.96; 95% CI 2.58–9.52), but the authors of the review suggest that further study in a well-designed randomized trial is necessary on the risks of single-layer uterine closure, given the limitations of the studies in this meta-analysis.[55] There is good evidence for the benefit of non-closure of the visceral and parietal peritoneum (decreased operating time) without clear indications for increased risk for adhesion formation or any other associated complication.[56]

The technique of fascial closure is critical as this provides the majority of wound tensile strength during healing. Care should be taken to avoid too much tension as strangulation of the wound edges could result in more postoperative pain and reduced wound healing quality. For transverse fascial incisions, a continuous closure with slowly absorbable braided suture (e.g. #0 or #1 polygalactin 910) is a common approach among general surgeons and obstetricians also commonly use this technique.[57] The subcutaneous adipose layer is closed with interrupted delayed-absorbable sutures if the layer is 2 cm or more in thickness to avoid the formation of a wound seroma.[58]

Reapproximation of the skin edges may be performed with staples or subcuticular suture; available data from randomized trials do not allow a strong recommendation for one method over the other both in terms of cosmetic result as well as postoperative complications.[59]

## Indications for caesarean delivery

While most CDS were performed traditionally for situations in which a vaginal delivery would jeopardize the health of the baby, the mother, or both, today, an increasing number of women are requesting a CD without medical indication. This 'caesarean on request' procedure is at the centre of a heated debate amongst health professionals and patients. As a result, CD rates have risen all over the world, both in developed as well as in developing countries. In China, a record level of 46% was recorded and many Asian, European, and Latin American countries report levels of 25% and above. In the United States, the rate has also increased significantly, from 21% in 1996 to 33% of all births in 2011. Also, in the United States the rate varied widely between hospitals in 2009 (range 6.9–69.9% of births). In Europe, there are significant differences between countries with the highest figures found in southern European countries: in Italy the CD rate is 40%, in Belgium, it is just below 20%, while in the Nordic countries it is around 15%. Strict guidelines for non-medically indicated CD before 39 weeks have been established[60] (NICE guidelines, ACOG guidelines, Roshan guidelines), as these procedures increase the risk for neonatal morbidity, especially respiratory adaptive problems.

**Table 12.8** Factors affecting the probability of a successful VBAC

| Decreased probability | Increased probability |
|---|---|
| Hispanic ethnicity, African American race | History of prior vaginal delivery |
| Increased maternal age | History of prior VBAC |
| Single marital status | Non-recurring indication for prior caesarean (malpresentation, non-reassuring fetal heart pattern, etc.) |
| <12 years of education | Greater cervical dilation/effacement at admission or rupture of membranes |
| Obesity (BMI ≥ 30 kg/m$^2$) | Spontaneous labour |
| Maternal disease (e.g. hypertension, diabetes) | |
| Delivery at a rural or private hospital | |
| Gestational age > 40 weeks | |
| Labour induction or augmentation | |
| Estimated fetal weight > 4000 g | |

Data from Eden KB, McDonagh M, Denman MA, *et al.* New insights on vaginal birth after cesarean: can it be predicted? *Obstet Gynecol* 2010:116:967–981.

**Table 12.9** Risk factors for uterine rupture in the context of VBAC

| Risk factor | Incidence of uterine rupture | References |
|---|---|---|
| Labour induction (prostaglandins) | 2.4% | Scott et al.[67] |
| Labour induction (oxytocin) | 1.1% | Landon et al.[66] |
| Labour augmentation (oxytocin) | 0.9% | Landon et al.[66] |
| Interval between deliveries < 18 months | 2.25% | Ship et al.[68] |
| Maternal age > 30 years | – | |
| Fetal macrosomia | Relative risk 2.3<br>3.6% after 1 caesarean delivery with no prior vaginal delivery | Elkousy et al. 2003[69] |
| Single layer closure versus double layer closure | ≥ 2-fold increase | Bujold et al.[70] |
| Fever at time of caesarean delivery | Increase<br>Odds ratio 3.5%; 95% confidence interval 1.2–11.3 | Ship et al.[71] |
| Prior uterine rupture (lower segment) | 6% | Ritchie et al.[72] |
| Prior uterine rupture (upper segment) | 32% | Ritchie et al.[72] |
| Induction > 40 weeks | 3.2% | Bangdiwala et al.[62] |

Data from various sources (see references).

## Vaginal birth after caesarean delivery

A woman with a previous CD has two options for mode of delivery in the subsequent pregnancy: a planned CD or a trial of labour after caesarean in order to try to achieve a vaginal birth after caesarean (VBAC). A trial of labour appears to be a reasonable option for most women with a single prior low transverse CD with no other contraindications to vaginal delivery. Contraindications for trial of labour after caesarean include:[61]

- prior uterine rupture
- classical (vertical) uterine scar or complete (from endometrium to serosa) uterine scar from other surgery (myomectomy, interstitial pregnancy, etc.)
- Medical or obstetrical complication precluding vaginal birth
- inability to perform emergency CD
- multiple uterine scars.

VBAC success rates vary in the general population from 60% to 80%.[60] Obese (body mass index (BMI) > 30) women, women with more than one CD in history and women with macrosomic fetuses (>4000 g) have lower success rates.[62] Much research has been dedicated to the development of tools to predict the success rate for VBAC in an individual patient. Most screening tools are not sensitive enough to be clinically useful. One available for clinical use can be accessed freely at www.bsc.gwu.edu/mfmu/vagbirth.html and is based on a large multicentric cohort.[63] Factors affecting the probability of VBAC are listed in Table 12.8.[64]

Complications and safety of VBAC are especially related to the risk of uterine rupture. The overall risk of uterine rupture during trial of labour after CD at term is 0.7% after one previous low transverse CD versus 0.026% with a planned repeat CD.[65] This means that overall there are about five to six additional ruptures per 1000 women undergoing trial of labour after caesarean. The lowest risk is present when labour occurs spontaneously (0.4%). Induction of labour without prior history of vaginal birth, especially when using prostaglandins for cervical ripening, strongly increases the risk for uterine rupture.[66] Other factors associated with an increased risk for uterine rupture are listed in Table 12.9.[62,66–72]

Fetal loss occurs in about 6% of women with uterine rupture at term which translates to an overall risk of intrapartum fetal death rate of about 20/100.000 in women attempting VBAC.[62]

## Conclusion

While the physical process of labour and subsequent delivery has largely remained unchanged over the last centuries, the circumstances and medical monitoring have evolved towards a safe environment for both mother and child.

The role of the anaesthesiologist in the birth process has become crucial not only in providing pain relief when requested or medically indicated, but also in contributing to the multidisciplinary team approach to rare, but potentially fatal obstetrical emergencies.

We hope this chapter helped to familiarize readers with the normal and dysfunctional birth and to enthuse anaesthetists, obstetricians, midwives, and other caregivers to further improve collaboration and qualitative care for the sake of mothers and children.

# CHAPTER 13

# Non-pharmacological methods of pain relief and systemic analgesia in labour

Grace McClune and David Hill

## Introduction

Pain in labour is a nearly universal experience for childbearing women; for many it is the most severe pain they will feel during their lifetime.[1] The management of labour pain, however severe, is one of the major goals of intrapartum care. The experience of labour pain is complex and individual. Women's desires for and expectations of pain relief during labour and delivery differ widely. Fortunately there are many options, both pharmacological and non-pharmacological, for the modification and relief of this pain. Epidural analgesia remains the most effective method of pain control and is a popular choice for many women, but it is not a universal solution.[2] Many women wish to avoid the risks of this invasive procedure and opt for other pharmacological solutions to reduce pain. Others prefer to completely avoid the pharmacological approach if possible, instead opting for complementary approaches to the reduction of pain and suffering. Their choice may be influenced by many factors including availability, possible side effects on themselves, their baby, or both, and the potential influence their chosen mode of pain relief may have on the birth process itself.[3]

A 2008 systematic review of women's expectations and experiences of pain relief in labour demonstrated that women were inadequately prepared for the reality of labour pain. They were therefore unable to make informed choices about pain relief. Women need to be informed antenatally about the options for pain relief in labour and the risks and benefits of the choices available.[4]

As part of the delivery suite team, anaesthetists should appreciate the need for labour analgesia and the merits and drawbacks of the varying options. This chapter will discuss the physiology behind labour pain, the history of analgesia in labour, the current non-pharmacological methods of pain relief available, and the use of systemic analgesia in labour.

## Pain in labour

The International Association for the Study of Pain describes pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage'.[5] The ability of the body to detect potentially tissue-damaging stimuli is an important protective mechanism that involves multiple interacting peripheral and central mechanisms. However, unlike other acute and chronic pain experiences, labour pain is not in most cases associated with pathology, but with the birth of a baby, one of the most basic and fundamental of life's experiences.[6]

Historically, pain was considered by the medical profession to be an inevitable response to tissue damage. No consideration was given to the roles of emotion, past experience, anxiety, or expectation. It would be a mistake to view pain simply as a sensory message of peripheral tissue trauma, coded in peripheral nerves, transmitted in central neural pathways, and decoded in the brain. If this were the only view taken then the management of pain in labour would concentrate on eradication of pain sensation through pharmacological means as the only relevant technique. Methods of decreasing the affective component of pain or of decreasing but not eliminating the sensory component may be dismissed as ineffective if a purely neurophysiological model is adopted.[7]

The gate control theory of pain, first proposed in 1965, suggested that the transmission of pain signals from peripheral nerves through the spinal cord is regulated by other peripheral nerves and by interneurons in the spinal cord and central supraspinal centres. Local processes within the spinal cord either 'open the gate', and allow for transmission to higher centres, or 'close the gate', preventing transmission of the signal. This emphasis on central neural mechanisms forced the medical and biological science worlds to accept the brain and spinal cord as active systems that filter, select, and modulate inputs. This hypothesis has been revised and expanded since its inception; the current theory describes pain as a neuromatrix that integrates multiple sensory and cognitive inputs to produce an output that is recognizable as the sensation of pain. This neuromatrix includes somatosensory, thalamocortical, and neurohumoral components that interact with the emotional and cognitive components of the limbic system and higher cortical centres (Figure 13.1).[8–10]

### Peripheral pain pathways in labour

The detection of noxious stimuli requires activation of peripheral nociceptors and signal transduction into action potentials for conduction to the central nervous system. Nociceptive afferents are widely distributed throughout the body and comprise

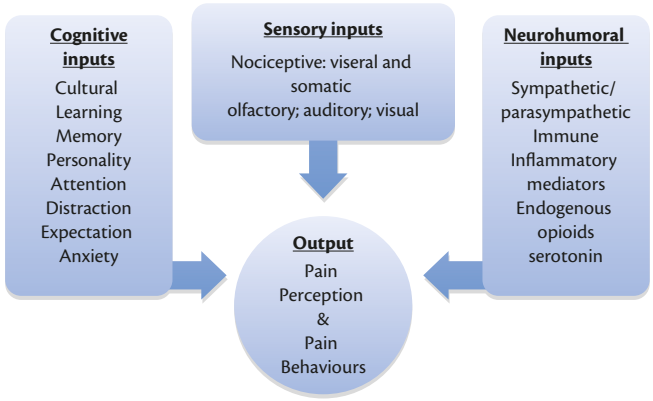

**Figure 13.1** Schematic representation of pain neuromatrix.
Data from Melzack R. From the gate to the neuromatrix, *Pain*, 1999; 6:S121–S126, Copyright © 1999 Elsevier.

both medium-diameter, lightly myelinated A-delta fibres and small-diameter, slow-conducting, unmyelinated C fibres. Polymodal C-fibre nociceptors, which respond to a broad range of physical and chemical stimuli, are responsible for the majority of labour pain.[11]

Pain originates from different sites as the process of labour progresses (Table 13.1). This process can be divided into three stages: the first stage from the onset of cervical change until 10 cm or full dilatation; the second stage from full cervical dilatation until delivery of the baby; and the third stage from delivery of the baby to expulsion of the placenta and membranes. Pain in the first and second stages is considered below.

**Table 13.1** Peripheral pathways and mechanisms of labour pain

| Site of stimulus | Mechanism of stimulus | Peripheral pathway | Site of pain sensation |
|---|---|---|---|
| Uterus | Pressure, distension, and ischaemia leading to release of inflammatory mediators | Visceral afferent fibres accompanying sympathetic nerves to dorsal rami of T10–L1 | Abdomen (upper, mid, and lower)<br>Groin<br>Lower back |
| Cervix | Pressure, dilatation, tearing of tissues, and release of inflammatory mediators | Visceral afferent fibres accompanying sympathetic fibres to dorsal rami of T10–L1 | Groin<br>Lower back |
| Lumbosacral region | Pressure (fetal malposition) | Lumbosacral plexus L5–S1 | Lower back<br>Thigh |
| Bladder | Pressure | Visceral afferent fibres accompanying sympathetic fibres to dorsal rami of T10–L1 | Suprapubic |
| Vagina | Distension and tearing of tissues | Somatic afferent fibres accompanying parasympathetic nerves to dorsal rami of S2–4 | Vagina |
| Perineum | Pressure and tearing of tissues | Pudendal nerve (S2–4) | Perineum |

## First stage of labour

Pain in labour begins with diffuse, poorly localized, cramping visceral sensations. The pressure generated during contractions of the uterus and in stretching of the cervix stimulates high-threshold mechanoreceptors.[12] At the same time, uterine chemoreceptors are activated by the release of bradykinin, histamine, serotonin, acetylcholine, and potassium ions from uterine myocytes due to ischaemia of the tissues during contractions, and to aid cervical ripening and dilatation.[13] Following stimulation of these mechano- and chemoreceptors, the pain signal is transmitted through A-delta and C primary afferent nerve fibres from the uterus to the spinal cord. These fibres accompany sympathetic nerves through the inferior and superior hypogastric plexus, and the lumbar and lower thoracic sympathetic chains; they end in communication with the dorsal rami of T10–L1 (Figure 13.2).[14]

Similar to other types of visceral pain, labour pain may be referred to the abdominal wall, lumbosacral region, iliac crests, gluteal areas, and thighs.[12] Many women experience contraction-related low back pain, for some this becomes continuous between contractions. Some women experience very widespread and diffuse pain sensations, whereas others may feel very localized pain in specific, well-defined areas.[6]

## Second stage of labour

Towards the end of the first stage of labour and during the second stage of labour, distension and traction on the pelvic structures, the pelvic floor, and the perineum results in predominately somatic pain. These stimuli are carried via mostly A-delta fibres passing in the parasympathetic bundle of the pudendal nerve to the dorsal rami of S2–4 and result in sharp well-localized pain.[15] In addition, the parturient experiences rectal pressure and an urge to 'bear down' as the presenting part of the fetus descends into the pelvic outlet (Figure 13.2).[16]

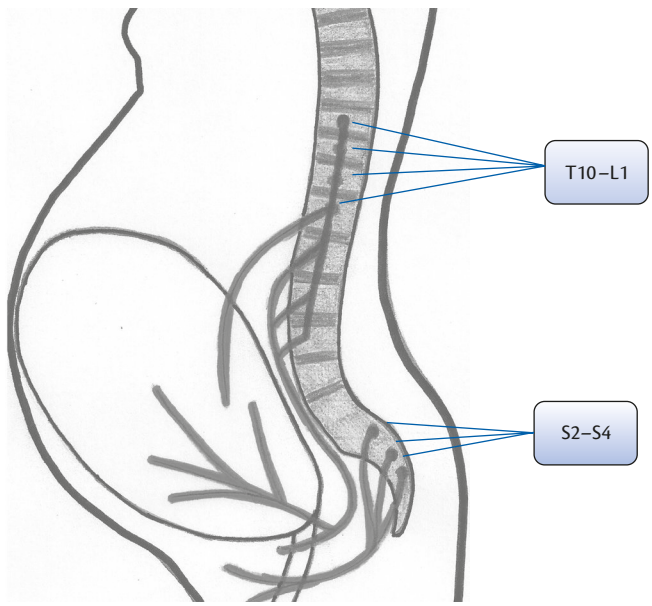

**Figure 13.2** Peripheral pain pathways in labour.

### Sensitization

The increasing intensity of pain commonly observed in labour may be partially attributable to a lowered activation threshold in the mechanoreceptors, and to chemoreceptor stimulation produced by the repeated uterine contractions. This process of sensitization of peripheral nociceptors occurs by way of the inflammatory products released from uterine myocytes during labour and in the process of cervical dilatation. These substances (prostaglandins, cytokines, and growth factors) result in a change in dorsal root ganglion cell numbers, peptide expression and release, receptor, and ion channel expression. For example, inflammatory mediators alter the expression of sodium channels subtypes resulting in more rapid, repetitive firing capabilities and spontaneous afferent activity.[8]

## Central pain pathways in labour

Labour pain transmission includes both the ascending and descending pathways of the central nervous system (Figure 13.3).

### Ascending pathways

Primary afferent terminals in the spinal cord contain excitatory amino acids, peptides, and neurotrophic factors, which act as neurotransmitters and are released by different intensity stimuli.[17] Most of the primary afferent neurons synapse initially in the substantia gelatinosa (the superficial laminae I and II) of the dorsal horn in the spinal cord. Locally projecting interneurons then synapse with the deeper wide dynamic range neurons of lamina V. Secondary neurons whose cell bodies lie in the dorsal grey matter of the spinal cord transmit the stimuli via the spinothalamic tract to the thalamus. There another synapse occurs before transmission reaches the brainstem and cerebellum, where spatial and temporal analysis occurs, and the hypothalamic and limbic systems, where emotional and autonomic responses originate.[18]

### Descending pathways

At the level of the dorsal horn, motor and sympathetic reflex activity is stimulated. Modulation of nociceptive impulse transmission may occur through several complex inhibitory systems activated at many levels of the central nervous system. Inhibitory modulation within the dorsal horn and can be mediated by non-nociceptive peripheral inputs, local inhibitory interneurons, descending bulbospinal tracts, and higher-order brain functions.[6,11]

## Psychological and environmental factors

Psychological factors that influence the experience of pain include attention, memory, or learning, thought processing, beliefs, mood, behavioural responses, and interactions with the environment. In comparison to the non-pregnant state there are a number of factors that can influence the perception of pain in pregnancy. Fear may be intense, particularly in nulliparous women, or in those with a previous bad experience. Generalized anxiety related to the pregnancy, its outcome, or its implications for the woman may enhance her perception of pain. Poor knowledge and/or misinformation may exacerbate this situation. Certain cultures are more emotive and expressive than other, more stoic ones, leading possibly to differences in pain behaviours rather than in the extent of pain felt.[19] Fatigue and general debility, common in late pregnancy, may also contribute to the experience of labour pain. Positive attitudes to pregnancy on the other hand, may increase tolerance to pain, with labour pain being seen as a positive force rather than a destructive one. For example, younger women have a physiological advantage in their tolerance to pain, but older or multiparous women may be more relaxed and less fearful, leading them to tolerate pain better.[11]

In summary, pain is a highly abstract and subjective experience, not simply the transmission of stimuli from nociceptors. Noxious or nociceptive stimuli are centrally received and interpreted through the interaction of a wide variety of emotional,

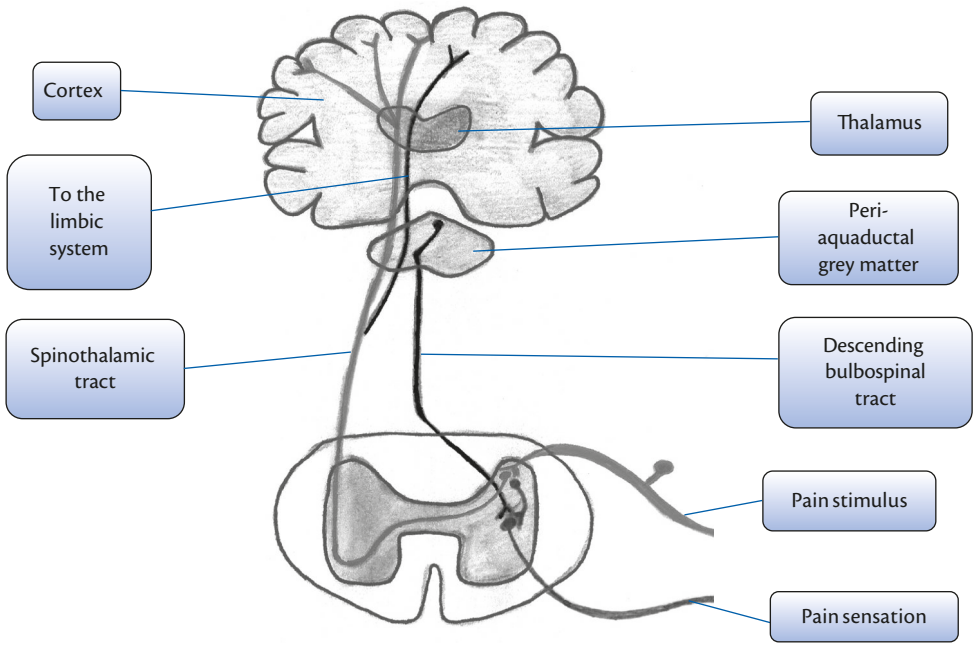

**Figure 13.3** Central pain pathways in labour.

motivational, social, cultural, and cognitive variables unique to the individual. It is this intensely personal interpretation of noxious sensory stimuli transmitted during labour that determines a woman's private experience of pain.[6,12]

## Adverse consequences of labour pain

Pain is undesirable due to its unpleasant physical sensations and emotional effects but also because of a variety of potential adverse physiological and psychological consequences.

### Hyperventilation

Hyperventilation in labour is common and can lead to hypocapnia and respiratory alkalosis. Profound hypocapnia may inhibit ventilatory drive between contractions leading to hypoxia, dizziness, and loss of consciousness. Maternal alkalosis decreases placental blood flow due to uteroplacental vasoconstriction and impairs the transfer of oxygen to the fetal circulation due to an increased affinity for oxygen by maternal haemoglobin and therefore decreased off-loading to the fetus (a shift in the oxygen dissociation curve to the left).[16,20]

### Hypertension

Increases in cardiac output and blood pressure via sympathetic activity and increased venous return associated with uterine contractions may cause hypertension, which can be problematic in cardiac disease and pre-eclampsia.[11]

### Catecholamine release

The neuroendocrine responses to pain and stress (increased maternal catecholamine secretion) can cause vasoconstriction and reduced placental perfusion; reduced fetal oxygenation; fetal acidosis; and fetal bradycardia.[16]

### Delayed gastric emptying

The effect of labour on gastric emptying and acidity is unclear; delayed emptying and increased acid secretion have been suggested.[11]

### Psychological

Severe labour pain has been implicated in contributing to long-term emotional stress, with potential adverse consequences on maternal mental health and family relationships. Women who experience unrelieved pain during labour may be more likely to develop postpartum depression and it is a recognized risk factor for post-traumatic stress disorder.[21,22]

# Non-pharmacological methods of pain relief in labour

There are a wide variety of non-pharmacological approaches to the relief of pain in labour, many of which are taught to women and their birthing partners at antenatal classes. Some methods reduce pain while others help women cope better with their pain by enhancing the psycho-emotional and spiritual components of care. Any technique that promotes mental and physical relaxation will decrease anxiety and catecholamine levels, and should promote increased uterine perfusion, more efficient and less painful uterine contractions, and less fetal distress. Some techniques are simple and can be performed by midwives or birthing partners with little training, others such as acupuncture require specialized accreditation and therefore have larger cost implications.

**Table 13.2** Non-pharmacological methods of pain relief in labour

| Reduction of painful stimuli | Activation peripheral sensory receptors | Enhancement of descending inhibitory neural pathways |
|---|---|---|
| Movement and positioning | Temperature modulation | Childbirth education |
| Counter-pressure | Hydrotherapy | Attention focusing and distraction |
| | Massage and reflexology | Relaxation, music, and audioanalgesia |
| | Acupuncture and acupressure | Hypnosis |
| | TENS | Biofeedback |
| | Sterile water injections | |
| | Aromatherapy | |

Non-pharmacological forms of pain relief can be classified as techniques that reduce painful stimuli, techniques that activate peripheral sensory receptors, and techniques that enhance descending inhibitory neural pathways (Table 13.2).[23] In most cases, there are few randomized control trials supporting the use of these techniques but maternal satisfaction is often high with almost half of women reporting the use of complementary therapies in labour.[24]

## The reduction of painful stimuli

Completely avoiding the painful stimuli that arise from uterine contractions or from pressure on maternal tissues by the fetus is not feasible without pharmacological intervention but techniques to reduce the extent of this stimulation do exist. This is the purpose of practices such as variations in maternal positioning, movement, and counter-pressure.

### Maternal movement and positioning

Labouring women find that they experience less pain in some positions than in others and consequently walk, move, and change positions spontaneously to make themselves more comfortable.[25] Pelvic dimensions vary with differences in maternal position and these changes may help to reduce labour pain. For example, pressure of the fetal head on the sacroiliac joint may be relieved if the parturient moves from a lying down position to being on her hands and knees. Changes in position may also help to accelerate labour by increasing pelvic diameter and facilitating the rotation and engagement of the fetal head.[26] The 'birth ball' is a large inflated exercise ball that has been adopted by many maternity units to aid movement of women in labour and help relaxation. The ball expands the number of positions women can use and offers support for movement, for example, bouncing during contractions.

#### *Efficacy*

Most trials of movement and positioning during the first stage of labour have compared various upright positions with horizontal positions for their effects on pain and labour progress. Women consistently find sitting or standing positions more comfortable than being supine, though they do favour lying on one side with

advanced labour.[27] Studies have also shown reduced pain scores in labour and at delivery in women who use birthing balls.[28,28] Despite anecdotal evidence, there is no trial confirmation that walking produces shorter labours.[30] A 2012 systematic review evaluated the routine use of the supine position during the second stage of labour to other positions and found that women experienced more severe pain in the supine position and had a preference for other birthing positions.[31]

#### *Limitations*

Many labouring women are restricted to bed due to the need for fetal heart rate monitoring or intravenous (IV) fluid and drug administration. In addition, midwives often need to suggest specific positions to accelerate labour or correct fetal or maternal problems (e.g. fetal heart rate decelerations or maternal hypotension). A survey in 2005 found that more than 75% of women did not walk around while in labour. Aside from those who were receiving pharmacological analgesia restricting them to bed, the most common reason women gave for not walking was: being 'connected to things' (e.g. fetal heart rate monitor), or being 'told not to walk around'. However, 60% of the women did report changing positions while in bed to relieve pain during labour.[32]

#### *Implications for practice*

Evidence suggests that in the first stage of labour the use of upright positions, interspersed with other positions, is associated with less painful labour; one popular option for achieving this is the use of birthing balls. Where possible, delivery in a position other than supine produces less discomfort.

### Counter-pressure

Counter-pressure consists of a steady strong pressure applied to the lower back or each side of the hips during contractions. This appears to alleviate back pain in some women particularly when pain is related to an occiput posterior position. There are currently no trials evaluating the effectiveness of this technique.

## Activation of peripheral sensory receptors

The transmission of pain from the uterus, cervix, and pelvic joints is potentially inhibited by the stimulation of large, afferent sensory nerve fibres, which carry impulses towards the central nervous system, and by the release of endorphins and encephalins, which mediate the experience of pain. There are a number of complementary therapies that utilize this process.

### Temperature modulation

Hot packs to the abdomen, back, or perineum or a warm blanket over the entire body in the second stage of labour have the potential to relieve the burning sensation of pain. Hot baths or showers produce a number of beneficial effects including relaxation and increased well-being. A reduction in pain perception occurs as a result of the stimulation of tactile and thermal receptors by warm water.[23] For some women, the use of extreme cold may be similarly useful in decreasing pain perception.

#### *Implications for practice*

The effects of temperature modulation have not been evaluated in controlled trials but observational evidence suggests that these techniques are effective. Provided care is taken not to cause burns to the skin, this practice is simple, inexpensive, and safe.[33]

### Hydrotherapy

Women labour in warm water for mental and physical relaxation and pain relief. Immersion takes place in a pool, tub, or bath, which is larger than a normal domestic bath, and may be use for one or more stages of labour, and for any duration.

#### *Maternal effects*

There are many proposed advantage to hydrotherapy in labour. The buoyancy of water enables women to move more easily. The warmth of the water may induce muscle relaxation and reduce anxiety, decreasing release of catecholamines and stimulating the release of endorphins. Water immersion is associated with improved uterine perfusion, less painful contractions, and potentially a shorter labour with fewer interventions.[34–36] Hydrotherapy also has marked physiological effects on the cardiovascular system; shoulder-deep warm water immersion reduces blood pressure due to vasodilatation of the peripheral vessels and redistribution of blood flow.[37] Immersion during labour also increases maternal satisfaction and sense of control. Subsequently, if the mother is not fearful, oxytocin release is optimized, stimulating effective contractions. In addition, the ease of mobility that water immersion offers may optimize fetal position.[38]

A number of potential maternal adverse effects of water immersion during labour have, however, also been proposed. There is the possibility that it may promote unrealistic expectations about labour, restrict choice of analgesia, reduce contraction effectiveness, and increase perineal trauma, an increased risk to the mother of infection caused by water entering the uterus. Potentiation of bleeding after delivery of the placenta and an increase in the incidence of manual removal of the placenta is also a concern. Injuries to women may occur when attempting to get out of the bath quickly and emergency interventions may be delayed if it is difficult to get the mother out of the bath or if the water does not flow out quickly.[39–41]

#### *Efficacy*

A 2009 systematic review stated that most of the evidence on the use of water immersion is based on observational studies with few randomized controlled trials. These have nevertheless shown immersion in water to significantly reduce maternal pain, the use of epidural/spinal analgesia, and blood pressure as well as demonstrating a decreased incidence in operative delivery and perineal trauma.[42] Factors such as depth of water, size of the pool, and whether the water is still or aerated/whirlpool water have not been compared, as pool design and practice have tended to be based on local availability and customs. Although the use of additives to the water, such as essential oils, appears to be gaining popularity, to date no trial has generated reliable evidence to support or refute the use of any additive.

#### *Neonatal effects*

The fetus potentially benefits from hydrotherapy by way of a relaxed mother, as this maximizes placental oxygen perfusion.[43] Concerns have been raised, however, in regard to neonatal respiratory difficulties, thermoregulation during labour, and infection. The diving reflex (apnoea on expiration with a closed larynx) prevents a healthy baby born in water from drowning. This reflex is stimulated via facial skin receptors triggered as the skin makes contact with the water. Fetal breathing is also inhibited by way of sensors in the oral pharynx, including free nerve endings/taste buds, which

prevents aspiration. Conversely, a compromised neonate born underwater has the potential to gasp before the nose and mouth are above the surface, inhaling bath water into the lungs. Inhalation of even a small quantity of fresh water can be absorbed quickly into the circulation causing appreciable haemodilution and fluid overload.[44] There have been two reports of neonatal death following water-birth attended by a midwife.[42] However, a direct causal link cannot be assumed on the limited evidence available in these cases.

The water temperature of a pool should not exceed the maternal body temperature, as immersing a woman in water above her natural core temperature will result in fetal hyperthermia. High temperatures have been identified as a safety issue by several authors as being associated with fetal mortality and morbidity, based on individual case studies and/or theory.[44–46] It has been suggested that neonatal infection may occur due to cross-contamination from the water and pool, and from the mother. However, a 2009 systematic review concluded there was not a significantly increased risk of infection for the fetus/neonate.[42]

#### *Implications for practice*

Overall, the evidence indicates that hydrotherapy decreases maternal pain levels and reduces the uptake of pharmacological analgesia. There is little evidence to support the concerns over adverse neonatal effects. The UK Department of Health currently recommends that a pool facility should be an option available to women in all UK maternity units, and is promoting water immersion during labour and water-birth as a means of empowering women and is consistent with the current agenda of normalizing birth.[47,48] Hydrotherapy during the first stage of labour can be supported for women at low risk of complications. There is no clear evidence to support or discourage a woman's decision to give birth in water.

### Massage and reflexology

Massage involves manipulation of the body's soft tissues. It is an ancient technique that has been widely employed during labour, to help relax tense muscles and to soothe and calm the individual. However, relatively little study has been undertaken examining its effects in the intrapartum period. Different massage techniques may suit different women: a woman who is experiencing backache during labour may find massage over the lumbosacral area soothing; others find light abdominal massage comforting. Women may vary in their response to massage. Some prefer to be massaged during contractions, which helps to 'spread the pain' while some prefer to be massaged after each contraction to relax and soothe tired muscles. Massage may help to relieve pain by relieving muscle spasm, distracting from pain, providing a sense of relaxation and reducing anxiety, decreasing pain intensity by inhibiting sensory transmission in the pain pathways, or by improving blood flow and oxygenation of tissues.[49]

Pressure applied to the feet has been shown to result in an anaesthetizing effect on other parts of the body. Reflexologists propose that these effects are due to reflex points on the feet corresponding to organs and structures of the body and that pain may be reduced by gentle manipulation or pressing certain parts of the foot.[50] It is claimed that by applying pressure to 'reflex zones', energy blocks or disturbances such as calcium, lactate, or uric acid crystals are reabsorbed and later eliminated. This process is more commonly known as detoxification. Reflexology may also reduce stress and tension.[51]

#### *Implications for practice*

There are few trials evaluating the benefits of massage therapy in labour, those that do exist suggest that massage is a useful therapy in alleviating pain for some women in labour without the risk of adverse effects.[52,53] There is only anecdotal evidence supporting the use of reflexology.[54] Professional training programmes for massage and reflexology therapists vary from country to country and may be undertaken as part of a broader health professional training or as a profession in their own right.[55]

### Acupuncture and acupressure

Acupuncture involves the insertion of fine needles into different, specific parts of the body. Other related techniques include acupressure—applying pressure on the acupuncture point. It uses fingers or small beads instead of needles at the same points on the skin. These techniques are ancient healing arts, which are regarded as conventional medicine in the Far East. The aim is that by stimulating acupuncture points located on the hands, feet, and ears, labour pain is reduced. Several ideas have been presented to explain how acupuncture works. Traditionally acupuncturists believed that health was dependent on the correct flow of energy through the meridians (invisible tracts running through the body). The strength and clarity of these meridians govern the vital health of all the vital organs in the body. If the person is ill, then the energy flow is blocked or unbalanced. The aim is to stimulate the appropriate meridians by using needles, heat, electricity, and pressure at certain points. When these blocks are removed, energy can flow and the body can heal itself.

Since most acupuncture points are either connected to, or located near, neural structures, this suggests that acupuncture stimulates the nervous system, supporting the gate control theory of pain modulation.[56,57]

#### *Efficacy*

For labour pain, the ideal placement of needles depends on the degree and location of pain, the stage of labour and a variety of other factors such as anxiety and fatigue.[56] The evidence for the use of acupuncture in labour is conflicting. Studies into its use have given conflicting results, with some concluding that it is ineffective, while others that it is a valuable analgesic technique. One reason for this may be the lack of standardization of acupuncture points and methods used.[58,59] Recent systematic reviews (2010, 2011, and 2012) of studies into complementary therapies for labour all concluded that acupuncture might play a role in increasing patient satisfaction with pain relief and in reducing the use of other analgesia; but it is unlikely to help reduce pain intensity. When asked, women receiving acupressure state that they experience less pain when compared with controls, but their use of pharmacological analgesia or satisfaction with this analgesia does not seem to be influenced. Acupuncture or acupressure may have different effects at different time-points and these effects may only be transient; increased maternal satisfaction with other methods of analgesia may be the real benefit.[54,60,61]

#### *Implications for practice*

The systematic reviews conclude that there is insufficient evidence on acupuncture to make firm clinical recommendations. This view is supported by the UK's National Institute for Health and Care Excellence clinical guideline on intrapartum care, which state that 'acupuncture, acupressure should not be provided (as

routine care), but women who wish to use these techniques should not be prevented from doing so'.[62]

## Transcutaneous electrical nerve stimulation

A transcutaneous electrical nerve stimulator (TENS) is a device that emits low-voltage pulsatile electrical impulses, which vary in frequency and intensity. In labour, the electrodes from the TENS machine are attached to the lower back, placed about 2 cm over the T10–L1 dermatomes either side of the spinous processes to provide analgesia for the first stage of labour. A second set of electrodes is placed over the S2–4 dermatomes for second-stage pain relief. Low-intensity, high-frequency (100–200 Hz) TENS stimulates the A fibres at these dermatomes blocking pain transmission to the brain. Lower frequency stimulation at 40–60 Hz, causes the release of endorphins, which bind to opiate receptors, increasing pain tolerance.[63,64] Women can alter the amount of current supplied to the electrodes providing some degree of control throughout their labour. TENS can also be applied to acupuncture points or directly to the head by trained staff.

TENS has minimal side effects and may be appropriate for women who have contraindications to other methods of pain relief or where other methods are not available. By reducing anxiety, increasing a sense of control, and by providing distraction, TENS increases a woman's sense of well-being and thereby also reduces pain in labour. TENS may also reduce the length of labour by suppressing the release of catecholamines, which can inhibit the contraction of the uterus and thereby, delay progress. It is contraindicated in patients with a cardiac pacemaker and is not advisable for use in patients with epilepsy and should be discontinued should any skin irritation occur on the electrode sites.[56,65]

### *Efficacy*

A 1997 systematic review of the evidence for TENS in labour found little evidence for the use of TENS.[66] One study, however, found that women reported moderate to good pain relief from TENS when surveyed post delivery, but that pain scores while in labour did not differ when compared to sham TENS. A significantly bigger proportion of women in the TENS treatment group claimed that they would chose to use TENS in future labours compared with those in the sham TENS control group. When considering the use of additional analgesia as a secondary measure of effectiveness there was a small but demonstrable benefit to TENS in a number of studies.[66,67]

### *Implications for practice*

The evidence from randomized trials for analgesic benefits from TENS during labour is not compelling but does hint towards an analgesic-sparing effect and a positive response from women with many choosing to use it again for future births. Experienced practitioners state that TENS may be more effective if initiated in early labour, to allow for the build-up of endorphin production before the pain becomes severe.[67]

## Sterile water injections

The incidence of low back pain in labour is estimated to be anything up to 75%. Sterile water administered intradermally can be used to reduce this pain. Intracutaneous injections of sterile water are used at four sites in the lower back, approximately corresponding to the borders of the sacrum. A small bleb is produced by injection of approximately 0.1 mL of water between the dermal layers of the skin. Two are placed 3–4 cm either side of the lumbar-sacral spine, with the other two sites 2–3 cm below and 1–2 cm medial to the original injection points. Injections may also be given subcutaneously. The exact location of injections does not appear to be critical to their success.[68] The injections themselves are associated with acute somatic pain so they are usually given at the height of a contraction, either sequentially or simultaneously. The injection site pain lasts around 30 seconds and as it begins to subside, so does the referred pain from the viscera, with the analgesic effect lasting for 2–3 hours.[69]

The mechanism of action of this therapy is not well understood. The injection of intradermal sterile water produces irritation in the skin; these changes may trigger the A-delta cutaneous afferent pain fibres leading to endorphin release similar to that seen with acupuncture. Alternatively, hyperstimulation of somatic nerves may overwhelm the visceral component; referred stimulation to relieve referred pain. Another explanation is that it may exert its effect through physiological distraction.[70] Similar injections of normal saline are not associated with such intense pain but do not then produce the subsequent analgesia effects.

### *Efficacy*

Several randomized control trials comparing the effects of intradermal water blocks to placebo or to an alternative non-pharmacological method for the treatment of low back pain in labour have reported that water blocks decrease low back pain in labour.[71–76] However, the authors of a 2012 systematic review of all studies to date felt that the comparatively low total number of participants severely limited the applicability of the evidence to clinical practice.[70]

### *Implications for practice*

Despite this rapidly becoming a popular form of analgesia, there is no robust evidence that it is effective for either intractable back pain in labour or the pain associated with uterine contractions.

## Aromatherapy

Aromatherapy is the use of essential oils, highly concentrated aromatic substances extracted from plants by a process of distillation or cold compression. The mechanism of action for aromatherapy is unclear: the oils are thought to increase the secretion of the body's own sedative, stimulant, and relaxing neurotransmitters (paracrine and endocrine) by activation of the limbic system. They may be massaged into the skin, or inhaled by using a steam infusion or burner.[65]

### *Efficacy*

Studies (in areas outside of obstetrics) investigating psychological and physiological effects of essential oils showed no change on physiological parameters such as blood pressure or heart rate but did indicate psychological improvement in mood and anxiety.[77] One large study looking at the use of aromatherapy in labour reported that half of the women found it 'helpful' in reducing fear anxiety and pain.[78] A 2011 systematic review reported no difference in pain intensity or the use of pharmacological agents when using aromatherapy.[79]

### *Implications for practice*

As aromatherapy is increasing in popularity among midwives and nurses, it is important to note that it may have undesirable side effects such as nausea and headache. Some experts have stated that 'essential oils are as potent as pharmacological drugs and

are equally open to misuse or abuse, whether intended or not … and until more clinical research trials have been undertaken, it would be prudent for midwives to work cautiously with essential oils, using the lowest possible dose and on the least number of occasions'.[80]

## Enhancement of descending inhibitory pathways

Techniques such as antenatal education, relaxation, music, and hypnotherapy aim to engage the brain's inhibitory response to pain, either consciously or subconsciously, potentially reducing the severity of the sensations and helping the parturient to cope with the pain.

### Childbirth education

Antenatal education consisting of individual or group classes is partly designed to inform pregnant women and their partners about the labour and birth process. Amongst other things this education covers analgesia options and 'self-help' measures. The content of these classes and other research done by expectant mothers can help them to identify and understand their own coping styles and preferences and develop their own coping strategies for labour. This influences expectations of labour pain and can therefore be beneficial in helping them to cope with the experience.[56] In one trial, women who received education in the antenatal period were less likely to request epidural analgesia in labour but not less likely to request some form of systemic analgesia.[81]

### Attention focusing and distraction

Many methods of coping with pain involve the conscious participation of the individual in activities that are designed to take their mind off the pain. Attention focusing activates include verbal coaching, visualization, concentration on visual, auditory, or tactile stimuli, and patterned breathing. Most antenatal classes advocate patterned breathing as a means of distraction and of increasing the sense of control women feel in labour.[56] There are no studies that evaluate these techniques as independent variables but surveys would suggest that the majority of women do find them helpful.[82]

### Relaxation, music, and audioanalgesia

Relaxation techniques are based on the practice of developing conscious awareness of muscular tension, releasing that tension, and then maintaining relaxation. Yoga, meditation, and music techniques may all have a calming effect and provide a distraction from pain and tension. Audioanalgesia is the use of music, white noise, or environmental sounds to decrease pain perception. Although there is no strong evidence that it significantly reduces pain intensity and analgesic requirements in labour, there are no adverse effects and it is a popular option for labouring women.[56,83]

### Hypnosis

Hypnosis has been described as a state of narrow focused attention, reduced awareness of external stimuli, and an increased response to suggestions—positive statements used in order to achieve specific therapeutic goals.[84] These suggestions may be verbal or non-verbal and result in apparent spontaneous changes in perception, mood, or behaviour. These therapeutic communications are directed to the person's subconscious and the responses are independent of any conscious effort or reasoning. Women can learn self-hypnosis, which can be used in labour to reduce pain from contractions. Common hypnotic pain relief techniques are 'glove anaesthesia', in which the woman imagines that they have a numb hand that can be used to relieve pain in other areas, or 'time distortion', which allows the women to imagine the contractions becoming shorter and further apart.[85] Recent advances in neuroimaging have led to increased understanding of the neurophysiological changes occurring during hypnosis.[86]

#### *Efficacy*

A 2011 systematic review of trials using hypnosis found that the use of hypnosis was associated with a strong trend in the reduction of requests for pharmacological intervention. In comparison to education and counselling alone, several studies have shown hypnosis to be superior in reducing pain.[56,85,87]

#### *Implications for practice*

There is little or no risk to the use of self-hypnosis in labour in women without a history of psychosis but it requires antenatal training by a trained hypnotherapist.

### Biofeedback

Biological feedback is a term that describes a therapeutic technique where individuals are trained to improve their health and well-being through signals coming from their own bodies, for example, temperature, heart rate, and muscular tension. The aim is that with the aid of electrical instruments to measure response, conscious changes in thoughts and emotions help the individual to gain control over physiological responses. Electromyography, measuring muscle tension, appears to have some positive effects in early labour but shows no benefit as labour progresses.[56]

### Birthing partners and doula

Many women like to have a birthing partner with them during labour and delivery. They provide both physical support, for example, massaging shoulders, help with positioning, support with breathing techniques; and emotional support, for example, reassurance, comfort, listening, and support with decision-making. Many different people can provide this help including fathers, other relations, and friends. Historically, women have been attended and supported by other women during labour. Some women therefore chose to employ the services of a doula, a professional who is trained in childbirth and provides continuous support to a mother before, during, and just after birth. Doula comes from a Greek word that means 'a woman who serves' or 'handmaiden'.[88,89]

#### *Efficacy*

A 2012 Cochrane review on the use of continuous support in childbirth evaluated evidence from 22 randomized controlled trials from 16 countries. Overall, women allocated to continuous support were more likely to have a spontaneous vaginal birth and less likely to have intrapartum analgesia or to report dissatisfaction. In addition, their labour was on average 40 minutes shorter and they were less likely to have a caesarean delivery or instrumental vaginal birth, neuraxial analgesia, or a baby with a low 5-minute Apgar score. The subgroup analyses suggested that continuous support was most effective when provided by someone neither part of the hospital staff nor the woman's social network, and in settings in which epidural analgesia was not routinely available. The review concluded that continuous support from a person who is present solely to provide support, is not a member of the woman's social

network, is experienced in providing labour support, and has at least a modest amount of training, appears to be most beneficial.[90]

### Non-pharmacological approaches to labour pain: summary of key points

- May reduce the intensity of pain sensation but are unlikely to entirely relieve pain. There is limited evidence for their efficacy.
- May help women maintain a sense of control in labour and subsequently cope better with labour pain.
- Have few serious side effects.
- May be combined or used alongside systemic analgesia to increase effectiveness.

## Systemic analgesia for labour

Systemic medications are the most common form of analgesia in labour. These medications are diverse in their mechanisms of action (Figure 13.4). Consequently they display varying efficacy and side effect profiles both for mother and baby.

### Inhalational agents

Inhalation labour analgesia involves the intermittent use of subanaesthetic concentrations of nitrous oxide or other volatile agents. Pain can be relieved while maintaining maternal consciousness and avoiding regurgitation or aspiration of stomach contents. Inhalational agents readily cross the placenta and the concentration in fetal blood soon approaches that of the mother but, since these agents are excreted almost entirely through the lungs, they are readily excreted from the newborn. The efficacy of inhalational analgesia depends on the analgesic strength of the agent and on how quickly it reaches analgesic concentration after the start of inspiration. A rapid offset with complete elimination between contractions would prevent accumulation completely. Nitrous oxide is the best match in current use.

#### Nitrous oxide

Intermittent inhaled nitrous oxide was first introduced to provide labour analgesia in the late nineteenth century and became routine in the 1930s. The precise mechanism of action for nitrous oxide analgesia remains uncertain but it appears to modulate pain stimuli by way of descending spinal cord nerve pathways.[91] Nitrous oxide has a low blood–gas partition coefficient (0.47) and so equilibrates rapidly with arterial concentration, thus the peak analgesic effect of nitrous oxide is at approximately 50 seconds. As the peak effect of uterine contractions is typically at 30 seconds the analgesic effects of nitrous oxide may be out of phase with the pain of contractions. Nitrous oxide can be used alone or to supplement other methods of analgesia.

Worldwide the use of nitrous oxide is very variable. It is widely available in Europe, and in the United Kingdom 60% of parturients choose to use it. This largely results from the ease with which midwives in the United Kingdom can prescribe Entonox® (a 50:50 blend with oxygen, in a pre-mixed cylinder) without involving a physician. Similarly, uptake in Australia and Canada is about 50%. However, nitrous oxide is not routinely available in many European countries (it is only available in one centre in Belgium, for example) or in the United States where only 1% of parturients uses this method of analgesia.[92–95] A reducing valve fitted to the nitrous oxide/oxygen cylinder or to a blender that mixes the two gases from separate cylinders connects to a breathing circuit that has a demand valve connected to a facemask or mouthpiece. This demand valve opens only when the parturient applies negative pressure by inspiring through the mouthpiece or a well-sealed mask covering her nose and mouth.

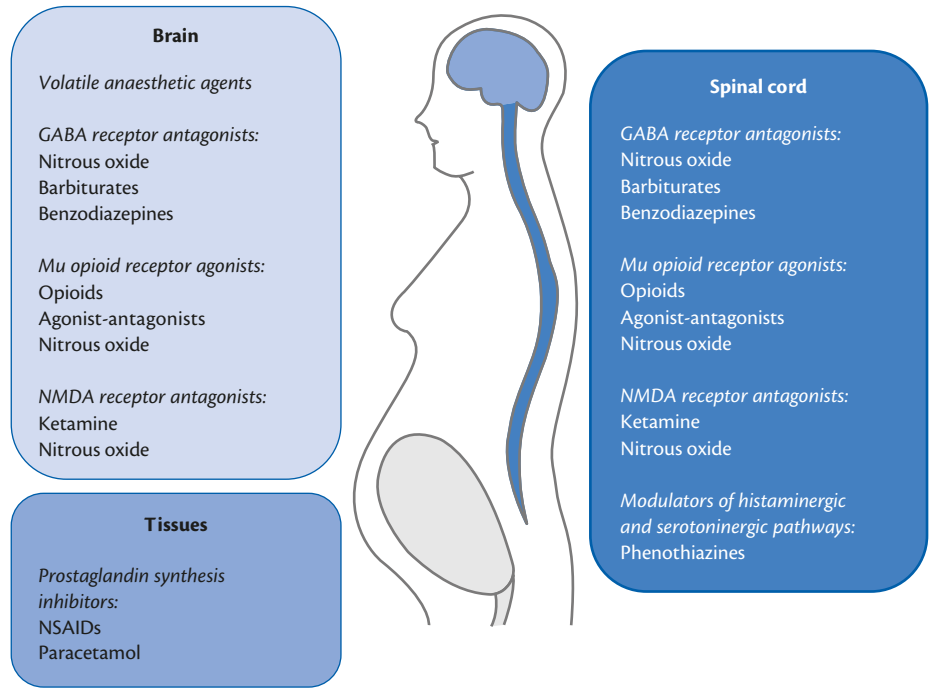

**Figure 13.4** Sites of action of systemic analgesia.

### *Efficacy*

Most efficacy studies of nitrous oxide have compared either its use to placebo (inhaled air), the analgesic benefit of increasing the inhaled concentration, or the effects of adding other volatile agents to the inhaled mixture. A 2002 systematic review of randomized controlled trials looking at the efficacy of inhaled nitrous oxide as labour analgesia concluded that current published work does not provide clear quantitative objective evidence of its efficacy.[91] A consistent finding in studies and surveys of nitrous oxide has been that 30–40% of mothers find its use of no benefit. Studies report conflicting results with regard to any improvement in pain scores of parturients but even those with negative results about analgesia report that many subjects wished to continue to use nitrous oxide after the study period. The majority of women who do report significant benefit state that they would choose nitrous oxide as a form of pain relief for subsequent labours.[91,92,96,97] This suggests that although it may not produce measurable analgesia for labour pain, nitrous oxide does have some benefits, though this may be in part a placebo effect.

Studies of non-pharmacological methods of pain relief suggest that the analgesia from TENS or sterile water injections may be similar to that associated with nitrous oxide use with comparable levels of patient satisfaction. One study found that 90% of women reported similar levels of partial relief from either TENS or nitrous oxide.[98–100] Reductions in pain with inhaled nitrous oxide use seem similar to that of systemic opioids, but inferior to those achieved with epidural analgesia.[101–103] One study directly compared the efficacy of self-administered nitrous oxide to intermittent patient-controlled administration of IV remifentanil. It found the analgesic benefit of nitrous oxide to be inferior to remifentanil.[104]

### *Maternal side effects*

Inhaled nitrous oxide analgesia for labour displays good safety outcomes for both mother and baby. Some women experience significant nausea with the use of nitrous oxide; however, in trials its use does not seem to appreciably affect the rates of maternal nausea or vomiting. It may increase the rate of maternal oxygen desaturation in between labour contractions and maternal drowsiness increases in a dose-dependent fashion. Long-term use of nitrous oxide may result in bone marrow suppression.[91,103,105,106]

### *Fetal and neonatal effects*

Nitrous oxide administration does not adversely affect uterine activity. Studies have failed to show significant neonatal respiratory depression, reduced Apgar scores, or fetal acidosis.[107,108] However, the full effects on human fetuses exposed to nitrous oxide or other anaesthetic agents *in utero* are unknown. Recently neurotoxic effects of anaesthetic agents have been demonstrated in the developing brains of rodents and primates. Nitrous oxide administration may have more risk for creating these changes than other agents.[109–111]

### *Effects on staff*

The long-term effects of nitrous oxide on healthcare workers is unclear; however, studies have shown that midwives are regularly exposed to levels of nitrous oxide higher than permitted by the Control of Substances Hazardous to Health (COSHH) regulations and may be at an increased risk of adverse reproductive outcomes. COSHH exposure limits mirror the Indicative Occupational Exposure Limit Values set out by the European Commission.[112–114]

### *Implications for practice*

Despite a lack of clear evidence supporting the efficacy of nitrous oxide in providing adequate analgesia in labour, it remains in widespread use and a popular choice for many women.

## Volatile anaesthetic agents

Although most inhalation anaesthetic agents have been studied for labour analgesia, they have not been adopted in recent years for widespread use. An anaesthetist must be present for their use, which undoubtedly reduces application. Halogenated hydrocarbons are slightly more effective than nitrous oxide for the reduction of pain and are less likely to precipitate nausea. The mechanism of action for these agents (e.g. trichloroethylene, methoxyflurane, cyclopropane, enflurane, isoflurane, and desflurane) is not well understood. Evidence suggests that they act by binding to proteins and selectively targeting synaptic ion channels, resulting in central nervous system depression.

Ether was the first volatile to be used as an anaesthetic but is unsuitable for labour analgesia as it is a potent emetic with an unpleasant pungent odour, is irritating to the respiratory tract, and is explosive. Chloroform has a pleasant odour, is non-irritant, more potent and faster acting than ether, but has undesirable, dose-related side effects, such as arrhythmias and hepatic damage. Methoxyflurane and trichloroethylene were used for analgesia in labour in the past but have been withdrawn for other, non-obstetric, reasons.[115]

Isoflurane (0.25%), when added to Entonox® produces superior analgesia than Entonox® alone but does not produce more maternal satisfaction. This concentration will not change uterine contractility or responsiveness to oxytocin. Desflurane, while having the advantage of rapid onset and offset of action, produces similar analgesic results as Entonox®, causes amnesia in a significant proportion of women. Sevoflurane 0.8% (Sevox) produces better analgesia than Entonox® but higher doses only increase maternal sedation.[116] The neonate is not affected by these analgesic concentrations of these inhalational agents. There is, however, a concern over environmental pollution, maternal amnesia, and loss of protective airway reflexes. Larger studies are needed to assess the incidence of maternal compromise.[117]

### *Implications for practice*

In comparison to other agents, volatile inhaled agents provide analgesia equal to or better than nitrous oxide either when administered alone, or when added to nitrous oxide. Because of its short onset and offset of action, sevoflurane appears to be the best-suited inhalational agent for labour analgesia and could potentially be administered as patient-controlled inhalation analgesia. Volatile agents produce increased maternal sedation and their use is limited by requirements for anaesthetic supervision and scavenging capabilities.[91]

## Sedatives and non-opioid analgesia

Sedatives and non-opioid analgesics may be effective for mild to moderate pain or alternatively can be used in combination with opioid drugs to enhance pain relief. They act in a variety of different ways and many have antipyretic or anti-inflammatory actions, as well as sedative or analgesic properties.

### Paracetamol

Paracetamol is a widely used and effective antipyretic and analgesic medication with well-established tolerability. It has a favourable safety profile when compared with other analgesics, opioids, and non-steroidal anti-inflammatory drugs and when used in pregnancy has been reported not to be associated with an increased risk of congenital anomalies.[118–120]

#### *Dosage*

Paracetamol 1 g (if >50 kg) orally or IV, 4–6-hourly with a maximum of 4 g in 24 hours.

#### *Efficacy*

Oral administration of paracetamol in labour does not appear to confer significant analgesic benefit; however, the investigation of IV paracetamol in labour is relatively recent. One study found the effectiveness of IV paracetamol to be comparable to that of IV pethidine with duration of action of up to 2 hours. Paracetamol had fewer maternal adverse effects than pethidine. A further study is currently ongoing aiming to assess the efficacy of IV infusion of paracetamol in comparison with placebo.[121,122]

#### *Implications for practice*

Paracetamol appears to be safe to use, however, its place in providing analgesia in labour is not yet established.

### Non-steroidal anti-inflammatory drugs

The primary mechanism of action of non-steroidal anti-inflammatory drugs (NSAIDs) is inhibition of prostaglandin formation. Blockade of the pro-inflammatory mediators by NSAIDs will reduce the inflammatory response and subsequent pain. Classically, their effect is anti-inflammatory, analgesic, and antipyretic.

#### *Efficacy*

A 2012 systematic review of non-opioid drugs for pain management in labour reported on several trials comparing NSAIDs with other forms of labour analgesia. One trial comparing ketorolac (NSAID) to pethidine found that for all measures of efficacy, the patients in the ketorolac group consistently reported higher pain severity compared to pethidine. In another study, women in the NSAID group were less likely to express satisfaction with pain relief when compared with the opioid group.[123]

#### *Maternal and neonatal effects*

As inhibitors of cyclooxygenase, NSAIDs given during pregnancy have the potential to cause adverse maternal and fetal effects. Maternal effects include prolongation of labour, whereas constriction of the ductus arteriosus, renal dysfunction, and haemostatic abnormalities can occur in the fetus and neonate.[124]

#### *Implications for practice*

NSAIDs may have a subsidiary role in the management of labour pain but they do not appear to be effective as sole agents.

### Ketamine

Ketamine is a phencyclidine derivative which when administered in small doses produces a dissociative state of analgesia. Some clinicians have promoted it as a suitable analgesic for labour, but although it has a rapid onset of action (~30 seconds) its effects are of short duration, up to 5 minutes, meaning frequent repeated administration is necessary.

#### *Dosage*

Ketamine 10–20 mg IV or intramuscularly (IM) repeated at intervals of 2–5 minutes. Maximum dose in 30 minutes should not exceed 1 mg/kg.

#### *Maternal side effects*

At higher doses (i.e. >1 mg/kg) ketamine can be used to induce general anaesthesia; it is therefore important that verbal contact must be maintained with the parturient at all times as excessive sedation may lead to airway compromise. At low doses, however, ketamine may still be the cause of maternal hallucinations and frequently causes amnesia.[125] It should be avoided in pre-eclampsia as it may exacerbate hypertension by stimulation of the sympathetic nervous system. Ketamine produces a dose-dependent increase in uterine tone, which at these doses is not clinically significant.[126]

#### *Fetal and neonatal effects*

High doses of ketamine have been associated with abnormal neonatal muscle tone but low doses do not result in neonatal depression.[127]

#### *Implications for practice*

The short duration of action of ketamine makes it unsuitable for analgesia during the first stage of labour but it may have a role immediately prior to delivery.

### Barbiturates

Barbiturates such as phenobarbital have a primarily sedative effect on the central nervous system. They may be used in the early phase of labour to decrease anxiety but lack analgesic properties and may heighten the perception of pain when given in the absence of opioid analgesia. Their use in labour is minimal as barbiturates are lipid soluble so readily cross the placenta; most have long elimination half-lives leading to prolonged neonatal depressive effects if given in repeated doses or close to the time of delivery.[128]

### Phenothiazines

Phenothiazines, such as chlorpromazine, prochlorperazine, or promethazine, are a group of drugs used primarily as antipsychotic and sedative drugs. They also have antimuscarinic, antiemetic, antihistamine, antidopaminergic, and alpha-adrenoceptor antagonist properties. They are used in combination with opioids in some obstetric patients to provide sedation and decrease nausea. They rapidly cross the placenta and may result in decreased fetal heart rate variability but do not seem to cause neonatal respiratory depression.[126]

### Benzodiazepines

Benzodiazepines may decrease opioid requirements during labour but at a cost of significant maternal sedation and neonatal respiratory depression, reduced tone, and impaired temperature control. They are not recommended for use as a sedative in labour.[128]

## Systemic opioids

Obstetric anaesthesia has an uneasy relationship with systemic opioids. While they are the most widely used systemic analgesia in labour, the variable efficacy of these drugs combined with a broad range of maternal side effects and concerns over neonatal depression have limited their use.[101,129] Until recently there has been little evidence to suggest that one agent or mode of administration is intrinsically superior to the others; consequently the choice of

opioid analgesic in labour is dictated largely by institutional tradition and/or personal preference.

Opioid drugs act by binding to opioid receptors, which are found principally in the central and peripheral nervous system and the gastrointestinal tract. Maternal side effects of opioids include nausea, vomiting, delayed gastric emptying, sedation, disorientation, pruritus, and respiratory depression. There is variable susceptibility amongst parturients towards these adverse effects, which are predominantly dose dependent rather than drug dependent.[130]

Opioids may affect the fetus directly by placental transfer or indirectly though effects on the mother, for example, by altered minute ventilation or uterine tone. As a group, opioid medications by virtue of their low molecular weight and high lipid solubility readily cross the placenta by diffusion.[131] The amount of free drug delivered to the placenta depends on placental blood low and maternal protein binding, and the amount of drug available to the fetus depends on the degree of placental uptake, fetal metabolism, and clearance (Figure 13.5).[132] The speed and amount of placental transfer and consequent umbilical vein to maternal artery concentration ratios vary with different drugs and modes of administration. Opioids are primarily associated with neonatal respiratory depression and decreased beat-to-beat fetal heart rate variability. However, subtle neurobehavioural changes may also be observed in the early neonatal period, for example, decreased alertness and a delay in effective feeding due to the inhibition of sucking reflexes. The long-term significance of these neurobehavioural changes remains unclear.[133] Maternal administration of an opioid antagonist during labour or immediately prior to delivery has not been shown to have any substantial neonatal benefit and only serves to reduce maternal analgesic benefit. Naloxone is best administered directly to the neonate if required (Figure 13.5).[134]

A link between opioids and an alteration in immune function is often referred to in the literature and extensive research has been directed at investigating the immunomodulatory effects of opioids. There appear to be differences amongst opioids in immunomodulatory effects with several proposed mechanisms and sites of action including: the mu opioid receptors, a direct action on the immunocyte, modulation of the hypothalamic–pituitary–adrenal axis and modulation of sympathetic activity.[135] The clinical significance of these effects, however, has not yet been fully established but it would be sensible to consider the potential for immunomodulation particularly in those already immunosuppressed.[136]

## Modes of administration

### *Intermittent bolus*

Opioid analgesia may be administered by any number of different routes: transdermal, buccal, oral, subcutaneous, IM, IV, epidural, or intrathecal. For the purposes of labour analgesia the IM, IV, and neuraxial routes are most common. Intermittent IM injections have the advantage of being midwife delivered and thus readily available but may be painful. There is variable drug absorption depending on the site of injection and an inevitable delay between time of injection and onset of action. The quality and duration of IM analgesia is inconsistent. By contrast, opioids given via IV injection have the advantage of quicker onset, the ability to titrate to effect, and more predictable quality and duration of analgesia (Table 13.3). In many institutions, however, IV administration of opioids requires the presence of a physician, so limiting ready availability.

### *Patient-controlled analgesia*

The use of intermittent bolus or continuous IV infusion of opioids for postoperative pain has largely given way to patient-controlled (IV) analgesia (PCA). Good analgesia has been shown to be achievable with lower drug doses, thus reducing side effects and improving patient satisfaction. Patient satisfaction in childbirth is important and though the use of PCA does not lead to the complete absence of pain the benefit of a perceived sense of control during

**Table 13.3** Examples of intermittent IV/IM bolus opioid analgesia for labour

| Drug | Dose (IV/IM) | Onset (IV/IM) | Duration of action | Frequency of administration |
|---|---|---|---|---|
| Pethidine[142] | 25–50 mg IV<br>50–100 mg IM | 5–10 min IV<br>40–45 min IM | 2–3 h | 2–4-hourly |
| Codeine[171] | 30–60 mg IM | 10–30 min IM | 3–4 h | 4–6-hourly |
| Tramadol[171] | 50–100 mg IV/IM | <60 min | 3–4 h | 4–6-hourly |
| Morphine[142] | 2–5 mg IV<br>5–10 mg IM | 2–3 min IV<br>20–40 min IM | 3–4 h | 4–6-hourly |
| Diamorphine[142] | 1–2.5 mg IV<br>2.5–5 mg IM | 2–3 min IV<br>5–10 min IM | 3–4 h | 4–6-hourly |
| Nalbuphine[142] | 10–20 mg IV/IM | 2–3 min IV<br>15 min IM | 3–6 h | 3–4-hourly |
| Butorphanol[171] | 1–2 mg IV/IM | 5–10 min IV<br>10–30 min IM | 3–4 h | 6–8-hourly |
| Pentazocine[171] | 30–60 mg IV/IM | 2–3 min IV<br>15–20 min IM | 2–3 h | 3–4-hourly |
| Fentanyl[189] | 25–50 mcg IV<br>50–100 mcg IM | 2–3 min IV<br>10 min IM | 30–60 min | >60 min |

Data from various sources (see references).

labour has been demonstrated in a number of studies.[137–139] This advantage, along with a growing need to find an effective alternative to neuraxial analgesia for those who do not want, cannot have, or simply do not need an epidural, has led to the increasing use of PCA systems for analgesia in labour. Frequent smaller doses of opioid result in more uniform analgesia and, through a more steady plasma drug concentration, may result in reduced placental transfer when compared to intermittent bolus IV administration. Various opioids have been suggested for PCA use in labour (Table 13.4); however, due to the changing nature, frequency, and intensity of labour pain, rapid-onset and short-acting agents such as remifentanil are most suitable. An ideal IV opioid should have an onset and offset that can match the time course of uterine contractions, so that the parturient experiences worthwhile analgesia. Uterine contractility and fetal heart rate variability should be preserved and there should be minimal respiratory depressive maternal and neonatal side effects so that administration can be continued up to and during delivery. Gastric emptying should not be delayed in case general anaesthesia is required.[140]

## Pethidine

Pethidine (meperidine) is a synthetic opioid. It is a weakly basic phenylpiperidine derivative related to fentanyl and sufentanil. It is legally available for independent use by midwives in the United Kingdom, and worldwide is the most extensively used and investigated opioid analgesic in labour. A recent survey of units in the United Kingdom reported that 95% are using IM pethidine.[141] It is approximately 28 times more lipid-soluble than morphine and 90% metabolized by the liver to the active metabolite norpethidine.

### *Dosage*

Pethidine is ten times less potent than morphine. The usual dose in labour is 50–100 mg or 1 mg/kg (maximum 200 mg) IM every 2–4 hours with half the dose being administered if the IV route is preferred. IV administration gives more predictable blood concentrations and a faster onset of analgesia when compared with the IM route (5 vs 45 minutes).[142]

**Table 13.4** Examples of intravenous patient-controlled analgesia regimens for labour

| Drug | Patient-controlled dose | Lockout time |
|---|---|---|
| Pethidine (bolus only)[155] | 15 mg | 10 min |
| Pethidine (loading dose with bolus)[155] | 49.5 mg loading dose plus 5 mg bolus | 10 min |
| Morphine[169] | 1 mg | 5 min |
| Diamorphine[169] | 0.5 mg | 5 min |
| Nalbuphine[187] | 1 mg | 6–10 min |
| Fentanyl[193] | 50 mcg loading dose plus 20 mcg bolus | 5 min |
| Remifentanil (bolus dose by weight)[210] | 0.25–0.5 mcg/kg | 2–3 min |
| Remifentanil (fixed bolus dose)[210] | 40 mcg | 2 min |
| Remifentanil (infusion with bolus)[219] | 0.025–0.1 mcg/kg/min infusion plus 0.25 mcg/kg bolus | 5 min |

Data from various sources (see references).

### *Efficacy*

Studies on pethidine have consistently cast doubts on its effectiveness as a labour analgesic and there are concerns about its maternal, fetal, and neonatal side effect profile.[143,144] Maternal satisfaction with pethidine is historically poor with a UK National Birthday Trust survey in 1990 reporting only 16% of women rating it as helpful with 25% rating it as unhelpful. A 2002 randomized controlled trial comparing IV pethidine with placebo found that pethidine provided effective pain relief in only 23.8% of patients. Midwives rate the efficacy of pethidine better than the women receiving it though this may be attributable to misinterpretation of sedation for analgesia.[101,116,145]

### *Maternal side effects*

Pethidine decreases gastric emptying in 70% of women by at least 5 hours and increases gastric volumes in labour. It causes dose-dependent respiratory depression with desaturation having been shown to occur between contractions, particularly when used in combination with Entonox®. Neurological effects include confusion, loss of control, and sedation. Norpethidine, the active metabolite, has proconvulsant properties making pethidine potentially unsuitable for use in parturients at increased risk of seizure activity such as those with pre-eclampsia. Although research into the effects of pethidine on the duration of labour is limited there is a strong suggestion in the literature that the use of this drug is associated with a lengthening of labour and that this association is dose related.[146]

### *Fetal and neonatal effects*

Both pethidine and norpethidine readily cross the placenta and equilibrium between the maternal and fetal compartments can be achieved in 6 minutes with an umbilical vein/maternal artery ratio of 0.61.[147] The dosage and timing of maternal administration of pethidine are the most important determinants of effects on the fetus and neonate. The highest fetal plasma concentration of pethidine occurs 2–3 hours after maternal IM administration. Pethidine has been shown to significantly affect fetal heart rate variability during labour with reduced variability being seen approximately 25 minutes after IV administration and 40 minutes after IM administration. Variability of the fetal heart rate typically recovers within 60 minutes.[148,149]

The fetal circulation is more acidic than the maternal, so pethidine is more ionized in this environment leading to accumulation. This phenomenon of ion trapping along with a greater free drug concentration caused by lower plasma protein concentrations and an immature respiratory centre make respiratory depression more likely in the neonate than in the mother.[150] The neonatal effects of pethidine are compounded by the metabolism in the neonate of pethidine to norpethidine. The half-lives of pethidine and norpethidine are 4 and 20 hours, respectively, in the parturient but two to seven times longer in the neonate.[147] The babies of women who have received pethidine in labour have been shown to be sleepier, less attentive, and less able to establish breastfeeding, despite normal Apgar scores at birth.[148,151] These neonatal effects are minimal if pethidine is given within 1 hour of delivery. Concerns over long-term risk of substance abuse in adult offspring after intrapartum pethidine were proven to be unfounded in a 2012 Dutch 20-year follow-up cohort study.[152]

### *Implications for practice*

Pethidine has questionable efficacy and significant side effects. However, with easy of availability, familiarity, and low cost it has continued to be the opioid of choice in many institutions and the standard that other analgesic options are measured against. With the emergence of viable alternatives, however, it may be time to consider abandoning the use of pethidine in the developed world.

### *Patient-controlled analgesia*

Pethidine has been used successfully for PCA in the postoperative setting; however, its use in labour has yielded unimpressive results with higher total doses of pethidine being administered compared to midwife-administered intermittent boluses and no significant change in the maternal or neonatal side effect profiles seen.[153]

Various different dosing regimens have been used, for example:

- Pethidine 49.5 mg loading dose and 5 mg boluses with a lockout of 10-minute and a maximum overall dose limit of 200 mg.
- Pethidine 15 mg bolus dose with 10-minute lockout.

Recent comparisons of pethidine PCA, with remifentanil and fentanyl in labour have favoured these shorter-acting agents for both analgesic effect and side effect profile.[154–156]

## Codeine

Codeine is a naturally occurring opioid with reduced potency and efficacy when compared to morphine. It can be administered orally or IM as a sole agent in doses of up to 60 mg 4–6-hourly. It is also available in combination with paracetamol. It is not commonly the opioid of choice in active labour due to an inability to achieve adequate analgesia yet still being associated with a risk of neonatal respiratory depression. If used long term during pregnancy, neonatal withdrawal symptoms may occur.[157] The use of codeine in children under 12 years of age and in breastfeeding mothers have recently been discouraged by the European Medicines Agency and Medicines and Healthcare products Regulatory Agency because of concerns over respiratory depression in individuals who have ultra-rapid metabolizer form of the enzyme CYP2D6.[158] Although no new recommendations have as yet been made regarding its use in pregnancy, it would be sensible to consider this potential effect if prescribing codeine to a labouring woman or breastfeeding mother.

## Tramadol

Tramadol is a synthetic opioid that acts as a mu-receptor agonist while also inhibiting serotonin and noradrenaline reuptake.

### *Dosage*

It has been used successfully in labour at doses of 50–100 mg, 4-hourly, and can be administered orally, IM, or IV.

### *Efficacy*

Studies comparing bolus tramadol with bolus pethidine for labour analgesia and have concluded that tramadol offers an analgesic effect similar to pethidine.[159,160]

### *Maternal side effects*

Studies of the general adult population would suggest that tramadol does not exhibit the same level of respiratory depression or delay of gastric emptying as morphine or pethidine.[161,162] However, other mu-receptor associated side effects such as dizziness, nausea and constipation do occur; tramadol is also a proconvulsant.

### *Fetal and neonatal effects*

In comparison to pethidine, tramadol has less potential for respiratory depressive effect on the neonate.[159,160]

### *Patient-controlled analgesia*

Like pethidine, tramadol PCA systems have been successfully used in non-obstetric situations. However, there is a paucity of published information regarding its use in labour with at present just one study comparing tramadol PCA use with combined spinal–epidural (CSE) analgesia. This study reported significantly better pain scores in the CSE group and significantly worse neonatal Apgar scores in the tramadol group. Therefore, despite the ability of tramadol PCA to provide moderate analgesic effect while causing less maternal respiratory depression, its adverse effect on Apgar scores and proconvulsant properties make tramadol an unsuitable agent for labour analgesia in PCA form.[163,164]

### *Implications for practice*

Tramadol does not appear to have significant benefits over pethidine and therefore has not become commonly used in practice.

## Morphine and diamorphine

Morphine is a mu-receptor agonist acting primarily in the central nervous system. It is metabolized by the liver to an inactive metabolite, morphine-3-glucuronide and the active metabolite morphine-6-glucuronide and is rapidly cleared by the kidneys from the maternal circulation. Diamorphine is semi-synthetic opioid, the diacetylated analogue of morphine. It is a pro-drug and is converted the active components of acetylmorphine and morphine by esterases in liver, plasma, and central nervous system. It is 1.5–2 times more potent than morphine and has a more rapid onset of action.

### *Dosage*

Morphine is ten times more potent than pethidine; the dose for maternal analgesia is 2–5 mg IV or 5–10 mg IM. When given IV it has an onset time of 2–3 minutes with a peak effect at 10–20 minutes, the onset of effect after IM injection is slower at 20–40 minutes with a peak effect at 1–2 hours.[154] Diamorphine is administered IM at a dose of 2.5–5 mg, half that of morphine.

### *Efficacy*

A small randomized controlled study comparing the efficacy of morphine and pethidine in labour showed little difference between the two drugs. It found that neither agent reduced pain scores but both increased sedation with increasing dosage. It has therefore been argued that both pethidine and morphine merely provide sedation rather than analgesia in labour with the authors of one review going as far as to say that it seems 'unethical and medically incorrect to meet parturients' requests for pain relief by giving them sedation'.[101,150]

Diamorphine is used in over a third of institutions in the United Kingdom and is the most commonly used opioid for analgesia in labour in Scotland.[165] The 1990 UK National Birthday Trust survey found that both midwives and parturients rated it as more effective than pethidine.[116] A small trial comparing IM pethidine with diamorphine, showed diamorphine to have some benefits over pethidine when used for labour analgesia but the trial did not study the potential adverse effects of either opioid.[166]

### *Maternal side effects*

The maternal side effects of morphine are dose related and similar to pethidine but its metabolites do not have proconvulsant effects.

Diamorphine has been reported to provide effective analgesia associated with euphoria and less maternal vomiting than traditionally associated with pethidine use.[166]

### *Fetal and neonatal effects*

Morphine is primarily bound to albumin and although it readily crosses the placenta with an umbilical vein/maternal artery ratio of 0.96 at 5 minutes, rapid maternal elimination reduced the overall fetal drug load.[167,168] The effect of drug transfer to the fetus depends on dose and gestational age with morphine metabolism being reduced in the immature fetal liver. As with pethidine, maternal administration of morphine may result in neonatal respiratory depression and decreased fetal heart rate variability. A 2010 Cochrane review found that diamorphine produces less neonatal respiratory depression than pethidine.[144]

### *Patient-controlled analgesia*

The use of morphine and diamorphine in PCA for labour has not been shown to offer any significant advantages over IM administration.[169]

### *Implications for practice*

Morphine does not display any real advantages over pethidine and therefore is not in common use. Diamorphine is widely used in some areas and a large randomized controlled trial to comparing IM diamorphine and pethidine in terms of their analgesic efficacy in labour and their side effects in mother, fetus, and neonate is current ongoing (2012). If this trial yields positive results, it may lead to more widespread use of diamorphine in clinical practice.[170]

## Nalbuphine, butorphanol, and pentazocine

Nalbuphine, butorphanol, and pentazocine are synthetic opioid agonist/antagonists. They are partial agonists at kappa and sigmoid opioid receptors but display antagonistic or partial agonist properties at mu opioid receptors. The hope that they would provide good analgesia without the same degree of adverse effects when compared to pure mu agonists initially prompted studies into their potential as labour analgesics.

### *Dosage and efficacy*

When compared to morphine 10 mg, nalbuphine is less potent with a dose of 10–20 mg being required every 4–6 hours. The onset of analgesia is 2–3 minutes with IV administration and within 15 minutes of IM injection. Nalbuphine has a plasma half-life of 5 hours, and in clinical studies the duration of analgesic activity has been reported to range from 3 to 6 hours.[142] Butorphanol is five times more potent than morphine with a typical dose of 1–2 mg given either IV or IM. It has a longer duration of action, of up to 10 hours due to receptor binding.[171] Pentazocine is less potent with a dose of 30–60 mg being required to achieve analgesic effects similar to that to morphine 10 mg. Peak analgesia occurs at 10 minutes after IV administration and within 60 minutes of IM injection.[172] The analgesic effects of nalbuphine and butorphanol are similar to pethidine in IM administration with pentazocine appearing to have inferior labour analgesic properties.[173–176]

### *Maternal side effects*

Despite being mixed mu agonist/antagonists these opioids still exhibit many of the mu-associated side effects. When compared to morphine these opioids result in similar maternal respiratory depression at equivalent analgesic doses but a ceiling effect is noted with increased dose and repeated administration. In comparison to pethidine, they produce less nausea and vomiting but more sedation and dizziness. One study comparing their use for labour analgesia determined that they caused significant maternal respiratory acidosis. These acidotic changes were most marked with pentazocine, moderate with nalbuphine, and minimal with butorphanol.[173,177,178] Pentazocine has limited popularity in obstetrics due to unpleasant psychomimetic effects.[179] A 2011 pilot study suggested that nalbuphine reduced duration of the labour regardless of oxytocin infusion and was without significant risks.[180]

### *Fetal and neonatal effects*

Placental transfer of nalbuphine occurs rapidly. Measurements of umbilical cord blood of nalbuphine levels demonstrate that newborn concentrations vary substantially, ranging from one-third to six times the simultaneous maternal concentration.[173] When comparing nalbuphine with pethidine, studies give some conflicting results regarding adverse effects on the fetus. Some cite nalbuphine as being associated with a decrease in Apgar scores, fetal acidosis, increase in incidences of fetal bradycardia and neonatal hypoxia requiring supplemental oxygen therapy, and even mechanical ventilation, while others do not demonstrate a significant difference in these factors.[181–184] One advantage of nalbuphine over pethidine is the absence of active metabolites, thus, the adverse effects on the neonate are much shorter in duration with nalbuphine than seen with pethidine. Butorphanol also undergoes rapid placental transfer but has a less pronounced acidotic effect on fetal blood gases when compared to nalbuphine and pentazocine. When compared to pethidine, no significant differences in fetal heart rate variability, Apgar scores or neurobehavioural effects have been shown.[174,175,178,185] Pentazocine has similar neonatal depressive effects as pethidine after a single-dose administration, but repeated doses do not have a similar cumulative effect.[186]

### *Patient-controlled analgesia*

In contrast to IV or IM bolus administration, a study comparing nalbuphine PCA, at a dose of 1 mg bolus with 6–10-minute lockout, against IV bolus nalbuphine found that while both methods produced effective pain relief, more satisfactory analgesia was obtained with PCA delivery.[187] When nalbuphine PCA is compared to pethidine PCA, nalbuphine provides more effective maternal analgesia without adverse fetal/neonatal effects.[183] There do not appear to be any studies considering butorphanol or pentazocine PCA for labour analgesia.

### *Implications for practice*

The use of synthetic opioid agonist/antagonists in labour is limited, despite the analgesic effects of nalbuphine and butorphanol being similar to pethidine in IM administration.[173–176] Overall, their side effect profiles do not confer a benefit when compared with pethidine.

## Fentanyl

Fentanyl is a phenylpiperidine derivative and is highly protein bound to albumin. It is about 50 times more lipid-soluble than morphine with potency 75–100 times that of morphine and 800 times that of pethidine. Its advantages include rapid onset with a peak effect after 3–4 minutes and lack of active metabolites but its terminal half-life of about 8 hours is longer than that of morphine or pethidine.[116]

### *Dosage and efficacy*

Studies into the use of intermittent bolus fentanyl in labour have typically given parturients 25–50 mcg IV as frequently as every hour with cumulative doses reaching 600 mcg. Parturients experienced worthwhile but transient analgesia, with peak effect at 3–4 minutes and effects lasting up to 45 minutes.[188–190] In one study the effects of fentanyl were rated equivalent to those of pethidine.[191]

### *Maternal side effects*

Maternal nausea, vomiting, and prolonged sedation occur less frequently with fentanyl when compared to pethidine.[191]

### *Fetal and neonatal effects*

Fentanyl crosses the placenta rapidly, with peak fetal concentrations at 5 minutes and an umbilical vein/maternal artery ratio of 0.31.[192] It produces a reduction in baseline fetal heart rate and in beat-to-beat variation lasting for up to 30 minutes and has a temporary respiratory depressant effect on the fetus, particularly with regard to breathing movements, which are abolished at 10 minutes after administration, but return to baseline by 20 minutes.[188,189] However, neonatal assessment of Apgar scores and incidence of respiratory depression show no difference between infants exposed to fentanyl and those with no opioid exposure. Neonates who have been exposed to fentanyl are less likely to require naloxone administration than those exposed to pethidine.[189,191]

### *Implications for practice*

Intermittent bolus fentanyl is not widely used in labour due primarily to its short duration of action.

### *Patient-controlled analgesia*

Fentanyl PCA first was reported in a case report in 1992 for a parturient with thrombocytopenia in which neuraxial blockade was contraindicated. Using a regimen of a fentanyl PCA bolus of 25 mcg with a 10-minute lockout and a background IV infusion of fentanyl at 25 mcg per hour effective analgesia was achieved over almost 12 hours of labour reporting Apgar scores of 9 at 1 and 5 minutes and no adverse effects on the neonate.[192]

### *Dosage*

A dose-finding study for the use of fentanyl PCA as an analgesic option for induced second-trimester termination of pregnancy (TOP) determined that a fentanyl 50 mcg demand bolus with a 6-minute lockout provided satisfactory analgesia for second-trimester labour. This obviously did not assess effects of fentanyl PCA on the fetus and could not be applied directly to normal live birth labour analgesia.[193] A suggested regimen for fentanyl PCA for normal live births consists of a 50 mcg loading dose, 20 mcg bolus, and a lockout period of 5 minutes, although no formal trials for a dose-finding study for fentanyl have been undertaken and published.

### *Efficacy*

An initial study into the use of fentanyl PCA assessed its usefulness for labour analgesia and safety for the newborn when compared with epidural analgesia. In one study, epidural analgesia was found to be significantly more effective with a 30% conversion rate from the PCA fentanyl group to the epidural group due to unsatisfactory pain relief. However, the overall satisfaction between the two groups did not differ.[194] A study comparing fentanyl PCA, with a 10 mch/h continuous infusion and a 10 mcg bolus with 12-minute lockout, with intermittent fentanyl boluses of 50–100 mcg/h, found analgesia, sedation levels, and neonatal to be equivalent for the two groups.[195] In a recent study, despite parturients receiving fentanyl PCA showing significantly longer labour and more need of oxytocin augmentation, compared to controls women expressed their satisfaction with fentanyl PCA use.[196]

### *Maternal, fetal, and neonatal effects*

Fentanyl PCA did not produce any serious maternal side effects and no significant differences in cardiotocography (CTG) abnormalities, Apgar scores, or fetal pH were reported in a 1997 study. However, during 12-hour postpartum monitoring of the neonates a significant number recorded lower $SpO_2$ levels after fentanyl PCA compared to epidural analgesia.[194] Two further retrospective studies have shown conflicting neonatal outcomes; one found there to be a 44% increase in 'moderately depressed' neonates with neurobehavioral effects lasting up to 7 days post delivery. The total maternal dose of fentanyl in this study was significantly higher for neonates who required naloxone administration. The second study reported no neonatal complications of fentanyl PCA use despite comparable fentanyl doses. The authors of the second study theorized that the major factor behind this difference was the last dose to delivery interval, which was increased from approximately 30 minutes in the first study to 82 minutes in the second.[197,198]

### *Implications for practice*

Fentanyl PCA has a role in clinical practice but it needs to be appreciated that the neonatal effects of fentanyl may persist for a significant period after delivery. If used, the fetus and neonate must be appropriately monitored and naloxone and oxygen should be available if neonatal distress occurs.

## Alfentanil and sufentanil

Alfentanil and sufentanil, like fentanyl, are phenylpiperidine derivatives. Alfentanil is highly bound to $\alpha_1$-glycoprotein and is less lipophilic than fentanyl. Due to its low volume of distribution it has a rapid onset of action, approximately 1 minute, and a shorter duration of action than fentanyl.[199] Theoretically, it therefore should be ideal for labour pain where there is a short period of intense pain easing off over several minutes. However, alfentanil performs disappointingly when tested clinically. Comparison of equipotent doses of alfentanil PCA and fentanyl PCA for labour analgesia found that fentanyl provided more effective analgesia in the first stage of labour than alfentanil PCA with no significant differences in side effects to the parturient or to the fetus/neonate.[200]

Sufentanil is more potent and lipophilic than fentanyl with a shorter duration of action. It has been studied extensively for epidural and intrathecal administration for labour analgesia but its potency limits systemic use in labour. One study comparing its effect for labour analgesia when delivered via intrathecal, epidural, and IV routes concluded that epidural and IV sufentanil did not provide evidence of satisfactory labour analgesia.[201]

### *Implications for practice*

Alfentanil and sufentanil offer less of an analgesic effect than pethidine with no benefit in maternal or neonatal safety profile and in fact alfentanil results in lower neonatal neurobehavioral scores than those parturients who received pethidine.[202] They are therefore not a viable alternative in clinical practice.

## Remifentanil

Remifentanil is an ultra-short-acting synthetic phenylpiperidine and a pure mu agonist. It is a derivative of fentanyl with similar potency, but a more rapid onset and offset of action. It exhibits onset of effect at around 1 minute, rapid metabolism by tissue and plasma esterase to inactive metabolites, and has a context-sensitive half-life of 3 minutes. Consequently, there is no accumulation, even after prolonged administration, giving this agent an advantage over other opioids for labour PCA. These properties predict that IV remifentanil could be suitable for the cyclical pain of uterine contractions. Because of this its introduction in the early 1990s heralded a growing interest among obstetric anaesthetists.[203]

### *Suitability for labour analgesia*

At the outset, computerized simulations of the effect site concentrations of remifentanil predicted that the half time for blood effect site equilibration was 1.3–1.6 minutes.[204] A study recording effects on ventilation in volunteers following a 0.5 mcg/kg bolus over 5 seconds reported onset of effect at 30 seconds and peak effect at 2.5 minutes.[205] This suggested that it would be difficult, if not impossible, to coincide peak effect with each uterine contraction with the peak effect being more likely to coincide with the second or subsequent contraction. This may explain why the first published attempt to use remifentanil for labour analgesia fell short of expectations.[206] However, in this study a third party administered the bolus doses of remifentanil, which inevitably lead to a delay in dosing. Though the investigators concluded that remifentanil was ineffective, it is likely that the peak effect occurred in the period between contractions.

Subsequent case reports[207–209] and studies[155,210–214] employing PCA IV devices were more successful. With tutoring, the parturients were able to learn to anticipate the next contraction and to make an early effective demand.[215,216]

### *Dosage*

The efficacy of remifentanil depends on both the dose and the manner in which it is administered. Two feasibility/dose-finding studies have been carried out regarding remifentanil PCA use. In the feasibility study, a bolus dose range of 0.25 to 0.5 mcg/kg produced a median reduction in pain score of 30 mm compared with baseline.[210] The dose-finding study reported a median reduction in pain scores of 42 mm with a median dose of 0.4 mcg/kg.[211] There is, however, no consensus on the optimal dosing regimen for remifentanil with each subsequent study using its own dosing schedule with bolus doses ranging from 0.2 to 0.93 mcg/kg (Table 13.5). The most popular dose by weight used in clinical practice is 0.5 mcg/kg, or for a fixed dose regimen of 40 mcg. Some investigators have commented on the wide individual variation of bolus dose required to achieve effective analgesia. This would suggest a fixed-dose regimen could under-dose and lead to failure of analgesia or could overdose and lead to maternal oxygen desaturation.

Variable dosing regimens may improve matters, particularly during the second stage when reported pain scores are high. However, this would require physician attendance to ensure appropriate monitoring. Two recent randomized crossover studies compared a set bolus dose and infusion rate regimen with a variable dose and infusion rate as it is not only the dose but also the bolus infusion rate and delivery time that are important for efficient pain relief for the developing contraction. They both found that the variable dose and infusion rate regimen was better titrated to individuals' remifentanil requirement, as shown by a lower rate of analgesic requests within the lockout period on the PCA pump.[217,218] The introduction of a background infusion has also been studied. In the feasibility study, which recommended a PCA bolus dose of 0.25–0.5 mcg/kg, the introduction of a background infusion of remifentanil did not improve analgesia, but caused excessive maternal sedation and oxygen desaturation.[210] In contrast, a Canadian study has recommended a PCA bolus of 0.25 mcg/kg with a background infusion of 0.025 to 0.1 mcg/kg/min.[219]

Reported lockout times have also varied, some described lockout times of 2 minutes while others describe a bolus dose delivered over 1 minute with a 1-minute lockout time. With an average uterine contraction time of 70 seconds, it would seem prudent to allow a dose every 2 minutes[220] but a recent editorial recommended a minimum 3-minute lockout time to prevent the administration of additional doses before the peak analgesic effects of a bolus has occurred.[221]

### *Efficacy*

Initial case reports involving women who could not have an epidural for one reason or another reported ineffective analgesia and doubts were raised concerning the effectiveness of IV remifentanil for labour pain.[222] In addition to the dose-finding studies there are three published observational studies regarding the efficacy remifentanil PCA in labour. The dosing regimen in these studies varied, with investigation of a fixed dose of 0.5 mcg/kg; a fixed background infusion dose and an escalating PCA bolus dose; a fixed bolus dose and an escalating background infusion dose and an escalating bolus dose. All of the observational studies reported analgesia with remifentanil with a reduction in significant pain scores from baseline (Table 13.5).[213,219,223]

A number of studies have evaluated remifentanil PCA to IM or IV pethidine, pethidine PCA and fentanyl PCA.[154,155,212,224–225] A recent meta-analysis evaluating randomized controlled trials investigating efficacy and safety of remifentanil administered via a PCA compared with any other analgesic technique for labour pain concluded that remifentanil PCA provided superior analgesia and higher patient satisfaction compared with pethidine with a comparable degree of adverse events.[226] In the most relevant studies where both drugs were administered by PCA, similar mean pain scores were reported with both drugs.

The analgesia provided by IV remifentanil PCA is not complete. In comparison to epidural anaesthesia, randomized control trials have confirmed that epidural analgesia provides superior pain relief, but remifentanil does achieve a reduction in pain scores particularly during the first stage of labour. Despite incomplete analgesia a common theme among all the studies was high maternal satisfaction with remifentanil.[227–231] Further studies are ongoing.[232]

Opioid analgesia in labour, originally introduced as an alternative to inhalational analgesia, does not provide complete analgesia. As a result, Entonox® and opioid analgesia together has become popular when neuraxial analgesia is not used. If remifentanil could provide worthwhile analgesia without the need for Entonox®, this would be a considerable advantage. There is evidence that remifentanil can provide superior analgesia to Entonox® alone.[104] However, it appears that, if given the choice, women would opt to use Entonox® concomitantly despite using remifentanil.[155]

**Table 13.5** Remifentanil studies for labour analgesia

| Study | Remifentanil PCA dose | Background remifentanil infusion | Lockout interval (min) | Comparison group | Nitrous oxide used | Median or reduction in pain scores with remifentanil | Conversion to neuraxial analgesia |
|---|---|---|---|---|---|---|---|
| Volmanen et al.[104] | 0.4 mcg/kg | None | 1 | Nitrous Oxide | No | Reduction of 15 mm | Not reported |
| Douma et al.[154] | 40 mcg | No | 2 | PCA pethidine<br>PCA fentanyl | No | Reduction of 32 mm | Not reported |
| Blair et al.[155] | 40 mcg | None | 2 | PCA pethidine | Yes | Median 64 mm | 2 of 20 |
| Blair et al.[210] | 0.25–0.5 mcg/kg | 0.025–0.05 mcg/kg/min | 2 | None | No | Reduction of 30 mm | 4 of 21 |
| Volmanen et al.[211] | 0.2–0.8 mcg/kg | None | 1 | None | No | Reduction of 42 mm | Not reported |
| Thurlow et al.[212] | 0.2 mcg/kg | None | 3 | IM pethidine | Yes | Median 48 mm | 7 of 18 |
| Volikas et al.[213] | 0.5 mcg/kg | None | 2 | None | No | Reduction of 23 mm | 7 of 50 |
| Evron et al.[214] | 0.27–0.93 mcg/kg | None | 3 | Pethidine infusion | No | Median 35 mm | 4 of 43 |
| Buehner et al.[217] | 0.5–1 mcg/kg | None | 1–2 | None | No | 94% rated analgesia as good—excellent | 9 of 153 |
| Jost et al.[218] | 20–55 mcg | 50 mcg/hour | 1 | None | No | Reduction of 25 mm | Not reported |
| Balki et al.[219] | 0.25–1 mcg/kg | 0.025 mcg/kg/min (fixed) | 2 | 0.25 mcg/kg + 0.025–0.1 mcg/kg/min (variable) | No | Reduction of 56 mm versus 41 mm in 2 groups | 1 of 20 |
| Tveit et al.[223] | 0.15–1.05 mcg/kg | None | 2 | None | No | Reduction of 47 mm | 3 of 41 |
| Ng et al.[224] | 25–30 mcg | None | 4 | IM pethidine | No | Reduction of 19 mm | Not reported |
| Volikas et al.[225] | 0.5 mcg/kg | None | 2 | PCA pethidine | Yes | Reduction of 25 mm | 1 of 9 |
| Stourac et al.[227] | 20 mcg | None | 2 | Epidural | No | Reduction of 59 mm | None |
| Douma et al.[228] | 40 mcg | None | 2 | Epidural | No | Reduction of 38 mm | None |
| Volmanen et al.[229] | 0.3–0.7 mcg/kg | None | 1 | Epidural | No | Reduction of 25 mm | Not reported |
| Marwah et al.[230] | 0.25 mcg/kg | None | 2 | PCA fentanyl | No | Reduction of 45 mm | 3 of 47 |
| Stocki et al.[231] | 20–60 mcg/kg | None | 2 | Epidural | No | Reduction of 45 mm | Not reported |

Data from various sources (see references).

### *Maternal effects, safety, supervision, and monitoring*

Like with other opioid analgesics the major concern is the potential for maternal sedation, respiratory depression, and oxygen desaturation. Virtually all studies report episodes of maternal oxygen desaturation yet comment that they were transient and easily corrected with nasal oxygen or reduction in dose.[233] The comparative studies found that remifentanil PCA caused incidences of maternal oxygen desaturation similar to that for pethidine PCA and slightly higher than that of fentanyl PCA. An appraisal of the literature suggests that 32% of patients in the published studies had some degree of ventilatory depression.[234] Although these findings are comparable to a study that included women with no analgesia where episodes of oxygen desaturation in labour occurred in 46% of women for between 30 seconds to 6 minutes per hour in the second stage of labour, both the timing and the mechanisms are clearly different.[218] A 2013 study comparing the efficacy and respiratory effects of remifentanil PCA with epidural analgesia showed evidence of apnoeic episodes in women without concurrent desaturation. This led the authors to suggest the use of capnography to identify respiratory depression in addition to saturation monitoring.[231] Sedation is also widely reported during remifentanil administration with one study in particular reporting an excessively sedated woman who subsequently desaturated[223] (Table 13.6). Nausea and vomiting is variously reported though as it is endemic in childbirth it is difficult to distinguish a true opioid effect. The highest incidence reported was 48%.[211]

**Table 13.6** Maternal and neonatal effects of remifentanil

| Study | Remifentanil bolus PCA dose | Maternal desaturation | Maternal sedation | Apgar scores at 1 and 5 minutes |
|---|---|---|---|---|

Data from various sources (see references).

As the use of remifentanil for labour analgesia has become more widespread there have been increasing questions asked about its safety profile with some calling for its use to be discontinued.[235–236] The incidence of maternal desaturation shown in the various studies highlights the need for appropriate monitoring, supervision, and training for the caregiver to manage potential adverse events. A recent survey of all UK delivery suites showed that 11% of respondents reported critical incidents related to the use of remifentanil, mostly respiratory depression.[237] Remifentanil is a potent agent and there is the potential for significant harm. To date there have been four case reports describing respiratory arrests with remifentanil PCA.[238–241] While each has their own set of circumstances and potentially confounding factors, their existence cannot and should not be ignored.

In contrast, with appropriate monitoring there is a reasonable volume of study and audit data to support the safe use of remifentanil PCA in labour,[242–243] but high standards must be maintained. There is potentially a temptation to view remifentanil as a cheap and therefore attractive option for labouring women but the appropriate resources and staffing must be available to ensure safety. As one 2013 article put it 'Remifentanil should be viewed as a complimentary method to the more potent neuraxial techniques and not as a "poor man's epidural"'.[244] The view expressed in a 2013 editorial that if appropriate monitoring and supervision of patients cannot be guaranteed at all times then units should not offer remifentanil as an option for labouring women, is a good one.[221] Units choosing to use remifentanil should have stringent guidelines in place to ensure appropriate safeguards for women and regular audit processes to ensure compliance. Women receiving remifentanil PCA must have continuous one-to-one nursing or midwifery care from appropriately trained staff, routine oxygen saturation monitoring, and oxygen supplementation if needed to treat maternal desaturation.[233]

### *Fetal and neonatal effects*

Fundamental to the use of remifentanil in obstetrics were data published in 1998 and 2001. The first study reported placental transfer of an IV remifentanil infusion during caesarean delivery under epidural anaesthesia. Remifentanil readily crossed the placenta with an umbilical vein/maternal artery ratio of 0.82 and,

if administered close to the delivery of the neonate, the umbilical artery/vein ratio was 0.29, suggesting rapid metabolism and redistribution in the neonate.[245] The second study reported the pharmacokinetics of remifentanil when used for postoperative pain relief in neonates. The pharmacokinetics was found to be similar to those for older children and adults.[243]

Studies have to date reported reassuring neonatal outcomes. No studies have identified an excess of non-reassuring CTG traces with remifentanil. No association has been found between commencement of PCA and deterioration in the CTG requiring intervention or fetal blood gas sampling. Apgar scores and cord blood gases, where reported, did not show any unexpected deviations from normal practice (Table 13.6). The comparative study of PCA remifentanil with PCA pethidine found fewer non-reassuring CTGs and better neurobehavioral scores in the remifentanil group, and in comparison to fentanyl PCA less neonatal resuscitation was required.[212,214,246] These results seem to confirm remifentanil's rapid metabolism and redistribution in the neonate following placental transfer.

### *Off-label use*

Remifentanil is not licensed for use in obstetric patients. However, the administration of drugs outside their product licence is common in obstetric anaesthesia.[247] Opioids by the spinal and epidural route, as well as all self-prepared mixtures of drugs, are not licensed. Propofol and doses above 250 mg of thiopentone are not licensed either. However, most obstetric anaesthetists are content to use drugs outside the product licence with almost all of the 169 members of the Obstetric Anaesthetists' Association surveyed in 1997 admitting to using drugs outside the product licence in obstetric anaesthesia.[91] It is unlikely that the manufacturers of remifentanil will invest in the cost of obtaining a licence for obstetric use. The onus remains on each clinician to assess the risk:benefit ratio.

### *Practical experience and implications for practice*

In the authors' institution, IV remifentanil PCA is offered for routine use as a labour analgesic. The dosing regimen is a fixed bolus of 40 mcg delivered over 20 seconds with a 2-minute lockout. Supervision is by trained midwives who give one-to-one care with a protocol that includes continuous oxygen saturation monitoring, the constant presence of a midwife, regular documentation of pain scores, respiratory rate, and sedation level, and use of a dedicated cannula with an anti-syphon valve. As with all areas where strong parenteral opioids are administered, full resuscitation equipment is immediately available, with supplemental oxygen and 'bag-valve-mask' apparatus in the room. Other aspects of antepartum care are normal, with intermittent monitoring of CTG unless otherwise indicated. Our continuous audit process has also demonstrated high levels of satisfaction with remifentanil PCA, with many women returning to the unit and choosing the same method of analgesia for subsequent labours. Remifentanil PCA is now the analgesic choice in almost 30% of our deliveries, and since its introduction, the epidural rate in our unit has dropped by one-third.[248] The safety aspects of our institution's guidelines for the administration of remifentanil for labour analgesia are summarized in Table 13.7.

Currently evidence would suggest that remifentanil is more suited than any other systemic opioid to obstetric anaesthesia. It is currently available in over a third of units in the United Kingdom.[238] Time will tell whether its use will become routine elsewhere. Particular care must be taken when other opioids have previously been administered in labour. Continued appraisal and study of administration techniques is needed, particularly in relation to safety, and adverse event reporting should be encouraged. Remifentanil is a potent opioid and its side effect profile demands guidelines and strict adherence to them to ensure maternal and neonatal safety. The risks and benefits of its use should therefore be jointly considered.

**Table 13.7** Guidelines for the safe administration of remifentanil patient-controlled intravenous analgesia

| | Criteria |
|---|---|
| Prescription and training | ◆ Prescribed by an anaesthetist<br>◆ Only nurses/midwives who have undergone a period of supervised practice and have been deemed competent may administer this infusion |
| Eligibility | ◆ 36 weeks' gestation<br>◆ In established labour<br>◆ Informed consent |
| Contraindications | ◆ Other opioid use in preceding 4 hours<br>◆ Allergy to opioids<br>◆ Multiple pregnancy<br>◆ Pre-eclampsia |
| Supervision and monitoring | ◆ Continuous one-to-one nursing/midwifery supervision<br>◆ Continuous $SaO_2$ pulse-oximetry established prior to first administration<br>◆ 30-minute observations: respiratory rate, sedation score, pain score |
| Equipment | ◆ Dedicated IV cannula<br>◆ Dedicated PCA administration pump<br>◆ Unidirectional anti-syphon valve on administration set |
| Indications for contacting anaesthetist | ◆ Excessive sedation score (not rousable to voice)<br>◆ Respiratory rate < 8 breaths per minute<br>◆ $SaO_2$ < 90% despite oxygen via nasal specs |

Data from D. Hill & E. Madden, Guideline: Remifentanil controlled analgesia for labour, Ulster Community & Hospitals Trust, Women & Child Health Directorate. 2005.

## Systemic analgesia for labour: summary of key points

- Systemic analgesic drugs have variable efficacy and side effect profiles. None produce complete analgesia.
- Inhaled nitrous oxide provides modest analgesic effects for some parturients and may be used either alone or in combination with other forms of analgesia.
- Simple non-opioid analgesics have a place in obstetric analgesia but are likely to be ineffective if used in isolation.
- Sedative drugs have limited application in early labour but are inappropriate as a substitute for analgesia; ketamine may have a role at the time of delivery but is unsuitable for use throughout the course of labour.
- All opioid analgesics readily cross the placenta and therefore all have the potential to cause fetal effects such as reduced heart

rate variability, neonatal respiratory depression, sedation, and neurobehavioural effects.

- Intermittent bolus delivery of opioids such as pethidine has traditionally been the mostly commonly used mode of administration of systemic opioids in labour.
- PCA with short-acting agents such as remifentanil is becoming increasingly popular and offers the parturient more effective analgesia with a greater sense of control in labour.
- PCA in the setting of on-to-one midwifery care is becoming a safe and viable alternative to neuraxial analgesia in for women provided that appropriate monitoring and resources are available and used to safeguard against the risk of respiratory depression.

# CHAPTER 14

# Initiation of neuraxial labour analgesia

Eva Roofthooft, Sarah Devroe, and Marc Van de Velde

## Introduction

Labour, although a natural process, can be very painful and lengthy. Many parturients will request some form of analgesia. Labour analgesia can be non-pharmacological (see Chapter 13) or pharmacological. Pharmacological options include inhalational analgesia with nitrous oxide and/or volatile anaesthetics (Chapter 13), parenteral opioids (pethidine, fentanyl, alfentanil, sufentanil, morphine, diamorphine, or remifentanil—see Chapter 13) or central neuraxial techniques (epidural, spinal or combined spinal–epidural (CSE)—see Chapters 14–19). Neuraxial labour analgesia has been extensively researched and debated in the recent decades. Arguably, neuraxial analgesia is the most effective strategy to manage labour pain in contemporary clinical obstetric practice.[1–3] It is the only method that can block both the impulses from the first stage of labour entering the spinal cord at T10–L1 and the impulses of the second stage of labour entering the spinal cord via sacral roots S2–S4 (see Chapter 13). Effective analgesia has significant maternal and fetal/neonatal advantages in terms of reducing the negative effects of stress. However, neuraxial analgesia is also associated with side effects which impact on mother, fetus, neonate, and the process of labour.[2–4]

When anaesthetists plan for a central neuraxial analgesic strategy, several vital choices have to be made (Figure 14.1):

- How should analgesia be initiated?
- How should analgesia be maintained (see Chapter 15)?
- What is the dose and concentration of the local anaesthetic that is used (see Chapter 16)?
- Which local anaesthetic agent (see Chapter 16) and which adjuvant drugs (see Chapter 17) should be used for initiation and maintenance of analgesia?

In this chapter we will discuss the various options of labour analgesia initiation.

Most commonly neuraxial analgesia is initiated using a conventional epidural approach in which an epidural catheter is threaded into the epidural space and used for initiation and maintenance. In the last 25 years, CSE analgesia has gained widespread acceptance and popularity. With a spinal injection, analgesia is rapidly achieved and the epidural catheter is used only for maintenance. Initiating analgesia using a single-shot spinal injection is less common and is usually reserved for very specific indications (such as full cervical dilatation). Also, continuous spinal analgesia using intrathecally inserted catheters has been used for labour analgesia, but is only recommended in very specific high-risk patients or following an accidental dural puncture.

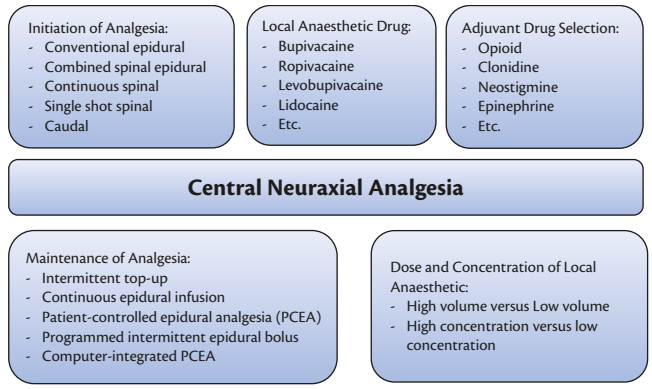

**Figure 14.1** When central neuraxial analgesia is performed to alleviate labour pain, anaesthetists need to make several decisions and have several choices: how is analgesia initiated? Which local anaesthetic and adjuvant drug is used? How is analgesia maintained? Which dose and concentration of local anaesthetic is used?

## Preparation for initiation of neuraxial analgesia

### Indications and contraindications

Whenever women in labour experience pain, analgesia should be offered. Neuraxial blockade is one of the options available and modern clinical guidelines clearly state that no women in labour, when requesting neuraxial analgesia, should be denied receiving it. In 2007, the National Institute of Clinical Excellence (now the National Institute of Health and Care Excellence (NICE)) first published its guideline on *Intrapartum Care: Care of Healthy Women and their Babies during Childbirth* and stated 'Women in labour who desire regional analgesia should not be denied it, including women in severe pain in the latent first stage of labour'.[5] The American College of Obstetricians and Gynecologists (ACOG) in 2006 and the American Society of Anesthesiologists in 2007 stated that in the absence of contraindications, a maternal request for analgesia is a sufficient enough reason to receive it and that neuraxial analgesia is an appropriate method of labour pain relief.[6,7] It used to be thought that initiating labour analgesia early

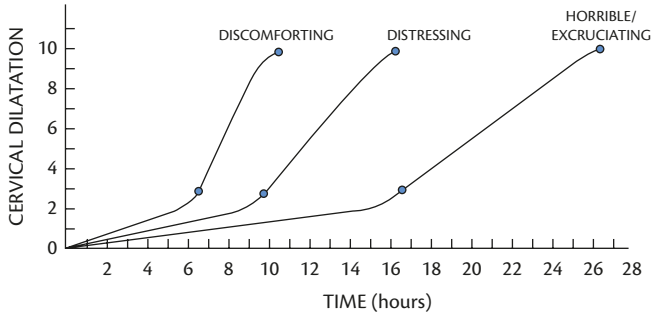

**Figure 14.2** Relationship between pain intensity in latent, early labour and speed of cervical dilatation. Severe pain in early labour also resulted in more instrumental deliveries and hence is an indicator of dystocia.

Reproduced with permission from Wuitchik M, Bakal D, Lipshitz J., The clinical significance of pain and cognitive activity in latent labor, *Obstetrics & Gynecology*, Volume 73, Issue 1, pp. 35–42, Copyright © 1989 Wolters Kluwer Health, Inc.

would have a detrimental effect on the course of labour. However, severe pain early in labour is an independent indicator of dystocia or difficult, prolonged labour, often resulting in an instrumental delivery (Figure 14.2).[8] It has also been clearly demonstrated that neuraxial labour analgesia initiated during early labour, does not impact on labour outcome (Figure 14.3).[9,10]

Although many contraindications exist for neuraxial anaesthesia, several contraindications are relative and an individualized risk/benefit analysis, especially in obstetric patients, should be considered. Absolute and relative contraindications are listed in Box 14.1. However, in most instances experienced obstetric anaesthetists will, based on an individualized risk assessment, initiate neuraxial analgesia.

## Preoperative assessment

Ideally every parturient undergoing peripartum neuraxial analgesia should be screened preoperatively for informed consent

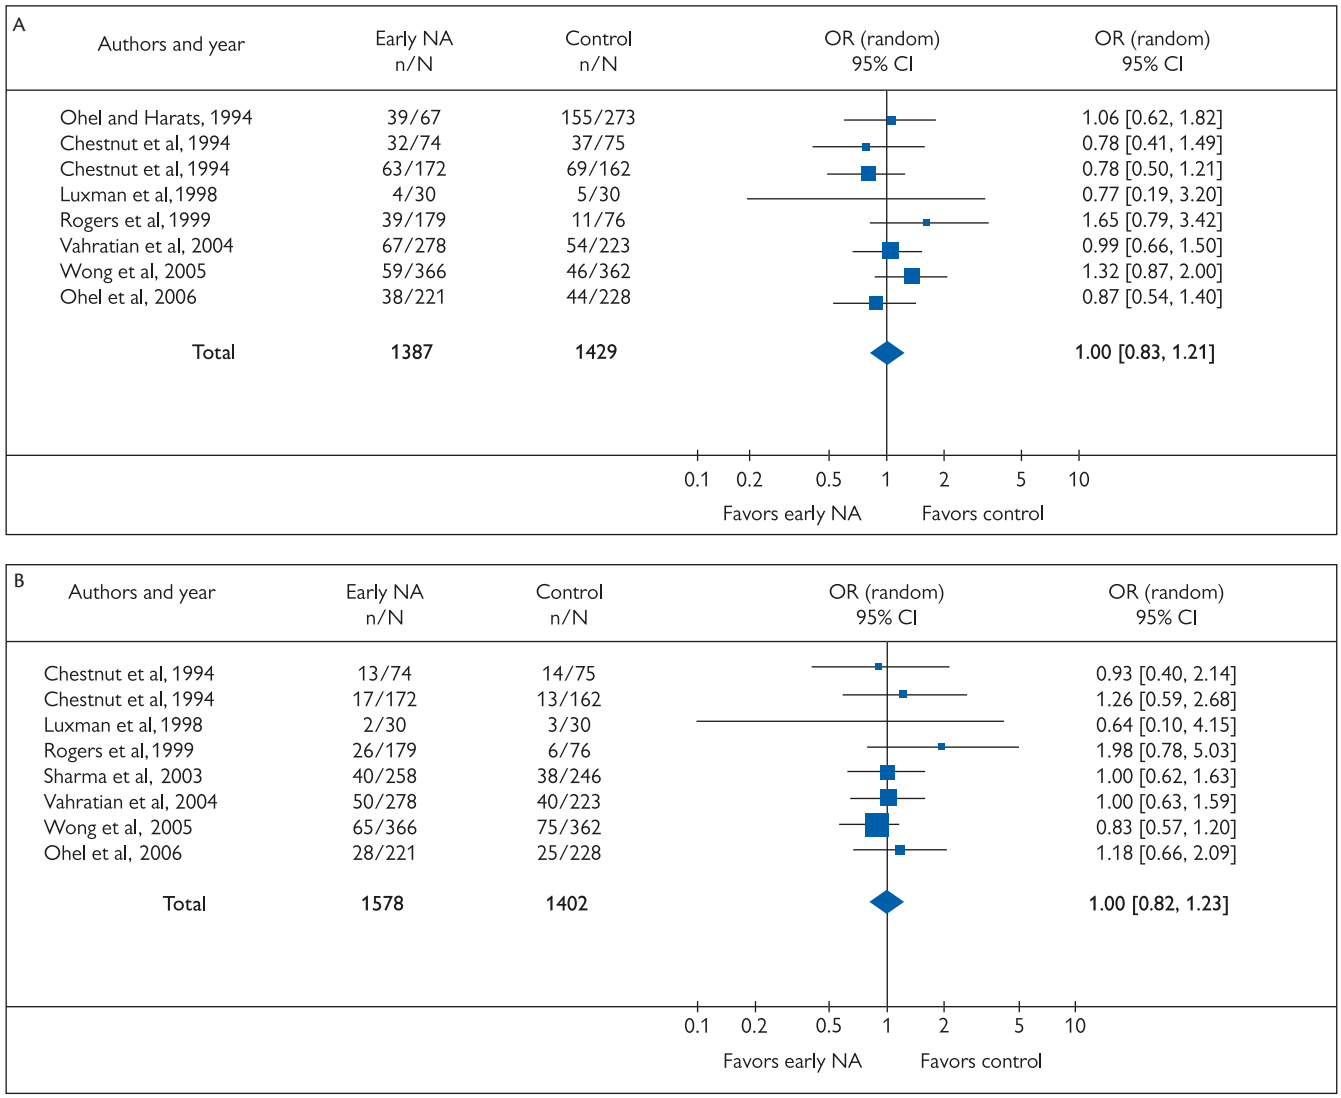

**Figure 14.3** Rates of instrumental vaginal delivery (A) and caesarean delivery (B) for each of the studies with odds ratios (ORs) and 95% confidence intervals (CI). The diamond represents the point estimate of the pooled OR, and the length of the diamond is proportional to the CI. Neuraxial analgesia on patient request did not increase the chance of an instrumental vaginal delivery or caesarean delivery. Please refer to original paper for references.

n = number of events in treatment or control group; N = total number of patients in treatment or control group; NA = neuraxial analgesia.

**Box 14.1** Absolute and relative contraindications to neuraxial anaesthesia/analgesia in the parturient

Of note: experienced anaesthesiologists will often insert, based on an individualized risk/benefit assessment, neuraxial anaesthesia in patients with relative contraindications.

**Absolute contraindications**

- Overt coagulopathy
- Infection at puncture site
- Acutely raised intracranial pressure
- Uncorrected, severe hypovolaemia
- Patient refusal
- Patient inability to cooperate.

**Relative contraindications**

- Mild or single-factor coagulopathy
- Chronic raised intracranial pressure
- Corrected hypovolaemia
- Systemic infection
- Stenotic valvular lesions
- Pulmonary hypertension (Eisenmenger type)
- Pre-existing neurological disease.

and to identify risks. In some countries, every parturient is seen antenatally prior to delivery. However, in everyday routine clinical practice in many regions, parturients are first seen by the anaesthetist on the day of labour. A focused history and short clinical examination should be made as well as a review of the patient's obstetric history.[11–13] According to the American Society of Anesthesiologists guidelines, the short clinical examination should include a baseline blood pressure measurement and airway, heart, lung, and back examinations. In healthy parturients, no laboratory investigations are required (also a routine platelet count is not necessary), but these may become necessary in selected patients.[11,12,14] All guidelines agree that close communication between obstetricians, midwives, and anaesthetists must be maintained, focusing on adequate handovers and early labour ward rounds to identify parturients at high risk for complications or operative delivery. Pre-anaesthetic assessment of fetal well-being by recording the fetal heart rate by a qualified individual is recommended.

## Informed consent

To inform parturients about neuraxial analgesia risks and benefits, structured information should be available in every unit that offers neuraxial analgesia (patient information sessions or antenatal classes, printed leaflets, possibility for an individualized pre-delivery consult, etc.). However, as already mentioned, patients will often not have received information about analgesia before entering the labour process. Information of risks should be given as well as advantages.[15] Several authors have questioned the women's capacity, especially when being distressed and in pain, to fully understand the information provided and to give consent.[16,17] However, anaesthetists act in the best interest of the patient and this should be made clear to the patient and her partner. For further information we refer to Chapter 29.

## Intravenous lines and fluids

All parturients undergoing neuraxial analgesia should have an intravenous (IV) line established. Most guidelines do not recommend a fixed amount of fluid, especially in circumstances when low-dose CSE or epidural analgesia is used.[5,7,12] However, many practitioners will prehydrate the patient with 500–1000 mL crystalloid solution. A bolus of glucose-containing fluids is best avoided.

## Necessary equipment and safety precautions

Equipment to resuscitate a patient and airway equipment should be readily available. Drugs to induce general anaesthesia (propofol, thiopental, ketamine, midazolam), opioid reversal (naloxone), cardiovascular support (ephedrine, phenylephrine, atropine, epinephrine, calcium) and treatment of local anaesthetic systemic toxicity (LAST; Intralipid® 20%) should be available in the labour and delivery area.[18,19] Cardiotocographic monitors should be available to monitor uterine activity and fetal heart rate immediately after initiation of analgesia. During initiation, fetal heart rate monitoring is not absolutely mandatory provided the pregnant patient is healthy and the fetal status was reassuring prior to initiation. However in some countries or regions, local guidelines may request cardiotocographic monitoring during neuraxial analgesia initiation. Non-invasive maternal blood pressure and heart rate monitoring should be instituted during neuraxial analgesia initiation.

## Patient positioning

Patient and anaesthetist preference should guide the best position to perform the neuraxial procedure. Both the lateral decubitus and the sitting position are widespread. However, both positions have advantages and disadvantages (Box 14.2). Immediately following the procedure the patient can be placed in the left lateral

**Box 14.2** Advantages of the lateral decubitus or sitting position to perform neuraxial analgesia in labour

**Advantages of lateral position**

- Less hypotension
- Increased parturient comfort
- Better continuous fetal heart rate monitoring
- Less venous cannulation by the epidural catheter.

**Advantages of sitting position**

- Better and more reliable identification of Tuffier's line.
- Better anatomical landmark identification in 'difficult back' patients (obesity, back surgery, scoliosis)
- Improved respiratory mechanics
- Better and more reliable identification of Tuffier's line.

position or wedged supine position. Careful attention is required to avoid aortocaval compression, essential to maintain cardiac output and uteroplacental perfusion.[20] The wedged supine position is often preferred with conventional epidural analgesia to enhance bilateral local anaesthetic spread. With CSE, spread of the intrathecal dose is excellent and bilateral irrespective of the position employed, therefore maintaining the left lateral position might be preferred.

### Aseptic technique

Before initiating neuraxial analgesia and placing spinals or epidurals, careful disinfection of the skin is required using either povidone-iodine or chlorhexidine 0.5% in alcohol. Checketts et al. showed that chlorhexidine is more effective then povidone-iodine.[21] However, it must be remembered that these substances are potentially neurotoxic and recently catastrophic cases of inadvertent administration of disinfectant into the epidural and spinal space have been reported, resulting in progressive quadriplegia.[22,23] Therefore, care must be taken not to contaminate needles with disinfectant so as not to introduce the disinfectant into the epidural or subarachnoid space. Hence the neuraxial analgesia procedure should only be started when the disinfectant has dried onto the skin, thus minimizing the risk of inadvertent transfer of disinfectant into the epidural or spinal space.

### Different options of neuraxial analgesia initiation

Several options to initiate analgesia exist with conventional epidural analgesia being the most popular and most widely employed technique (Boxes 14.3 and 14.4). Since the early 1990s, the CSE technique for labour analgesia has gained worldwide acceptance and is an established method of labour pain relief.[24,25] In certain institutions and countries, it is even as popular as an epidural.[26] Rarely used methods to initiate labour analgesia are the caudal, continuous spinal, and single-shot spinal technique. We refer to other textbooks for extensive information regarding the technical aspects of the different neuraxial techniques.

**Box 14.3** Possible procedure to initiate epidural analgesia

1. Site IV line and administer crystalloid IV fluid load (500 mL).
2. Position patient sitting or full left lateral.
3. Have assistant disinfect the skin (with chlorhexidine solution). No disinfectant should be on the epidural tray. Only initiate neuraxial anesthesia when skin is dry.
4. Prepare epidural set and prepare necessary drugs in a sterile fashion.
5. Site epidural catheter.
6. Administer test dose (note: this is questioned by many practitioners).
7. Fixate epidural catheter.
8. Position parturient supine with left lateral tilt.
9. Administer low-concentration local anaesthetic solution with adjuvant (usually opioid) in a volume of 10–20 mL in incremental doses.
10. Have maternal vital signs and fetal heart rate monitored for at least 30–45 minutes.
11. Assess efficacy of epidural analgesia and initiate appropriate measures if pain relief is not achieved after 30 minutes.
12. Start maintenance analgesia (see Chapter 15).

**Box 14.4** The ideal drug or drug combination for labour analgesia

- Rapid onset of analgesia
- Large sensory–motor separation thus avoiding motor block
- Long-acting drug
- Low risk of local anaesthetic systemic toxicity (LAST)
- No effect on uterine activity
- No effect on uteroplacental perfusion
- Limited transplacental passage
- No direct effects on the fetus.

To perform safe neuraxial analgesia or anaesthesia, a thorough understanding of the anatomy of the vertebral column, the spinal canal, and epidural space is required. Seven cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 3–5 (most commonly 4) fused coccygeal vertebrae comprise the vertebral column. The spinal cord comes down from the brainstem and terminates as the conus medullaris at the lower border of the L1 vertebral body (and even lower in at least 5% of individuals).[27] The lower lumbar and sacral nerve roots run down to the coccyx as the cauda equina. Three membranes surround the spinal cord within the vertebral column: the pia mater, the arachnoid mater, and the dura mater. In between the pia mater and the arachnoid mater lies the subarachnoid space containing cerebrospinal fluid (CSF) which runs down to the level of S2. Spinal anaesthesia is performed by injecting anaesthetics in this space. Between the arachnoid mater and the dura mater, lies a potential space called the subdural space, which can be created by traumatic punctures and this may explain patchy or failed epidural blocks with higher than expected cephalad spread.[28,29] The epidural space surrounds the dura mater circumferentially and extends from the foramen magnum, where the dura mater and periosteum fuse, to the sacrococcygeal ligament. The space contains adipose tissue, blood vessels, nerve roots, and loose connective tissue in a non-uniform distribution. The ligamentum flavum is the posterior boundary of the epidural space. Epidural anaesthesia/analgesia is performed by inserting a catheter and/or injecting drugs into the epidural space.

## Initiation using conventional epidural analgesia

### Epidural anaesthesia technique

To identify the epidural space, special equipment is required, including an epidural needle, an epidural catheter, and a loss of resistance (LOR) syringe. The epidural needle is usually a 16 G to 18 G needle with an end opening and Huber tip (Tuohy

needle). The epidural catheter is made out of plastic and depending on the type and manufacturer has varying degrees of stiffness. Another difference between various epidural catheters is that they can be single-orifice catheters or multi-orifice catheters. Advantages of multi-orifice catheters include better spread of local anaesthetic and the ability to aspirate blood or CSF to identify inappropriate location of the catheter. The epidural space is usually identified using the LOR technique. The medium used for LOR is either saline or air. Several investigators have suggested that the LOR to air technique should no longer be used because of a higher incidence of accidental dural puncture,[30,31] more postdural puncture headache (PDPH),[32] more pneumocephalus, more risk for patchy analgesia,[31] and more paraesthesias. However, in experienced hands, LOR to air is a safe technique.[33]

The epidural needle is advanced into the interspinous ligament and gradually advanced by the operator's non-dominant hand while the thumb of the operator's dominant hand applies constant or intermittent pressure to the LOR syringe. Upon entering the epidural space, the content of the LOR syringe flows easily into the epidural space. Then a catheter is advanced into the epidural space, and the needle pulled back, after which the catheter is pulled back until the catheter remains 3–5 cm in the epidural space. In many institutions, micropore filters are used in between the epidural catheter and the infusion fluid to protect against infection. However, there is no evidence that they actually do have a protective effect.[34] It must be emphasized that filters may hamper the aspiration of CSF or blood, hence aspiration, using a 2 mL syringe needs to be performed without a filter. Following fixation of the epidural catheter, the patient is positioned supine with left lateral tilt.

## Test dose

Following insertion of an epidural catheter, the catheter can accidentally have been placed intrathecally or intravascularly. Intravascular cannulation of the epidural catheter occurs in up to 9% of obstetric patients.[35,36] Especially when high doses of local anaesthetic are administered, the risk of LAST or high/total spinal anaesthesia is significant and potentially life-threatening. Therefore, identification of catheter misplacement is crucial. For this purpose a so-called test dose is administered (Box 14.5). Ideally a test dose should have a high specificity (low false-positive rate) and high sensitivity (low false-negative rate). Unfortunately no test dose is 100% full proof. A negative response to a test dose decreases the chance of catheter malpositioning, but does not exclude it. Also throughout the course of labour, epidural catheter migration has been described.[37,38] Hence a catheter tested following placement, should always be re-tested when high doses of local anaesthetic are administered as a bolus (e.g. when topping up a labour epidural for caesarean delivery).

**Box 14.5** Disadvantages of a formal test dose to evaluate intravascular or intrathecal placement of the epidural catheter

- Low specificity: large heart rate variability in labour resulting in a false-positive test dose
- Effects of epinephrine on uteroplacental perfusion
- Effects of lidocaine and epinephrine on motor function
- Difficulty testing the catheter when placed as part of a CSE.

When dilute epidural analgesic solutions are used, several obstetric anaesthetists question the need to use a formal test dose. They argue that the risk of LAST or high spinal block is virtually non-existent when low-concentration epidural solutions are given and incremental dosing is used when top-ups are given. The first dose then serves as a test dose. Moreover, an epinephrine-containing test dose may increase the risk of motor block in the parturient[39] and detrimentally affects uteroplacental perfusion,[40] while lidocaine 40–60 mg intrathecally will produce some degree of motor block which is undesirable in labour.[41] Furthermore, during CSE analgesia, because of the immediate effect of the spinal component, a test dose to assess intrathecal placement of the epidural catheter is not useful. Finally, in labouring patients, test doses that rely on a tachycardic response to evaluate intravascular catheter placement are found to be difficult to interpret, because of significant maternal heart rate variability during labour. Additionally, when multi-orifice catheters are used, careful aspiration of the catheter (without a micropore filter) will in many instances allow identification of misplacement since CSF or blood will be aspirated. Therefore, many practitioners will not give a formal test dose when low-concentration epidural solutions are used for labour pain relief.[42] They will aspirate the catheter and give the first therapeutic dose fractionated and consider this the test dose.

However, when large doses are given, a test dose is necessary. Table 14.1 gives an overview of the various testing modalities of an epidural catheter and the expected response when the catheter is intravascular or intrathecal.

## Choice of local anaesthetic: drug, concentration, and dose

We refer to more detailed information in Chapter 16. Although theoretically all local anaesthetics can be used for epidural labour analgesia, in clinical practice the choice is limited to one of four local anaesthetics: lidocaine, bupivacaine, levobupivacaine, and ropivacaine. In contemporary obstetric anaesthesia practice, lidocaine is rarely used for neuraxial labour pain relief because of its short duration and concerns about neonatal neurobehavioral scores.[43–47]

Bupivacaine is probably the most popular local anaesthetic worldwide for neuraxial labour analgesia. The advantages of high-volume, low-concentration solutions to initiate epidural analgesia have been clearly demonstrated. Less motor block and better labour outcome of lower epidural local anaesthetic concentrations were well demonstrated by the Comparative Obstetric Mobile Epidural Trial (COMET) trial.[48] Christiaens et al. and Lyons et al. in two methodologically different studies elegantly showed that high-volume analgesia results in better quality analgesia with less local anaesthetic consumption probably due to better epidural sacral spread.[49,50]

It has been shown, using the up-and-down sequential allocation methodology, that ropivacaine and levobupivacaine are less potent then bupivacaine at the effective dose in 50% of subjects ($ED_{50}$).[51–53] However, more recent work by Ngan Kee et al. showed that at the $ED_{95}$ this difference was much smaller and not statistically significant[54] (Figure 14.4). Theoretically ropivacaine

**Table 14.1** Epidural catheter testing modalities

| Testing modality | Result when IV catheter | Result when IT catheter |
|---|---|---|
| Lidocaine 1.5% with epinephrine 5 mcg/mL (1:200,000) 3–4 mL | An increase in heart rate of 20 bpm within 60 seconds | Motor blockade (reduced hip flexion) within 5 minutes |
| Bupivacaine 0.25% with epinephrine 5 mcg/mL (1:200,000) 3–4 mL | Increase in heart rate of 20 bpm within 60 seconds | Motor blockade (reduced hip flexion) within 5 minutes |
| Lidocaine 100 mg | Tinnitus, circumoral paraesthesia | Motor blockade (reduced hip flexion) within 5 minutes |
| Ropivacaine 25 mg | Tinnitus, circumoral paraesthesia | Motor blockade (reduced hip flexion) within 5 minutes |
| Fentanyl 100 mcg | Dizziness, sleepy feeling | No effect |
| Air 1 mL | Doppler heart sound changes | |
| Lidocaine 40–60 mg | No effect | Motor blockade (reduced hip flexion) within 5 minutes |
| Bupivacaine 7.5 mg | No effect | Motor blockade (reduced hip flexion) within 5 minutes |
| Aspiration of catheter | Blood | Cerebrospinal fluid |

Note that an epidural catheter can migrate and re-testing is required whenever a large bolus dose is administered.

bpm, beats per minute; IT, intrathecal, IV, intravascular.

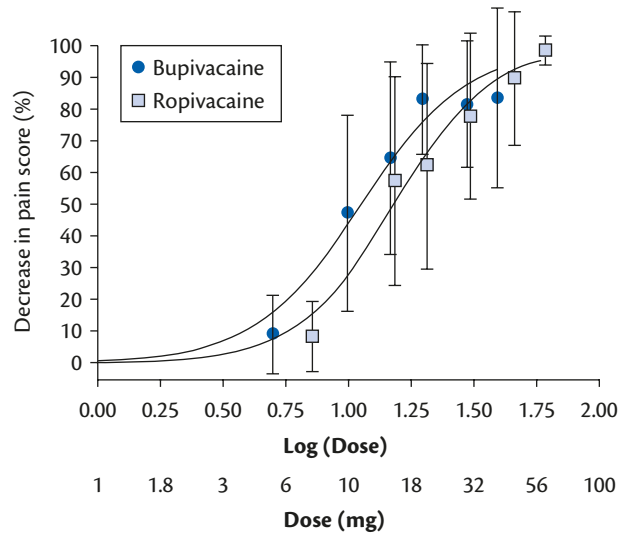

**Figure 14.4** Dose–response curves for effective analgesia in labour comparing bupivacaine and ropivacaine. At the $ED_{95}$ both drugs had similar potency.
Data from Scanlon JW, Brown WU Jr, Weiss JB, Alper MH. Neurobehavioral responses of newborn infants after maternal epidural anesthesia, *Anesthesiology*, 1974, volume 40, issue 2, pp. 121–128.

and levobupivacaine produce less systemic toxicity and have the potential for reduced motor block, which is especially important in labouring patients.

All local anaesthetics can produce systemic toxicity by direct and indirect mechanisms that derive from their mode of action, that is, inhibition of voltage-gated ion channels.[55–57] Furthermore, local anaesthetics also interfere with mitochondrial respiration by impeding oxidative phosphorylation, thus depleting the cell's energy reserve. Ropivacaine and levobupivacaine both have lower systemic toxicity then bupivacaine.[55–57] Evidence from *in vitro* studies, *ex vivo* whole-organ studies, animal studies, studies in volunteers, and case reports shows that ropivacaine is the least toxic, levobupivacaine has intermediate toxicity, and bupivacaine is the most toxic.[58] Reduced systemic toxicity has also been demonstrated in pregnant animals.[59]

Halpern and Walsh performed a meta-analysis of 23 randomized trials that compared ropivacaine and bupivacaine during labour analgesia.[60] Onset, duration, and quality of analgesia were similar between the two local anaesthetics. No differences in mode of delivery or other outcome parameters were identified, except for a more frequent incidence of motor block with bupivacaine. Several individual studies using low concentrations of local anaesthetic (≤0.125%) did demonstrate differences in motor block with ropivacaine producing less motor block then bupivacaine.[61–69] This difference in motor block especially becomes apparent when analgesia is required for more than 4–5 hours as Gautier et al. and Halpern et al. clearly demonstrated (Figure 14.5).[63,69] In the study by Gautier et al.,[63] this difference persisted even if lower concentrations of epidural bupivacaine were used to provide analgesia. Table 14.2 gives an overview of motor block reported in several studies that compared low and similar concentrations of ropivacaine and bupivacaine during labour analgesia. However, for completeness, most studies were not powered to evaluate motor block effects.

This has been confirmed using the minimum local anaesthetic concentration (MLAC) methodology. Lacassie et al. determined the motor block MLAC concentration of ropivacaine,

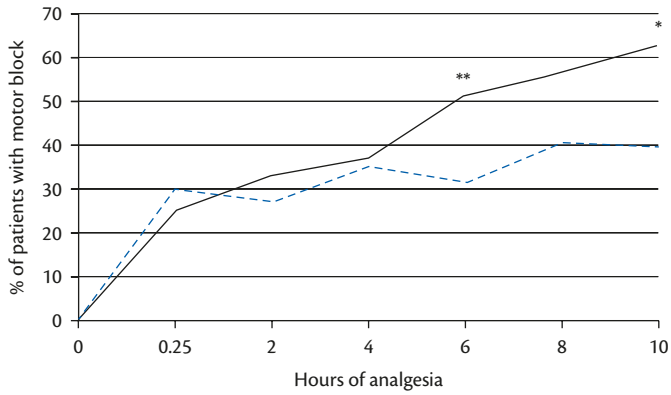

**Figure 14.5** Percentage of patients over time with any motor block in a multicentre trial comparing ropivacaine 0.1% and bupivacaine 0.1% both combined with fentanyl 5 mcg/mL for labour analgesia. Especially with prolonged labour, ropivacaine is less potent in terms of motor blocking properties.
Dotted line is ropivacaine; solid line is bupivacaine.

Data from various sources (see references).

levobupivacaine, and bupivacaine using a model of up-and-down sequential allocation.[70,71] The authors noted that at equianalgesic doses, if motor block with racemic bupivacaine was 1.0, motor block with ropivacaine was 0.66 and with levobupivacaine was 0.87.

## Choice of adjuvant drug in epidural solutions

### Opioids

Opioids used for labour pain relief act through mechanisms in the dorsal horn. Activation of μ, δ, and κ-receptors induces presynaptic inhibition of neurotransmitter release and produces postsynaptic neuronal membrane hyperpolarization. Pure epidural opioid analgesia is feasible in the early stages of labour. Capogna et al. determined the $ED_{50}$ of epidural fentanyl and sufentanil using the MLAC methodology.[72] To produce analgesia in 50% of patients a dose of 124 mcg fentanyl and 21 mcg sufentanil was required, establishing a potency ratio of 5.9 between sufentanil and fentanyl. However, usually opioids are combined with local anaesthetics. It has been repeatedly shown that opioids have a synergistic effect with various local anaesthetic agents. Opioids reduce the $ED_{50}$ of different local anaesthetics.[73] Buyse et al. showed that sufentanil reduced local anaesthetic consumption fourfold.[74] In clinical practice, the addition of opioids reduces the onset of analgesia, prolongs the duration of initial epidural analgesia, reduces local anaesthetic consumption, and decreases the incidence of patients with insufficient analgesia.[75] The incidence of troublesome motor block is reduced and the rate of spontaneous vaginal delivery is increased.[75] Unfortunately, more patients experience pruritus.[75]

### Clonidine

Clonidine, an $\alpha_2$-receptor agonist, acts through $\alpha_2$-receptors located in the dorsal horn to produce labour analgesia. Presynaptic stimulation of $\alpha_2$-receptors inhibits neurotransmitter release and postsynaptic stimulation prevents neuronal transmission through hyperpolarization. Animal safety studies established that clonidine was not neurotoxic and did not affect spinal cord blood flow.[76,77] Several clinical trials have studied various doses (30–150 mcg) of epidural clonidine during labour.[78–81] Doses above 100 mcg induce maternal hypotension, bradycardia, and sedation and in some trials also new-onset fetal heart rate changes.[79] Based on work by Landau et al. the optimal epidural dose of clonidine is probably 75 mcg.[81] Prolonged analgesia, reduced local anaesthetic consumption, and less epidural top-ups for breakthrough pain without an increase in side effects were noted. However, Nakamura et al. reported worse neonatal adaptive capacity scores when clonidine 75 mcg was added to an epidural ropivacaine mixture.[82]

### Epinephrine

Epinephrine also acts through $\alpha_2$-receptors. However, vascular effects, especially with epidural administration, might also be involved. Epidurally administered epinephrine significantly reduces the MLAC concentration of bupivacaine in labouring patients and improves the quality of analgesia.[83] Unfortunately, epinephrine also induces an increased incidence of maternal motor deficit.[84,85] Epidural epinephrine might also prolong labour duration by β-agonist effects, especially when higher doses are infused in the epidural space.[86–88] Furthermore, adding epinephrine to pharmacist pre-prepared solutions complicates storage and significantly increases the price of handling and preparation. Thus, this author has abandoned the addition of epinephrine from the local anaesthetic solution used for spinal and epidural administration when used for labour analgesia.

### Neostigmine

Acetylcholine is an important neurotransmitter in the dorsal horn of the spinal cord for the descending inhibitory pathways. Neostigmine, a cholinesterase inhibitor, increases the concentration of acetylcholine in the synapses and this produces analgesia by stimulating acetylcholine-mediated mechanisms. Naguib and Yaksh demonstrated that the analgesic effects of neostigmine and clonidine are synergistic.[89] Following reassuring safety studies, in which no neurotoxic effects and no detrimental effects on spinal cord perfusion were identified, neostigmine has been evaluated for labour pain relief.[90,91] Although not a potent analgesic as a single drug, it does have analgesic effects when combined with other drugs such as opioids, clonidine, and local anaesthetics.[92–94]

Van de Velde et al. evaluated the combination of clonidine 75 mcg with neostigmine 500 mcg given epidurally following the spinal component of a CSE.[95] They noted a local anaesthetic-sparing effect, increased duration of initial spinal analgesia, and fewer problems with breakthrough pain. Ross et al. noted that adding neostigmine to the patient-controlled epidural analgesia (PCEA) mixture reduced bupivacaine consumption during labour.[96] Eisenach, along with Paech and Pan, concluded that neostigmine is a promising adjuvant drug to assist in managing labour pain but that further research is required.[97,98]

# Initiation using combined spinal–epidural analgesia

## Technique

The CSE technique combines the advantages of a conventional epidural technique with the advantages of single-shot spinal (SSS) technique. Most practitioners use the single interspace needle-through-needle CSE technique. Following identification of

the epidural space, a longer spinal needle is advanced through the epidural needle into the subarachnoid space. An initial dose of drug is administered. The spinal needle is removed and an epidural catheter advanced as in a conventional epidural technique. Alternatively, but currently rarely used, is the double-space CSE technique in which a SSS is performed followed by an epidural at a different interspace. The double-space technique has advantages (time to redo the epidural if required and easier testing of the epidural catheter) and disadvantages (two punctures; higher chance of damaging the conus if a lower interspace cannot be used for the spinal).

### Testing the epidural catheter following CSE

Since epidural catheters can inadvertently be misplaced in either the CSF or in an epidural vein, anaesthetists have been using test doses to verify the correct position of the catheter. Unfortunately, test doses are neither sensitive nor specific[99,100] (Table 14.1). Furthermore epinephrine-containing test doses can induce motor impairment and thus reduce ambulation during labour. Some authors also suggested that an epinephrine-containing test dose has potential adverse effects on uteroplacental perfusion. As a result, several authors have abandoned routine testing of the epidural catheter and look for signs of IV or intrathecal injection with each bolus given through the catheter.[101]

With CSE, analgesia occurs rapidly and testing the functionality of the epidural catheter is not possible until the initial spinal dose wears off. Many anaesthetists consider the fact that the reliability of the epidural catheter is uncertain during this period as a major disadvantage. Their concern is related to the possibility that the catheter may be dysfunctional when an emergency caesarean section is required. Especially in high-risk pregnancies this is considered a major drawback. However, it is important to note that even with a well-tested epidural catheter, it can never be absolutely sure that several hours later the catheter remains correctly positioned.[37,38] Even with conventional epidural catheters, fractionated dosing or a *de novo* test dose are required the moment the catheter is used for the injection of high doses of local anaesthetics.

A second concern involves the fact that some anaesthetists do not want to initiate epidural analgesia immediately after the spinal dose. Only once the spinal dose has worn off, the epidural catheter is formally tested and used throughout labour. As a result most patients will experience breakthrough pain until the epidural dose is effective. However, several authors initiate an epidural infusion immediately following the initial spinal dose.[102] With low-volume, low-dose techniques, the risk of total spinal anaesthesia or toxic side effects is minimal. However, if continuous epidural infusion or patient-controlled epidural analgesia does not produce adequate analgesia, one must consider an intravascular position of the catheter and resite the catheter.

### Choice of intrathecal drug combinations

Plain intrathecal opioids are successful in producing labour analgesia. Palmer et al. established that fentanyl 25 mcg, used alone, was the optimal intrathecal dose.[103] Increasing the dose above 25 mcg did not improve the duration or quality of analgesia, but increased the incidence of side effects. For sufentanil, an $ED_{95}$ of 8.9 mcg was established.[104] However, certainly in Europe, most anaesthetists prefer the intrathecal combination of local anaesthetics and opioids, often pre-mixed solutions, prepared by the hospital pharmacy.[105] Adding opioids to the spinal mixture, reduces the $ED_{50}$ of the local anaesthetic agent and prolongs in a dose-dependent manner the duration of initial spinal analgesia.[106] Respiratory depression following intrathecal opioids has been described. This occurred usually in short-stature patients receiving high doses of opioids following initial parenteral opioid analgesia. Respiratory depression occurred within 30 minutes from injection. Vigilance following the intrathecal injection of opioids is therefore required. During labour analgesia, intrathecal opioids have been associated with new-onset fetal heart rate changes.[107,108] Usually these changes were related to uterine hyperactivity and not maternal hypotension. Several authors postulated that an imbalance between maternal catecholamines following rapid spinal analgesia produces uterine hypertonicity. It remains unclear why this only occurs following high-dose intrathecal opioids and not following the combination of lower doses of opioids and local anaesthetics.[109]

Chiari et al. studied the use of pure spinal clonidine labour analgesia.[110] This is not feasible since doses producing adequate analgesia also induce unacceptable hypotension. Adding lower doses of clonidine (15–45 mcg) to spinal analgesics does improve the duration and quality of initial spinal analgesia, but hypotension remains problematic.[111,112]

Nelson et al. investigated the analgesic potential and side effect profile of 5, 10, or 20 mcg intrathecal neostigmine alone.[113] Ten mcg was considered the optimal dose to be added to intrathecal sufentanil. The $ED_{50}$ of spinal sufentanil with and without neostigmine was determined. Neostigmine successfully reduced the $ED_{50}$ of spinal sufentanil. In a further step, they compared twice the $ED_{50}$ of spinal sufentanil with neostigmine to twice the $ED_{50}$ of plain spinal sufentanil. A synergistic effect on duration of analgesia of neostigmine was observed. D'Angelo et al., however, reported no increase in analgesic duration with neostigmine as part of a multidrug combination (local anaesthetic, opioid, clonidine, and neostigmine).[114] Furthermore, several authors reported a very high incidence of severe nausea and vomiting.[115]

Currently bupivacaine is mostly used for intrathecal labour analgesia, usually in combination with opioids. Also levobupivacaine and ropivacaine have been used successfully during labour analgesia. Lim et al. compared 2.5 mg bupivacaine with 2.5 mg ropivacaine and 2.5 mg levobupivacaine.[116] Bupivacaine produced the longest duration of analgesia but with the highest incidence of motor block. These results were not confirmed by Sah et al. who found no difference between levobupivacaine and bupivacaine.[117] Camorcia and co-workers described the minimum local analgesic doses of all three local anaesthetics and suggested a potency hierarchy of spinal bupivacaine > levobupivacaine > ropivacaine.[118] Whitty et al. described the $ED_{95}$ of spinal bupivacaine combined with fentanyl.[119] Van de Velde et al. were the first to construct the full dose–response relationship of spinal ropivacaine, levobupivacaine, and bupivacaine combined with opioids for labour analgesia.[120] They noted that bupivacaine was significantly more potent than both the other local anaesthetics, but that ropivacaine and levobupivacaine were of similar analgesic potency (Figure 14.6).[120]

## Initiation using single-shot spinal, continuous spinal, or caudal analgesia

### Single-shot spinal

SSS anaesthesia is a simple and highly effective technique using a spinal needle which can be cutting (e.g. Quincke) or non-cutting

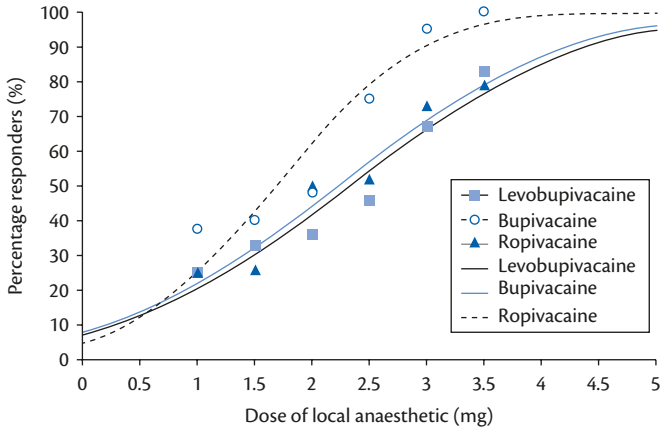

**Figure 14.6** Full dose–response curves for bupivacaine, ropivacaine, and levobupivacaine combined with sufentanil throughout all stages of labour. Bupivacaine is significantly more potent then both other agents.
Reproduced with permission from Van de Velde M, Dreelinck R, Dubois J, Kumar A, Deprest J, Lewi L, Vandermeersch E , Determination of the full dose-response relation of intrathecal bupivacaine, levobupivacaine, and ropivacaine, combined with sufentanil, for labor analgesia, *Anesthesiology*, Volume 106, Issue 1, pp. 149–156, Copyright © 2007 Wolters Kluwer Health.

(e.g. Whitacre/pencil-point). Cutting needles produce a high incidence of PDPH especially in obstetric patients and are currently rarely used in obstetric anaesthesia. Spinal needles also vary in size between 24 and 29 G needles. SSS is rarely used for labour analgesia and usually only in situations where brief analgesia is required shortly before anticipated delivery or when patients have difficulty in remaining immobile during neuraxial insertion.

### Continuous spinal

In rare situations, continuous spinal anaesthesia can be used. A spinal needle punctures the dura and a catheter is threaded into the subarachnoid space. This can be done using the Tuohy epidural needle and the epidural catheter following accidental dural puncture or by using specifically designed spinal catheter sets. However, especially in obstetric patients, a very high incidence of PDPH occurs following continuous spinal analgesia.[121] Additional risks include technical difficulties inserting the catheters, unreliability of the catheters, and injecting an accidental epidural dose intrathecally. Therefore this technique is reserved for high-risk patients in which pure opioid analgesia is useful.[122]

## Choosing between combined spinal–epidural and conventional epidural analgesia

Obstetric anaesthetists are divided when questioned on the place of CSE in labour analgesia. In a 2012 Cochrane review, it was concluded that CSE offers little benefit as compared to conventional epidural analgesia.[123] However, it was acknowledged that CSE produces faster analgesia. Side effects on mother, infant, and labour were similar between techniques, apart from a slight increase in the incidence of pruritus with CSE. However, because of this ongoing discussion, we feel that a more detailed overview of the available literature is required. Also perhaps this more detailed discussion might aid clinicians in choosing one over the other technique for individual patients and situations.

### Onset Time of Analgesia

Arguably the most obvious advantage of the CSE technique is the rapid onset of effective analgesia.[123] Consistently, effective labour analgesia is accomplished within 4–8 minutes following the intrathecal injection of drugs.[123–139] Following conventional epidural analgesia, initial analgesia is usually achieved within 10 to 25 minutes[133,134] (Figure 14.7).

It is important to note, however, that although the onset time of epidural analgesia might be reasonable, a wide interpatient variability exists depending on parity, stage of labour and other relevant obstetric and non-obstetric factors. Especially during late or active labour, analgesia following an epidural is often delayed and always requires local anaesthetics. With CSE, onset time is short in all patients irrespective of the stage of labour and can be achieved using pure opioid analgesia. Importantly, in many studies, epidural mixtures used relatively high concentrations of local anaesthetic (>0.2%).

### Quality of pain relief: visual analogue scale scores, satisfaction, and anaesthetist intervention rate

Several trials demonstrated lower visual analogue scale (VAS) scores for labour pain during the first hours after initiation with CSE,[140–143] whilst other comparative trials could not demonstrate a difference in VAS scores.[144,145] No trials report higher VAS scores with CSE. A recent trial by Gambling et al. demonstrated better first-stage analgesia with CSE, despite fewer epidural top-ups.[146]

Less unilateral analgesia with CSE was reported as compared to conventional epidural analgesia.[138] Interestingly, Hess et al. found that patients treated with conventional epidural analgesia experienced more recurrent breakthrough pain as compared to CSE-treated women.[147] Goodman et al., however, failed to corroborate these findings.[142]

The presence of a dural puncture may facilitate the passage of epidurally administered drugs during maintenance of analgesia to the CSF; at least in animals, such an effect has been reported.[148] In patients, Leighton et al. also reported that epidural bupivacaine blocked more dermatomes when administered following an initial dural puncture as compared to epidural bupivacaine administered without prior dural puncture.[149] Cappiello et al. perforated the dura with a 25 G Whitacre needle without administration of spinal drugs.[150] The control group had no dural puncture. In both groups, analgesia was initiated with an epidural local anaesthetic/opioid mixture. Patients treated with a dural puncture had better sacral spread, shorter onset of analgesia, and better quality pain relief. In a similar study using a 27 G Whitacre needle, no difference between patients treated with or without a dural puncture could be identified.[151]

### Local anaesthetic consumption

Local anaesthetic requirements are significantly reduced with CSE as compared to low-dose epidural techniques.[133,137,138,141,143] Discussion is ongoing as to whether this is the result of the omission of the initial epidural bolus or that also during labour a dose-sparing effect persists (as a result of the dural hole).

However, a recent trial by Patel et al., using the MLAC methodology, determined that with CSE local anaesthetic requirements might be increased for the second epidural injection as compared to conventional epidural analgesia.[152] However, it must be noted

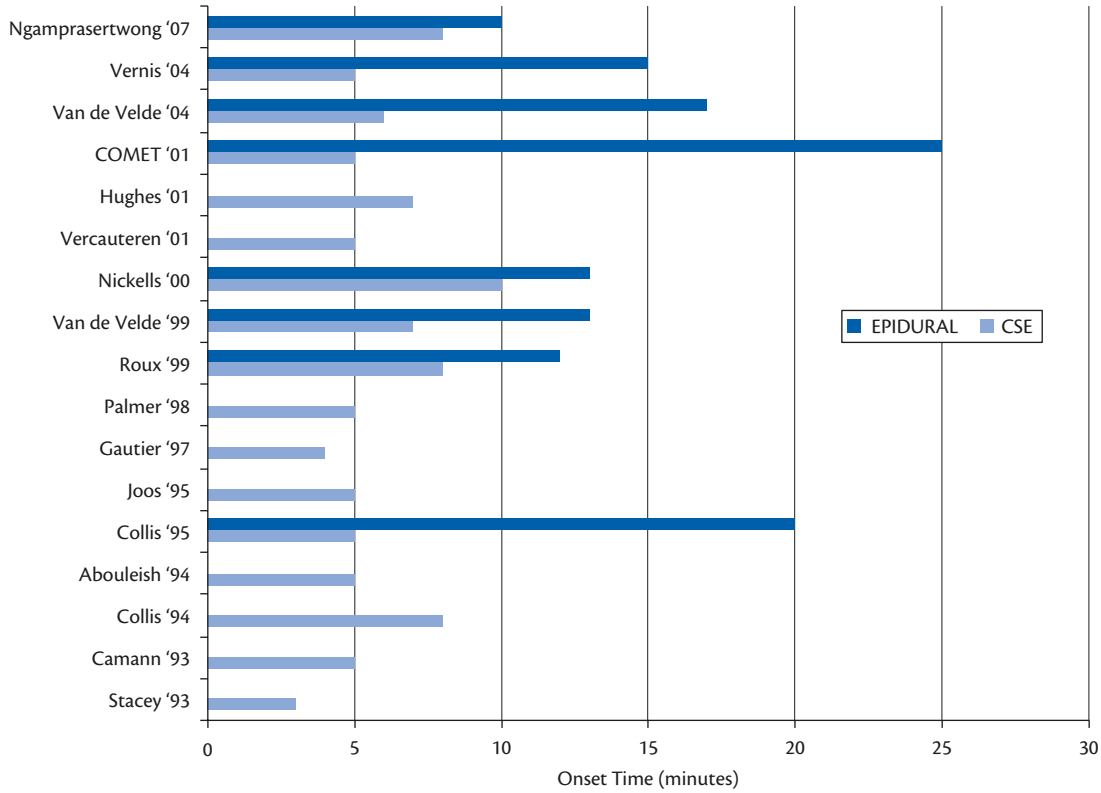

**Figure 14.7** Onset time of analgesia in different studies in patients treated either with combined spinal epidural analgesia (CSE, light blue bars) or conventional epidural analgesia (dark blue bars).
Data from various studies (see references).

that the effect was marginal and that the methodology of the study does not reflect clinical practice in which the epidural maintenance strategy is started immediately following the initial dose and not when the patient has pain once again.

### Duration of initial analgesia

Spinal analgesia typically lasts for 90–150 minutes, but a wide variety exists depending on administered spinal drugs and pain-modulating factors such as parity, stage of labour, type of labour, frequency, and strength of contractions. The initial duration of the spinal dose is similar to an initial epidural bolus.[153–163] In ideal circumstances using multidrug combinations, spinal analgesia can last more than 4 hours.[156,160] Many authors continue the search for long-lasting spinal analgesia, hoping that SSS analgesia will ultimately be achieved. Despite extensive research, disappointingly, no more (and often less) than 50% of patients deliver during initial spinal analgesia.

### Epidural catheter reliability

Following the initial spinal injection, due to bilateral analgesia and sensory changes, testing of the epidural catheter can be difficult and one is unsure if the epidural is in the correct space. Furthermore, the reliability of the catheter to achieve bilateral analgesia once the spinal dose has worn off has not been proven until used. However, various investigators noted that the reliability of epidural catheters following CSE was similar or increased as compared to stand-alone epidural catheters.[138,150,164–170] There was less need for epidural catheter replacement and there was less unilateral analgesia requiring catheter manipulation. Unfortunately many of these studies are retrospective or have catheter reliability as a secondary outcome factor.

When using a CSE technique, a perfect midline approach is required to identify the subarachnoid space and consequently more epidural catheters are positioned reliably into the epidural space. Interestingly, Thomas et al. noted that when no CSF was obtained following attempted CSE, subsequently much more epidural catheters required replacement as compared to those catheters placed when CSF was noted.[151]

### Failed spinal component

Failure to identify the spinal space and produce good spinal analgesia is reported in 0–18% of patients.[151] As with every technique, failure may occur, but in these instances the epidural catheter can still be used to provide analgesia. Failure of the spinal component indicates that the epidural needle is not perfectly situated on the midline and is a risk factor for subsequent epidural catheter failure.[151]

## Side effects of neuraxial analgesia initiation

### Pruritus

This is the most common side effect of neuraxial opioids, occurring in almost all patients. In the most recent Cochrane review, pruritus was more frequent following CSE and was reported to be the only complication occurring more frequently with CSE.[123] It usually develops shortly after analgesia. It is mild and hardly ever requires antipruritic therapy.

## Nausea

Nausea and vomiting are very rare complications during CSE and conventional epidural analgesia. No differences in the incidence of nausea have between reported when comparing the two techniques, except in the retrospective trial by Miro et al. who reported more nausea and vomiting in patients treated with epidural analgesia.[166] We must remember that nausea is a part of the birth process especially during induced labour.

## Hypotension

As with any neuraxial technique, hypotension can occur following labour analgesia. Both CSE and conventional epidural analgesia have been associated with usually mild hypotension, which is easily treated.[133] Hypotension following the spinal injection is transient and occurs within the first 30 minutes following initiation of analgesia. In clinical, routine practice it is important to avoid the supine position. Although opioids do not produce sympatholysis, hypotension is observed with pure intrathecal opioid analgesia.[171] When local anaesthetics are combined, hypotension seems to be more pronounced, but clinically is usually easily treated. Intrathecal clonidine, however, is often associated with severe hypotension and this author cannot recommend its routine use based on his personal experience with this drug. Hypotension can be severe and is often protracted requiring prolonged supportive vasopressor therapy.[172]

## Respiratory depression

Several case reports have demonstrated that lipid-soluble opioids may induce respiratory depression.[173] In some, but not all, cases respiratory arrest occurred in relatively short-stature women who had received parenteral or epidural opioids prior to the spinal injection. Fortunately, respiratory depression occurred typically within the first 30 minutes and was easily treated and reversed using naloxone. In one patient, chest compressions and resuscitation were required.[173] Ferrouz et al. performed a retrospective chart analysis and reported one respiratory arrest in over 5000 CSEs performed with 10 mcg spinal sufentanil.[174] As this complication is rare, most authors advocate vigilance and advise using lower doses of intrathecal opioids than those initially used on empirical grounds.

Other complications related to excessive rostral spread of opioids and local anaesthetics have been described and include aphonia, aphagia, dysphagia, altered levels of consciousness, high sensory block, and transient swallowing difficulties. Sudden hypoglycaemia has also been described.[175]

## Motor block

For many years, strategies to reduce the incidence and severity of motor block, associated with epidural analgesia, have been designed. Lower concentrations of local anaesthetics, the addition of opioids and other adjuvant drugs, the introduction of patient-controlled epidural analgesia, and the use of newer local anaesthetics have been instrumental in reducing problematic motor block. Low-dose epidurals are successfully used to allow labouring women to maintain mobility whilst being completely pain free.[137] With CSE it is easier to provide effective analgesia with no or very minute doses of local anaesthetics. As already described, CSE decreases both the total local anaesthetic consumption[133,137] and the occurrence of motor block compared to standard epidural techniques.[133,137]

Some have questioned the safety of walking during labour and neuraxial analgesia.[176] However, several authors demonstrated that with CSE and epidurals motor function and balance remained intact, similar to pregnant patients without neuraxial analgesia.[177]

Although reduced motor block and ambulation during neuraxial analgesia are certainly feasible, controversy concerning the benefits of ambulation remains. Several trials demonstrated that ambulation during labour does not affect the outcome of labour,[178] whilst others did note a beneficial effect of ambulation. In patients without epidural analgesia, ambulation halved the operative delivery rate.[179] Ambulation also reduced the length of the second stage of labour.[180] In the COMET trial, mobile techniques for labour analgesia were associated with an improved labour outcome.[137,164]

## Fetal heart rate changes

Abnormal fetal heart rate recordings and fetal bradycardia are worrying side effects that may follow any type of effective labour analgesia. Wong et al. reported more abnormal cardiotocographic readings following CSE as compared to systemic analgesia.[9] Some authors reported that this complication could be more common following intrathecal opioids than following conventional epidural analgesia.[107,108] Clarke et al. were the first to describe in detail the association between intrathecal opioids, uterine hyperactivity, and fetal bradycardia in the absence of maternal hypotension.[107]

Mardirossof et al. performed a meta-analysis of several prospective trials comparing intrathecal opioid analgesia with non-intrathecal opioid analgesia with respect to fetal bradycardia (Figure 14.8).[181] It was concluded that intrathecal opioids were associated with significantly more fetal heart rate abnormalities. Vercauteren et al. suggested that the incidence of fetal bradycardia depended on the dose of the intrathecal opioid.[182] Van de Velde et al. performed a prospective, randomized trial specifically designed to evaluate the effects of intrathecal opioids on the incidence of non-reassuring fetal heart rate changes.[109] These authors concluded that high doses of intrathecal opioids increased the incidence of fetal heart rate abnormalities despite a reduced incidence of hypotension. The presumed mechanism of opioid-induced non-reassuring fetal heart rate tracings is uterine hyperactivity caused by rapid analgesia and, as a result, a rapid decrease in maternal circulating catecholamines.

Recently, Patel et al. compared CSE and conventional epidural analgesia and found that both techniques influenced the fetal heart rate, but that there was no difference between the two techniques with respect to inducing non-reassuring fetal heart rate changes.[183]

## Postdural puncture headache

Since CSE includes a dural puncture, there is a theoretical risk of PDPH. This is a devastating complication in an otherwise healthy mother, keen on taking care for her newborn child. However the use of small-gauge atraumatic spinal needles (26–29 G) has dramatically decreased the problem. From the available literature it seems that PDPH due to neuraxial analgesia occurs in no more than 1% of patients. Furthermore, the incidence is not increased as compared to conventional epidural analgesia.[132,184] Norris et al. reported that unintended dural puncture with the

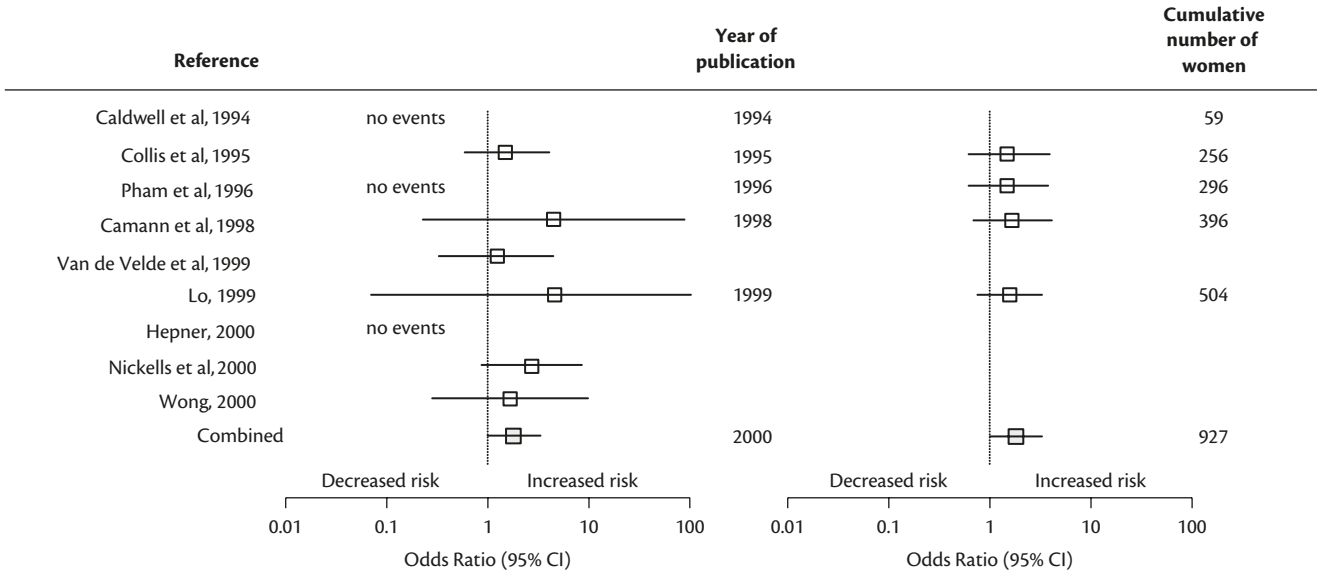

**Figure 14.8** Meta-analysis of randomized, double-blind trials evaluating the effect of intrathecal opioids on fetal heart rate changes as compared to analgesia without intrathecal opioids. Please refer to original paper for references.

[a]P < 0.05 versus bupivacaine.

epidural needle occurs much more frequently when using conventional epidural analgesia as compared to CSE.[184] Rarely the spinal needle itself is responsible for PDPH. Usually a dural tap with either the Tuohy needle or the epidural catheter causes postural headache. It is also worthwhile to mention several reports advising the insertion of the epidural catheter in the subarachnoid space following an accidental dural tap. The incidence of PDPH and blood patching seems reduced when the epidural catheter is threaded intrathecally, although the evidence is conflicting.[185–187]

### Neurological deficit

With any central neuraxial technique permanent neurological deficit is a rare but devastating possibility. If a CSE is inserted at a level higher then L3–4 interspace, direct trauma to the conus medullaris is possible by the spinal needle. Reynolds published a series of seven obstetric patients who had damage to the conus following a CSE performed at a much higher interspace.[188] Anaesthetists are notoriously poor in identifying the correct interspace using landmarks and usually miss the correct interspace by one or more segments cranially.[189] Hence caution when determining the correct interspace is absolutely mandatory.

In 2009, the 3rd National Audit Project of the Royal College of Anaesthetists was published.[190] The report gathered data from hospitals in the United Kingdom over a 2-week period and extrapolated it for 1 year. It looked at major complications following central neuraxial blocks in the United Kingdom, both in obstetric and non-obstetric patients. The report indicated that CSE might carry a higher risk of permanent injury as compared to epidural anaesthesia as it was used in less than 6% of cases but resulted in 13–14% of major complications.

### Meningitis

Several case reports have been published in which meningitis developed after CSE.[191–194] In at least some of these cases an inappropriate aseptic technique was possibly involved. However breaching of the dura carries a theoretically higher risk of infection than when the dura is not perforated. Infectious complications have also been described with epidural techniques. Therefore it must be emphasized that with both CSEs and epidurals a scrupulous aseptic technique is mandatory.

## Conclusion

Epidural analgesia is the most popular method to initiate neuraxial analgesia for labour. However, CSE analgesia is also a very popular technique for labour pain relief and in some parts of Europe (e.g. Belgium) is as common as standard epidurals for initiation of labour analgesia. Epidural analgesia is reliable, relatively simple, and with modern approaches (e.g. drugs, adjuvants, and maintenance strategies) has limited effects on the labour process. However, its onset is relatively slow and a high percentage of epidural catheter failures have been described. A recent Cochrane review suggests that CSE produces much faster analgesia then conventional epidural analgesia. Although various authors limit the use of the technique to specific indications, a wide variety of indications have been described by different authors (Box 14.6). CSE analgesia provides rapid, highly effective analgesia with minimal motor block and low local anaesthetic consumption. Maternal satisfaction is improved. A possible important advantage of the CSE technique is enhanced epidural catheter reliability, but this needs further study and confirmation. PDPH and infections do not occur more frequently than with conventional

**Box 14.6** Indications reported in the literature for the CSE technique to initiate labour analgesia

- Advanced labour with greater than 6 cm cervical dilation
- Rapidly advancing labour such that the mother is severely distressed
- Pushing against a cervix that is not fully dilated
- Repeated epidural failures or attempts
- Ruptured membranes
- Distressed mothers
- Full cervical dilation
- Early labour to produce analgesia without local anaesthetics to minimize motor block or to minimize haemodynamic side effects
- High-risk pregnancies (cardiac, preeclampsia, twins, etc.)
- Obese parturients.

epidural analgesia. However, non-reassuring fetal heart rate tracings occur significantly more frequently following high doses of intrathecal opioids in CSE and occasionally, respiratory depression, also following high doses of opioids intrathecally, can occur.

CHAPTER 15

# Maintenance of neuraxial labour analgesia

Alex Tiong Heng Sia, Ban Leong Sng, and Serene Leo

## Introduction

Labour pain is one of the most painful experiences a woman can undergo;[1] physical and psychological factors have been shown to influence the extent and severity of pain suffering.[2] Although neuraxial analgesia is relatively invasive, with years of medical research and improved safety, epidural analgesia is now considered the gold standard of labour pain relief. It is the only method that provides excellent analgesia without significant maternal and fetal sedation. Understanding the dynamic and multifaceted nature of labour pain is essential to providing the optimal regimen in the maintenance of analgesia.

Apart from providing the desired degree of pain relief, the other objectives of maintaining an effective neuraxial block would give the mother the ability to titrate the most satisfactory level of pain relief and minimal side effects such as motor blockade. With the introduction of patient-controlled epidural analgesia (PCEA) by Gambling et al. in 1988, parturient 'self-titration' of epidural analgesia was made possible.[3] In spite of that, some women may still require rescue epidural supplementation from 'breakthrough' pain due to a multitude of factors, including misplaced epidural catheters producing inadequate blockade as well as dysfunctional labour and cephalopelvic disproportion that may predispose women to increased pain during labour. The effectiveness of the maintenance of neuraxial blocks is dependent on a variety of factors. The effective and correct placement of the epidural catheter in the epidural space, the use of an appropriate epidural maintenance analgesic drug solution, and the utilization of newer drug delivery systems and technology will contribute to the effectiveness and the ability to individualize therapy.

## The initiation of neuraxial block

An effective induction of labour analgesia is critical to allow a successful continued maintenance of epidural analgesia (see also Chapter 14). There has been an ongoing debate regarding the advantages and disadvantages of epidural labour analgesia versus the newer combined spinal–epidural (CSE) technique. Indeed, the induction of labour analgesia using the CSE technique has gained much popularity in recent years. The advantages of a CSE include a rapid onset of uniform analgesia and minimal motor blockade with the judicious use of small analgesic doses of local anaesthetic and opioid. Consequently, CSE is able to achieve a reliable block of sacral nerve roots with minimal maternal and umbilical cord blood concentrations of analgesics.[4–6] The CSE technique employing the 'needle-through-needle' technique has also been thought to improve the chances of the placement of a properly functioning epidural catheter by prior verification of the subarachnoid space with the spinal needle.[6–8] In addition, the dural puncture created during the CSE technique is thought to allow some subarachnoid transfer of epidurally administered drugs and thus improve the quality of epidural analgesia.[9]

There is also evidence to suggest that blocks initiated by CSE could potentially reduce the risk of breakthrough pain during the subsequent maintenance of epidural analgesia.[10] In a randomized controlled trial of 100 women, Goodman et al.[10] compared initiation of neuraxial analgesia with epidural analgesia (3 mL of epidural bupivacaine 2.5 mg/mL, followed by 10 mL of bupivacaine 1.25 mg/mL with 50 mcg fentanyl) to CSE (intrathecal bupivacaine 2.5 mg with 25 mcg fentanyl). Both groups received epidural infusions of bupivacaine 0.625 mg/mL with 2 mcg/mL fentanyl at 12 mL/h. The visual analogue scale scores for pain were lower in the CSE group at 10 minutes and 30 minutes after initiation of neuraxial analgesia, although subsequent analgesia was comparable.

The potential benefits of CSE are also supported by a retrospective observational study of 6497 parturients; the authors concluded that though comparable in terms of safety, the quality of analgesia was better in patients who received CSE when compared to conventional epidural analgesia.[11] While the current literature supports a faster onset time to effective analgesia when the CSE technique is used for initiation of labour analgesia as compared with epidural analgesia, it is still equivocal with regard to the impact of CSE on overall maternal satisfaction with analgesia.[12,13]

The latest Cochrane systematic review by Simmons et al. has shown that CSE confers no advantage over epidural analgesia in terms of maternal satisfaction scores or the percentage of patients requiring physician-administered top-up doses[14] for breakthrough pain. Moreover, there were no differences in the incidence of maternal side effects such as motor block, hypotension, postdural puncture headache, or adverse effects on the neonate.[10,12]

CSE may be associated with a greater incidence of pruritus compared to epidural analgesia owing to the administration of intrathecal opioids.[5,11,12] There were earlier concerns of the effects of the spinal component of CSE on fetal heart rate abnormalities. Van de Velde et al. showed that the use of intrathecal opioids could be related to a higher incidence of non-reassuring fetal heart rate patterns, particularly in those who had received an analgesic mixture that contained a relatively higher dose of intrathecal opioids, that is, sufentanil 7.5 mcg versus 1.5 mcg.[15] This could be

attributed to the rapid onset of pain relief associated with a higher dose of intrathecal opioids leading to a more sudden decrease in plasma epinephrine and beta-endorphins; this imbalance causes an unopposed action of oxytocin and norepinephrine, with the resultant uterine hypertonus and reduced blood flow, respectively. A smaller dose of intrathecal opioid may reduce the risk of uterine hypertonus. A meta-analysis by Mardirosoff et al. concluded that only 28 women need to receive intrathecal opiates for one fetal bradycardia to occur.[16]

However, Skupski et al.[17] found that there were no differences between epidural and CSE analgesia with similar outcomes in the rate of caesarean delivery and presence of prolonged decelerations in a randomized non-blinded trial. More recently, Patel et al. conducted a double-blinded randomized controlled trial comparing CSE with epidural analgesia.[18] CSE analgesia during the first stage of labour did not increase fetal heart rate abnormalities or have an adverse effect on neonatal or obstetric outcomes when compared to epidural analgesia. However, these authors admitted that only two of the studies in the Mardirosoff meta-analysis were directly comparable with their study, which could explain the different conclusions.

## The role of drugs used for epidural analgesic solutions

When the effect of the induction dose of neuraxial blocks wears off, the maintenance of labour epidural analgesia largely depends on the mode of administration of drugs through the indwelling epidural catheter. Over the past decade, labour epidural research has been focused on maintaining effective pain relief throughout labour while minimizing the undesirable effects of maternal motor blockade to preserve maternal comfort and retaining the option of ambulation. Reducing motor blockade also retains perineal muscle power to perform expulsive efforts at the time of delivery.

The choice of drugs for labour epidural analgesia should be safe for mother and fetus, and ideally not affect the progression of labour.[19] Historically, undiluted plain bupivacaine (0.5%) was used for the maintenance of epidural analgesia and resulted in dense motor blockade. The addition of a short-acting opioid (e.g. fentanyl) to the local anaesthetic solution permitted a significant reduction in the effective concentration of bupivacaine, so alleviating the problem of dense motor blockade. Chestnut and colleagues[20] reported effective analgesia with concentrations as low as 0.0625% bupivacaine when combined in a solution with 2 mg/mL fentanyl. In the Comparative Obstetric Mobile Epidural Trial (COMET)[19] conducted in the United Kingdom, traditional epidural labour analgesia (using 0.25% bupivacaine) was compared with low-dose CSE and a low-dose epidural infusion (using 0.1% bupivacaine and 2 mg/mL fentanyl). The investigators randomly assigned 1054 nulliparous women requesting epidural pain relief to traditional epidural (n = 353), low-dose CSE (n = 351), or low-dose infusion epidural (n = 350). The authors found that the use of a low-dose maintenance infusion after the induction of labour analgesia with either CSE or plain epidural led to higher rates of spontaneous vaginal delivery. The spontaneous vaginal delivery rate was 35.1% in the traditional epidural group, 42.7% in the low-dose CSE group (odds ratio (OR) 1.38; 95% confidence interval (CI) 1.01–1.89; P = 0.04) and 42.9% in the low-dose epidural group (OR 1.39; 95% CI 1.01–1.90; P = 0.04). These differences were accounted for by a reduced incidence of instrumental vaginal delivery in the low-dose groups, most likely due to better preservation of motor function during labour and delivery. Analgesic efficacy was similar in all three groups and there was no difference in the rates of caesarean delivery. In current obstetric anaesthetic practice, continued routine use of traditional epidurals using concentrated solutions of local anaesthetics cannot be justified, and the use of low-dose epidurals for labour analgesia maintenance has since gained popularity.

A combination of a low-dose local anaesthetic with a lipid-soluble opioid is commonly administered as the spinal component of the CSE technique. A recent review has found that the dose of 2.5 mg intrathecally of bupivacaine, ropivacaine, and levobupivacaine used for CSE labour analgesia, with or without lipophilic opioids, should provide adequate analgesia[5] (Table 15.1). Bupivacaine, in concentrations from 0.0625% to 0.125%, is a very commonly used local anaesthetic for epidural analgesia. It is often used in combination with fentanyl (1.5–3.0 mcg/mL) and sufentanil (0.2–0.33 mcg/mL) for the maintenance of epidural and CSE analgesia. Levobupivacaine is the S enantiomer of bupivacaine with comparable potency. However, levobupivacaine may have the advantage of being potentially less cardiotoxic, even though this may not be clinically relevant since low concentrations are typically used in modern labour epidurals.

Ropivacaine is another popular local anaesthetic that confers a lower potential for cardiotoxicity and less motor blockade when compared to bupivacaine. Although early studies on ropivacaine have suggested that its potency is 60% of bupivacaine, recent evidence concluded that ropivacaine is equipotent with bupivacaine to produce sensory blockade at clinically relevant doses.[21] The maintenance epidural concentration with ropivacaine is recommended to be 0.08% and 0.2%.[22] Ropivacaine has limited transfer across the placenta, reducing fetal exposure similar to bupivacaine, possibly due to its high protein binding limiting uteroplacental transfer.[23] There could be an increased incidence of motor blockade in parturients receiving bupivacaine compared to ropivacaine, although this difference may not be clinically significant during a relatively short labour.[24–28] However, in prolonged labour, bupivacaine may result in a significantly higher incidence of motor blockade.[29]

Typically, the combination of local anaesthetic with lipid-soluble opioids such as fentanyl or sufentanil allows the use of lower doses of both agents and minimizes the adverse effects such as motor blockade and other risks due to systemic absorption. The use of opioids in combination with local anaesthetics is common practice and confers a synergistic effect.[30] Both fentanyl and sufentanil are suitable when used with epidural local anaesthetics for neuraxial analgesia.[31] The doses of epidural fentanyl (commonly about 2 mcg/mL) and epidural sufentanil (commonly up to 1 mcg/mL) used in labour analgesia are safe and effective for both mother and neonate.[32,33] For instance, a continuous epidural infusion (CEI) with 0.125% bupivacaine with 2 mcg/mL fentanyl at a rate of 10 mL/h showed a constant maternal and neonatal drug concentration with no fetal accumulation; the umbilical gas values and neurobehavioural scores were within normal limits with no significant neonatal adverse effects.[32]

Epidural clonidine (an alpha-2-receptor agonist that modulates pain perception at the spinal level) has shown some promise in

recent research as an adjuvant for labour epidural analgesia; the addition of clonidine to a bupivacaine–adrenaline–sufentanil mixture improved the quality and duration of analgesia as compared with solutions not containing clonidine.[34] Epidural clonidine 2 mcg/mL when added to levobupivacaine 0.0625% with sufentanil 0.25 mcg/mL using PCEA has been shown to improve labour analgesia, reduce manual supplementation for rescue analgesia, and reduce pruritus.[35] However, there was no improvement in maternal satisfaction using this regimen. Furthermore, blood pressure was found to be lower in the clonidine group but without adverse clinical consequences. Epidural clonidine (75 mcg) when given with neostigmine 500 mcg after intrathecal ropivacaine and sufentanil via a CSE technique resulted in significantly prolonged initial analgesia 114 (105–163) minutes compared to placebo 95 (70–120) minutes.[36] There was also a reduced hourly ropivacaine consumption. Therefore, epidural clonidine may have distinct advantages to improve the quality of labour neuraxial analgesia, although its routine use is generally not recommended due to the potential risk of hypotension and sedation.

Spinal clonidine has been investigated also for its efficacy and safety during initiation of neuraxial analgesia.[37] Spinal clonidine 50 mcg has been shown to prolong analgesia when added to sufentanil 7.5 mcg and bupivacaine 2.5 mg early in the first stage of labour. This was achieved with similar pain scores and side effects, including motor block, sedation, and hypotension. However, there is more evidence to suggest that spinal clonidine may not be recommended for routine use.[38] There is an increased risk of hypotension and abnormal fetal heart tracing patterns with the use of low-dose spinal clonidine.[38] Other studies have suggested that spinal clonidine may not increase the duration or quality of analgesia when used for initiation of labour neuraxial analgesia.[39]

Similarly, a continuous epidural administration of neostigmine has been shown to result in a bupivacaine-sparing effect.[40] The addition of epidural neostigmine 4 mcg/mL reduces the hourly consumption of bupivacaine by 19–25% with PCEA during labour. There was no increased risk of nausea, uterine hypertonus, or fetal heart rate abnormalities. However, mild sedation was present. Despite studies reporting the advantages of using epidural clonidine and neostigmine for epidural labour analgesia, safety concerns have been raised on their use for neuraxial labour analgesia.[41,42]

## The role of epidural drug delivery systems: patient-controlled epidural analgesia

The earliest method of maintaining labour epidural analgesia was via manually administered epidural boluses, a practice that is certainly labour intensive and cumbersome.[43] With the advent of automated infusion pumps, it became possible to administer

a continuous infusion of an analgesic solution via an indwelling epidural catheter. Recently, due to increasing awareness of the benefits of providing parturients greater autonomy over their own labour analgesic regimens, more interactive and flexible analgesic modalities have been developed.

PCEA is a mode of epidural drug delivery that allows the parturient to administer intermittent boluses of epidural solution herself. This provides flexibility to accommodate her escalating analgesic requirements as labour progresses or as labour augmentation regimens are started. PCEA programme settings such as demand bolus, lockout interval, background infusion rate, and hourly maximum dose limits are usually decided upon by the attending anaesthetist.

The earliest study comparing PCEA with CEI was published in 1988 by Gambling et al.[3] Since then, there have been numerous studies confirming the various advantages of PCEA over CEI as a mode of labour epidural drug delivery. The use of PCEA has been shown to reduce the total volume of local anaesthetic solution used without compromising quality of analgesia, resulting in a lower incidence of side effects and greater maternal satisfaction with labour analgesia.[43]

An earlier meta-analysis by Van der Vyver et al.[44] reviewed nine studies involving a total of 640 parturients, which compared demand-only PCEA (without background infusion) with CEI. The authors found that parturients in the PCEA group required lower total doses of local anaesthetic solution, had less lower limb motor blockade, and were less likely to require epidural rescue medication than parturients in the CEI group. D'Angelo[45] conducted another review of 19 PCEA studies, which demonstrated that PCEA had several advantages over CEI and intermittent epidural boluses. These include reduced consumption of local anaesthetics, reduced motor blockade, reduced pain scores, reduced clinician and midwife workload, and increased maternal satisfaction.

Although PCEA for labour analgesia has gained widespread acceptance, research to optimize the PCEA programme settings are still ongoing. The need for a basal infusion, in particular, had been a topic of much debate. Some studies found that a background infusion helped to reduce the incidence of breakthrough pain requiring clinician supplementation and reduce pain scores without any increase in local anaesthetic consumption.[46–48] On the other hand, other studies found that a background infusion led to an increase in local anaesthetic consumption without any improvement in analgesic efficacy.[49–51]

Common PCEA parameters include a background infusion of 5–8 mL/h, a bolus dose of 5–10 mL, and a lock-out interval of between 10 to 20 minutes.[22] A review by Halpern et al. also suggested that administration of approximately one-third of the hourly dose via a continuous infusion may minimize the risk of breakthrough pain, whilst optimizing dose titration for the parturient.[52] Furthermore, a meta-analysis reported in the American Society of Anesthesiologists practice guidelines for obstetric anaesthesia suggested that a background infusion as part of a PCEA regimen does provide better analgesia (OR 3.33; 95% CI 1.87–5.92).[13] Although many of studies report a decrease in consumption of local anaesthetic without the basal infusion, there are no reports of toxicity or excessive motor block associated with the use of a basal infusion.

This conclusion was shared by Loubert et al. who in a review, reported that most studies seem to recommend a moderate basal infusion (around 4–6 mL/h) for benefits of reduced pain scores and reduced incidence of breakthrough pain without increasing the risk of side effects or overall local anaesthetic consumption.[5] However, increasing background infusion rates may lead to greater local anaesthetic consumption. To find a balance between fewer physician interventions and reducing local anaesthetic use, Smiley and Stephenson have suggested a strategy that consists of administering about a third of the expected local anaesthetic hourly demand as a background infusion.[53]

Unfortunately, the ideal bolus dose and lockout interval for PCEA remain unknown. Stratmann et al. compared a 5- versus 15-minute lock-out interval and concluded that the shorter lock-out interval resulted in a better bolus-delivered-to-bolus-attempted ratio, which is thought to be an index of PCEA efficiency. However, there was no demonstrable improvement in any other outcomes such as pain scores, physician intervention, or maternal satisfaction.[54] Halpern and Carvalho compared six studies with various PCEA settings to determine the ideal bolus volume and lock-out interval.[52] They suggested that larger boluses (with a corresponding longer lock-out interval) may improve spread of the local anaesthetic solution in the epidural space with a potential for better analgesia. However, there were no significant improvements in outcomes such as analgesic efficacy, maternal satisfaction, or physician top-up requirements. They concluded that there was no ideal bolus dose or lock-out interval setting for labour PCEA. Loubert and colleagues shared a similar opinion, concluding that there is no strong evidence to favour one regimen over another.[5]

## The role of automated mandatory boluses

After PCEA gained popularity and became established, interest was shown in administering epidural solutions as automated mandatory boluses or programmed intermittent boluses instead of a slow continuous infusion. In a laboratory experiment, Kaynar et al. found that a bolus injection, administered at greater injection pressures, allowed drug exit from all holes of a multi-orifice catheter, whereas a slow continuous infusion, given at lower injection pressures, caused the drug to exit almost exclusively from the most proximal hole.[55] Based on his study in human cadavers, Hogan also suggested that the use of intermittent boluses could produce a more uniform epidural block due to an increased injectate pressure compared to a continuous infusion.[56]

The above experimental evidence has been explored in a clinical setting in several trials. Fettes et al. recruited 40 primigravidae who after initiation of epidural analgesia were randomized to receive either an infusion of 0.2% ropivacaine with fentanyl 2 mg/mL at 10 mL/h, or hourly boluses of 10 mL of the same solution.[57] Their results showed that regular intermittent epidural injections were associated with a reduced need for epidural rescue medication, less epidural drug use, and a longer time to first rescue bolus, while providing equivalent pain relief, than continuous infusion of the same solution of ropivacaine and fentanyl. Chua and Sia randomized 42 nulliparous parturients who initially received CSE analgesia, to receive either automated intermittent boluses of 0.1% ropivacaine with fentanyl 2 mcg/mL at 5 mL every hour, or a continuous infusion of the same solution at 5 mL/h.[58] Their results showed that parturients in the intermittent bolus group had a longer duration of analgesia after CSE, reported lower pain scores,

and achieved a higher sensory block than those in the continuous infusion group.

Lim et al. went on to investigate the effect of administering automated mandatory boluses in a smaller volume.[59] The authors randomized 50 parturients after induction of analgesia with a CSE technique to receive either automated intermittent boluses of 2.5 mL every 15 minutes or a continuous infusion of 10 mL/h. In both groups, the epidural solution consisted of 0.1% ropivacaine with fentanyl 2 mcg/mL. The results showed that there were no significant differences between the two groups in terms of breakthrough pain and that the low-volume bolus did not appear to improve analgesic efficacy compared to a continuous epidural infusion.

Attempts were soon made to incorporate background automated mandatory boluses into a PCEA programme. Wong et al. investigated 158 multiparous women scheduled for induction of labour at cervical dilation between 2 and 5 cm to receive CSE analgesia. The two groups received either boluses of 6 mL every 30 minutes in conjunction with PCEA or continuous basal infusion of 12 mL/h with PCEA, using a dual pump system.[60] The epidural solution used for the basal infusion was bupivacaine 0.0625% and fentanyl 2 mcg/mL. The bolus group had less bupivacaine consumption, similar analgesic efficacy, and higher patient satisfaction scores compared to those in the infusion group.

Sia et al. devised a computer program that allowed a single infusion pump to function as a PCEA pump with the ability to deliver either background intermittent boluses or a basal infusion in addition to patient-demand boluses.[61,62] This was achieved by uploading pre-programmed PCEA algorithms into a personal digital assistant that was connected to a normal infusion pump. Their initial study was done on 42 parturients whom after successful induction of CSE analgesia, were randomized to receive either a PCEA with a continuous basal infusion of 5 mL/h or PCEA with automated boluses of 5 mL every 60 minute.[61] They found that the automated bolus group had a reduced overall consumption of ropivacaine, longer duration of analgesia before the first PCEA self-bolus, as well as a smaller proportion of patients who self-administered PCEA boluses compared to the infusion group. There was, however, no difference in the need for clinician interventions between both groups. A follow-up study using a modified version of the original algorithm demonstrated very similar results to the first study, suggesting that further refinement of the automated bolus PCEA regimen was needed in order to reduce the incidence of breakthrough pain requiring clinician intervention.[62]

Capogna et al. performed a double-blind randomized controlled trial in which 145 women in labour, after initiation of epidural analgesia, were randomly assigned to receive 10 mL boluses of levobupivacaine 0.0625% with sufentanil 0.5 mcg/mL every hour or a continuous epidural infusion of 10 mL/h.[63] A second pump functioning as a PCEA pump containing levobupivacaine 0.125% was used to treat breakthrough pain. The outcome of interest was the degree of maternal motor blockade as assessed in both lower extremities using the modified Bromage score. The authors found that motor block was reported in 37% of patients in the infusion group and in 2.7% in the intermittent bolus group ($P < 0.001$; OR 21.2; 95% CI 4.9–129.3). Also, motor block occurred earlier and was more frequent at full cervical dilation in the infusion group. The incidence of instrumental delivery was 20% for the infusion group and 7% for the bolus group ($P < 0.03$). Total levobupivacaine consumption, number of patients requiring additional PCEA boluses, and mean number of PCEA boluses per patient were lower in the bolus group. There were no observed differences in pain scores. The authors concluded that maintenance of epidural analgesia with intermittent boluses compared with a continuous infusion resulted in a lower incidence of maternal motor block and instrumental vaginal delivery.

Attempts have also been made to study the effects of manipulating the programmed intermittent bolus time interval and injection volume on total drug use for labour analgesia. Wong et al. randomized 190 nulliparous patients in labour to a PCEA regimen along with either one of the three bolus dose regimens for maintenance of labour analgesia: 2.5 mL every 15 minutes, 5 mL every 30 minutes, or 10 mL every 60 minutes.[64] They found that the total bupivacaine consumption decreased significantly when the bolus time interval and bolus volumes were increased. However, there was no difference in pain scores, PCEA demands or administrations, incidence of breakthrough pain requiring physician top-ups, time to first PCEA self-bolus, and patient satisfaction in all three groups.

The studies discussed in the previous paragraphs have investigated fixed doses of automated boluses in combination with a PCEA program for labour analgesia. However, it is known that labour pain intensifies with progressive cervical dilatation and hence the parturient's analgesic needs may escalate as her labour progresses or as augmentation regimens are started. Hence, a variable frequency of background automated boluses that is responsive to the patient's needs may provide more efficacious analgesia[65] (Figure 15.1). Novel software enables a PCEA pump to determine the patient's analgesic usage over the past hour and deliver 5 mL machine boluses once, twice, three, or four times per hour depending on the patient's most recent analgesic usage (hence the term variable frequency). The trial included 102 nulliparous women in labour who were randomized to receive either a PCEA with variable frequency automated mandatory boluses or a PCEA with a basal infusion of 5 mL/h following initiation of labour analgesia with a CSE technique. The epidural solution was ropivacaine 0.1% with fentanyl 2 mcg/mL. Patients in the automated bolus group were found to have a significantly lower incidence of breakthrough pain requiring clinician intervention (5.9% vs 23.5%; $P = 0.023$) as well as higher maternal satisfaction scores. There were no differences in mean hourly consumption of ropivacaine, mean hourly pain scores or sensory levels, maternal side effects, mode of delivery, or neonatal outcomes.

George, et al. performed a systematic review and meta-analysis comparing the automated mandatory bolus technique with the use of basal infusion during maintenance of epidural analgesia for labour pain.[66] The review did not find any statistical difference in the rate of caesarean delivery (OR 0.87; 95% CI 0.56–1.35), duration of labour (mean difference (MD), –17 minutes; 95% CI –42 to 7), or the need for anaesthetic intervention (OR 0.56; 95% CI 0.29–1.06). However, the bolus group did result in a small but statistically significant reduction in local anaesthetic usage (MD –1.2 mg bupivacaine equivalent per hour; 95% CI –2.2 to –0.3). Maternal satisfaction score (100 mm visual analogue scale) was higher with the bolus technique (MD 7.0 mm; 95% CI 6.2–7.8).

## Computer integrated patient-controlled epidural analgesia

Despite having patient feedback on analgesic demands on the PCEA, the conventional PCEA still lacks the flexibility to vary its basal infusion rate. The role of a basal infusion is likely to become increasingly important as pain intensifies with labour progresses or when labour oxytocin augmentation is instituted.

The novel clinical algorithm using smart pump technology was devised in 2005. This converts an ordinary continuous infusion pump into a computer-integrated PCEA (CIPCEA) that is more responsive to the parturient's needs. The CIPCEA hardware utilizes a laptop computer with a programmed algorithm to run a standard epidural infusion pump for research (Figure 15.2). This interactive program records the history of the patient's analgesic requirements over the past hour and increases the magnitude of its basal infusion proportionally to the number of demand boluses made. The CIPCEA algorithm adjusts the background infusion to 5, 10, or 15 mL/h if the patient required one, two, or three demand boluses respectively in the last hour and decreases the background

**Figure 15.2** Computer integrated patient-controlled epidural analgesia pump.

infusion by decrements of 5 mL/h if there were no bolus demands in the preceding hour[67] (Figure 15.3). The algorithm is designed to respond to the patient's analgesic requirement to improve analgesic efficacy whilst minimizing increases in local anaesthetic use-associated background infusions.[68]

The feasibility of the CIPCEA was assessed in a pilot study by Sia et al. involving 40 parturients in early labour who were randomized to receive either CEI of ropivacaine 0.1% with 2 mcg/mL with a continuous infusion of 10 mL/h or the CIPCEA regimen following successful induction with CSE analgesia.[69] The CIPCEA regimen was associated with a significant reduction in the incidence of breakthrough pain without increasing local anaesthetic consumption or incidence of side effects.

In a follow-up study, Lim et al. compared the CIPCEA pump with a conventional demand-only PCEA pump, looking specifically at epidural drug consumption.[67] There was no difference in the time-weighted consumption of local anaesthetic between the two groups. The incidence of breakthrough pain requiring unscheduled anaesthetist supplementation was 35% in the conventional PCEA group and 15% in the CIPCEA group, although this difference did not reach statistical significance. The CIPCEA group had significantly higher maternal satisfaction scores.

Sng et al. investigated the administration of CIPCEA versus PCEA with a moderate fixed 5 mL/h basal infusion.[68] The results showed a higher maternal satisfaction with the CIPCEA regimen. Local anaesthetic consumption, visual analogue pain scale scores, and incidence of breakthrough pain were similar in the two groups. The CIPCEA group had a higher basal infusion rate during the second stage of labour, compared with PCEA with moderate fixed basal infusion. This may support earlier findings by Capogna et al. who showed an increased epidural local anaesthetic requirement as labour progresses.[70]

From the studies, the CIPCEA program appears to reduce the incidence of breakthrough pain during maintenance of labour epidural analgesia and increases the maternal satisfaction. There was no increased local anaesthetic consumption or side effects.

Pump technology has progressed and improved to enable novel algorithms to deliver smart interactive systems such as the CIPCEA and variable frequency automated mandatory bolus regimens. Commercially available systems delivering programmed intermittent epidural boluses incorporating programmed boluses and patient boluses are also available (Figure 15.4).

## Conclusion

Labour pain is an extremely subjective and constantly evolving experience. It would be simplistic to apply one epidural regimen to suit all parturients. Instead, individualization of therapy is imperative in providing effective labour analgesia. There have been recent advances in clinical research and medical technology which could aid clinicians in administering the seamless labour epidural analgesia that will hopefully enable every parturient to have a relatively pain-free birthing experience.

## Conflict of interest

Professor Alex Sia has filed for a patent for the variable frequency automated mandatory bolus regimen.

# CHAPTER 16

# Labour analgesia: choice of local anaesthetics

Giorgio Capogna

## Introduction

Local anaesthetics were the mainstay of epidural labour analgesia in the past. The ideal local anaesthetic agent would provide a rapid onset of effective analgesia, with minimal motor block, risk of maternal toxicity, placental transfer, and effects on labour and the fetus, as well as a long duration of action. Traditionally, for many years racemic bupivacaine (hereafter referred to as 'bupivacaine') has been, and is still, the most widely used local anaesthetic for labour analgesia. Bupivacaine provides effective epidural analgesia but produces dose-dependent motor block and has a poor safety profile, causing life-threatening cardiovascular and neurological sequelae if given in overdose. In order to overcome these two problems, opioids were introduced to be added to local anaesthetics because they interact synergistically to provide analgesia. An opioid combination allows for a decreased concentration of local anaesthetic, and so reduces motor block.[1] Nowadays with the widespread use of ultralow-dose epidural infusions of bupivacaine and opioid and in some units, with the use of the combined spinal–epidural (CSE) technique, it is very unlikely that systemic toxicity will be a problem during labour epidural analgesia.[2] Concerns about bupivacaine cardiac toxicity and the intensity of its motor block have also led to the investigation of other agents. The two new local anaesthetics, levobupivacaine and ropivacaine, have been compared to bupivacaine and have been proposed as alternatives, to provide satisfactory labour analgesia with a possible reduced incidence of motor blockade and decreased cardiotoxicity.

Unfortunately the research into local anaesthetic dosing requirements and the effects of other analgesics such as opioids initially took the form of 'recipe' designs or methodology containing comparisons of fixed combinations of drugs.[3–5] These early studies assumed that the new local anaesthetics (ropivacaine and levobupivacaine) were equipotent with bupivacaine. In addition, all too frequently, comparative studies using protocols with combinations of drugs have been carried out without fully understanding the relative potencies or the dose–response curves of the drugs under examination. In these studies,[3–5] any differences in potency may have been imperceptible owing to the use of local anaesthetics at relatively high concentrations, above the 95th centile for efficacy, and therefore clinically effective in almost all cases.

It is now clear that although bupivacaine and levobupivacaine may be equipotent,[10] this may not be the case with ropivacaine.[7,8] It has therefore been argued that the modest motor-sparing properties and even the reduced systemic toxicity of ropivacaine shown in some initial studies may merely reflect the potency difference (i.e. ropivacaine is a less potent drug), and should be re-evaluated.

The dose-varying methodologies would obviously be more informative than the fixed-dose alternative allowing for the calculation of any type of effect. The introduction of the minimum local analgesic concentration (MLAC) model[9–10] designed for a clinical setting, for example, epidural analgesia in the first stage of labour, has allowed the evaluation of the concentration–response relationship of local anaesthetic drugs.

## The analgesic level

Local anaesthetics have been shown to be active in the dorsal horn of the cord, but the main action is actually the conduction blockade of the nerve root. A band of analgesia with definable upper and lower limits can be achieved through epidural administration. Experimenting with different doses of lidocaine, the pioneers of epidural anaesthesia, Bromage and Covino,[11] discovered that, in terms of dermatomes, the size of the dermatomal area was proportional to the mass of local anaesthetic administered. However, this original idea of dermatomal spread being only dependent on the dose was later re-evaluated. Columb et al.[12] gave a fixed dose of chloroprocaine in different dilutions to parturients and found that the analgesia no longer proved effective when the concentration was below 0.5%. This indicates that a desired analgesic effect can be obtained by considering not only the local anaesthetic dose but also the concentration to be given.

## Differential block

The impulse conduction block by local anaesthetics is a complex and dynamic process. In non-myelinated axons, the nerve impulse is propagated slowly by the progressive spread of the depolarization front along the membrane. In myelinated axons, the insulating properties of myelin allow the impulse to travel rapidly by jumping from (Ranvier) node to node (saltatory conduction). The block of at least three nodes of Ranvier is necessary to obtain an almost complete conduction block.

Ideally if all the axons in a nerve bundle (such as spinal roots) are exposed to a concentration of local anaesthetic greater than the minimum blocking concentration (the lowest concentration of local anaesthetic that blocks impulse conduction within a specified time) and to a sufficient volume to affect three or more successive nodes of Ranvier, the nerve is completely blocked. The innervated

parts are anaesthetized and the muscles are paralysed.[13] In non-myelinated axons, the impulse is propagated slowly by progressive spread of the depolarization front along the membrane.

Effects of the local anaesthetic depends on where and what kind of nerve fibres are involved. Differential block occurs when an impulse in one nerve fibre is completely blocked while in another fibre it continues wholly or in part resulting, for example, in the occurrence of analgesia without motor block. This differential block may be due to differences in nerve properties or to a non-uniform local anaesthetic distribution, where a fibre totally immersed by local anaesthetic may be blocked while a similar fibre lying deeper may remain unblocked. Differential block may also be achieved by lowering the concentration of the local anaesthetic solution in order to mainly block the small fibres (pain sensation) rather than the larger ones (motor function). In fact, sensory inputs related to pain are carried by two separate conduction systems: one relaying signals rapidly via myelinated, small A-delta fibres and the other conveyed via slowly conducting, non-myelinated, very small C-fibres. Motor function is supported by the myelinated, large, and fast A fibres, in particular by A-alpha and A-beta fibres.

Ideally the best solution in labour would be to block all the nociceptive afferent transmission while at the same time sparing all non-nociceptive fibres. This may be accomplished, in clinical practice, by using very dilute local anaesthetic solutions with or without the addition of opioids

The visceral pain experienced in the first stage of labour might be C-fibre mediated, while the A fibres may play a larger role in the somatic pain of the second stage. Capogna et al.[5] demonstrated that more local anaesthetic is needed as labour progresses. This may be the result of increasing A-fibre recruitment as the fetal head descends. This is confirmed by the observation that intrathecal or epidural opioids, which typically affect the C fibres, work well in the first stage, where the pain is mostly mediated by C fibres, but not in the second stage of labour where the A fibres are much more involved.[15]

## Addition of opioids

Opioids are usually added to the analgesic mixture to allow for the use of a very diluted concentration of local anaesthetic, so reducing the occurrence of motor block.

Adding an opioid to bupivacaine when bupivacaine is used at a concentration equal to or higher than 0.125% is of no benefit since this concentration corresponds approximately to the $EC_{95}$ of bupivacaine, that is, the concentration at which 95% of mothers are pain free.[16] Conversely when using a bupivacaine concentration lower than 0.125%, an opioid must be added to provide satisfactory and reliable analgesia.[16] The addition of epidural opioids to epidural local anaesthetic solution also reduces the amount of local anaesthetic needed to produce analgesia and so, in turn, reduces motor block and the likelihood of operative delivery.[17]

## Role of volume

One of the least researched areas of epidural dosing is the need for epidural drugs to be administered in liquid form in order to effect an adequate spread to the nerve roots. Often the dose creates more problems than volume. Anaesthetists, for example, may give 10 mL of 0.25% bupivacaine more readily to treat a suboptimal labour analgesic block instead of giving a larger volume of a more dilute solution. However, bupivacaine 0.125% when compared with 0.25% produced equivalent analgesia at an increased volume but with a reduced total drug dose.[18] Certainly reducing the dose of local anaesthetic with no loss of analgesic efficacy can only be beneficial. It must be remembered that any dose reduction, without loss of efficacy, reduces the risk of toxicity, improves safety, and may also reduce the likelihood of motor block. With the use of a dilute local anaesthetic solution the mother can ambulate and this is also commonly perceived as leading to a reduced risk of perineal motor block, so favouring a spontaneous vaginal delivery.

## The dose/concentration–response curve

To identify the best analgesic solution for labour analgesia, several comparative studies have been performed, but unfortunately many of them were clinically of little value because of the inability to identify equivalent analgesia between differing combinations of local anaesthetic and opioid or other analgesic adjuvants.

In effect, in the past, there has been a scarcity of pharmacodynamic information about the analgesic dose–response relationship of epidural local anaesthetics in labour. This has led to a clinical model being developed which determines the MLAC based on an up–down sequential allocation method.[9]

The up-down method was originally developed for explosives research in the 1940s and has subsequently been applied to many fields of research including engineering, psychology, poisons, and volatile anaesthetics (minimum alveolar concentration (MAC)). This methodology has been extensively described by Dixon and Massey.[10]

This model has been applied to local anaesthetic drugs, similarly to that which was in routine use for inhalation anaesthetics, the MAC. Before this, much of the clinical research into local anaesthetic drugs involved comparisons of fixed doses or combinations with other adjuvants. Most of these studies used supramaximal doses with the resulting conclusions of similar efficacy being difficult to interpret correctly.[3–5]

The MLAC model uses 'up-and-down' sequential allocation to identify the median effective concentration ($EC_{50}$) or dose ($ED_{50}$) of local anaesthetic in a given clinical scenario. This is an experimental design in which the dose received by a subject is determined by the response of the previous subject. For the model to apply, the response being measured must be 'all-or-none' in nature, for example, yes or no, effective or ineffective. If a subject's response to a given dose level is above threshold (an effective outcome), there is a step-by-step reduction in the dose given to the subsequent subject. A below-threshold response (an ineffective outcome) leads to an increase by the same amount. Using this approach, testing is eventually centred on the median threshold ($EC_{50}$ or $ED_{50}$) for the response, above which 50% of subjects will respond and below which 50% will not (Figure 16.1).

The $ED_{50}$ is the point at which the pharmacological strength/potency is defined, so it is here that the dose–response relationship is established with the greatest accuracy Comparisons between different $ED_{50s}$ should therefore permit:

- the comparison between the potency ratio of two different local anaesthetics
- the local anaesthetic-sparing effect of other adjuvant drugs
- the calculation of the effects on requirements due to non-pharmacological or obstetric factors.

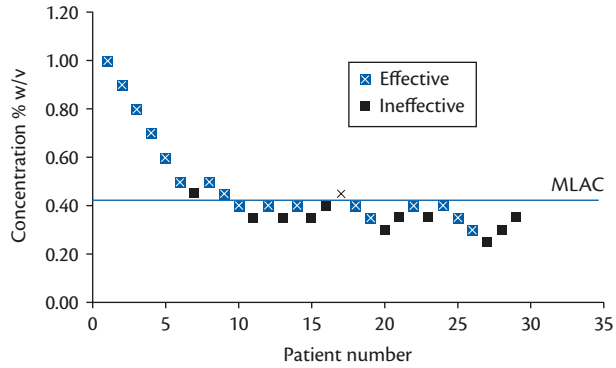

**Figure 16.1** The up–down sequential allocation study design.

The concept was initially created to study epidural drugs but can now also be used in a similar way for intrathecal local anaesthetics.

Box 16.1 lists the main findings using the MLAC method.

## $EC_{50}$ and the relative potency of epidural bupivacaine, ropivacaine, and levobupivacaine

There has been an interesting controversy around the studies which address the epidural analgesic potency issue of bupivacaine, ropivacaine, and levobupivacaine. The potency ratio between bupivacaine and ropivacaine for analgesia given in the first stage of labour was found to be 0.60 in two MLAC studies carried out in 1999 in both Italy and the United States.[7,8] The studies therefore showed that ropivacaine was approximately 40% less potent than bupivacaine.

Another study compared the effectiveness of the pain relief in the first stage of labour, by examining the epidural analgesia potency of both levobupivacaine and bupivacaine and found the potency ratio to be 0.98.[19]

Taking into consideration the two MLAC studies which compared the potency ratio between the three local anaesthetics, the results showed that bupivacaine is considerably more potent than ropivacaine and slightly more potent than levobupivacaine so permitting the conclusion that levobupivacaine is more potent than ropivacaine (Table 16.1).[6,20]

This potency hierarchy, confirmed by additional clinical studies,[21–25] is no more evident where the three local anaesthetics are compared at equipotent concentration.[23,24]

**Box 16.1** The main findings obtained by using the MLAC method

- $EC_{50}$ and relative potency of **epidural** bupivacaine, ropivacaine, and levobupivacaine
- Differential blockade
- $ED_{50}$ and relative potency of **spinal** bupivacaine, ropivacaine, and levobupivacaine
- $ED_{50}$ of opioids and sparing effect on local anaesthetic requirement
- MLAC and obstetric variables:
  - Progression of labour
  - Dystocia
  - Induced labour.

**Table 16.1** Relative potencies for analgesia and for motor block of epidural bupivacaine, levobupivacaine and ropivacaine

| | Relative potencies (95% CI) | Reference |
|---|---|---|
| **Analgesia** | | |
| Bupivacaine: ropivacaine | 0.60 (0.47–0.75) | 7,8 |
| Bupivacaine: levobupivacaine | 0.98 (0.67–1.41) | 19 |
| **Motor block** | | |
| Bupivacaine: ropivacaine | 0.66 (0.52–0.82) | 26 |
| Bupivacaine: levobupivacaine | 0.87 (0.77–0.98) | 27 |

CI, confidence interval.

## Differential blockade

It is widely understood that the differential blockade of sensory and motor fibres can be brought about by the three local anaesthetics, bupivacaine, ropivacaine and levobupivacaine, all members of the chemical family of the pipecoloxylidines.

As previously indicated, early traditional studies[3–5] showed that racemic bupivacaine demonstrated a worse clinical profile than ropivacaine or levobupivacaine as it seemed to produce more motor block. Lacassie et al.[26,27] set out in two studies to specifically assess the epidural motor blocking potency of the three local anaesthetics and their relative potency ratio for motor block using a modification of the MLAC design.

When investigating relative potencies, one intuitively assumes that motor block will be less affected by obstetric variables such as the progression of labour, which can in turn affect analgesia, which is the end point of the potency ratio studies.

The motor block potency ratios shown in Table 16.1[26,27] are very similar to the analgesic potency ratios in the previous MLAC studies.[6–8,19,20] Once again it is because ropivacaine is less potent in that it causes less motor block of the lower limbs compared to bupivacaine and levobupivacaine. It can therefore be concluded that when traditional comparative studies reported less motor block for ropivacaine and levobupivacaine it could only have been due to differences in analgesic potency and not to some intrinsic drug property (pharmacological effects).

## $ED_{50}$ and relative potency of spinal bupivacaine, ropivacaine, and levobupivacaine

The pharmacodynamics of intrathecal local anaesthetics and their relative potency ratio have also been investigated by a modified up–down technique. Since the pharmacodynamics for intrathecal drugs depend on dose rather than on the concentration, the most suitable term to use is the minimum local analgesic dose (MLAD) rather than concentration (MLAC).

The intrathecal MLAD studies observed a potency hierarchy between the three local anaesthetics, which has been confirmed for both analgesia and motor block[28,29] as shown in Table 16.2.

The intrathecal MLAD studies show that the hierarchy between intrathecal bupivacaine levobupivacaine and ropivacaine in terms of the potency ratio values for analgesia and those for motor block are approximately the same as those found for epidural use.

## Epidural and spinal sensory motor separation

Bupivacaine, levobupivacaine, and ropivacaine have a wide sensory–motor separation when given epidurally, and this means

**Table 16.2** Relative potencies for analgesia and for motor block of spinal bupivacaine, levobupivacaine and ropivacaine

| | Relative potencies (95% CI) | Reference |
|---|---|---|
| **Analgesia** | | |
| Bupivacaine: ropivacaine | 0.59 (0.42–0.82) | 28 |
| Bupivacaine: levobupivacaine | 0.71 (0.51–0.98) | 28 |
| Levobupivacaine: ropivacaine | 0.83 (0.64–1.09) | 28 |
| **Motor block** | | |
| Bupivacaine: ropivacaine | 0.65 (0.56–0.76) | 29 |
| Bupivacaine: levobupivacaine | 0.81 (0.69–0.94) | 29 |
| Levobupivacaine: ropivacaine | 0.80 (0.70–0.92) | 29 |

CI, confidence interval.

Data from various sources (see references).

that there will rarely be motor block when these local anaesthetics are administered for labour epidural analgesia at ultralow concentrations. However the sensory–motor separation advantages observed with epidural administration are considerably less with the intrathecal administration.

## The opioid-sparing effect on local anaesthetic requirement and the $ED_{50}$ of opioids

Previous traditional studies were not able to show differences in analgesic efficacy between a full analgesic supramaximal dose of local anaesthetic and the addition of a single opioid.[30,31] Furthermore these studies used local anaesthetics at high concentrations, such as bupivacaine 0.25% or 0.125%, which appear at the top of the dose–response curve and need no additional drugs to provide effective analgesia. After examining a number of different adjuvants the results show that only opioids have significant local anaesthetic-sparing effects that can be used in routine clinical practice.

This sparing effect was seen using both fentanyl and sufentanil, in fact up to a 90% reduction in the $EC_{50}$ with both epidural and intrathecal local anaesthetics.[32–38] A reduction in $EC_{50}$ for fentanyl and sufentanil also indicated a clear dose–dependent sparing effect (Figure 16.2).[16,38]

The potency ratio between two single opioids without adding any local anaesthetic can also be determined by using the MLAC method and Capogna et al.[39] observed that the potency ratio between epidural sufentanil and fentanyl for labour analgesia is 5.9.

## MLAC and obstetric variables

Because the standardization of labour pain is difficult, being a subjective and dynamic process, it is not surprising to find differences in MLAC estimates and relative potencies.[14,40] This is also true in most areas of research, including human toxicity studies.

Parity and cervical dilation at the moment of epidural insertion plus other obstetric variables should be considered. The comparison of drugs should be undertaken using parturients at similar points of their labour as the analgesic effectiveness of a drug is often related to the progress in labour when it is administered. A reasonable approach would therefore be to standardize the progression of labour using only parturients with a comparable dilation and fetal head descent and excluding those with scores less than 30 (0–100 mm) on a visual analogue pain scale.

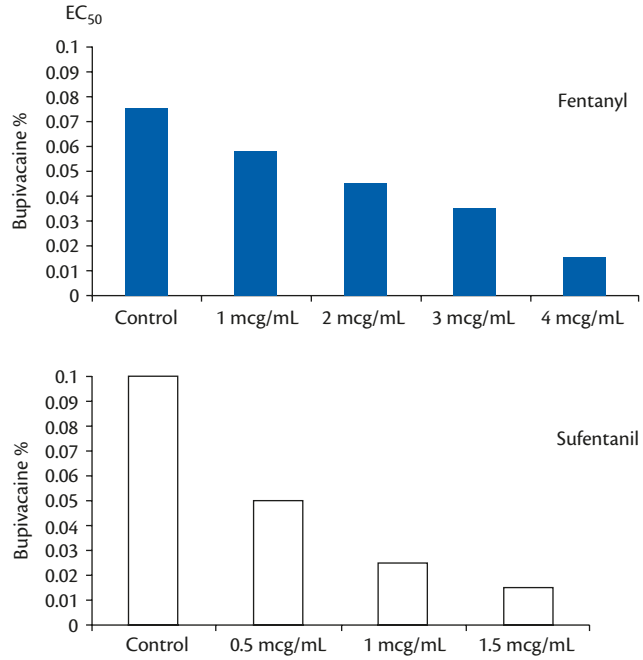

**Figure 16.2** Dose-dependent sparing effect of opioids on $EC_{50}$ of bupivacaine. Data from G Lyons, MO Columb, L Hawthorne *et al.* Epidural pain relief in labour: bupivacaine sparing by epidural fentanyl is dose dependent, *British Journal of Anaesthesia*, volume 78, pp. 493–497, Copyright © 1997 Oxford University Press. Data from Polley LS, Columb MO, Wagner DS, Naughton NN. Dose-dependent reduction of minimum local analgesic concentration of bupivacaine by sufentanil for epidural analgesia in labor. *Anesthesiology*, volume 89, pp. 626–632, Copyright © 1998 Wolters Kluwer.

Several obstetric variables may have an effect on the level of labour pain and the subsequent local anaesthetic requirement. The MLAC method has also been used to investigate these variables, which can include the occurrence of dystocia, the progression of labour, and its induction.

One MLAC study examined the effect of a cervical dilation (less or greater than 5 cm) on the $EC_{50}$ of epidural bupivacaine.[14] The results indicated that three times more bupivacaine is needed as the cervix dilates and labour progresses (Figure 16.3).[14]

The need for local anaesthetic has been shown to be significantly higher in dystocic labours. When comparing women who eventually delivered by caesarean as a result of dystocia with those who delivered spontaneously, an interesting MLAC study[40] showed that the $EC_{50}$ of bupivacaine was higher in parturients with dystocia where the labour was more painful (Figure 16.4). A possible inference from these results may be that the local anaesthetic consumption could be a possible indicator for dystocia.

Capogna et al.[41] have also shown that there is a significantly higher analgesic requirement in induced parturients when compared to women who deliver spontaneously. Induced labour was therefore found to be more painful, with patients needing a higher ED50 of epidural sufentanil.

## MLAC and other issues

### Second epidural dose

Utilizing the MLAC method it has been possible to determine if subsequent epidural requirements are reduced by using an initial epidural bolus for establishing labour analgesia compared to an initial spinal bolus using a CSE technique. Patel et al.[42] compared the MLAC of epidural bupivacaine given after first administering

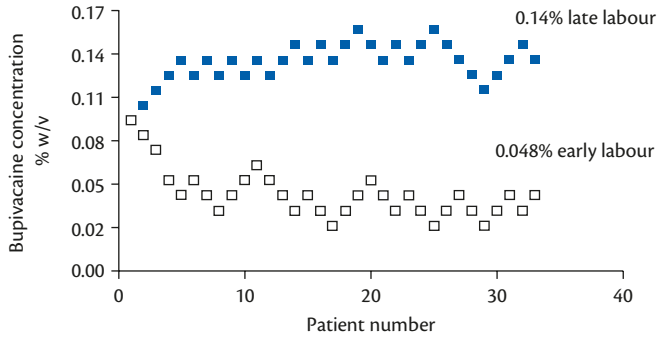

**Figure 16.3** MLAC of epidural bupivacaine and progression of labour.
Data from Capogna G, Celleno D, Lyons G, *et al.* Minimum local analgesic concentration of extradural bupivacaine increases with progression of labour. *British Journal of Anaesthesia*, volume 80, pp. 11–13, Copyright © 1998 Oxford University Press.

an intrathecal (bupivacaine 2.5 mg and fentanyl 5 mcg) or epidural (bupivacaine 20 mg and fentanyl 40 mcg) injection. The MLAC method was used to assess the bupivacaine requirements for the second (epidural) injection. The results showed that when compared with epidural analgesia, the requirements increased after intrathecal analgesia by a factor of 1.45. This was surprising and although interesting statistically, these results will probably not be clinically important as the doses used in routine clinical practice are on the upper flat portion of the dose–response curve so the above-noted effect will probably not be realized. It does, however, indicate that any differences seen by clinicians between CSE and epidural analgesia are not the result of a reduction in drug requirement in the maintenance period of epidural analgesia.

## Dose, volume, and concentration in the intrathecal space

Traditionally dose has always been thought to be the most important factor affecting the characteristics of the intrathecal block.[43] One study conducted by Camorcia et al.[44] has, however, shown that the characteristics of the block may also be affected by the concentration of local anaesthetic when administered in the intrathecal space. This study demonstrated that the $ED_{50}$ of intrathecal 0.1% ropivacaine caused 50% less motor block when compared to the 1% solution suggesting that considerably less motor block is caused by a more diluted local anaesthetic solution in the subarachnoid space. This might be very useful information when using the CSE technique to reduce motor block.

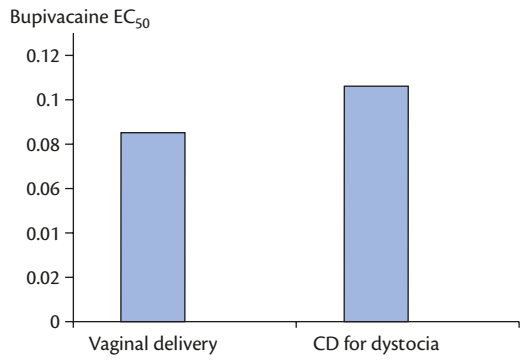

**Figure 16.4** $EC_{50}$ of bupivacaine in women who deliver by caesarean delivery (CD) for dystocia.
Data from Panni MK, Segal S. Local anesthetic requirements are greater in dystocia than in normal labor. *Anesthesiology*, volume 98, pp. 957–963 Copyright © 2003 Wolters Kluwer.

## Effect of gender on local anaesthetic requirement

Studies show that females show a higher sensitivity to noxious stimuli than males, and that there are also different responses to non-opioid drugs between the sexes.[45] Anaesthetic requirements, particularly for morphine, may also importantly depend on gender.[46] It has been found that female patients also need more propofol for general anaesthesia than men.[46]

Camorcia et al. investigated how the intrathecal bupivacaine requirement changes with gender and pregnancy.[47] The study results showed that the $ED_{50}$ needed to achieve motor block in term pregnancy was considerably reduced and it was also greater (30%) in males than in females (Figure 16.5).[47] Another study[48] confirmed these findings, their results indicating that the ropivacaine MLAC for caudal anaesthesia in male patients was 31% less than in female patients. Physical differences of weight and height must of course have an effect on the MLAC of local anaesthetics and further studies should investigate the different responses of men and women to local anaesthetics given for both neuraxial and peripheral nerve blocks.

## Pharmacogenetics

The focal point of many genetic studies has been the mu-opioid receptor (μOR), encoded by the gene *OPRM1* because a large number of endogenous opioid peptides, among which are beta-endorphin and encephalin, have this receptor as their main point of action. It is also the principal target for opioid analgesics.[49]

Landau et al.[50] used two distinct methodologies in two different groups to calculate the $ED_{50}$ and showed that labouring women carrying the 304G allele of *OPRM1* responded much more sensitively to the analgesia provided by intrathecal fentanyl. In this study, women were genotyped in late pregnancy, and this allowed the researchers to enrol patients in two separate groups according to their genotype at the time of the labour analgesia request. They reported that 304A homozygous women needed much more fentanyl to achieve labour analgesia and this result was similar to that obtained in another study[51] where there was a pharmacogenetic effect of μOR on $ED_{50}$ of epidural sufentanil.

The analgesic response to neuraxial opioids can be considerably influenced not only by the complexity of different labour and obstetric considerations but also by the labour pain itself and the

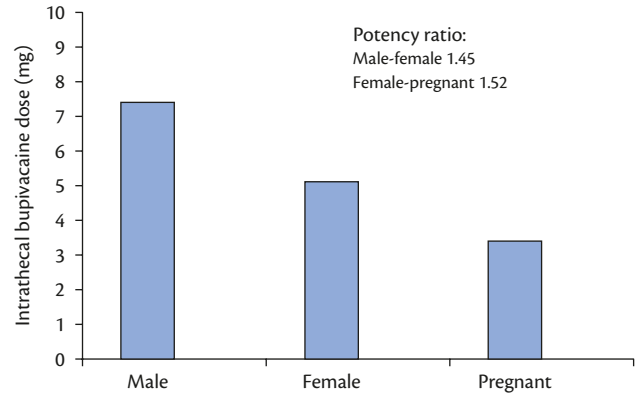

**Figure 16.5** Effects of pregnancy and gender on bupivacaine requirement.
Data from Camorcia M, Capogna G, Columb MO. Effect of sex and pregnancy on the potency of intrathecal bupivacaine: determination of $ED_{50}$ for motor block with the up-down sequential allocation method. *European Journal of Anaesthesiology*, volume 28, pp. 240–4, Copyright © 2011 Wolters Kluwer.

diversity found in labour management. It is therefore difficult to judge what part this polymorphism or any genetic variant plays in the clinical efficacy of opioids.

Caucasian parturients show a high incidence of genetic polymorphism for opioid receptors[52] but whether this is clinically important or if it influences the dose of opioid administered epidurally or intrathecally to the subset of women carrying the genetic variant must still be proven.

### Caesarean delivery

The dose of the intrathecal local anaesthetic for caesarean delivery has been calculated using a MLAC design.[53–56] These studies consider a dose to be effective when it gives satisfactory sensory dermatomal anaesthesia to a definite dermatomal level with no additional need for other analgesic medications during surgery, which must continue unimpeded for a definite length of time after the intrathecal injection.

It should, however, be said that using the MLAC design in these kinds of studies in a surgical setting, may create ethical problems if patients are exposed to intraoperative pain during their caesarean delivery but these can be overcome by using a CSE technique where the epidural can be used if the intrathecal component is insufficient.

## Criticism of minimum local analgesic concentration studies

MLAC studies have shown that there are potency differences among local anaesthetics, but the real significance of these differences as demonstrated by the up–down studies is unclear. Until this uncertainty is answered, prospective randomized (dose–response) clinical studies should not be replaced by data arising from up–down studies.

One of the major criticisms of MLAC studies is that the function of MLAC, $EC_{50}$, and $ED_{50}$ is to simply describe pharmacologically the measurement of the median of a dose–response distribution.[57–59] As such, they are in essence mathematically comparable to the means or medians used in almost every other study design. An example of this are local anaesthetic toxicity studies which are really $ED_{50}$ estimates as they compare the mean or median tolerated doses, although they are never specifically described as such. However, even if the $EC_{50}$ or $ED_{50}$ are very useful and precise to estimate the potency ratios and therefore to evaluate differences in potency between two drugs, they may not be so precise in estimating the $ED_{95}$ or $EC_{95}$ which is approximately the therapeutic dose.

New study designs are needed and their results validated by further trials.[60,61,62] Until this time care should be taken when taking information from up–down studies and applying it to clinical situations. These studies should, however, be used to help determine clinical practice. Their information should be the first step in designing good clinical trials that examine the relationship between drugs and anaesthetic or obstetric outcomes.

## Conclusion

Local anaesthetics vary in their potency and motor–sensory separation and knowledge of these are important for clinicians to achieve the type of analgesia and anaesthesia they require. The MLAC model has enabled clinical comparisons of local anaesthetics at equipotent concentrations. It has quantified what contribution opioids make to the overall effectiveness of the analgesic mixture and provided a means of optimizing combinations of local anaesthetic–opioid solutions. MLAC has also demonstrated the effect of inter-individual and obstetric variables on local anaesthetic potency and provided a pharmacological-based rationale for analgesia solutions used for labour analgesia. Importantly, MLAC studies confirm that the intensity and nature of labour pain is always changing, as labour progresses, and therefore the analgesic approach should be equally dynamic. Although various controversial issues still exist with the MLAC methodology, it has firmly become established in determining local anaesthetic dosing in clinical practice.

# CHAPTER 17

# Adjuvant drugs in neuraxial anaesthesia

Catherine Cromey and Susan Catling

## Introduction

An adjuvant is defined as a substance that enhances the activity of another substance.[1] In obstetrics, neuraxial (spinal and epidural) local anaesthetics provide effective analgesia and anaesthesia when used alone as single agents, but can cause dose-related undesirable side effects such as maternal hypotension[2,3] and motor blockade, with its associated higher risk of instrumental delivery.[4] An alternative to single-agent therapy is the use of adjuvants from different pharmacological classes.

When two or more drugs are administered together their effects may be:

- additive (the sum of the effects produced by each agent alone)
- subadditive (i.e. less than the sum of effects from each agent alone)
- supra-additive (i.e. synergistic; greater than the sum of the effects of each agent alone).[5]

By combining drugs with additive or synergistic effects, maximal efficacy can be obtained whilst simultaneously limiting the dose of each individual drug to minimize side effects.

Neuraxial adjuvants in the context of local anaesthetics reduce the amount of drug required, so lessening side effects (e.g. motor block and hypotension), or provide better analgesia by increasing the efficacy of the technique

Neuraxial adjuvants can be classified as opioid and non-opioid drugs:

- Opioid:
  - morphine
  - fentanyl
  - sufentanil
  - alfentanil
  - pethidine
  - diamorphine

  Many of the opioid neuraxial adjuvants have a long established role in anaesthetic obstetric practice with well-defined safety profiles
- Non-opioid—this is a diverse group of substances including:
  - simple chemicals (e.g. bicarbonate, magnesium)
  - alpha-adrenergic agonists (e.g. clonidine, epinephrine, droperidol)
  - cholinesterase inhibitor (e.g. neostigmine)
  - gamma-aminobutyric acid (GABA) receptor agonists (e.g. midazolam)
  - *N*-methyl-D-aspartate (NMDA) receptor antagonists (e.g. ketamine)
  - steroids (e.g. dexamethasone)

  Many of these non-opioid agents remain largely theoretical or experimental, or have an unacceptable or undefined safety profile.

Most neuraxial adjuvants are not licensed and each agent has side effects. Preservative-free agents must be used to minimize the risks of neurotoxicity. This chapter will discuss the mechanism of action, efficacy, safety, and practical uses of each adjuvant.

## Adjuvants: mechanisms of action and routes of administration

Several mechanisms to explain antinociceptive interactions between drugs in the spinal cord[6–8] have been suggested:

- Pharmacokinetic mechanisms—addition of the adjuvant drug can change the physical properties of the injectate[9,10] by affecting:
  - density—for example, changed by hypertonic dextrose, which is used therapeutically to make 'heavy' bupivacaine. It has also been demonstrated that the addition of fentanyl reduces the density of plain 0.5% bupivacaine *in vitro* sufficiently to alter its movement in simulated cerebrospinal fluid (CSF)[9]
  - ionization—for example, changed by addition of bicarbonate to alter pH
  - vascular absorption—epidurally administered drugs must first diffuse through the dura to gain access to the intrathecal space and hence their site of action in the spinal cord, and this is affected by local vasoconstriction, for example, by addition of epinephrine to the injectate.

  These pharmacokinetic effects of the adjuvant will change the concentrations of injected local anaesthetic at the spinal effector sites, thus increasing or prolonging antinociception.[9] The effective dose, speed of onset, duration of action, and side effect profile of the local anaesthetic can be changed to produce a more

intense, reliable sensory block to permit instrumental delivery or surgery with smaller doses of local anaesthetic.[11] These mechanisms are discussed in detail for each individual agent later in this chapter.

- Pharmacodynamic mechanisms—a pool of second-messenger molecules are coupled to a single class of ion channels.[5] Different opioid (and $\alpha_2$-adrenoceptor) receptor subtypes activate these second-messenger molecules leading to the same outcome via different activity causing multiplication of effect. These exist together on individual neurons and share second-messenger mechanisms.[12,13] For example, clonidine appears to act synergistically with opioids at the delta (δ)-opioid receptor[5] but not mu (μ)- or kappa (κ)-opioid receptors. There is also synergism between μ-opioid and δ-opioid receptor agonists, due to allosteric change in the receptor binding site, which leads to greater binding affinity of the next agonist.[5]
- There may be interaction from different drugs inhibiting spinal nociceptive processing at different sites leading to a multiplied effect. For example, presynaptic (inhibition of transmitter release) and postsynaptic (hyperpolarization of rostral transmission neurons) sites of action have been identified for opioids and $\alpha_2$-adrenoceptor agonists in the spinal cord.[14]

## Clinical uses of various adjuvants

So far, non-opioid intrathecal adjuncts have shown limited clinical application and are not in general use in most delivery suites, whereas opioids increase duration and quality of spinal block without delaying recovery and have become 'standard practice' in most maternity units. In 2010, Wahlen and colleagues investigated 'standard practice' in Germany and Austria using an online survey of 39 university hospitals (Table 17.1).[15,17,18]

This is in contrast to practice in the United Kingdom, where sufentanil is unlicensed and therefore not used. In 2011, Jagannatha showed in an electronic survey that fentanyl (78.8%) and diamorphine (79.1%) were the more commonly used adjuvants for neuraxial block in the United Kingdom, with morphine used in 14.9%.[16] The commonly used doses of fentanyl, diamorphine, and morphine were 15–25 mcg, 200–300 mcg, and 100–200 mcg respectively. Most of the patients with spinal opioids including morphine were sent straight back to the ward postoperatively, but the lack of a high dependency unit prevented the use of opioids in epidurals in 46%. Interestingly, this survey showed that more than 70% of anaesthetists were unsure about the licence for the use of neuraxial opioids.

**Table 17.1** Neuraxial opioid adjuvant use in Germany/Austria 2010[15–18]

| Drug | Spinal for CD | Epidural for CD | Epidural for labour |
|---|---|---|---|
| Sufentanil | 63 | 51 | 84.3 |
| Fentanyl | 12 | 3 | 3.1 |
| Morphine | 3 | 0 | 0 |
| No adjuvant | 22 | 46 | 12.5 |

Data refers to the % of each opioid used as a total of all opioid adjuvants used.

Data from various sources (see references).

This differing pattern of opioid use in Germany and the United Kingdom has remained constant over the last decade. In Germany in 1996, Stamer and colleagues showed that 62% of units added an intrathecal opioid adjuvant for caesarean delivery (CD), of these, 56.5% were sufentanil, 5% fentanyl and 1.3% morphine, and these figures have hardly changed.[17] The pattern of neuraxial opioid use seems to vary significantly between and within European countries. Rawal and Allvin conducted an electronic survey of 105 European hospitals and found that in 1 year, 55,117 patients (7% of all surgical patients) received neuraxial opioid analgesia.[18] The most common spinal opioid was morphine, followed by fentanyl but 12 different opioids and 8 non-opioids were mentioned. Epidural opioid administration was far more common than intrathecal (89% vs 11%). By contrast, two surveys in 1996 in the United Kingdom showed that fentanyl was the lipophilic opioid most often used for labour epidurals, with alfentanil and diamorphine used infrequently.[19,20] In the nearly 20 years since this survey, the use of alfentanil and diamorphine in labour epidurals has declined even further and they can be regarded as obsolete in this context.

## Opioid adjuvants

### Opioid receptors

Opioid receptors span the membrane seven times and are linked to inhibitory G-proteins.[21] Specific opioid receptors are classically grouped according to their agonists—mu (μ), kappa (κ), and delta (δ)—and the non-classical (nociception, opioid receptor-like 1) receptor. New terminology has renamed them according to their receptor type as MOPr (μ), DOPr (δ), KOPr (κ), and NOPr ($ORL_1$). When an opioid agonist stimulates the receptor, voltage sensitive calcium channels are closed and potassium flows out of the cell causing hyperpolarization and reduced cAMP. This leads to inhibition of neurotransmitter release.

μ-receptors are found throughout the central nervous system (CNS) and are responsible for most of the analgesic effects of opioids. In the spinal cord, they are located presynaptically on primary afferent neurons within the dorsal horn.[22] Apart from analgesia, μ-receptor stimulation produces respiratory depression (by reducing chemoreceptor sensitivity to carbon dioxide), constipation (by reducing secretions and peristalsis), and cardiovascular depression.

KOP or κ-receptor stimulation produces analgesia at the spinal level but may cause sedation, dysphoria, and hallucinations. κ-receptor agonists have the advantage that they do not cause respiratory depression but their action as antagonists at μ-receptors limits their usefulness.

The δ-receptor is spread widely throughout the CNS, and when stimulated causes inhibition of neurotransmitter release. It may be involved in regulating mood and movement but its stimulation may be proconvulsant.[23]

### Opioid receptor mechanisms in the spinal cord

Opioids injected intrathecally access opioid receptors in three different areas:

1. The major site is direct interaction with presynaptic primary afferent nerve terminals in the substantia gelatinosa of the dorsal horn of the spinal cord inhibiting neurotransmitter release.[14] This reduces signalling between primary and

secondary afferent neurons, thereby inhibiting transmission of nociceptive impulses through the dorsal horn and suppressing nociceptive spinal reflexes. There is also postsynaptic binding to receptors on the secondary afferent neurons, causing hyperpolarization and decreasing excitability. Opioids vary in their receptor specificity and in their efficacy at the different types of receptor,[24] so that some opioids can be agonists or partial agonists on one type of receptor, and antagonists or partial agonists at another. Intrathecal opioids preferentially modulate transmission in C- and A-fibres, with little effect on dorsal root axons, and different opioid agonists can act synergistically when co-administered.[25] Opioids (with the exception of pethidine (meperidine)) have no effect on nerve conduction.

2. CSF flow causes cephalad movement of intrathecally injected opioids, which then act supraspinally on descending inhibitory pathways. Endogenous opioid peptides may be released both at supraspinal and spinal sites, and at the spinal level analgesia also results from the release of serotonin (5-HT) from descending inhibitory fibres.[22]
3. A minimal amount will diffuse into the epidural space and be absorbed systemically through the epidural venous plexus, causing centrally mediated analgesia. Epidural administration of sufentanil, fentanyl, and morphine produces plasma levels equivalent to intramuscular injection of similar doses.[14]

## Neuraxial opioids: clinical uses

Numerous trials have shown that the addition of opioids to local anaesthetic solutions significantly improves pain relief, permits smaller doses of local anaesthetic with subsequent reduced motor block and hypotension, reduces postoperative analgesic requirements, and reduces the frequency of patchy block.[26,27] Individual opioids vary in their potency, lipophilicity, and side effect profile—these are discussed later, but some general principles apply. The dose of epidural opioid is usually about five to ten times that needed for intrathecal use.[14] See Table 17.2.[28–43]

**Table 17.2** Equivalent spinal and epidural doses of commonly used neuraxial opioids[28–43]

| Drug | Clinical intrathecal dose range | Clinical epidural dose range |
|---|---|---|
| Fentanyl | *10–25 mcg*<br>Labour (sole agent) $ED_{95}$ 17.4 mcg (95% CI 13.8–27.1 mcg)[28]<br>Labour (with bupivacaine) 10–15 mcg[29]<br>CD (with bupivacaine) 10–25 mcg[30] | *50–100 mcg (1 mcg/kg)*<br>33–92 mcg[36] (*'optimal' 50–100 mcg*)<br>Labour (sole agent): $ED_{50}$ 124 mcg[37]<br>Labour (with bupivacaine): $ED_{95}$ 50 mcg[38]<br>C.D $ED_{95}$ 92 mcg[36] |
| Sufentanil | *2.5–20 mcg*<br>Labour $ED_{95}$ 8–10 mcg[28,31]<br>Labour (with bupivacaine) 'optimal' 1.5–2 mcg[32]<br>CD (with bupivacaine) 2.5–20 mcg 'Optimal' 5 mcg[33] | *25–60 mcg*<br>Labour: $ED_{50}$ (alone) 21 mcg[37]<br>Labour: $ED_{95}$ (with bupivacaine) 8 mcg[28]<br>CD: (with bupivacaine) 10–20 mcg[39,36] |
| Morphine | *50–500 mcg*[34]<br>(CD with bupivacaine) | *3.75–5.0 mg*<br>*'Optimal' 3.75 mg* (postop CD)[40] |
| Diamorphine | *0.3–0.4 mg*[35]<br>(CD with bupivacaine) | *2.0–5.0 mg*[41]<br>(CD with bupivacaine)<br>Labour (with bupivacaine) 250–500 mg/h[42,43] |

CD, caesarean delivery; $ED_{50}$, effective dose required for desired effect in 50% of people receiving the drug; $ED_{95}$, effective dose required for desired effect in 95% of people receiving the drug.

Data from various sources (see references).

## Side effects/disadvantages of opioid adjuvants

The addition of opioid adjuvants to neuraxial solutions has several disadvantages. Extra time will be required to draw up, mix, and administer controlled drugs and their use must be properly documented. The use of multiple drugs increases the chance of drug errors and cautious rechecking of drug ampoules must occur.

The other disadvantage of using opioids as neuraxial adjuvants are the side effects that their addition brings. All complications of opioids, such as nausea, vomiting, pruritus, and respiratory depression, are dose dependent[44] and each is discussed in detail in the following sections. High opioid doses may also lead to decreased fetal heart rate (FHR) variability.[45]

### Pruritus

This is seen in up to 70% of patients receiving neuraxial morphine, and is less common (10%) with lipophilic opioids such as fentanyl.[14] Onset is variable and is usually localized to the face, neck, and chest areas. It is thought to be due to cephalad spread of opioid to receptor sites in the trigeminal nucleus. Although the pruritus is not mediated by histamine release, histamine-1 receptor antagonists (e.g. chlorpheniramine) can be helpful, but cause sedation. Small doses of opioid receptor antagonists such as naloxone (<2 mcg/kg/h) and naltrexone (6–9 mg) are the most effective at reversing pruritus without reversing analgesia.[46]

A high concentration of 5-$HT_3$ receptors is found in the dorsal horn of the spinal cord and the spinal tract of the trigeminal nerve in the medulla, and it has been suggested that an interaction between opioids and 5-$HT_3$ receptors may play a role in the generation of neuraxial opioid-induced pruritus. Prophylactic treatment with a single intravenous (IV) bolus of 4–8 mg of the 5-$HT_3$ receptor antagonist ondansetron provides a significant decrease in the incidence and the intensity score of pruritus after neuraxial opioid administration, particularly when morphine is used.[47]

### Nausea and vomiting

This occurs in 20–50% of patients receiving neuraxial opioids, and is commoner in females and with intrathecal morphine. It is thought to be due to cephalad spread of the opioid to the area postrema where it acts as a partial dopamine-2 receptor agonist in the chemoreceptor trigger zone.[22,23]

### Urinary retention

This occurs in approximately 30–40% of cases of neuraxial opioid use[14] and is more common with spinal morphine. Stimulation of opioid receptors in the sacral spinal cord causes inhibition of sacral parasympathetic outflow. Ureteric and bladder sphincter tone is increased and detrusor relaxation is inhibited.[23]

## Respiratory depression

The incidence of respiratory depression with neuraxial opioids is similar to that found with parenterally administered opioids.[48] This is a μ-receptor response causing reduced sensitivity of the chemosensitive neurons in the respiratory centre in the medulla to carbon dioxide. The normal compensatory increase in minute ventilation when arterial carbon dioxide rises fails to occur, but the response to hypoxia is less affected. In theory, if the hypoxic stimulus is also removed by supplementary oxygen, then respiratory depression may be potentiated. Medullary generation of the respiratory rhythm is also inhibited at the pre-Botzinger complex, causing a decreased respiratory rate.[23] Respiratory depression can occur early or late with neuraxial opiate administration.

Early respiratory depression, occurring within 2 hours, is due to systemic absorption of opioid and is therefore less common after intrathecal administration and after administration of hydrophilic opioids such as morphine, but commoner after epidural administration of lipophilic opioids (e.g. sufentanil and fentanyl).[49]

Delayed respiratory depression occurring at 6–12 hours is seen after intrathecal administration of hydrophilic opioids such as morphine and is caused by cephalad spread of the opioid in the CSF to the respiratory centre. Delayed respiratory depression is uncommon with lipophilic opioids as they bind rapidly to spinal opioid receptors, removing most of the drug from the CSF before significant cephalad spread can occur.

Respiratory depression is a potentially life-threatening complication of neuraxial opioids and appropriate monitoring is mandatory (Table 17.3).[14,26,28,41,48,49,53,61,69,77,78,80,96,98]

The American Society of Anesthesiologists published guidelines in 2009[50] which recommend the following:

1. Patient identification

   All patients should have a focused history and examination to identify risk factors for increased susceptibility to respiratory depression (including sleep apnoea, diabetes, obesity, current medications) before administering neuraxial opioids.

2. Drug selection

   The duration of monitoring should be appropriate to the drug, whether delivered by single injection or continuous epidural. Lipophilic opioids such as fentanyl and sufentanil are safer than hydrophilic drugs such as morphine. Diamorphine is rarely available outside the United Kingdom.

**Table 17.3** Lipophilicity of neuraxial opioids and time of peak respiratory depression risk (clinically observed ranges)[14, 26, 28, 41, 48, 49, 53, 61, 69, 77, 78, 80, 96, 98]

| Intrathecal opioid | Onset of analgesia (minutes) | Duration of analgesia (hours) | Maximum risk of respiratory depression (hours) |
|---|---|---|---|
| Morphine (hydrophilic) | 60–120 | 15–24 | 5–12 |
| Fentanyl/ sufentanil (lipophilic) | 10 | 1–5 | <0.5 |

3. Dose selection

   Administer the lowest effective dose of neuraxial opioids. Simultaneous administration parenteral opioids, sedatives, hypnotics, magnesium requires increased intensity and duration of monitoring.

4. Detection of respiratory depression

   Monitoring of patients receiving neuraxial opioids should include depth of respiration, oxygenation (with pulse oximetry when appropriate), and level of consciousness. These observations can be assessed in the sleeping patient, unless there are any concerning signs in which case the patient should be woken to allow evaluation of level of consciousness.

Individual groups of agents require specific recommendations:

1. Neuraxial lipophilic opioids via single injection (e.g. fentanyl):
   - Monitor for a minimum of 2 hours following injection.
   - Repeated monitoring should be performed for the first 20 minutes after administration, followed by monitoring at least every hour until 2 hours have passed.
   - Once 2 hours have passed, the clinical condition of the patients will dictate the frequency of monitoring.
2. Neuraxial lipophilic opioids via continuous infusion or patient-controlled epidural analgesia (PCEA):
   - Perform monitoring for the duration of the infusion.
   - Continual monitoring should occur for the first 20 minutes after the infusion has begun, and continued at least every hour until 12 hours have passed.
   - During the period of 12–24 hours of infusion, the monitoring should be repeated at least every 2 hours.
   - After 24 hours, repeat monitoring at least once every 4 hours.
   - Once the infusion or PCEA of lipophilic opioids has finished the frequency of monitoring will be dictated by the patient's condition and other medications.
3. Neuraxial hydrophilic opioids (e.g. morphine, not including sustained- or extended-release epidural morphine) via single injection:
   - Monitor the patient for at least 24 hours after administration.
   - Patient monitoring should be repeated at least hourly for the first 12 hours and then at least every 2 hours for the 12–24-hour period.
   - Once 24 hours have passed, the patient's clinical condition and other medications should dictate the frequency of monitoring.
4. Continuous infusion or PCEA with neuraxial hydrophilic opioids:
   - The patient should be monitored throughout the duration of the infusion.
   - The frequency of monitoring should be hourly for the first 12 hours and then at least every other hour for the next 12 hours.
   - Once 24 hours have passed, repeat the monitoring at least every 4 hours.

- Once the infusion or PCEA has stopped, the patient's condition and administration of other medications should dictate the frequency of monitoring.

5. Respiratory depression—management and treatment:

- If patients have altered level of consciousness, respiratory depression, or hypoxaemia, administer supplemental oxygen and continue until the situation has resolved.
- Supplemental oxygen should not be used routinely as it may increase the duration of apnoeic episodes, or limit the detection of transient apnoea and hypoventilation.
- If respiratory depression persists or recurs, IV access should remain.
- All patients with any degree of respiratory depression following the neuraxial administration of opioids should have reversal agents readily available.
- If severe respiratory depression occurs, resuscitation should be initiated rapidly and effectively.

In theory, a drug which acts on the κ-opioid receptor should provide analgesia without respiratory depression, and butorphanol has been studied as a likely candidate. Butorphanol is a μ-receptor antagonist and κ-receptor agonist and therefore could be predicted to reduce the side effects of epidural opioids without lessening the analgesic effect.[51,52] However, clinical studies comparing postsurgical pain found that the addition of epidural butorphanol to a bupivacaine/fentanyl mix did not result in additional analgesia or reduce side effects. Studies in obstetric patients for labour analgesia and CD found no significant reduction in pain scores but less pruritus, nausea, and vomiting (reduced μ-receptor effect, as predicted). However, there was an increased incidence of somnolence[51–53] (an unwanted κ-receptor agonist effect) associated with the butorphanol group. The role of this type of agent remains unclear.

## Opioid adjuvants: individual agents

For a summary of opioid adjuvants see Table 17.4.[58,62,63,67,74]

### Morphine

#### Pharmacology

Morphine is a naturally occurring, hydrophilic phenanthrene derivative. It was the first opioid administered neuraxially for labour analgesia[54] and is the most widely studied adjuvant. Early studies showed significant analgesic synergy[55,56] between morphine and local anaesthetic, with the local anaesthetic potentiating the antinociceptive effects of morphine by enhancing the morphine binding to the κ-opioid receptor.

Morphine is a weak base (pKa 8.0). Its half-life is 3–4 hours with up to 70% metabolized in the liver to morphine-3-glucuronide, (which affects arousal and is possibly a μ-receptor antagonist) and to morphine 6-glucuronide, which is 13 times more potent than morphine and has a similar duration of action. Both these metabolites are excreted in the urine and accumulate in renal failure.[22,23]

#### Lipophilicity and binding: onset and duration

Because morphine is poorly lipid-soluble (lipophobic), it is slow to bind to the dorsal horn receptors, taking 15 minutes to work intrathecally and 30 minutes epidurally. However, its longer duration of action, (~12–24 hours), means that a single dose of epidural or spinal morphine will improve the quality of pain relief for the first stage of labour and is more effective than a single dose of fentanyl at providing postoperative pain relief.[14]

#### Doses: intrathecal/epidural

Both intrathecal and epidural morphine have a ceiling analgesic effect; at doses greater than 100 mcg (intrathecal) and 3.75 mg (epidural) there is minimal additional analgesic benefit, but increased incidence of adverse effects, particularly pruritus.[57]

#### Side effects

Intrathecal and epidural morphine are associated with a high incidence of dose-related nausea, vomiting, pruritus, urinary retention, sedation, and delayed respiratory depression when compared to fentanyl. These effects can occur even at very low doses.[58]

### Sustained- or extended-release epidural morphine

Extended-release epidural morphine (EREM) by single bolus injection can extend effective postoperative analgesia for up to 48 hours and was approved by the US Food and Drug Administration (FDA) in 2004.

In a randomized controlled trial (RCT) of 70 women for elective CD using a combined spinal–epidural (CSE) technique, patients received an intrathecal injection of bupivacaine 12 mg and fentanyl 10 mcg and a single-dose epidural bolus of either conventional morphine 4 mg or EREM 10 mg. Significantly improved pain scores at rest and during activity were found in those women receiving EREM, with a decrease in supplemental opioid medication usage for 48 hours post CD. (In milligram-morphine equivalents, median and interquartile range from 17 (22) to 10 (17) mg with EREM compared to conventional epidural morphine ($P = 0.037$).[59])

In 2009, Hartrick and Hartrick compared the adverse effects of EREM ($N = 801$) to IV opioids and standard epidural morphine.[60] EREM doses of 15 mg or greater were associated with a trend towards a higher incidence of hypoventilation (odds ratio 0.48; 95% confidence interval (CI) 0.21–1.09; $P = 0.081$; number-needed-to-treat (NNT) = 14) compared with placebo. The incidence of pruritus was significantly higher for all EREM doses compared with both placebo ($P = 0.004$) and standard epidural morphine ($P = 0.03$). Vomiting was also increased with EREM doses of 15 mg or greater compared with placebo (odds ratio 0.40; 95% CI 0.18–0.89; $P = 0.02$; NNT = 5). For these reasons, EREM has not been widely embraced by the obstetric anaesthetic community.

If EREM is used, then monitoring at least once every hour should be performed during the first 12 hours after administration, and at least once every 2 hours for the next 12 hours (i.e. from 12 to 24 hours).[50]

After 24 hours, monitoring should be performed at least once every 4 hours for a minimum of 48 hours.[50]

### Fentanyl

The profiles of fentanyl and sufentanil are very similar except for their relative potency.

#### Pharmacology

Fentanyl is a phenylpiperidine derivative. It is a lipophilic opioid, which acts as an adjunct to local anaesthetics to increase

**Table 17.4** Summary of opioid adjuvants[58, 62, 63, 67, 74]

| Opioid | Epidural clinical dose range and optimal doses | Intrathecal dose | Epidural onset (mean, minutes) | Intrathecal onset (mean, minutes) | Epidural duration (mean, hours) | Intrathecal duration (mean, hours) | Advantages | Disadvantages |
|---|---|---|---|---|---|---|---|---|
| Sustained-release morphine | *10 mg–15 mg* *('optimal'10 mg)* | N/A | 5 | N/A | 48 | N/A | Longest duration | Increased pruritus compared to standard morphine, more hypoventilation and vomiting at doses >15 mg |

CD, caesarean delivery; $ED_{50}$, effective dose required for desired effect in 50% of people receiving the drug; $ED_{95}$, effective dose required for desired effect in 95% of people receiving the drug.

Data from various sources (see references).

the duration and intensity of spinal anaesthesia[54,61–64] without intensifying motor and sympathetic block[65,66] or prolonging recovery.[67,68]

### Lipophilicity/binding: onset and duration

Fentanyl has a pKa of 8.4 and is approximately 800 times more lipid-soluble than morphine. It binds rapidly to dorsal horn receptors in the spinal cord and has a corresponding rapid onset of action (5 minutes intrathecally, 10 minutes epidurally). This is advantageous for labour analgesia and emergency CD and also means that cephalad spread and delayed respiratory depression are rare. Its duration of action is short (2–4 hours intrathecally and epidurally) due to redistribution and systemic absorption, so it does not provide clinically useful postoperative analgesia.[14]

### Doses

For labour analgesia, intrathecal fentanyl is effective as a sole agent, in which context it has been shown to have a median effective dose of 14 mcg (95% CI 13–15 mcg), and a ceiling effect at 25 mcg.[69]

The effective epidural dose is 100 mcg, which can be used to improve an inadequate block without prolonging recovery time,[67,68] but larger doses do not prolong the duration of analgesia in any clinically significant way.[57]

### Side effects: intrathecal/epidural

Intrathecal fentanyl has been shown to decrease intraoperative nausea and vomiting,[61–64] and while respiratory depression has been described, it is unlikely with doses less than 25 mcg. Intrathecal fentanyl produces a dose-dependent incidence of pruritus in approximately 50% of patients.[67] Urinary retention is far less common with lipophilic opioid use than with morphine, and the incidence of urinary retention is not increased by the addition of intrathecal fentanyl to hyperbaric bupivacaine.[65,70]

As an adjuvant to low-dose local anaesthetic epidural solutions for labour, fentanyl can potentiate analgesia, but epidural bolus doses may result in early respiratory depression due to systemic absorption. There has been considerable controversy in the literature about the site of action of epidurally administered lipophilic opioids, with conflicting evidence suggesting that the analgesic action of epidural fentanyl may be entirely due to its action in the brain following systemic absorption rather than at spinal receptors. Ginosar et al. clarified the situation in 2003 by comparing a continuous infusion of epidural fentanyl given as a sole agent with bolus epidural fentanyl administration.[71] This human volunteer study showed that after a 100 mcg fentanyl epidural bolus, fentanyl plasma levels reached a maximum of 0.47 ng/mL (standard deviation (SD) ± 0.39 ng/mL) at 45 minutes after injection and this was accompanied by *segmental* analgesia, suggesting relevant opioid binding in the spinal cord. When fentanyl was administered by infusion at a rate of 100 mcg/h the maximum plasma concentration was 0.80 ng/mL (SD ± 0.24 ng/mL) at 180 minutes after injection, and this was accompanied by non-segmental analgesia, suggesting relevant opioid binding in the brain.

The authors speculated that administration of the bolus dose of fentanyl might create a large concentration gradient of drug between the epidural space and CSF, thereby enabling a higher concentration of drug to access the spinal sites, which might not be achieved with the lower concentration gradient at infusion doses.

The same authors have shown that in labouring women, the required dose of epidural bupivacaine can be reduced by a factor of three when co-administered with an epidural fentanyl infusion as compared with an IV fentanyl infusion.[72] This is accounted for by the supra-additive, or synergistic, effect of the two drugs; an otherwise insignificant analgesic effect by a spinal mechanism may become predominant if epidural fentanyl is infused jointly with a local anaesthetic. This study used a technique known as 'minimum local anaesthetic concentration' (MLAC), whereby the efficacy of an adjuvant, and the reduction in dose of local anaesthetic that can be achieved can be measured.[73] This technique involves systematic evaluation of dose–response pharmacodynamics and allows the median effective concentration ($EC_{50}$) and median effective dose ($ED_{50}$) to be established for local anaesthetics. This is analogous to the minimum alveolar concentration (MAC) for inhalational anaesthetics and is an accurate way of quantifying the local anaesthetic-sparing properties of adjuvants. It has been used widely in the clinical context of epidurals in labour.

Using this tool, Lyons and co-workers demonstrated that the MLAC of epidural bupivacaine can be reduced by 31–72% in a linear, dose-dependent manner by the addition of 2–4 mcg of fentanyl per mL of local anaesthetic solution.[74] The first woman in each fentanyl group received an arbitrarily chosen concentration of bupivacaine based on estimations of MLAC from preceding studies. If this produced an effective outcome (using a 100 mm visual analogue pain score (VAPS) where VAPS was <10 mm within 30 minutes), the next patient in the series received a predefined reduction of 0.01% weight/volume concentration of local anaesthetic but at the same volume and with the same dose of fentanyl. An ineffective response (VAPS ≥ 10 mm within 30 min) resulted in the next patient in the series receiving an increase in concentration of local anaesthetic by the same predefined interval. This process of sequential allocation of local anaesthetic dose continued until the concentration administered was the $EC_{50}$ or MLAC.

## Sufentanil

### Pharmacology

Like fentanyl, sufentanil is a synthetic phenylpiperidine derivative. It is five to seven times more potent than fentanyl. Sufentanil has a terminal elimination half-life of 150 minutes, so accumulation is unlikely.

### Lipophilicity/binding: onset and duration

Sufentanil is 1600 times more lipid-soluble than morphine[14] with a consequent very fast onset time of 2–3 minutes intrathecally, and 4–6 minutes epidurally. Its short duration of action (1–3 hours intrathecally and epidurally) means it has no useful clinical postoperative analgesic effect, and its main indication is to improve the quality of pain relief during the second stage of labour via administration as an epidural bolus or in combination with local anaesthetic agents intrathecally for CD. The use of sufentanil has been shown to be an independent significant predictor of effective analgesia in labour when used as an adjunct with epidural bupivacaine, levobupivacaine, and ropivacaine[75] and MLAC studies show that the $EC_{50}$ of bupivacaine is reduced by 91% by the addition of sufentanil 1.5 mcg/mL.[76]

### Doses: intrathecal/epidural

Doses of 2.5–5 mcg are recommended for intrathecal use and 25–50 mcg for epidural bolus use.[39]

### Side effects: intrathecal/epidural

Its rapid onset time means there is a corresponding increased risk of early respiratory depression after an epidural bolus because of systemic absorption, but with a low risk of cephalad spread leading to less delayed respiratory depression. There are case reports of rapid-onset life-threatening respiratory depression occurring 5–15 minutes after intrathecal sufentanil 10–15 mcg[26,77–79] including during intrathecal use for labour analgesia.[79] However, during CD significant sedation or respiratory depression has not been reported.[53,61–63] Neurotoxicity has not been reported with clinical doses of 1.5 mcg/kg of intrathecal sufentanil, but animal studies have noted histopathological changes with doses of 7.5 mg/kg.[81]

## Alfentanil

### Pharmacology

Alfentanil is a lipid-soluble, synthetic phenylpiperidine derivative and a μ-receptor agonist.

### Lipophilicity/binding: onset and duration

It has a pKa of 6.5 so at a pH of 7.4, 89% is present in the unionized form and able to cross lipid membranes.[23] This is why it has a faster onset of action than fentanyl, despite having lower lipid-solubility.

### Dose

It is rarely used in obstetrics because of its short duration of action. Intrathecal alfentanil alone provides analgesia for 40 minutes.[82] In an epidural infusion study used at 30 mcg/kg/h, analgesia was inadequate for late first stage and second stage of labour in 30% of patients.[83]

### Side effects

Neonatal hypotonia following delivery has been reported.[84]

## Pethidine (meperidine)

### Pharmacology

Pethidine is a lipophilic phenylpiperidine derivative, which is a combined μ-receptor and κ-receptor agonist.[85] Pethidine is the only opioid that has local anaesthetic actions, and it also has anticholinergic and stimulant effects,[22,23] which in high concentrations may cause seizures and hallucinations.[86]

### Lipophilicity/binding: onset and duration

Pethidine is ten times more lipid-soluble than morphine and therefore has a faster onset (5 minutes intrathecally, 10 minutes epidurally) and shorter duration (4–8 hours intrathecally and epidurally) of action than morphine.[87] Its active metabolite norpethidine is less lipid-soluble and can accumulate in the fetus.

### Doses: Intrathecal/epidural

When used as a single agent, intrathecal pethidine 10–20 mg produces analgesia in 2–12 minutes, which can last for up to 3 hours[87] and 1 mg/kg produces surgical anaesthesia.[86,88]

When used as an adjunct to local anaesthetics for CD, the addition of 25 mg pethidine intrathecally provides better blood pressure stability and a lower incidence of side effects than 5 mg bupivacaine alone, with rapid motor recovery and prolonged postoperative analgesia.[4,89] When given via the epidural route as a sole agent in labour, pethidine 25 mg provides analgesia for 50–160 minutes,[27] but opioid side effects restrict its clinical use. Doses of 50 mg given via the epidural route to non-labouring parturients resulted in no maternal haemodynamic change, but did show some local anaesthetic effects.[90]

### Side effects: intrathecal/epidural

Intrathecal pethidine has a narrow therapeutic window. Respiratory depression, nausea and vomiting,[91] pruritus, bradycardia, and urinary retention can occur with doses as low as 0.5 mg/kg.[92] The incidence of nausea and vomiting was as high as 76% in one study,[86] so its use is not recommended. Epidural pethidine 10 mg reduces the shivering side effect of epidural analgesia, probably by agonist action at the κ-receptor.[85,89,93,94]

## Diamorphine

### Pharmacology

Diamorphine is a diacetylated semisynthetic morphine derivative with no affinity for opioid receptors.[23] It is a pro-drug, which, when administered intrathecally, diffuses across the dura more easily than morphine but more slowly than fentanyl, leading to relatively rapid clearance from the CSF. Its low pKa (7.6) means that only 37% is in its unionized form and able to diffuse onto the opioid receptors on the dorsal horn at physiological pH. Esterase metabolism in the spinal cord converts diamorphine to metabolites (6-momoacetyl morphine and morphine), which are water-soluble μ-receptor agonists with their own pharmacological effects.

### Lipophilicity/binding: onset and duration

Diamorphine is 280 times more lipid-soluble than morphine and therefore has a rapid onset (<10 minutes) of analgesia and is less likely to cause delayed respiratory depression.

### Doses: intrathecal/epidural

Diamorphine 0.3–0.4 mg intrathecally or 2.5–5.0 mg epidurally both effectively reduce the need for supplemental analgesia after CD.

A RCT comparing diamorphine 0.25 mg intrathecally with 5 mg epidurally as an adjunct to intrathecal bupivacaine 10 mg in 50 patients for CD using a CSE technique showed that the quality and duration of postoperative analgesia was similar in both groups (mean of 14 hours) but that the intrathecal route had significantly less nausea and vomiting than the epidural route (24% vs 4%; $P < 0.05$).[41] This is due to systemic absorption of diamorphine from the epidural space into the bloodstream and transportation to the chemoreceptor trigger zone. The degree of pruritus was 80–88% in both groups. The addition of 5 mg of diamorphine to epidural bupivacaine 0.25% significantly improves analgesia and reduces motor block in labour compared to bupivacaine alone.[95] For postoperative pain after CD, epidural diamorphine 3 mg provides significantly longer analgesia than 10 mg intramuscular morphine (mean 11 vs 6.5 hours), but more patients in the diamorphine group required catheterization and had nausea and vomiting. There was no evidence of respiratory depression on overnight pulse oximetry.[96]

### Side effects

The National Institute of Health and Care Excellence (NICE) 2011 guidelines for CD[97] recommend diamorphine (0.3–0.4 mg intrathecally, or 2.5–5 mg epidurally). Both morphine and diamorphine are effective adjuvants for intra- and postoperative analgesia for

CD by the intrathecal and epidural route, but diamorphine has fewer side effects, particularly delayed respiratory depression and nausea and vomiting[98] and is therefore recommended.

The availability and use of diamorphine is limited outside the United Kingdom.

## Non-opioid adjuvants

In addition to opioids, drugs from other pharmacological classes may produce spinal analgesia and have been used as adjuvants in neuraxial analgesia.

These include vasoconstrictors, agonists at the α-adrenergic, serotonergic, cholinergic, and GABA receptors, and antagonists at the NMDA receptor.

### Epinephrine

#### Pharmacology/mechanism of action

Epinephrine works as an adjuvant to neuraxial local anaesthetics by two mechanisms, local vasoconstriction, and as a direct $\alpha_2$ adrenoceptor agonist with a specific spinal analgesic action.

Vasoconstriction of epidural veins reduces vascular absorption of local anaesthetic and maintains a higher concentration at the nerve roots for a longer period, which prolongs the duration of blockade and reduces the risk of toxicity.

The efficacy of epinephrine as a vasoconstrictor adjunct depends upon the lipid solubility of the local anaesthetic used. The addition of epinephrine to epidural lidocaine decreases systemic absorption by approximately 30%.[81,82] Bupivacaine has higher lipid solubility than lidocaine, so there is less systemic absorption from the epidural space in the first instance. Consequently the addition of epinephrine to epidural bupivacaine only decreases systemic absorption by around 10–20%,[99,100] and it is less effective at prolonging the duration of blockade when compared to lidocaine.

#### Epidural/intrathecal use

In labouring patients, the addition of epinephrine increases the duration of epidural bupivacaine analgesia and decreases the local anaesthetic requirement,[101–104] and can be specifically shown to reduce the MLAC of epidural bupivacaine.[105] The addition of 1:300,000 epinephrine to spinal bupivacaine and sufentanil prolongs the duration of analgesia from 100 min to 140 min.[106]

Despite these advantages, the use of epinephrine for labour analgesia is now uncommon, partly because of the potential tocolytic effects due to $\beta_2$ adrenergic actions on the myometrium, which can lead to prolonged labour.[107]

There is also a theoretical concern that neuraxial adrenaline/epinephrine could cause spinal artery vasoconstriction but there is no conclusive evidence for this. If used, the dose should be kept to a minimum of 1–1.25 mcg/mL.

#### Systemic side effects

Epinephrine is detected in plasma after neuraxial administration and may cause dose-related sympathomimetic effects. Tachycardia and hypertension could be clinically significant in cardiac patients, pre-eclamptic patients, or patients taking tricyclic antidepressants and monoamine oxidase inhibitors. The addition of epinephrine also prolongs the time until voiding of urine,[70,108,109] and increases the incidence of nausea and vomiting.[63]

#### Special circumstances/specific uses of epinephrine

##### *'Test dose'*

Historically, an epidural test dose 45 mg of lidocaine with 15 mcg of epinephrine was advocated to identify accidental intravascular injection by the occurrence of tachycardia and palpitations if the catheter had been placed or migrated intravascularly.[110] A review article in 2006 examined the efficacy of test doses and concluded that, in the pregnant population, the injection of epinephrine had low sensitivity for the clinical detection of intravascular injection. It included studies that looked at the injection of 10–15 mcg of epinephrine alone and the injection of a combination of bupivacaine 12.5 mg + epinephrine 12.5 mcg and found that both had low sensitivity for the clinical detection of intravascular injection (95% CI for sensitivity 78–100 for epinephrine alone) and (95% CI for sensitivity 75–100 for bupivacaine and epinephrine combined).[111]

For the detection of intravascular catheter misplacement in pregnant women, the injection of epinephrine has a low positive predictive value (<80) and may also have significant side effects (e.g. decreased uteroplacental blood flow after epidural or IV injection). The injection of epinephrine in labour is therefore unjustified, but could be considered if the epidural is performed for CD where a larger dose of local anaesthetic is anticipated.

##### *'Rapid top-up for operative delivery'*

In practice, the main use of epinephrine on the delivery suite is as an additive to local anaesthetics in order to rapidly top-up a labour epidural for emergency CD. A 2011 meta-analysis of 11 RCTs including 779 parturients has confirmed that lidocaine 2% with epinephrine ± fentanyl gives the most rapid onset of block.[112] In one RCT, the combination of lidocaine–bicarbonate–epinephrine (concentrations 1.8%, 0.76%, and 1:200,000) reduced the median time to extend a labour epidural block for CD (sensory block to T4 for cold, T5 for touch) to 7 minutes, compared with 14 minutes for levobupivacaine 0.5% alone.[113] In all the trials included in the meta-analysis by Hillyard et al., solutions containing lidocaine and epinephrine, with or without fentanyl, showed median onset times of under 15 minutes, making epidural top-up for CD a realistic option in all but the most urgent emergency situations.

### Neostigmine

#### Pharmacology/mechanism of action

Neostigmine is a quaternary amine, which acts by inhibiting acetylcholinesterase. This prevents the breakdown of acetylcholine so that more is available at the neuromuscular junction.[14] Neostigmine does not cross the blood–brain barrier.[22] It is a cholinesterase inhibitor which produces analgesia by increasing the concentration of acetylcholine adjacent to the muscarinic and nicotinic receptors in the superficial layers of the dorsal horn of the spinal cord.[58] This mechanism of analgesia does not produce motor or sympathetic blockade.[114] Although it has been shown to produce analgesia on its own,[114] it is most useful as an adjuvant rather than a sole agent.

#### Intrathecal neostigmine

Both animal and human studies show that intrathecal neostigmine does not affect spinal cord blood flow and does not induce any significant toxic effect in the spinal cord.[115–117] In animal studies it reduces the risk of hypotension induced by spinal local anaesthetic.[118,119]

Intrathecal neostigmine increases the analgesia from systemically administered opioids and neuraxial administered $\alpha_2$-adrenoceptor agonists. However, with doses larger than 200 mcg, there are significant systemic effects ranging from severe nausea and vomiting to motor blockade, sedation, and hypertension.[120] This high incidence of nausea and vomiting precludes intrathecal use clinically.[14]

### Epidural neostigmine

When administered epidurally neostigmine also enhances the duration and intensity of analgesia from systemic and neuraxial $\alpha_2$-adrenoceptor agonists, opioids and local anaesthetics. Unlike intrathecal neostigmine, epidural neostigmine is not associated with an increased risk of nausea and vomiting.

The effective epidural dose for postoperative pain is 50–100 mcg, but the reduction in pain scores and opioid consumption is equivalent to that achieved by administration of simple analgesics (e.g. oral non-steroidal anti-inflammatory drugs).[121] Low-concentration epidural neostigmine given continuously in non-obstetric patients has a local anaesthetic-sparing effect similar to opioids, but without nausea and vomiting.[122]

For reliable analgesia via the epidural route in early labour, at least 300–500 mcg of neostigmine is required, and then only in combination with other drugs (sufentanil, clonidine, local anaesthetic). When used in this way, neostigmine may have a local anaesthetic-sparing effect similar to fentanyl and sufentanil[106] and also an opioid-sparing effect.[123,124]

Doses greater than 100 mcg have been associated with sedation[14] but neostigmine does not cause respiratory depression or pruritus either alone or increase the risk of these side effects when used in combination with neuraxial opioids. In an editorial in 2009, Eisenach considered the case for replacing epidural lipid-soluble opioids with neostigmine in view of its lack of respiratory depression and pruritus.[121] However, the safety and efficacy of epidural neostigmine in the postoperative period has not been widely studied, and there are some unusual drug interactions (e.g. the combination of systemic opioid and intrathecal neostigmine is additive for analgesia but synergistic for nausea[122]). While it is assumed that epidural neostigmine enhances analgesia from epidural or systemic drugs by its cholinergic action in the spinal cord, there are no studies with systemically administered controls to specifically test this assumption[121].

There are also theoretical concerns about the effect of neostigmine on the fetus. Stimulation of spinal cholinergic receptors can increase sympathetic nervous system activity[124], which may decrease the perfusion to the uteroplacental unit. Also, systemic absorption of neostigmine could result in stimulation of myometrial activity[124] or if enough is transferred to the fetus, fetal bradycardia.[125] However, a small observational study of 12 women showed that a neostigmine epidural bolus of 40–80 mcg did not induce contractions, alter FHR or cause nausea in non-labouring women.[124] In the same study, 40 healthy labouring women were randomized to receive bupivacaine 1.25 mg/mL alone or with neostigmine 4 mcg/mL by PCEA. Epidural neostigmine infusion reduced bupivacaine requirement by 19% in all patients and 25% in those with greater than 4 hours of treatment ($P < 0.05$ for both) but might have contributed to the incidence of mild sedation. Mode of delivery, incidence of maternal nausea, incidence of FHR abnormality, and Apgar scores were similar between groups. Larger studies are required to provide more information before neostigmine can be recommended for clinical use.

## Clonidine

### Pharmacology/mechanism of action

Clonidine hydrochloride, an imidazoline derivative[126] is a centrally acting partial $\alpha_2$-adrenoceptor agonist with an affinity for $\alpha_2$ receptors 200 times that for $\alpha_1$ receptors.[14]

Clonidine binds to postsynaptic G-protein coupled inhibitory $\alpha_2$ receptors, in the laminae of the dorsal horn of the spinal cord thereby inhibiting adenylate cyclase and reducing intracellular cAMP formation.[127] This reduces excitation via sodium and potassium channels and inhibits calcium channels. Within the spinal cord, $\alpha_2$ receptor stimulation augments endogenous opioid release and modulates descending noradrenergic pathways involved in spinal nociceptive processing. This produces a dose-dependent analgesia not antagonized by opioid antagonists which is limited to the body regions innervated by the spinal segments where analgesic concentrations of clonidine are present.[126]

In mice, nociceptive responses induced by intrathecal substance P are inhibited in a dose-dependent manner by intrathecal clonidine,[5] indicating a synergistic effect of clonidine at the δ-opioid receptor, but not μ- or κ-opioid receptors.

Within the brainstem, $\alpha_2$-receptor stimulation in the lateral reticular nucleus reduces central sympathetic outflow and causes a decrease in peripheral resistance, renal vascular resistance, heart rate, and blood pressure. It also stimulates $\alpha_2$ receptors in the locus coeruleus,[128] which is responsible for vigilance and sympathetic tone,[129,130] producing sedation and ventilatory abnormalities that are usually mild[126] and have only been reported with bolus doses that are significantly larger than those used in the obstetric population.

When used via the subarachnoid or epidural route, clonidine provides prolonged analgesia without causing respiratory depression or sensory–motor blockade and exhibits synergism with concurrently administered neuraxial opioids.[23]

### Intrathecal clonidine

For CD with spinal anaesthesia, intrathecal clonidine 30–60 mcg increases the duration of sensory block by 30%, delays the onset of postoperative pain, and reduces overall postoperative opioid requirements.[57]

### Epidural clonidine

Epidural clonidine 75 mcg has been shown to prolong labour analgesia, reduce local anaesthetic requirements, and reduce the number of top-ups for breakthrough pain without an increase in side effects when used in combination with either bupivacaine or ropivacaine.[131] Clonidine has been shown to reduce the MLAC of epidural bupivacaine.[105] However, there remains serious concern regarding unacceptable levels of hypotension.

### Side effects

At epidural doses above 100 mcg, there is evidence of maternal hypotension, bradycardia, sedation, and FHR abnormalities. This is thought to be due to vascular absorption of clonidine via the epidural veins. Systemic concentrations of 0.5–2.0 ng/mL are readily achieved, and these are associated with a hypotensive effect mediated by the CNS.[126] These cardiovascular effects are usually seen

within 15–30 minutes of epidural administration and last for up to 3 hours.

It has been suggested that clonidine may mask the increase in heart rate associated with hypovolaemia.[132] Consequently, in the United States, an FDA 'black box warning' recommends that the neuraxial administration of clonidine is avoided in the obstetric population because of this risk of hypotension and bradycardia.[126] The FDA states that 'there are no adequate controlled clinical trials evaluating the safety, efficacy, and dosing of clonidine in obstetric settings. Because maternal perfusion of the placenta is critically dependent on blood pressure, use of clonidine as an analgesic during labour and delivery is not indicated'. In the presence of such a warning, clonidine should be used with caution and only when other methods of rescuing the epidural have failed.

## Neostigmine and clonidine combinations

The situation with neostigmine and clonidine is further complicated by a trial in 2009, which studied the use of both agents together.[133] This was a RCT during labour in which initial intrathecal analgesia with ropivacaine and sufentanil was supplemented 15 minutes later by an epidural bolus containing clonidine 500 mcg and neostigmine 75 mcg Compared with placebo, this combination resulted in a longer initial duration of pain relief and a lower subsequent local anaesthetic requirement for maintenance of labour analgesia. There was no clinically significant hypotension and no sedation using this combination, which is difficult to achieve when using clonidine or neostigmine as single adjuvants. This study was the subject of an editorial by Paech[134] in which the risk:benefit ratio of the use of multiple neuraxial drugs was questioned, with emphasis on the dose limitations of clonidine and the limited safety data of neostigmine. Paech cautions that 'in addition to safety and efficacy, data on more definitive outcome measures are required to define the potential benefits, before these adjuvants are accepted for routine use in obstetric anaesthesia and analgesia'.

## Ketamine

### Pharmacology/mechanism of action

Ketamine is a phencyclidine derivative, which acts as a non-competitive NMDA receptor antagonist.[22] NMDA receptors are activated by glutamate, which is the major excitatory neurotransmitter in the CNS. Ketamine blocks activation of the ligand gated channel and reduces NMDA receptor-mediated responses[23] leading to inhibition of excitatory pathways. The channels controlled by NMDA receptors are highly permeable to $Ca^{2+}$ and are blocked by $Mg^{2+}$. Ketamine is lipid-soluble and freely crosses the blood–brain barrier.

When used neuraxially, ketamine blocks NMDA receptors located on secondary afferent neurons in the dorsal horn of the spinal cord, reducing the transmission of nociceptive information in the spinal pathways.[135] In high doses it may have additional minor analgesic effects by binding opioid μ-receptors and modulating descending inhibitory pathways through inhibition of reuptake of neurotransmitters[14].

### Intrathecal ketamine

Early animal studies suggested that intrathecal ketamine has local anaesthetic properties[136–138] and might provide anaesthesia without hypotension. However, when the animals were killed, their spinal cords showed vacuoles indicating neural death, so human studies on intrathecal ketamine have rarely been undertaken. The finding that ketamine can induce apoptosis when used in high doses or for prolonged periods in animal studies has caused concern from the FDA and National Institutes of Health about potential human neurotoxicity.[139] Even with the availability of a preservative-free formulation for 20 years, these concerns remain.

Previous studies have shown ketamine to be a useful neuraxial adjunct for surgery. Bion demonstrated that intrathecal ketamine in doses above 50 mg provided satisfactory rapid onset (1.7 minutes) surgical anaesthesia lasting 45–90 minutes for lower limb surgery in war field conditions.[140] For ethical reasons, such a study could probably not have been conducted other than in the setting of war conditions.

There are no studies of intrathecal ketamine in obstetrics.

### Epidural ketamine

In a small prospective RCT of non-obstetric abdominal surgical cases, epidural ketamine 1 mg/kg plus morphine 50 mcg/kg produced more rapid postoperative analgesia (median 11 vs 25 minutes) and more prolonged analgesia (median 19 vs 12 hours) than the group which received only morphine.[141] The ketamine group had higher sedation scores in the first 2 hours, there was no respiratory depression or hallucinations, and the incidence of pruritus, nausea, and vomiting was the same in both groups. There are no studies of epidural ketamine in obstetrics.

Due to unresolved safety concerns, the use of neuraxial ketamine cannot be recommended, despite early hopes that it would provide anaesthesia without hypotension.

## Midazolam

### Pharmacology/mechanism of action

Midazolam is a benzodiazepine, which acts by enhancing presynaptic inhibition through benzodiazepine binding sites in the $GABA_A$ receptor in the spinal cord.[142] $GABA_A$ receptors are ligand-gated receptors located throughout the CNS, but the substantia gelatinosa of the dorsal horn of the spinal cord contains a particularly high density of $GABA_A$ receptors. GABA is the major inhibitory neurotransmitter of the CNS. GABA binding results in a change of receptor configuration, opening chloride ion channels and resulting in hyperpolarization of the neuron and reduced action potential propagation. Benzodiazepines have their own binding site on the $GABA_A$ receptor and the effect of binding is to increase the frequency of chloride channel opening, which enhances the effects of GABA.

There are limited studies assessing the clinical safety of neuraxial midazolam.[14] The most serious side effect reported in animal studies is neurotoxicity, but this has been attributed to the effects of injection of an acidic solution.[142,143] Midazolam has a pH of 3.5 and its structure depends on the surrounding pH. At pH 3.5 its di-asinine ring is open, resulting in an ionized molecule, which is water-soluble.[23] When the surrounding pH is greater than 4, the ring structure closes so that it is no longer ionized and therefore becomes lipid-soluble. Its pKa is 6.5 so that at physiological pH 89% is present in an unionized form and available to cross lipid membranes. The pH of CSF does not decrease below 7.0 when adding midazolam in the amounts used in clinical practice and no adverse reactions have been reported when using epidural[144] or intrathecally administered midazolam.[145]

### Intrathecal midazolam

Midazolam in intrathecal doses up to 2 mg has not been shown to cause any neurological deficit in humans. In a study of 100 patients scheduled for elective non-obstetric surgery, the addition of preservative-free midazolam 2 mg to bupivacaine intrathecally resulted in prolonged sensory block (mean 90 vs 115 minutes) without prolongation of motor block, while effective analgesia was prolonged from mean 121 to 221 minutes.[145] Sedation scores were the same for both groups.

To resolve the conflicting evidence from animal studies, Tucker followed up 574 non-obstetric patients for a month after intrathecal midazolam, evaluating 18 risk factors for neurotoxicity.[146] This large cohort study compared two groups of patients who received intrathecal anaesthesia with or without intrathecal midazolam, evaluating the presence of neurological symptoms in the period following intrathecal administration. They showed that intrathecal midazolam in doses up to 2 mg did not increase the occurrence of neurological or urological symptoms, whereas age greater than 70 years and accidental venous puncture involve relative risks of 8.72 and 8.07 respectively.

In a prospective RCT of 124 patients for elective CD, Prakash and colleagues compared 1 mg and 2 mg intrathecal midazolam as an adjunct to subarachnoid block with 10 mg intrathecal bupivacaine.[147] Postoperative analgesia was significantly prolonged (mean 6.1 ± 1 hours vs 3.8 ± 0.5 hours; P = 0.001) and supplemental diclofenac analgesic requirements were significantly decreased (mean 93 ± 29 mg vs 145 ± 12 mg) by the addition of 2 mg midazolam compared to bupivacaine alone, but not by 1 mg. Both 1 mg and 2 mg doses significantly reduced the incidence of postoperative nausea and vomiting. No significant difference in sedation score was seen between groups, and no neurological complications were noted.

Intrathecal midazolam 2 mg therefore appears to prolong spinal anaesthesia, decrease postoperative analgesia requirements, and reduce the incidence of nausea and vomiting, although more evidence is required to ensure that there are no short- or long-term neurological side effects.

### Epidural midazolam

Nishiyama compared postoperative thoracic epidural bupivacaine as a 6 mL 0.25% bolus with the same solution containing 0.05 mg/kg midazolam in 30 non-obstetric cases.[148] The area of analgesia was significantly larger in the midazolam group 10 and 30 minutes after administration and involved the entire spinal area and the head and face 10 minutes after administration. Sedation and amnesia were significantly greater in the midazolam group. Sedation and amnesia are probably due to the action of midazolam on benzodiazepine-$GABA_A$ receptors in the CNS, as the dose used resulted in a high enough systemic midazolam concentration to induce these effects.[149]

When midazolam is given as part of a continuous epidural infusion for postoperative pain after gastrectomy, those patients receiving 10 mg or 20 mg of midazolam, as part of a 40 mL infusion of epidural bupivacaine over 12 hours, had better analgesia as measured by the frequency of rescue analgesia compared to those receiving plain bupivacaine.[150] The midazolam groups also had increased early sedation (mean 120 minutes) and amnesia compared to the plain bupivacaine groups.

There are no studies of epidural midazolam use in obstetrics.

## Droperidol

### Pharmacology/mechanism of action

Droperidol is an antiemetic drug, which acts as an $\alpha_2$ adrenoreceptor agonist, dopamine receptor antagonist, and 5-$HT_3$ receptor antagonist.[5] Theoretically, a drug active at these receptors could reduce the required dose of neuraxial opioids and improve the quality regional analgesia and anaesthesia.

### Intrathecal droperidol

The only intrathecal use appears to be in chronic pain patients with intractable nausea, in which intrathecal droperidol 5–300 mcg/day was a safe and effective antiemetic to use along with opioid analgesics,[151] but there is no experience of its use in obstetrics.

### Epidural droperidol

Naji studied 40 patients for hip replacement receiving 4 mg epidural morphine with or without 2.5 mg droperidol for postoperative analgesia. The droperidol group had significantly less pruritus, nausea and vomiting, and hypotension, but there was no difference in mean pain scores over 24 hours.[152]

An RCT in obstetric patients compared the addition of epidural or IV droperidol 2.5 mg to epidural morphine 5 mg for postoperative pain after CD.[153] This study found no difference between the groups with respect to pain, pruritus, or satisfaction, but the incidence and severity of nausea and vomiting was significantly lower in the group that received IV droperidol, as would be expected for an antiemetic drug. This effect was not seen in the epidural droperidol group.

The addition of epidural droperidol 2.5 mg to epidural sufentanil for postoperative pain has been studied in a RCT of 40 orthopaedic patients.[154] The incidence of nausea, vomiting, and pruritus associated with epidural sufentanil was significantly decreased by epidural droperidol, but sedation was increased and the duration of analgesia after sufentanil and droperidol was significantly shorter than after sufentanil and placebo. The addition of epidural droperidol therefore appeared to significantly reduce the side effects of epidural sufentanil while diminishing the duration of analgesia, which would limit its clinical usefulness.

## Dexamethasone

### Pharmacology/mechanism of action

Dexamethasone is a potent steroid with anti-inflammatory, immunosuppressive, and antiemetic actions.

### Intrathecal dexamethasone

In an RCT involving 120 women, 8 mg intrathecal dexamethasone significantly decreased postoperative nausea and vomiting and improved patient satisfaction after CD compared to intrathecal morphine alone[155] This trial did not however, compare the antiemesis achieved with intrathecal dexamethasone to that achieved with IV dexamethasone.

### Epidural dexamethasone

An RCT in non-obstetric patients showed that the epidural administration of dexamethasone 5 mg has opioid-sparing effects with lower VAPS scores after laparoscopic cholecystectomy compared with epidural bupivacaine alone or epidural bupivacaine with IV dexamethasone. This would suggest a specific neuraxial analgesic effect of the dexamethasone, the mechanism for which is unknown.[156]

A similar small trial in non-obstetric abdominal surgical cases showed that the addition of 4 mg of epidural dexamethasone to 10 mL 0.25% bupivacaine significantly improved postoperative analgesia, as measured by VAPS scores and a reduction in analgesic consumption, as well as providing significant antiemesis.[157] The analgesia produced was equivalent to the addition of 50 mcg fentanyl to the bupivacaine, again suggesting a specific analgesic effect of dexamethasone.

Maternal pyrexia has been reported in association with labour epidurals, and may be due to altered maternal thermoregulation and production of inflammatory mediators.[158–161] Maternal pyrexia may be an independent risk factor for adverse neonatal outcomes.[162,163] Following vaginal delivery, a history of epidural analgesia may be associated with a higher maternal interleukin (IL)-6 level.[164] In an RCT of 60 parturients, those receiving epidural dexamethasone 0.2 mg/mL in addition to epidural bupivacaine/fentanyl had similar pain scores and block levels to those receiving bupivacaine/fentanyl PCEA alone. The patients in the dexamethasone group did not have a rise in temperature or IL-6 levels which did occur in the control group.[164]

### Side effects

Epidural dexamethasone may be associated with increased blood glucose levels, adhesive arachnoiditis, and a reduced threshold for infections including epidural abscess and meningitis.[165]

More information regarding the incidence of side effects is required before neuraxial dexamethasone can be recommended for routine clinical use.

## Magnesium sulphate

### Pharmacology/mechanism of action

Magnesium is a non-competitive NMDA receptor antagonist. It produces voltage-dependent membrane receptor block, preventing calcium influx. This interferes with the gating of calcium channels, transmembrane ion flux, and regulation of adenyl cyclase and will therefore affect neuronal activity, neurotransmitter release, and modulation of pain.[135,166] This can prevent induction of central sensitization due to peripheral nociceptive stimulation, abolish hypersensitivity, and may prevent post-injury pain.[167,168]

Older studies of neuraxial magnesium investigated 50 mg either as an intrathecal or epidural dose with variable results,[169,170] but two more recent prospective RCTs in obstetric patients have confirmed the analgesic effects of adding 500 mg epidural magnesium to both epidural bupivacaine with morphine[170] and with fentanyl.[171]

### Intrathecal magnesium

In a recent systematic review involving 1145 patients, Albrecht et al. examined 18 trials of neuraxial magnesium published since 2002 in an attempt to define its analgesic efficacy and safety.[172] Five of the included trials examined intrathecal use in obstetric patients.[167,173–176] The meta-analysis shows that the time to first analgesic request increased by 11.1% after intrathecal magnesium administration. Although this confirms a modest improvement in pain relief for these patients, Albrecht warns that the risk of neurotoxicity has not been well defined.

### Epidural magnesium

In Albrecht et al.'s systematic review,[172] only one of the trials examined epidural use in obstetric patients.[171] The review showed that overall, the time to first analgesic request increased by 72.2% after epidural magnesium administration with doses of between 50 and 100 mg.

In an RCT which was not included in the systematic review, Sun et al. demonstrated in 200 parturients that the addition of magnesium sulphate 500 mg to 0.1% epidural bupivacaine 10 mL and morphine 1.5 mg for postoperative pain relief after CD produced significantly ($P < 0.001$) lower VAPS scores at rest and on movement, increased time to first analgesia request, increased satisfaction ($P < 0.001$), and less shivering ($P < 0.02$) compared to bupivacaine alone or bupivacaine with just morphine at 6, 24 and 36 hours postoperatively.[170]

Similarly, in a prospective RCT of 90 parturients undergoing elective CD under CSE, Yousef showed that the addition of 500 mg $MgSO_4$ to 10 mL 0.25% epidural bupivacaine with 100 mcg of fentanyl following a spinal dose of 2 mL intrathecal 0.5% bupivacaine resulted in significantly later onset of postoperative pain and reduced postoperative analgesic requirement ($P < 0.05$) compared to the control group which received 10 mL N saline instead of magnesium.[171] The magnesium group had greater motor block and muscle relaxation ($P < 0.05$) and less shivering. There was no significant difference in the incidence of hypotension, nausea and vomiting, and duration of motor blockade between the groups.

### Side effects

Animal studies have reported clinical and histological evidence of neurological complications with similar weight-adjusted doses,[177] and two case reports have described patients suffering from disorientation and continuous periumbilical burning pain following the injection of magnesium into the neuraxis.[178,179]

Surprisingly, only four of the 18 trials reviewed by Albrecht et al. appear to have been monitored for signs of temporary (headaches, back and leg pain, temporary nerve injury) or permanent (paraplegia, quadriplegia, peripheral nerve injuries) neurological complications, and only one of the six that involved obstetric patients (and which used 50 mg intrathecal magnesium) records having done so.[176] This corresponds to just 140 patients, and of these, only one case of a 4-day persistent headache was recorded, which was treated conservatively.

In the RCT by Sun et al.,[170] which was not included in Albrecht et al.'s systematic review, although 200 patients were studied, the authors state that the trial was not designed or powered to look for neurotoxicity.

The safety of neuraxial magnesium remains undefined.

## Sodium bicarbonate

### Pharmacology/mechanism of action

Sodium bicarbonate can be used to speed up the onset of action of epidural lidocaine. Unlike every other adjuvant drug, sodium bicarbonate has no intrinsic analgesic activity, and it acts by raising the pH of the injectate. Lidocaine is a weak base, pKa 7.9, and in solution the ionized and unionized fractions exist in equilibrium depending on the pH, the more alkaline the solution, the greater the unionized fraction. Although it is the ionized form which blocks the membrane sodium channel, only the unionized form is lipid-soluble and able to diffuse from the epidural space across the lipid neural membrane to the receptor site. The speed of onset of epidural lidocaine block is therefore determined by the pH of the injected drug solution and alkalinization by the addition of 1 mL

of 8.4% $NaHCO_3$ per 10 mL of lidocaine results in a more rapid onset of neural blockade.[14] This is useful when rapid epidural top up for urgent CD is required.

Spinals work so quickly that there is no justification for using intrathecal bicarbonate.

### Epidural bicarbonate

As previously mentioned, in a prospective double-blinded RCT, Allam et al. showed using a sequential analysis technique that a lidocaine–bicarbonate–adrenaline mixture (final concentrations 1.8%, 0.76%, and 1:200,000, respectively) halved the time taken to top up the epidural to T5 to touch and T4 for cold for urgent CD from a mean of 14 minutes with plain levobupivacaine to 7 minutes with the mixture. Intraoperative maternal sedation was greater with lidocaine–bicarbonate–adrenaline but this difference was not statistically significant (P = 0.07).[113]

### New agents

Several drugs are currently under evaluation as potential neuraxial adjuvants, including adenosine, calcium channel blockers, non-steroidal anti-inflammatory agents, calcitonin, and cannabinoid receptor agonists.[14] There is as yet no information regarding their efficacy or safety.

## Conclusion

A variety of chemical compounds and drugs from several classes have been considered as neuraxial adjuvants in order to improve analgesia and anaesthesia in obstetrics. Robust data for safety is still lacking with many of these agents, and obstetric anaesthetists are rightly cautious in adopting new theoretical interventions until safety for both mother and fetus is well established by good evidence. In worldwide practice, opioid adjuvants are universally accepted as beneficial, and well-established monitoring regimens are in place to ensure safety. All other agents, with the exceptions of epinephrine and bicarbonate, although interesting, remain controversial and cannot be recommended for use in routine obstetric clinical practice.

# CHAPTER 18

# Alternative neural blocks for labour analgesia

Outi Palomäki and Petri Volmanen

## Introduction

Although neuraxial analgesia, either epidural or spinal, is the most effective,[1] widely examined, and most often used method for pain relief during labour, alternatives are necessary due to the variety of parturients' wishes, unavailability of the anaesthetist, or rapidity of required delivery. Globally, the majority of labouring women in the world do not have the choice of epidural analgesia.[2] Some parturients may also prefer less invasive methods of analgesia as well as wishing to stay mobile and in an upright position for as long as possible. In situations where neuraxial analgesia is contraindicated, due, for example, to a low platelet count, it is possible to block the distal parts of the pain pathways transvaginally.

This chapter deals with four alternative regional analgesia techniques. The paracervical and pudendal blocks are usually administered by an obstetrician, and the two others, the sympathetic and paravertebral blocks, may be administered by an anaesthetist.

## Paracervical block

Although epidural, spinal, and/or a combination of these forms of analgesia are the most effective and most widely used pain relief methods during labour, the paracervical block (PCB) has remained as an alternative method used by obstetricians.

Labour pain has both visceral and somatic components. In the first stage of labour, visceral pain predominates, arising from the uterine contractions, mechanical distension of the lower uterine segment, and from cervical dilatation. Stretching and distention of the lower segments of the uterus and the cervix stimulate mechanoreceptors, with uterine contractions causing myometrial ischaemia. Pain impulses from this area are transmitted by afferent nerves to the dorsal root ganglia in the spinal cord from T10 through L1. The object of the PCB is to block pain transmission at the paracervical ganglion, which lies posterior and lateral to the cervicouterine junction. Later in labour, at the end of the first stage and during the second stage, the descent of the presenting fetal part produces distension and traction on pelvic structures. The transmission of these painful perineal stimuli are conducted via the pudendal nerve though the anterior rami of S2 through S4, and cannot be blocked by PCB.[3–5]

The pathways of labour pain, the injection sites of PCB, as well as pudendal block (PB) are shown in Figure 18.1.

### Paracervical block technique

PCB is administered transvaginally by an obstetrician when the presenting part has descended well into the pelvis, the cervix is in the active phase of dilatation, and the contractions are frequent and painful. During injection the mother lies supine with her knees flexed and hips fully abducted. To avoid aortocaval compression, left lateral tilt is recommended. After giving the injection on one side, the mother turns to a lateral position for the next one or two contractions. At the end of this, the same procedure is repeated on the other side. Continuous cardiotocography (CTG) monitoring during the procedure is recommended.

The obstetrician palpates the cervix and then inserts her/his index and middle fingers to the lateral vaginal fornix, and the needle is placed along the fingers into contact with the vaginal epithelium. The injecting needle should be kept strictly tangential to the presenting fetal part.[6] The injection technique is shown in Figure 18.2.

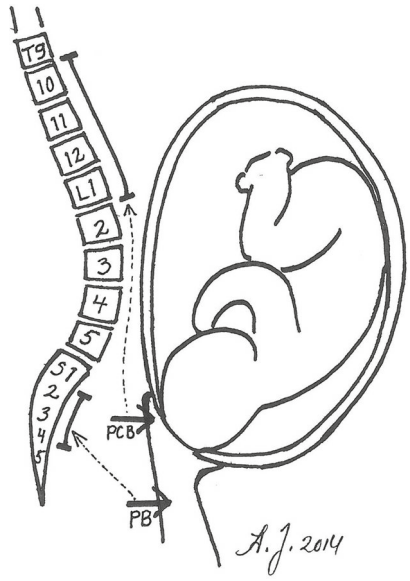

**Figure 18.1** Paracervical and pudendal blocks (sagittal view).

The instrument used for the procedure, a Kobak needle, was originally introduced in 1960 by Kobak and Sadove.[7] It has a round-tipped sheath that can be introduced to the injection site safely and without injury to the mother or fetus. After placement of the rounded tip at the injection site, the needle is advanced in the sheath, from which it is possible to control and limit the depth of needle penetration. In the original instrument this limit was 15–20 mm, but with the modern version of the needle used in obstetric practice, the injection depth has been limited to 3 mm for safety reasons.[8] With a Kobak needle it is possible to penetrate the endopelvic fascia just under the vaginal epithelium and to inject the analgesic drug into the base of the broad ligament, thereby blocking the afferent nerves and visceral pain.[8,9] After careful aspiration the analgesic agent is injected at two different points—3 and 9 o'clock or 4 and 8 o'clock—with the operator facing the patient who is the lithotomy position. Another possibility is to inject a quarter of the total drug volume at each of these four sites. In some studies, four-site administration has been shown to be more effective and reliable than two-site injection.[10] In any method, it is essential to aspirate at every injection site. It has been shown in X-ray studies, that both 3 and 9 o'clock and 4 and 8 o'clock positions are equal in effectiveness as drug dispersion is identical in the base of the broad ligament space.[9] When carrying out the block to the patient's left-sided fornix, the operator sits on the parturient's right side, and palpates the fornix with the right hand while aspirating and injecting with the left hand. While waiting for the next contraction, the operator moves to the left side of the patient and changes hands. With this technique, the needle's course is naturally tangential to the fetal head.

Excluding the oldest studies which were performed using deep injection techniques and high doses of local anaesthetic agent, the most widely used and studied drug in PCB, especially in European delivery units, is 0.25% racemic bupivacaine, 10 mL[11–20] but even a 0.125% solution of bupivacaine 10 mL has been showed to be effective.[17]

There are two studies in which racemic bupivacaine and levobupivacaine, the S (-)-enantiomer of racemic bupivacaine, were used.[21,22] No differences were observed in safety profiles as examined with incidence of CTG—pathology or neonatal outcome—and the analgesic effect was equal with both drugs using similar doses of drug. In a few studies, amino amides other than bupivacaine, such as mepivacaine,[23–25] lidocaine,[25,26] or prilocaine,[25] have been used for PCB at total doses of 200–300 mg, 100–200 mg, and 200 mg, respectively. In the United States, some early studies with the amino ester 1–2% 2-chloroprocaine have been published.[27–29] The main problem with this local anaesthetic is the short duration of pain relief. In two studies comparing chloroprocaine to bupivacaine,[30,31] bupivacaine was determined to be the drug of choice for PCB due to its longer-lasting analgesia (mean ± standard deviation (SD); 66.8 ± 28.7 minutes vs 35.4 ± 10.2 minutes).[31]

## The analgesic effect of paracervical block

### Paracervical block compared to other pain relief methods

PCB has been compared to other pain relief methods, such as epidural analgesia, single-shot spinal analgesia, and intramuscular meperidine in a few small series.

In a study of 62 women, parturients were offered a choice between PCB and epidural analgesia. Thirty-nine women chose PCB for pain relief while 23 chose epidural analgesia.[12] Bupivacaine was the drug of choice for both pain relief methods with a total dose of 25 mg (10 mL of 0.25% solution) for PCB and 30 mg (6 mL of 0.5% solution) for epidural block. PCB was given by an obstetrician using two 5 mL injections, and epidural analgesia was administered by an anaesthetist using an initial bolus of 4 mL followed by a further 2 mL, 10 minutes later. Pain intensity was assessed on a linear scale of 0–10. Pain score values decreased significantly within 5 minutes in the PCB group and within 30 minutes in the epidural group. Although PCB had a rapid onset of pain relief, the analgesic effect at 30, 45, and 60 minutes after analgesia was significantly better in the epidural group. In another study, the pain relief method was randomized for 44 parturients using similar doses of bupivacaine as in the study above.[19] The main objective in that study was to compare the haemodynamic effects of PCB and epidural analgesia, but a maternal overall assessment on the efficacy of pain relief was also estimated on a 4-point scale. Excellent or good pain relief was achieved in 87% of cases in the epidural group and in 67% of cases in the PCB group (not significant, P = 0.14). Two parturients in the PCB group and none in the epidural group graded the pain relief as poor.

In a study by Junttila et al., among 104 multiparous women who were randomized to receive either PCB (with 10 mL of 0.25% racemic bupivacaine) or a single-shot spinal anaesthetic (with 2.5 mg hyperbaric racemic bupivacaine +2.5 mcg sufentanil), median pain scores were found to decrease from the baseline significantly in both groups, but the decrease was greater in the spinal group. The need for subsequent analgesia was more common in the PCB group, whereas shivering and pruritus occurred more often in the spinal group. There were no differences between the groups with regards to progress of labour, CTG findings, or neonatal outcome.[20]

In a double-blind, randomized study, PCB with 12 mL 0.25% racemic bupivacaine was compared with a 75 mg intramuscular injection of meperidine. Pain score data was available from 99 patients out of a total of 117 study patients. The analgesic effect was estimated by the parturient and recorded by the midwife every 20 minutes for up to 2 hours. A 4-point scale was used (full/acceptable/slight/no pain relief). The pain relief during the first hour after administration of the analgesia was rated as full or acceptable in 78% of the parturients in the PCB group and 31% in the meperidine group. The average pain relief in the PCB group stayed significantly higher than in the meperidine group for up to 60 minutes after administration of the drugs. The difference

between groups was no longer statistically significant at 80 minutes after administration, although 50% of women in the PCB group and 20% in the meperidine group still experienced the pain relief as being either full or acceptable. During the study period, there was a learning curve for the five doctors involved in the study, with pain relief being complete or acceptable in 68% of women during the first half of the study compared to 85% in the latter half.[32]

### Rating the effect of paracervical block

Verbal rating scores (VRS) and visual analogue scales (VAS) have been used as pain rating methods in studies on PCB only. Table 18.1 summarizes pain relief results by rating method.

Among the studies using a VRS, the study by Jägerhorn stands out with better rates (excellent or good in 94% of 204 PCBs) than the others. In this study, all PCBs were administered by the same obstetrician.[6]

The pain relief effect from a PCB has been statistically significant compared to baseline up to the beginning of the second stage of labour,[16] for up to 120 minutes in another study,[17] or for 90 minutes after PCB in a third study.[22] In a study by Jensen et al., the pain relief effect was full or acceptable in 62% of parturients 60 minutes after PCB, while 50%, 30%, and 26% found the pain relief to be full or acceptable at 80, 100, and 120 minutes after PCB respectively.[32] Since the median of the length of the delivery has found to be about 2 hours after PCB including the second stage,[12,14,15,32] it seems probable that a single PCB is sufficient for many parturients until the end of the first stage, but some women will need a second injection or another method of pain relief method to get them through the second stage of labour.

In a study of 341 women receiving PCB in the first stage of labour, pain relief was reported to be good if the VAS score had dropped by more than 50% from the baseline 30 minutes after PCB. Parturients who had delivered before the 30-minute time limit or who were already fully dilated were excluded from the analysis. Among these patients, good pain relief was achieved in 47% of the cases. In 23% of cases, the pain score had dropped to less than 20% from the baseline. Twelve per cent of parturients needed a subsequent epidural or spinal analgesia. Primiparity, a high pain score before PCB, and PCB given by a specialist obstetrician compared to a trainee obstetrician were found to be associated with better pain relief in a logistic regression analysis.[22]

Summarizing the findings from the above studies and from our own clinical experience, it appears that the effect of PCB is, on average, moderate and more variable than the effect of neuraxial analgesia. The findings that a single obstetrician or specialized obstetrician administering the block had a greater chance of success in terms of PCB and achieved lower pain scores demonstrates the importance of educational aspects. Patient selection also plays an important role. In clinical practice, it appears that the primiparae whose labour progresses rapidly, benefit from PCB the most. In other cases in which poor pain relief is achieved after a PCB, the next step is to administer a more efficient analgesic method straight away, neuraxial analgesia being the most common alternative.

**Table 18.1** Studies on the analgesic effect of paracervical block with 25 mg bupivacaine

## Safety of paracervical block

### Safety studies during labour

In the oldest studies on PCB from the 1960s and early 1970s, 20 mL mepivacaine (1–1.5%), lidocaine (1–1.5%), or bupivacaine (0.25–0.5%) was used, and the depth of the needle injection was up to 20 mm.[33] In these initial studies, major complications such as a high prevalence of fetal bradycardia and even fetal death were reported.[33–35] On the other hand, a study with 500 PCBs and a 1.2% incidence of transient fetal bradycardia was also published during the same decade.[10]

In 1975, Jägerhorn studied the spread of the anaesthetic agent in paracervical tissue. He used serial X-rays in a case study of 20 women undergoing termination of pregnancy between 14 and 19 weeks' gestation. He also introduced an improved technique, in which an injection depth of no more than 3 mm together with a low dose and concentration of local anaesthetic was used. With this lower injection depth of 2–3 mm no intravenous spread of contrast medium was noticed in X-rays of any patient. There is also practically no risk for injection directly into the nerve plexuses of the pelvic wall, lower uterine segment, or fetal head. In a clinical series including the parturients presented in the same article, maternal side effects were also absent.[6]

Table 18.2 is a meta-analysis of PCB studies with a relevant sample size (N > 50), in which a superficial puncture technique and low-dose administration of analgesic agent were used. CTG analysis of the study patients, criteria for fetal bradycardia, as well as fetal outcome are clearly described. Among 1566 PCBs, the bradycardia frequency was 2.8%. Among these cases, there was no need for interventions, and neonatal outcome was good. The frequency of fetal bradycardia after intrathecal analgesia has been quoted as being 5–7.3%, is transient, and does not result in the need for caesarean delivery.[36,37] One theory, which could explain the appearance of fetal bradycardia in some subjects after different pain relief methods, proposes that the onset of pain relief rapidly

**Table 18.2** Rate, duration. and associated interventions of post-PCB bradycardia

attenuates maternal catecholamines. When the plasma concentration of circulating beta-adrenergic agonists decrease, there is a predominance of alpha activity leading to an intensification in uterine contractions inducing fetal heart rate deceleration.[38]

The exact cause of fetal bradycardia is not clear; vasoconstriction of the uterine arteries, increased uterine activity, a direct effect on the fetal myocardium via circulation, or a combination of these have all been proposed as explanations.[11,13,15]

### Neonatal safety studies

Fetal oxygenation measured by fetal oximetry was studied in a prospective study in which 20 healthy parturients were enrolled in PCB or epidural groups according to their own preferences and clinical situation. No change was seen in maternal oxygen saturation between groups. In the PCB group, fetal oxygen saturation was slightly elevated compared to the baseline, while in the epidural group fetal oxygen saturation values remained at baseline or slightly below. This difference was statistically significant (P = 0.009), but the finding was not thought to be clinically important by the authors.[18]

Levy et al.[26] prospectively studied the effect of PCB on neonatal umbilical artery pH values using linear regression analysis. They found no statistically significant association between PCB use and umbilical artery pH at birth. Comparing PCB to any other pain relief method, Carlsson et al.[13] found that 469 PCB cases had significantly fewer low Apgar scores than 1013 other cases who delivered vaginally following other methods of analgesia or indeed no analgesia at all. The incidence of 1-minute Apgar scores of 7 or less was 1.7% and 8.4% in PCB and other vaginal deliveries groups, respectively, and 0.6% and 2.0% for 5-minute Apgar scores. Meis et al. reported similar findings in a smaller study comparing neonates after PCB to those who did not receive any form of regional analgesia. The PCB group showed slightly, but statistically significant higher 1-minute Apgar scores and umbilical artery and vein pH values.[39] In a study comparing PCB to intramuscular opioid (meperidine), signs of asphyxia (pH ≤ 7.15, 1-minute Apgar score ≤ 7) were significantly more frequent in the opioid group than in the PCB group.[32] In two studies comparing PCB and epidural analgesia, no statistical difference in umbilical artery pH levels or Apgar scores were found.[12,18]

In most studies on PCB, chronic maternal illness such as diabetes or hypertensive disorders, pre- or postmaturity, signs of fetal distress before pain relief, intrauterine growth restriction, or meconium-stained amniotic fluid are exclusion criteria, therefore the method cannot be recommended for high-risk patients.[6,13,16,17,21,32,39] In one study, however, 785 risk patients were allowed to receive PCB. Among these parturients, prematurity, postmaturity, cigarette use, pre-eclampsia, or oxytocin use combined with PCB were not associated with low 5-minute Apgar scores.[25]

Neurobehavioural responses have been studied in a few series including neonates born after PCB and those without any neuraxial analgesia. The groups were compared in terms of neurobehavioural responses from 0–3 hours up to 1–5 days after birth, with the investigators blinded as to the analgesic method during labour. No statistically significant differences were found in neurobehavioural scores after delivery between the groups of neonates.[14,39,40]

## Haemodynamic effects of paracervical block

One study from the 1980s used radiolabelled xenon washout to measure intervillous blood flow before and after PCB. The blood flow was shown to have stayed constant, even in three cases of post-PCB bradycardia where the flow changes were minimal.[11]

In later studies, the haemodynamic effects of PCB have been examined in three small studies using Doppler ultrasonography. Fetal and maternal blood flow was measured before and after PCB. In two studies, both with 12 patients, the maternal uterine artery pulsatility indices (PIs) did not change,[15,21] whereas in one study, which randomized 44 primiparous parturients to receive either

PCB or epidural labour analgesia, the maternal uterine artery PI increased after PCB while they remained unchanged after epidural analgesia.[19]

In two studies, no differences in fetal umbilical circulation were found after PCB in a total of 60 cases.[19,21] In a third study, the PI values in the umbilical artery were not affected if the CTG stayed normal after PCB. However, in two cases, in which post-PCB bradycardia developed, a marked increase in the PI of the umbilical artery was seen. The velocity waveforms of blood flow retuned to baseline when the CTG pattern normalized.[15]

### Uterine activity after paracervical block

In some clinical PCB trials, the contractility of the uterus has been measured using an intrauterine pressure catheter. In one study with high-dose administration of local anaesthetic, a significant correlation between post PCB fetal bradycardia and uterine activity was found. In 11 out of 14 cases of bradycardia, an increase of uterine contractility of 100 Montevideo units was found, and in three cases there was no change in uterine activity.[41] In another study, intrauterine measurement was used in 52 cases, and a mean increase of 29 Montevideo units was found among parturients.[21] In a third study with 51 parturients, no statistically significant change in uterine activity was found.[42] In all these studies, bupivacaine was used as the analgesic agent.

### Impact on the method of delivery

In some studies, PCB has been compared to other pain relief methods. The rate of spontaneous vaginal delivery has been higher in a group receiving PCB compared to intramuscular opioid[32] or epidural analgesia.[20] In the study by Carlsson et al. the incidence of normal vaginal birth was significantly higher in the PCB group compared to the group with any other pain relief method (88.7% vs 76.5%, $P < 0.001$).[13]

In the two biggest studies examining PCB alone, the spontaneous delivery rates have been as high as 91% and 96% and the caesarean delivery rate 4% and 0.25% respectively, with none of the indications for operative delivery being due to any complication of PCB.[16,21] Once again, this probably reflects patient selection for this type of pain relief (i.e. parturients with a rapid progression of labour).

### Maternal complications

Maternal complications after PCB are rare. In all the studies referred to above, there were no maternal complications. A theoretical risk for systemic toxicity of an anaesthetic agent could occur if aspiration is not performed properly and the injection is intravascular. Insertion of the needle too deeply could result in nerve plexus trauma. Haematomas in the paracervical or parametrial area and laceration at the injection site are also possible maternal complications. In the studies reviewed above, with a total study material of 2995 PCBs, there were no maternal complications reported.

### Conclusion

PCB provides an alternative pain relief method for parturients without some of the disadvantages typical of neuraxial analgesia, such as an increased risk for assisted vaginal birth, longer second stage of labour, occiput posterior presentation of fetus at delivery, hypotension, fever, postdural puncture headache, or pruritus.[1,43–49] PCB is easily available in the labour room with a minimal need for preparation or cost, its effect is rapid, and it does not interfere with the normal progress of labour or spontaneous delivery.[13,16,21] It can be used as an option for term parturients with uncomplicated pregnancy by experienced obstetricians with knowledge of the appropriate anatomy, correct technique, and clinical skills.

## Pudendal block

PB is another method of providing labour analgesia, which is usually performed by an obstetrician. It is used for pain relief during the second stage of labour for spontaneous or vacuum deliveries and during repair of perineal tears. It can be combined with first-stage PCB analgesia and is especially helpful for multiparas with severe perineal pain during the final stage of delivery.[7]

### Technique of pudendal block

Labour pain during the second stage and delivery is transmitted to the central nervous system via the pudendal nerve and the sacral spinal nerve roots S2–4.[50] The nerve block procedure is conducted with the mother adopting a similar position to that used for PCB with a similar Kobak needle.[51] The landmark for the site of injection, however, is the ischial spine, which can be palpated on each side of the birth canal. Two different injection techniques have been described: in the first, after injecting an initial dose into the mucosa over the tip of the ischial spine, the remainder of the dose is injected behind the ligament. Careful aspiration before injection is essential. The other technique aims to block the nerve at two different levels—on the dorsal and anterior sides of the ischial spine. If 1% lidocaine is used, the first 1 mL is injected into the mucosa, and the next 3 mL is infiltrated into the sacrospinous ligament. Then the tip of the needle is advanced behind the ligament until a decrease of resistance is felt when a further 3 mL is injected in this area. After drawing the needle back into the introducer, it is turned to the anterior side of the ischial spine, and the final 3 mL of drug is injected here under the mucosa to block the more distal part of the pudendal nerve.[52] The procedure is repeated on the other side to achieve bilateral analgesia. The palpating and injecting hands can be changed at this stage, if the operator is comfortable interchanging hands. When this form of analgesia is given for an episiotomy and its repair, a unilateral injection is sufficient. The injection site of PB is shown in Figure 18.3.

Doses of 7–10 mL of solution containing 1.0% lidocaine without epinephrine to each side gives a fast block onset.[53,54] If a PB is given for episiotomy repair, bupivacaine, ropivacaine, or levobupivacaine in equivalent doses should be used because of their longer-lasting pain relief effects and the decreased need for additional analgesics.[55]

PB has traditionally been administered with a Kobak needle, palpating the injection site using the fingers. The technique can benefit from other methods, however, such as nerve stimulation or ultrasound. A motor response to a 0.5–0.6 mA electronic nerve stimulator in the anal sphincter, vulva constrictor muscle, or movement of the clitoris should confirm close contact between the pudendal nerve or the right tissue plain in which the three tributaries of the nerve lie.[55] Ultrasound-assisted techniques for PB has been reported for non-obstetric indications.[56]

## Analgesic effect of pudendal block

Wilds used a spinal needle and 10 mL of 1–2% procaine or 1% hexylcaine for each side with a transvaginal technique noting an 84% success rate for analgesia.[50] One failure out of 24 blocks has been reported in testing the perineal anaesthesia by pinpricking 10 minutes after injection using a transvaginal technique with lidocaine.[54] Up to 50% uni- or bilateral failures have been reported, however, making it understandable that a perineal infiltration with local anaesthetic may often be needed along with the PB.[57,58]

The transperineal technique has been employed when PB is used to provide anaesthesia for suturing lacerations and episiotomy wounds. This block has been noted to provide analgesia and reduce the need for pain medications for up to 48 hours when 15 mL of 0.5% bupivacaine is injected unilaterally after delivery.[55]

## Complications of pudendal block

Some complications for PB have been described as case reports in the literature; these are haematoma, infection, and fetal local anaesthetic toxicity.[59–61] Nerve injury is another potential complication. In clinical use, these complications are rare. Occasionally the nerve block extends to include the sciatic nerve with a subsequent transient motor block in the lower extremity.

# Paravertebral techniques for labour analgesia

Afferent pain impulses from the uterine cervix travel via the lumbar sympathetic ganglia at L2–3 and enter the dorsal root of the spine at T10–L1 through the rami communicantes lying adjacent to the vertebral discs. The use of the paravertebral techniques for the treatment of labour pain began after Cleland's experiments showing that uterine pain impulses could be blocked paravertebrally were first published in 1933.[62] By the end of the 1950s a number of large case series showing the analgesic effect of lumbar sympathetic block (LSB) were published. With the increasing popularity of epidural analgesia, LSB has disappeared from use as a method of labour analgesia in most places. Thoracic paravertebral block (PVB) for labour analgesia has been increasingly used in Petrozavodsk and Arkhangelsk in Russia.[63] Paravertebral techniques are still frequently used, however, in the treatment of chronic pain and for anaesthesia and analgesia, for example, in thoracic surgery.[64,65]

## Technique of sympathetic and paravertebral blocks

The LSB provides the opportunity to block pain impulses at the sympathetic trunk. The intended location for local anaesthetic is in the retroperitoneum anterolateral to the vertebra and separated by the psoas muscle and fascia from the lumbar plexus. According to the classical blind technique suggested by Bonica, the lumbar sympathetic trunk is accessed with a needle sited 8 cm laterally from the top of the L3 spinous process at a right angle to the longitudinal axis and is directed medially at a 60° angle to the plane of the back with the parturient in a sitting position. The needle is advanced to 7 cm, at which point the stylet is removed and a loss-of-resistance (LOR) syringe attached. A LOR at 9–12 cm distance should signal that the anterior border of the psoas muscle has been reached.[66] Datta and Pai noted, however, that the LOR technique gives a position anterior to the ganglion. They advocated an extraforaminal paradiscal technique in order to avoid injury to the nerve as well as contact with the lumbar vessels.[67] This method requires fluoroscopy, however, making it impractical in the delivery suite.

Visualization of the lumbar paravertebral anatomy has been noted as being feasible utilizing an ultrasound technique with curved-array transducers operating at low frequencies (3.5–5 MHz). It has been reported for needle placement in the lumbar sympathetic chain in treating chronic pain syndromes, but not for labour analgesia to date.[68] Pain impulses can also be blocked at a higher level by inserting local anaesthetic into paravertebral space at T11–12 levels.[62,69] A volume of 10 mL of 0.25–0.5% bupivacaine with epinephrine has been used for each side, although larger volumes up to 25 mL for each side have also been employed.[69–72] Needle sizes of 16–22 G have been employed with or without catheters to be left in place for further doses.

The injection and effect sites of thoracic PVB and LSB are shown in Figure 18.4.

### Analgesic effect of sympathetic and paravertebral blocks

The reported failure rates have been low (0–5%) with LSB, which is surprising considering the difficult anatomic location and blind method.[70,71] The mean pain score was reduced from 7 to 4 for the first 30 minutes after the block using 10 mL 0.5% bupivacaine with epinephrine and 25 mcg fentanyl for each side with no difference from a control group which received epidural analgesia. However, subsequently the pain scores began to increase in the group receiving LSB.[70] With bupivacaine, the duration of the analgesic effect of single injections has been reported as mean (± SD) of 283 (± 103) minutes.[71] Leighton et al. noted a shorter labour when LSB was employed compared with epidural analgesia.[70] With the currently available data, no conclusion on the analgesic effects of thoracic PVB can be drawn. However, case reports suggest 3–4 hours of analgesia for the first stage of labour after paravertebral injections of bupivacaine 0.25-0.5% with epinephrine.[69] LSB and thoracic PVB do not provide analgesia for the second stage of labour unless the block is extended to the sacral somatic roots and plexuses. Therefore, a PB should be included in the transitional phase with these methods.

### Complications of sympathetic and paravertebral blocks

The correct placement of the needle tip for LSB is paramount as the aorta and vena cava as well as kidneys are in close proximity to the sympathetic chain. The roots of the spinal nerves are the target for the thoracic PVB and the anatomic space for LSB communicates with the nerve roots.

With LSB, psoas muscle injections at the L2 level and intravascular injections have been noted with frequencies of 7.4% and 6.8%, respectively, even when the advancement of the needle is guided by a fluoroscopy.[73] The likelihood of the tip of the needle remaining in the psoas muscle is higher if a lower lumbar vertebra is chosen for the block level. The sensitivity of an aspiration test for intravascular injection has been shown to be only 40.7% in a non-obstetric situation.[73]

The reported complications of LSB include sensory and motor block, hypotension, dural puncture, subdural block, and haematoma.[74–79] Thoracic PVB is also associated with risk of pneumothorax.[80] It is not advisable to use paravertebral techniques in those parturients with a tendency to bleed, such as those using low-molecular-weight heparins.[70,81]

## Conclusion

Alternative methods of analgesia are necessary, as many women cannot, for various reasons, benefit from neuraxial blocks. Blocking the pain pathways distally with PCB and PB is a practical and effective way with a low risk of side effects or complications. LSB and PVC are interesting methods used quite early on during the history of labour analgesia, but abandoned later with the rising popularity of epidural anaesthesia.

CHAPTER 19

# Prevention and management of breakthrough pain during neuraxial labour analgesia

Jessica Bauerle and Mieke A. Soens

## Introduction

Neuraxial analgesia is considered the gold standard for pain relief in labour. When compared to other options for labour analgesia, such as intravenous opioids or inhaled anaesthetics, neuraxial analgesia is associated with consistently lower pain scores and side effects.[1,2]

While, fortunately, the majority of epidural catheters placed for labour provide satisfactory analgesia, they also sometimes fail. In this chapter, we review potential causes of failure and strategies that can be used to prevent problems and rescue poorly functioning catheters.

## Incidence and characteristics of breakthrough pain during neuraxial labour analgesia

The incidence of breakthrough pain during neuraxial labour analgesia has been reported to be 0.9–25%.[3–5] This wide variation is mostly dependent on the definition of breakthrough pain used. Some studies define failure rate as the need to replace the epidural catheter, while others assess pain relief by using visual analogue scale scores.

Recurrent episodes of breakthrough pain in labour lead to decreased maternal satisfaction and identifying those patients at high risk for breakthrough pain is beneficial as it allows the anaesthetic provider to adjust his/her anaesthetic regimen accordingly. Additionally, breakthrough pain and a frequent need for supplemental medication can be a sign of a suboptimal functioning catheter, which may fail to provide adequate anaesthesia should obstetric intervention be required.

The risk of failed analgesia and the potential need for replacement should be discussed with the patient during the pre-anaesthetic evaluation.

## Risk factors for breakthrough pain

### Obstetric-related risk factors

Certain obstetric factors are associated with a higher incidence of breakthrough pain (Table 19.1). Often, these factors have in common that they are associated with more severe pain. Hess and colleagues[6] performed a prospective observational study, looking at nearly 2000 parturients who received epidural analgesia during labour. The authors found that nulliparity, increased fetal weight, and epidural placement at earlier cervical dilation were risk factors for the development of breakthrough pain in labour. Also, a prolonged labour course, abnormal fetal presentation (e.g. occiput posterior), and dysfunctional labour ultimately requiring caesarean or instrumental delivery have all been associated with an increased need for repeated supplementation.[5–8] Another important consideration is that pain intensity increases as labour progresses. The median local anaesthetic concentration[9] required to achieve adequate epidural analgesia in late labour is approximately three times that required during early labour.[9] As such, an unpredictably rapid labour course can also be a cause of breakthrough pain.[5]

### Maternal risk factors

Maternal obesity has been associated with a significantly increased rate of epidural catheter failure.[10] Melzack et al.[11] studied the influence of physical variables on the severity of labour pain using the McGill Pain Questionnaire and reported a positive correlation between body mass index (BMI) and severity of labour pain. Maternal obesity is also linked with an increased incidence of fetal macrosomia, which is a known risk factor for more painful contractions and complicated labour. In addition, maternal obesity significantly increases the degree of difficulty of epidural insertion, as well as the risk for subsequent epidural

**Table 19.1** Risk factors for breakthrough pain

catheter migration.[5,12,13] Hamilton et al.[14] demonstrated that epidural catheters not fixed at the skin could move 1–2.5 cm inward when the patient's posture was changed from the sitting to the lateral recumbent position, with the greatest change seen in patients with a BMI greater than 30. Therefore it may be prudent to place the parturient in the lateral position before securing the catheter to the skin.[15]

Chronic low back pain and/or a history of lumbar spine surgery also increase the risk of inadequate epidural analgesia. Benzon and colleagues[16] compared the onset of lumbar epidural anaesthesia in patients with low back pain and/or radicular pain, with patients without back pain. They found that the patients with back pain and/or radicular pain had a significantly delayed onset of sensory block. In particular, the nerve roots that were involved in the lumbar radicular pathology or those adjacent to them, as determined by myelogram and electromyography, were blocked 10–70 minutes after the contralateral unaffected nerve roots.

Also, patients with prior back surgery have an increased risk of epidural failure. The epidural space may be difficult to find and the spread of local anaesthetic may be patchy due to instrumentation (arthrodesis, Harrington rods, etc.), bone graft material, or scar tissue. However, despite these possible difficulties, a success rate of 91% has been reported for epidural anaesthesia in patients with prior lumbar spine surgery.[17]

## Neuraxial technique-related risk factors

### Initial placement

#### *Patient position*

One possible reason for inadequate analgesia after epidural placement is intravascular placement or migration of the epidural catheter. The incidence of intravascular placement has been reported to be 1–10%. The pregnant patient is at increased risk for accidental epidural vein cannulation because inferior vena cava compression by the enlarged uterus results in dilation of collateral veins in the epidural space.[18] A systematic review of randomized controlled trials that evaluated strategies to avoid epidural vein cannulation in obstetric patients found that placement of the epidural catheter with the patient in the lateral recumbent position compared with the sitting position may decrease the incidence of intravascular placement of catheters (5.1% versus 9.5%).[19] One possible explanation is that the sitting position is associated with an increased epidural venous pressure and therefore an increased risk of vessel puncture. However, an anaesthetist unaccustomed to using the lateral recumbent position is more likely to encounter difficulty in identification of the midline, which may in turn be associated with a greater risk for blood vessel puncture and accidental dural puncture compared to an operator that has experience with the lateral position.[20] Indeed, many practitioners prefer the patient in the sitting position for administration of neuraxial analgesia, because it allows better identification of anatomical landmarks and is often found to be technically easier.

#### *Loss of resistance to air or saline*

The loss-of-resistance (LOR) technique to identify the epidural space utilizes either air or saline. It has been suggested that LOR to air may lead to a higher incidence of patchy blocks by introducing pockets of air and therefore not allowing optimal spread of local anaesthetic. Beilin et al.[21] conducted a prospective randomized study comparing 2 mL of air versus 2 mL of saline for a LOR technique. They found that the LOR to air group had higher pain scores overall and were more likely to need supplemental medication than the saline group. Another study evaluating nearly 3000 patients that allowed experienced anaesthetists to use the technique they were most comfortable with, also found that LOR to air was associated with more recurrent breakthrough pain than LOR to saline.[22] These findings were confirmed in other studies.[23,24] In contrast, others believe that LOR with saline dilutes the local anaesthetic in the epidural space and may lead to a less potent local anaesthetic effect.[25] Some providers inject large amounts of saline to distend the epidural space prior to catheter insertion, as this technique may reduce the risk of epidural vein cannulation.[19] Also, Segal and colleagues[26] found no significant difference between LOR to air versus saline in a retrospective study, in which operators used their preferred technique. They suggested that success rates are better when anaesthetists use the technique they are most comfortable with. Nevertheless, the majority of evidence suggests improved quality of epidural analgesia when a LOR technique with saline is used instead of air.

#### *Conventional epidural technique versus combined spinal–epidural technique*

Several retrospective studies have found that the incidence of failure of catheters, inserted as part of a combined spinal–epidural (CSE) technique, was significantly lower than that of catheters inserted with a conventional epidural technique.[4,27] In a retrospective analysis of 19,253 deliveries, Pan and colleagues[27] found that CSE was associated with a significantly lower failure rate than epidural (10% versus 14%), with failure defined as inadequate analgesia or no sensory block after adequate dosing at any time after initial placement, inadvertent dural puncture, intravenous epidural catheter, or any other situation requiring replacement of the epidural catheter. Another recent randomized controlled study comparing epidural analgesia and CSE analgesia for labour found that patients in the CSE group reported faster onset and better analgesia during the first stage of labour. Also, the need for epidural top-up boluses during the course of labour was significantly less in the CSE group than in the conventional epidural group.[28] Several aspects of the CSE technique could contribute to the improved subsequent functioning of the epidural catheter. For example, more accurate midline placing of the epidural catheter in the posterior epidural space, after confirmation provided by cerebrospinal fluid flow during the spinal component, and/or presence of a dural hole, which may increase subarachnoid transfer of epidurally administered medications. Cappiello and colleagues[29] demonstrated that performing a CSE with a 25 G spinal needle without injecting spinal medication, that is, 'dural puncture epidural' (DPE) is associated with faster onset, improved sacral spread, and less unilateral blocks when compared to the traditional epidural technique. However, Thomas et al.[30] did not find a benefit of DPE over conventional epidural analgesia, when they used a 27 G spinal needle.

A Cochrane review of 27 trials involving 3274 women, comparing traditional dose epidural, low-dose epidural, and CSE techniques, found little difference between low-dose epidural and CSE in terms of the maternal satisfaction, mobility in labour, headaches, caesarean delivery, or fetal adverse effects. However, CSEs had a slightly faster onset of effective pain relief, although more women had pruritus compared to low-dose epidurals.[31]

Nevertheless, the NAP 3 study of the Royal College of Anaesthetists raised some concerns about the safety of CSE. It was found to have a relatively high incidence of complications. While CSE represented less than 6% of all central neuraxial blocks performed in this study, they were associated with 13–14% of major complications, which is unexpected and should be borne in mind.[32]

### Epidural catheter

#### *Multi-orifice versus single-orifice catheters*

It has been suggested that epidural catheter characteristics, such as number of ports, affects the quality of the epidural block. However, studies directly comparing these two types of epidural catheters yield conflicting results. Single-holed, open-ended (uniport) and three-holed, closed-ended (multiport) catheters are commonly used. Many studies have found that multiport catheters have been associated with reduced incidence of inadequate analgesia, since local anaesthetic distribution may be enhanced.[33–37] For example, Michael et al.[36] found a 33% incidence of unsatisfactory block with single-orifice catheters compared to only 14% when multi-orifice catheters were used. Segal and colleagues[35] evaluated 872 parturients undergoing epidural analgesia for labour and found that multi-hole catheters were associated with fewer incomplete blocks (unilateral block or unblocked segments) and a reduced need for catheter replacement. Collier and Gatt[37] also found that multi-orifice catheters were associated with superior blocks. However, a more recent study comparing an open-ended flexible, soft uniport catheter with a stiffer multiport catheter in 2612 patients found a decreased incidence of paraesthesias and intravascular placements when soft uniport catheters were used, without a reduction in the quality of analgesia.[38]

#### *Length of the catheter into the epidural space*

Several studies have looked at the optimal distance that epidural catheters should be threaded into the epidural space. Catheters that are inserted shorter distances (2–5 cm) are less likely to result in unilateral sensory analgesia, but are more likely to be dislodged. However, catheters inserted longer distances (7–8 cm) into the epidural space are more likely to be intravascular or result in unilateral blocks.[39,40] Bromage[41] recommended inserting single-orifice catheters 3–4 cm into the epidural space. For multi-orifice catheters, however, Beilin and colleagues[40] recommended an optimal distance of 5 cm. Conversely, D'Angelo et al.[39] suggested that the length of epidural catheter insertion should vary with the anticipated duration and mode of delivery. They recommended 2 cm when rapid labour is anticipated and 6 cm when prolonged labour or caesarean delivery is likely. The practicalities of varying the insertion length of the epidural catheter during different stages of labour, however, are unknown.

**Table 19.2** Neuraxial technique-related risk factors

| | |
|---|---|
| Patient position | Lateral position may decrease incidence of intravenous cannulation |
| Loss of resistance (LOR) | LOR to air compared to saline may be associated with higher incidence of patchy blocks and more breakthrough pain in labour |
| Combined spinal–epidural (CSE) vs conventional epidural | CSE has been associated with lower epidural catheter failure rates; however, there is no difference in maternal satisfaction |
| Epidural catheter | Multi-orifice catheters have been associated with superior blocks compared to single-orifice catheters. However, no reduction in quality of analgesia with newer soft uniport catheters<br>The suggested optimal length in the epidural space is 3–5 cm |

## Drugs

### Local anaesthetics

#### *Choice*

One of the most commonly used local anaesthetics for labour neuraxial analgesia is bupivacaine, because of its long duration of action and limited placental transfer. Bupivacaine is an amide local anaesthetic that exists as a racemic mixture of both the laevorotatory and dextrorotatory enantiomers. Some of the concerns with bupivacaine, such as cardiotoxicity and neurotoxicity, especially at higher concentrations, have been mainly attributed to the dextrorotatory form. Therefore two new long-acting local anaesthetics have been developed: ropivacaine and levobupivacaine. These are both pure laevorotatory forms and may therefore have some advantages over bupivacaine. Several studies have compared bupivacaine, ropivacaine, and levobupivacaine in terms of central nervous system and cardiac toxicity. In animal models, the convulsive doses of ropivacaine and levobupivacaine were found to be 1.5–2.5 times larger than for bupivacaine.[42–44] Ropivacaine has also been shown to produce fewer myocardial depression changes and conduction changes than bupivacaine.[45] Several animal studies demonstrated that the fatal dose was larger for ropivacaine than for bupivacaine.[42,46] Also, most animal studies found that it is easier to resuscitate an animal from a toxic dose of ropivacaine than from bupivacaine.[47,48]

However, to correctly interpret systemic toxicity data, the relative potency of the different drugs should be taken into account. The median effective concentration ($EC_{50}$) or minimal local anaesthetic concentration (MLAC) can be used to determine different potencies of local anaesthetics (see Chapter 16). Using this method, the analgesic potency of ropivacaine was found to be approximately 60% that of bupivacaine.[50,51] However, some argue that the complete dose–response curve of both drugs is unknown, and it is possible that the $EC_{95}$ (effective concentration for 95% of the population) is not that different, despite the fact that the $EC_{50}$ of bupivacaine is less than that of ropivacaine.

Several studies have compared the analgesic efficacy of epidural infusions of levobupivacaine, bupivacaine, and ropivacaine in labour. No significant differences were found in obstetric outcomes, nor were there any differences in overall maternal satisfaction or need for supplemental boluses of local anaesthetic.[52–55]

#### *Concentration*

Different concentrations of local anaesthetic solutions with or without adjuvants have been tested. The concentration of the epidural mixture has been trending downwards in attempts to reduce toxicity and side effects such as hypotension and motor blockade. Typically, bupivacaine concentrations of maintenance bupivacaine/opioid solutions range from 0.05% to 0.125%. Chestnut and colleagues[56] conducted a study comparing bupivacaine 0.125% with bupivacaine 0.0625% with fentanyl 2 mcg/mL

and found no significant difference in pain scores throughout labour. Furthermore, the higher concentration of bupivacaine was associated with significantly more motor blockade. Similarly, Hess et al.[57], compared two concentrations of bupivacaine, 0.125% and 0.0625%, both with fentanyl 2 mcg/mL, administered at 8–12 mL/h, and bupivacaine 0.04% with fentanyl 1.7 mcg/mL and epinephrine 1.7 mcg/mL, administered at 15 mL/h. They found that there were more interventions for breakthrough pain in the two low-concentration groups, but more interventions for hypotension and motor blockade in the high-concentration group. A meta-analysis of studies comparing low concentrations versus high concentrations of local anaesthetic for labour found that high concentrations (bupivacaine > 0.1% or ropivacaine > 0.17%) were associated with more assisted vaginal deliveries, possibly because of the increased motor blockade. It is therefore recommended to use lower concentrations of local anaesthetic.[58] Capogna et al.[50] estimated MLACs of epidural bupivacaine and ropivacaine for women in the first stage of labour. For bupivacaine, the MLAC was 0.093% and for ropivacaine 0.156%. Another study comparing the relative potencies of levobupivacaine with racemic bupivacaine reported the MLAC of racemic bupivacaine to be 0.081% and of levobupivacaine to be 0.083%.[59]

#### *Mode of epidural drug delivery*

The mode of delivery of local anaesthetic solutions has also been shown to affect the quality of epidural analgesia for labour. Several studies have found that administration of maintenance epidural solutions through mandatory intermittent boluses rather than continuous infusions, results in lower local anaesthetic consumption, decreased need for manual top-up boluses by the anaesthetist, and higher patient satisfaction (see Chapter 15).[60–65] Furthermore, patient-controlled epidural analgesia (PCEA) allows the patient to adjust the dose of epidural medication according to individual needs and as labour progresses. A meta-analysis of randomized controlled trials that compared PCEA versus continuous infusion for labour analgesia demonstrated that patients who receive PCEA experience less breakthrough pain requiring anaesthetic intervention, need lower total doses of local anaesthetic, and have less motor block than those patients receiving a continuous epidural infusion.[66] However, the optimal PCEA regimen is still a subject of some debate. Initial studies favoured PCEA regimens without a continuous background infusion.[67,68] However, Ferrante et al.[69] investigated whether a continuous background infusion in addition to patient-controlled demand boluses is advantageous when compared to PCEA without continuous background infusion. The authors found that a continuous background infusion of 33% of the maximal hourly demand dose in addition to PCEA resulted in a decreased need for physician-administered supplemental local anaesthetic when compared to PCEA alone or PCEA with lower rates of background continuous infusion. A systematic review of studies comparing PCEA with continuous-infusion techniques for labour concluded that PCEA is associated with fewer patients requiring unscheduled clinician top-ups and lower dose requirements for local anaesthetics. In addition, fewer patients experience motor block.[70]

### Opioids

Traditionally, epidural labour analgesia was most often maintained with local anaesthetic alone, but most anaesthetists currently use a combination of a low-dose, long-acting amide-type local anaesthetic with a lipid-soluble opioid. The addition of small doses of opioids to local anaesthetics has been shown to be associated with a local anaesthetic-sparing effect. Chestnut and colleagues[56] demonstrated that the combination of 2 mcg/mL of fentanyl with 0.0625% bupivacaine for epidural analgesia provided equivalent analgesia to 0.125% plain bupivacaine, with significantly less motor block in the fentanyl-bupivacaine group. Furthermore, the hourly and total doses of local anaesthetic were found to be significantly less when opioids were combined with local anaesthetic versus local anaesthetic alone. In addition, epidural analgesia is frequently associated with sacral sparing, resulting in persistent perineal pain or pressure. In such cases, the epidural administration of a lipid-soluble opioid (e.g. 50–100 mcg fentanyl) can often improve analgesia. Adding an opioid can also be particularly helpful when the patient is experiencing back pain because the fetus is in the occiput posterior position.[71] Of the lipid-soluble opioids, fentanyl is found more often in umbilical artery blood samples when compared to sufentanil, but this does not seem to be of clinical significance, as neonatal outcomes are good after maintenance epidural analgesia with either drug.[72]

## Prevention of breakthrough pain

There is no better example of the saying 'Prevention is better than cure' than in the delivery suite, with respect to epidurals for analgesia during labour. The identification of risk factors for breakthrough pain during labour analgesia may prompt the anaesthetic provider to adjust his/her anaesthetic plan, for example, choice of CSE technique in high-risk patients or increasing the concentration of local anaesthetic in patients with rapidly progressing labours. Despite this, it is inevitable that some epidural catheters will fail to provide adequate analgesia. Therefore, it is important to discuss the risk for failed anaesthesia and the potential need to place a second epidural catheter with the patient during the pre-anaesthetic evaluation, before placement of the first epidural catheter.

In addition, after placement of an epidural catheter, regular epidural evaluation to identify problems is necessary, not only in terms of providing adequate maternal analgesia and hence satisfaction, but also in anticipation of using the epidural catheter for other potential obstetric interventions. A poorly functioning catheter will not only cause maternal dissatisfaction, but may also make another anaesthetic procedure necessary in potentially stressful circumstances. Regular epidural review will also improve communication with the obstetric and midwifery team and highlight important details which may alter epidural management, for example, failure to progress in labour or the presence of a non-reassuring fetal heart rate tracing, both of which need a good working epidural in preparation for potential surgical interventions and so lowering the threshold for replacing a less than ideal epidural catheter.

## Management of breakthrough pain during neuraxial labour analgesia

When breakthrough pain occurs, despite preventative efforts, it should be managed promptly and aggressively, with the goal to restore adequate analgesia within a maximum of 60 minutes (Figure 19.1).

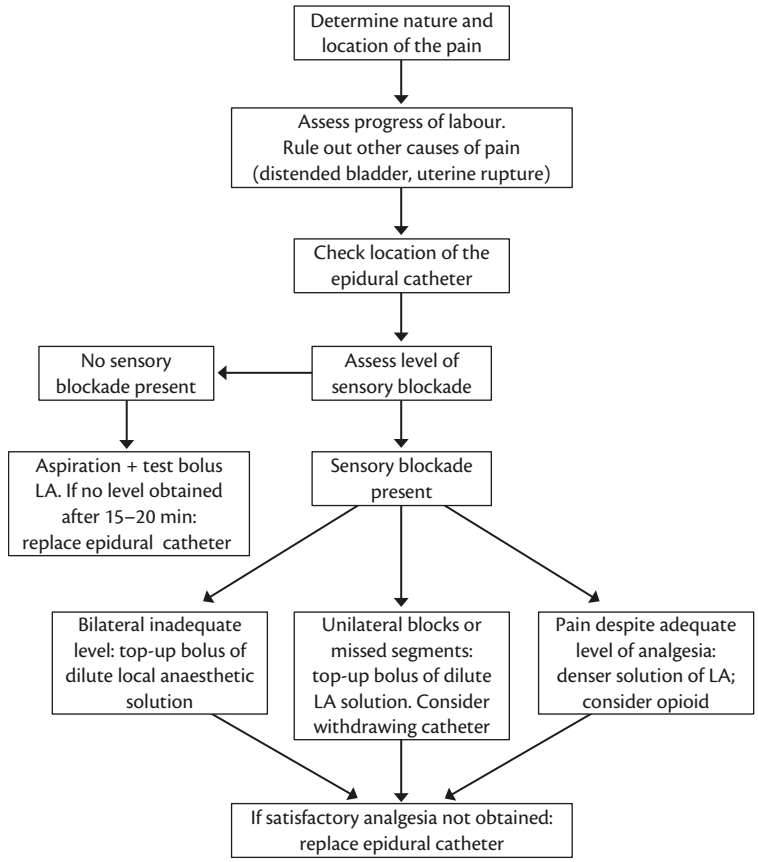

**Figure 19.1** Management algorithm for breakthrough pain during neuraxial labour analgesia.

Firstly, the nature and location of the pain should be determined and the progress of labour evaluated, including the cervical dilation and rate of progression, as this may affect pain intensity which could increase local anaesthetic requirements. Although rare, other underlying obstetric causes that could lead to breakthrough pain, such as uterine rupture or placental abruption, should be ruled out. Bladder distension can also be a cause of breakthrough pain.

Secondly, the location of the epidural catheter should be examined to make sure that it still remains in the epidural space.

Subsequently, the extent of neural blockade can be assessed by loss of sensation to cold, sharp pinprick, or light touch. There has been some discussion as to which modality is preferred. In general, block to cold sensation is usually at a higher level than to sharp pinprick[73] and block to light touch is usually lower than the block to both pinprick and cold.[74] Adequate analgesia for the first stage of labour requires blockade of the T10–L1 segments. Sacral blockade is needed for the second stage of labour.

During testing, one of the following situations can be encountered:

1. *No sensory blockade:* the complete absence of sensory block, despite appropriate dosing, usually means that the epidural catheter is not in the epidural space. However, intravascular migration is also possible. After careful aspiration, a test dose can be administered. If there is no sensory block, the epidural catheter should be replaced.
2. *Bilateral inadequate level of analgesia:* if the extent of sensory blockade is inadequate to cover the required segments, a top-up bolus of a dilute local anaesthetic solution (e.g. bupivacaine 0.0625–0.125%) should be given. Larger volumes (10–15 mL) of a dilute local anaesthetic solution are often preferred in this case, over more concentrated solutions, as this allows for a better spread of analgesia.
3. *Unilateral blocks or missed segments:* asymmetric blocks or patchy blocks are usually caused by uneven spread of drug solutions. This can be due to unfavourable positioning of the epidural catheter tip or due to the presence of an anatomic barrier, such as fibrous septa, limiting the free flow of local anaesthetic solution. Some reports have suggested the presence of a dorsal median connective tissue band as a possible cause of unilateral blocks, although this is generally thought to be rare and has been attributed to an artefact of how the epidural space was studied.[75] A paramedian position for an epidural catheter is thought to be a more common cause of asymmetric block than anatomic barriers to solution spread. Hogan[76] evaluated epidural catheter tip positions by computed tomography in patients with normal functioning epidural analgesia and found that catheter tips were often situated lateral to the dura close to the intervertebral foramen. As mentioned previously (see 'Length of the Catheter into the Epidural Space', some studies have suggested that threading the catheter no more than 5 cm in the epidural space leads to fewer one-sided blocks, perhaps because these catheters are less likely to be sited laterally or even worse, exit the epidural space along the course of a nerve root.[18,40]

Different management strategies have been proposed for unilateral or patchy blocks. Some authors advocate pulling the epidural catheter 1–2 cm before administering a bolus of local anaesthetic.[39] However, Beilin and colleagues[77] performed a study in which they randomly assigned patients with breakthrough pain to receive either 5 mL of bupivacaine 0.25% after withdrawing the epidural catheter 1 cm or without withdrawal of the epidural catheter. In both groups about 75% of women were successfully treated with this first intervention. For the 25% of women that were not comfortable 15 minutes after this first intervention, a cross-over was performed, in which the catheter was withdrawn 1 cm and an additional 5 mL of 0.25% bupivacaine was administered to the initial local-anaesthetic-only group, whereas 5 mL 0.25% bupivacaine was given to the initial catheter manipulation group, without further withdrawal of the epidural catheter. All patients were comfortable after the second intervention. While this study does not reject the benefits of catheter withdrawal in certain patients, it does suggest that most women can be effectively treated with the administration of a bolus of local anaesthetic without withdrawal of the epidural catheter. Indeed, the injection of a large volume of local anaesthetic (e.g. 10 mL of bupivacaine 0.0625–0.125%) can often overcome a variety of catheter positions and non-uniform spread of local anaesthetic solution in the epidural space.[71,76] If analgesia cannot be rescued, however, the epidural catheter should be replaced.

The importance of maternal position during labour epidural analgesia is subject to some debate. While several studies have suggested that the lateral position is associated with a faster onset and increased spread and duration of anaesthesia on the dependent side compared to the upper side during the initial bolus injection, most authors think that this is of only minor clinical significance.[71,78,79] Others, however, advocate a modified supine position as this may result in more equal spread of local anaesthetic and better pain relief.[80]

4. *Breakthrough pain despite an adequate extent of sensory blockade:* if the patient experiences breakthrough pain despite a bilateral adequate level of analgesia (T10–L1), a more concentrated solution of local anaesthetic may be needed. Labour may be advancing quicker than expected and local anaesthetic requirements may be rapidly increasing. Furthermore, the patient may be experiencing dysfunctional labour or abnormal fetal presentation, both of which are associated with increased pain.[6,7,81] Also, the administration of a lipid-soluble opioid (e.g. 50–100 mcg fentanyl) can often improve analgesia, particularly if the patient is experiencing back pain because the fetus is in the occiput posterior position, or in case of persistent perineal pain or pressure.[71] Clonidine is another drug which has been used in such circumstances, although less commonly than fentanyl.

   While the above-mentioned measures will often succeed in restoring adequate analgesia it is important to assess the results in a timely fashion. If satisfactory analgesia is not obtained, the epidural catheter should be replaced.

   If, despite epidural replacement, the block is still less than ideal, a CSE technique should be performed. This will result in rapid analgesia as the intrathecal route is more reliable than the epidural one and is important as, by now, the patient would have been in pain for several hours during all the previous epidural manoeuvres.

PART 6

# Anaesthesia for caesarean delivery

# CHAPTER 20

# Neuraxial anaesthesia for caesarean delivery

Sarah L. Armstrong, Michelle Walters, Katherine Cheesman, and Geraldine O'Sullivan†

## Introduction

Caesarean delivery (CD) rates continue to increase worldwide. The reasons for this trend are multifactorial and include maternal, obstetric, fetal, medicolegal, and social factors. Significant variation exists in practice between different countries. In 2009, the World Health Organization (WHO) reported that 47.4 of 100 live births in Brazil were born by CD, compared to only 14.3/100 in the Netherlands (Figure 20.1).[1]

There is also a significant variation in the CD rate at local levels. Maternity statistics from National Health Service (NHS) hospitals in England 2012–2013 report a national average CD rate of 25.5% (including both planned and emergency CD). During the same time frame, the rates from different regions within England varied from 15% to 35%.[2] Diverse local population characteristics and different thresholds for performing emergency CD may account for this.[3]

Planned CD (compared to emergency CD) accounts for approximately 40% of all CDs in England.[2] A large proportion of these are repeat CDs or CDs for fetal breech position. Factors contributing to the rising CD rate include an increase in multiple gestation secondary to assisted reproduction, advancing maternal age, maternal obesity, patient preferences, improved operative safety, and changing practice amongst professionals. Evidence-based practice, a culture of litigation, and a risk-averse society may have led to a decrease in planned vaginal breech deliveries and vaginal births after previous CD.[4,5] In addition, there is an increasing demand for 'maternal request' CD in the absence of any medical indications, a controversial topic that has recently been addressed in national guidelines.[6,7]

The rising CD rate has wider implications and complications. The financial cost to the healthcare provider is greater than after a vaginal delivery and the hospital stay tends to be longer.[7] Maternal complications such as infection, haemorrhage, and thrombosis may occur and in subsequent pregnancies there is an increased risk of abnormal placental implantation and uterine rupture.[3,7] Neonatal morbidity and mortality may be increased, for example, neonatal respiratory distress syndrome and admissions to the neonatal intensive care unit.[8]

The upsurge in CD caseload has increased the demands on obstetric, anaesthetic, and midwifery staff. The increasing complexity of these cases (e.g. raised body mass index (BMI), placenta praevia, and multiple gestation) requires regular senior medical input on the delivery suite.[9]

## Classification of caesarean delivery

CDs are classified by the degree of urgency caused by the presence or absence of fetal or maternal compromise. The traditional simple classification of 'elective' or 'emergency' was unhelpful, as this did not highlight the range of urgencies within and this could potentially lead to communication problems and high levels of stress on the labour ward. In 2010, the Royal College of Obstetricians and Gynaecologists (RCOG) and the Royal College of Anaesthetists (RCoA) produced a 'Good Practice' guideline, with a recommendation to universally accept a classification based on Lucas et al.'s 4-point classification with the addition of the colour-coded continuum scale proposed by Dupis.[10–12] This classification helps to reinforce the idea of a clearly communicated 'continuum of risk', but also allows for clearly defined categories for the purpose of audit. It allows all providers to understand the urgency and can help to highlight specific cases that require immediate delivery (category 1).

## The 'emergency' caesarean delivery: how urgent is 'urgent'?

The maximal safe time to delivery from fetal distress to fetal compromise is unknown; the '30-minute rule' that is often quoted is not based on clinical trials and originates from early animal studies.[13,14] More confusing is when to 'start' and 'stop the clock'. The Association of Anaesthetists of Great Britain and Ireland (AAGBI) and the Obstetric Anaesthetists' Association (OAA) have together stated that in emergency cases the time from informing the anaesthetist to the start of operative delivery should not exceed 30 minutes, whereas the RCOG starts the clock from the time the decision to proceed to CD is made and ending at delivery of the baby—the decision to delivery interval (DDI), again aiming to achieve delivery within 30 minutes.

How feasible is this time scale and how necessary is it? The UK National Sentinel Caesarean Section Audit measured CD rates and assessed the quality of care given to woman having emergency CDs in England and Wales and included 99% of births between 1 May and 31 July 2000. There were 17,780 singleton births in this

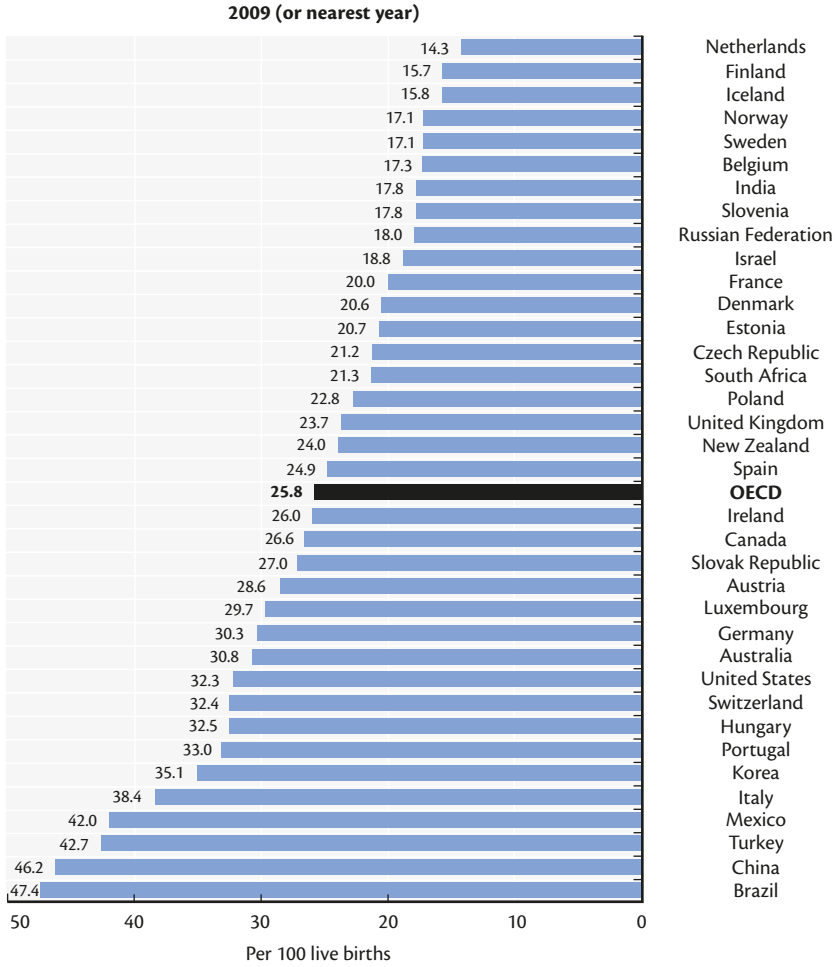

**Figure 20.1** Caesarean deliveries worldwide per 100 live births in 2009. OECD, Organisation for Economic Co-operation and Development.
From OECD (2011). *Health at a Glance 2011: OECD Indicators*, OECD Publishing. http://dx.doi.org/10.1787/health_glance-2011-en

audit.[15] The perceived urgency was classified as category 1 for 26% (n = 4622), category 2 for 51.3% (n = 9122), and category 3 for 20.8% (n = 3689). Seven per cent of all CDs were delivered within 15 minutes and 22% within 30 minutes of the decision to deliver. Overall, 46% (n = 2137) of women with category 1 urgency, 16% (n = 1422), with category 2 and 9% (n = 330) with category 3 were delivered within 30 minutes.

Further analysis of this data looked at the association between DDI and neonatal outcomes (Apgar scores of <7 and <5 at 5 minutes and stillbirths).[16] The audit found that while prolonged DDIs of greater than 75 minutes were associated with poorer maternal and neonatal outcomes, reducing DDIs to less than 30 minutes neither improved nor worsened maternal or neonatal outcome (adjustment was made for clinical factors). While this research would suggest extending the clinically significant threshold from 30 to 75 minutes, the authors felt that to avoid complacency it would seem prudent to keep the '30-minute DDI' as a benchmark but add the '75 minute DDI' as an audit standard that all emergency CDs should occur within this time. In 2011, the National Institute for Health and Care Excellence (NICE) in the United Kingdom incorporated this into its CD guidelines recommending that 30 minutes be the audit standard DDI for category 1 CD and that 75 minutes the audit standard for category 2 CD. It was stressed that these times are for audit to examine the efficiency of the delivery team and not to judge performance in individual cases.[7] In certain situations such as a persistent bradycardia associated with a vasa praevia or ruptured uterus a delivery time of less than 10 minutes is warranted as well as appreciating that undue haste itself in surgery and anaesthesia can lead to maternal and neonatal harm.[17,18]

## Human factors during emergency caesarean delivery

One must consider the processes required to achieve safe prompt CD and meet audit standards. Human factors such as communication and situational awareness need to be highlighted; 87% of CDs are predictable and early assessment by obstetrician or midwife can identify women who are at greater risk of CD who can then be referred promptly to the anaesthetic team (Box 20.1).[19] Anaesthetists should themselves be proactive by attending the delivery suite ward rounds and frequently reviewing high-risk mothers. High-risk women should be counselled that there might be a potential need for operative delivery and may be advised to have an early epidural for labour analgesia that could be extended to cover surgery.

**Box 20.1** High-risk pregnancies that anaesthetists should be aware of

- Multiple pregnancy
- Breech/malpresentation
- Meconium-stained liquor
- Slow progress
- Oxytocin infusion in labour
- Fetal distress—pathological cardiotocograph (CTG)
- Intrauterine growth retardation (IUGR)
- Prematurity less than 36 weeks
- Antepartum haemorrhage (APH)
- Previous caesarean delivery (CD)
- Pregnancy-induced hypertension
- BMI higher than 35
- Diabetes
- Trial of labour after caesarean (TOLAC).

**Box 20.2** Advantages of neuraxial anaesthesia for caesarean delivery

- Reduced risk of dental damage, failed intubation, failed ventilation, and hypoxia
- Reduced risk of pulmonary aspiration of gastric contents
- Removes risk of 'awareness' during general anaesthesia (see the 5th National Audit Project of the RCoA with the AAGBI—'NAP5: Accidental awareness during general anaesthesia in the United Kingdom'—results discussed in Chapter 22)
- Improved postoperative pain relief
- Reduced vomiting and postoperative ileus incidence
- Reduced thromboembolism incidence
- Ability to have birth partner present
- Alert mother and baby, improved bonding and breastfeeding
- Increased patient satisfaction.

Practical issues such as the time it takes to move the woman to the operating theatre is critical; if more than 10 minutes elapses it is considerably less likely that the baby would be delivered within 30 or 40 minutes.[17] This rapid transfer can be distressing for women who may feel they have lost control of the situation as well as being concerned about their baby's well-being. This may be heightened by language barriers or cultural differences. Education and teamwork are vital.

Units should design guidelines that result in the shortest safely achievable DDI and it is the recommendation of the RCOG and AAGBI that formal drills be run for 'emergency CDs' with in-house teaching programmes to 'test' local channels of communication.

## Advantages of neuraxial anaesthesia over general anaesthesia

Neuraxial anaesthesia is the safest and preferred method of anaesthesia for both planned and emergency CD and has significant advantages over general anaesthesia (see Chapter 22). In the United Kingdom, the RCoA recommends that 95% of planned CD and 85% of emergency CDs be performed under neuraxial anaesthesia.[20] Pregnant women are susceptible to increased morbidity and mortality from the risks of general anaesthesia including failed intubation, failed ventilation, awareness, hypoxia, and pulmonary aspiration of gastric contents.[21–23] The advantages of neuraxial anaesthesia are summarized in Box 20.2.

The Confidential Enquiry into Maternal Deaths in the United Kingdom in the triennium 2006–2008 identified two deaths directly caused by general anaesthesia for CD: one failed intubation and one aspiration on emergence.[24]

Patients in whom general anaesthesia had previously been preferable, for instance, high-risk parturients with significant cardiac co-morbidities, are increasingly being considered for regional techniques with modifications to improve haemodynamic stability.[20]

For these reasons, current obstetric anaesthetic practice minimizes the use of general anaesthesia whenever possible. In the last decade, many European countries have completed national surveys examining their obstetric anaesthetic practice. In the south of England the use of neuraxial anaesthesia for planned CD has increased from 69% in 1992 to 95% in 2002. Spinal anaesthesia was used in 87% of cases and 1.3% of these converted to general anaesthesia during planned CD.[25] Similarly, in 2005, Benhamou reported that 99% of planned CDs in French obstetric units were carried out under neuraxial anaesthesia.[26] Likewise, both German and Polish surveys identify spinal anaesthesia as the most common anaesthetic technique for CD.[27,28]

Neuraxial anaesthesia for emergency CD has also increased although rates vary; of the 97,000 category 1 and 2 CDs that took place within NHS hospitals in the United Kingdom in 2011–2012, two-thirds were performed under neuraxial anaesthesia. For category 1 delivery, rates vary between 54% and 72%.[29,30] This may be due to a number of reasons: an increase in epidurals for labour, an increased incidence of epidurals particularly in high-risk patients, and greater awareness of the risks of airway complications during general anaesthesia. There have been improvements in understanding from the obstetric team regarding the benefits of a neuraxial technique and therefore reduced pressure on anaesthetists to rapidly perform a general anaesthetic.

Women without labour epidurals will need to be rapidly assessed and the use of general or neuraxial anaesthesia will depend on the urgency of the situation, although a general anaesthetic will usually provide the quickest onset of anaesthesia. Retrospective and simulation studies indicate that spinal anaesthesia is only marginally slower than general anaesthesia, the limiting factor being the unpredictability of the time to achieve an adequate neuraxial anaesthetic block.[31] Many situations, including a prolapsed cord, do not exclude the use of a neuraxial technique, which in emergency situations may be the safest option (see 'Rapid Sequence Spinal' section later in the chapter).

## Contraindications to neuraxial anaesthesia

See Box 20.3.

### Patient refusal

(See also Chapter 29.)

- Patients undergoing neuraxial anaesthesia must consent to the procedure.
- Any woman with ability to consent is entitled to refuse treatment even if it would benefit her own or her baby's health.[7]

### Cardiovascular instability

(See also Chapter 23 and Chapter 35.)

- The sympatholytic effects of neuraxial anaesthesia reduce blood pressure, systemic vascular resistance, and venous return.
- The response to pre-existing hypovolaemia, inferior vena cava compression, or hypovolaemia (e.g. during major haemorrhage) is exaggerated as neuraxial anaesthesia prevents compensatory vasoconstriction.[32]
- Women with congenital or acquired cardiac disease resulting in fixed cardiac output states (aortic stenosis, hypertrophic obstructive cardiomyopathy) may decompensate following spinal neuraxial anaesthesia.[33]

### Infection

(See also Chapter 28.)

- Epidural abscess, meningitis, encephalitis, or adhesive arachnoiditis after neuraxial anaesthesia are rare but potentially devastating.
- It is suggested that neuraxial anaesthesia is avoided in patients with active untreated systemic infection, but consider single-shot techniques (no indwelling epidural catheter) on an individual basis if clinically responding to antimicrobial therapy.
- Active superficial skin infection (e.g. herpes zoster) at the site of injection may cause colonization of indwelling epidural catheters and spread inwards to epidural and intrathecal spaces.[34]

### Central nervous system or spinal pathology

(See also Chapter 45.)

- Neuraxial anaesthesia is contraindicated in patients with raised intracranial pressure.

**Box 20.3** Contraindications to neuraxial anaesthesia

- Patient refusal
- Anticoagulant drug therapy—see Table 20.1
- Uncorrected coagulopathy, international normalized ratio 1.4 or higher
- Thrombocytopenia—see Table 20.1
- Haemodynamic compromise
- Active local skin infection, untreated systemic sepsis
- CNS or spinal pathology precluding neuraxial anaesthesia.

- There is no evidence to support or refute central neuraxial anaesthesia in patients with pre-existing neurological disease. Each case should be analysed individually with neurological or neurosurgical input and a risk:benefit assessment performed. Any pre-existing neurology requires robust documentation.
- Women who have had spinal surgery may prove a technical challenge. There is an increased risk of accidental dural puncture, and scarring of the epidural space may prevent the normal expected spread of local anaesthetic solution. The posterior elements of the vertebral column are usually still intact and spinal anaesthesia is often possible.[35] There is also the devastating potential complication of infection of scoliosis rods.

### Coagulopathy, low platelets, and anticoagulant drug therapy

(See also Chapter 28 and Chapter 48.)

- In the obstetric population, spinal cord or nerve root compression due to spinal or epidural haematoma has been estimated at 1/168,000.[36] Reported cases usually occur in conjunction with coagulopathy or anticoagulation therapy (see Table 20.1).
- The thrombotic tendency of parturients combined with an increase in procoagulant risk factors (e.g. raised BMI, antiphospholipid syndrome, and assisted fertility) has led to larger numbers of antenatal patients on anticoagulant medication.
- Reduced platelet counts may occur in idiopathic thrombocytopenia (ITP), gestational thrombocytopenia, and pre-eclampsia.

**Table 20.1** Relative risks related to neuraxial blockade in obstetric patients with abnormalities of coagulation or anticoagulation therapy

| Risk factor | Normal risk | Increased risk | High risk |
|---|---|---|---|
| LMWH prophylactic dose | >12 h | 6–12 h | <6 h |
| LMWH treatment dose | >24 h | 12–24 h | 6–12 h |
| Unfractionated heparin infusion | 4 h after stopping and aPTTr ≤ 1.4 | | |
| Unfractionated heparin bolus dose | >4 h | <4 h | |
| Warfarin | INR ≤ 1.4 | INR 1.4–1.7 | INR 1.7–2.0 |
| Pre-eclampsia | Platelets > $100 \times 10^9$/L within 6 h of block | Platelets $75–100 \times 10^9$/L (stable) and normal coagulation tests | Decreasing platelet count $75–100 \times 10^9$/L, abnormal coagulation tests, HELLP syndrome |
| Idiopathic or gestational thrombocytopenia | Platelets > $75 \times 10^9$/L within 24 h of block | Platelets $50–75 \times 10^9$/L | Platelets $20–50 \times 10^9$/L |

aPTTr, activated partial thromboplastin time ratio; HELLP, haemolysis, elevated liver enzyme levels, and low platelet count; INR, international normalized ratio; LMWH, low molecular weight heparin.

Reproduced with permission from *Regional Anaesthesia in Patients with Abnormalities in Coagulation*, A guidance document produced by a Joint Working Party of the AAGBI, OAA, RA-UK, 2011.

In ITP and gestational thrombocytopenia, the platelet number rather than function is limited, and if stable and tested daily, levels above 75 × $10^9$/L are considered adequate for neuraxial blockade if the count is not decreasing. Pre-eclampsia can affect platelet function and is a dynamic pathological process. In some cases, 6-hourly platelet counts and clotting studies may need to be done if neuraxial blockade is being considered. Decreasing trends would be considered a higher risk procedure and individual risk:benefit assessments should be made.[37]

- Coagulopathy may develop following other obstetric conditions such as cholestasis, intrauterine death, or placental abruption. Coagulation tests and platelet counts should be checked according to the clinical picture.

## Preoperative assessment

Pregnant women are generally healthy with minimal co-morbidities, however with the increasing age of the maternal population, obesity, and the potential for unexpected events, baseline assessment of all women is important. High-risk women should be seen antenatally by both anaesthetist and obstetrician and birth plans fully discussed and documented. Routine anaesthetic assessment should be undertaken in all cases and modified for the obstetric patient as shown in Box 20.4. Preoperative assessment should not missed in the case of emergency CD. In cases of severe fetal distress, this assessment should be done simultaneously with other tasks such as obtaining intravenous (IV) access, transferring and positioning the patient as well as establishing monitoring.

## Nil by mouth during labour

The policy of no food during labour was adopted universally following Mendelson's paper on pulmonary aspiration in 1946.[38] In the United Kingdom, there are currently no nationally recommended guidelines on eating/drinking during labour. Deaths from aspiration in obstetric patients are now extremely rare, an outcome that owes more to the widespread use of neuraxial analgesia/anaesthesia rather than to nil-by-mouth policies.

**Box 20.4** Preoperative anaesthetic assessment

- Anaesthetic history
- Past medical/surgical history
- Obstetric history
- Current medication and allergies
- Airway assessment
- Confirm position of placenta
- Recent haemoglobin and platelet count
- Valid group and screen or cross match for women at increased risk of blood loss of more than 1000 mL
- Prescription of preoperative antacid medication
- Fasting guidelines
- Consent for neuraxial anaesthesia.

Although many women do not feel like eating in labour, some may find the nil-by-mouth restriction unpleasant, particularly those with an effective epidural who are pain free. A large randomized controlled trial of more than 2400 low-risk women showed that eating a low-fat, low-residue diet during labour does not affect obstetric (mode of delivery and labour duration) or neonatal outcome.[39]

Women with risk factors for aspiration (morbidly obese, difficult airway) or women who have increased risk for operative delivery (Figure 20.2) may have their oral intake restricted to clear fluids but this should be determined on a case-by-case basis. Low-risk women, who have not had opioid analgesia, can probably be allowed a light diet during labour.

## Antacid prophylaxis and fasting times

Pregnancy increases the risk of pulmonary aspiration of gastric contents and subsequent development of aspiration pneumonitis.[38] Although awake during surgery, women undergoing neuraxial anaesthesia remain at risk due to the ever-present possibility of conversion to general anaesthesia. All patients undergoing planned CD should have an adequate period of fasting to minimize the volume of gastric contents and receive pharmacological antacid therapy to increase the pH of gastric contents.[7]

Current preoperative United Kingdom and European fasting guidelines recommend stopping solids 6 hours preoperatively with only water being consumed up to 2 hours before.[40] Some institutions advocate unrestricted sips of water until surgery.[41]

A 2010 Cochrane review looked at interventions during CD for reducing the risk of lung damage from inhaling gastric contents under general anaesthesia.[42] While the risk of aspiration is difficult to estimate due to the need for a vast sample size, studies have looked at surrogate markers such as gastric pH and volume. The review found that the quality of the evidence was poor, but the findings suggest that the combination of antacids plus an $H_2$ antagonist was more effective than no intervention, and superior to antacids alone in preventing low gastric pH at CD. Therefore, it seems sensible to administer oral ranitidine (150 mg 6-hourly) during labour in women at high risk of requiring a CD. In the event of an unexpected emergency CD, a slow IV injection of 50 mg ranitidine can be administered (if time allows), but this is unlikely to be effective before general anaesthesia is induced. However, due to the timescale of onset of action of both oral and IV ranitidine an oral antacid such as sodium citrate 0.3M 30 mL should also be administered, in theatre, immediately before general anaesthesia.

The $H_2$ antagonist ranitidine is used to neutralize stomach acid. The dose 150 mg orally is effective in 90–120 minutes and administered the night before surgery and repeated in the morning on the day of surgery. The prokinetic agent metoclopramide 10 mg is administered orally in the morning on the day of surgery to facilitate gastric emptying.[7] Proton pump inhibitors (PPIs) such as omeprazole may be of use in the elective situation to reduce gastric pH.[43,44] However, a meta-analysis comparing the ability of $H_2$ antagonists and PPIs to achieve appropriate gastric PH and volume showed that premedication with $H_2$ antagonists was more effective than PPIs in achieving a low gastric volume with a high pH.[45] Metoclopramide may have some benefits as it a prokinetic agent that increases gastric emptying and increases lower oesophageal tone as well as acting as an antiemetic.[46] However, young

patients as in obstetrics, have a higher incidence of oculogyric crisis with metoclopramide.

## Consent for neuraxial anaesthesia

The consent process is a two-way dynamic discussion of treatment options and potential complications of treatment (see Chapter 29). Information shared should respect the right of the woman to express birth preferences and take into account her culture and views. Concerns are acknowledged and explored and questions answered.[47] Ideally this is carried out at the pre-admission clinic prior to the day of surgery if an elective CD. Information is also available for mothers via leaflets and the Internet.[48]

Consenting for neuraxial anaesthesia may include explanation of the following side effects and risks:

- Pruritus (itching), shivering, nausea, and vomiting
- Hypotension
- Postdural puncture headache (PDPH): 1/100–200
- Block failure
- Permanent injury from nerve damage or infection: 1/66,000 (spinal); 1/166,000 (epidural)[49]
- Expected sensations of pushing, pulling, and pressure
- Treatment options if pain or discomfort experienced
- Conversion to general anaesthesia if required
- Short-term bruising to back at puncture site
- Urinary catheter to prevent bladder over-distension
- Rectal suppositories for postoperative analgesia
- Options for postoperative analgesia.

## Neuraxial anaesthesia technique

Neuraxial anaesthesia for CD can be performed using the following techniques:

- Single-shot spinal anaesthesia (SSS)
- Combined spinal–epidural anaesthesia (CSE)
- Low-dose or sequential CSE anaesthesia
- Epidural anaesthesia
- Continuous spinal anaesthesia.

The choice of technique will depend on local institutional guidelines, anaesthetist experience, surgical technique, clinical

judgement, and individual patient requirements. A sample procedural checklist for neuraxial anaesthesia for CD is shown in Box 20.5. Busy elective operating lists with quick turnaround times may require a neuraxial anaesthetic technique with a more rapid speed of onset. Whichever technique is used, the neuraxial block must spread sufficiently to provide anaesthesia lasting the duration of surgery and minimize perioperative discomfort. Proactive therapies are necessary to reduce side effects, in particular avoiding hypotension leading to maternal nausea and vomiting, uteroplacental hypoperfusion, and neonatal compromise.[26]

The popularity of epidural analgesia during labour means that many women presenting for unplanned CD have an epidural already in place. Anaesthesia can take longer to establish so in a true emergency (e.g. prolapsed cord or massive placental abruption), a spinal or general anaesthetic might be the technique of choice.

**Box 20.5** Procedure for neuraxial anaesthesia for caesarean delivery

- Communication with team members
- Patient preparation, discussion, and consent
- Ensure antacid prophylaxis
- Confirm group and save/cross-match if required
- Check equipment and prepare medication (including emergency)
- Transfer patient
- WHO checklist—sign in
- Mandatory monitoring (electrocardiogram, non-invasive blood pressure, $SpO_2$)
- CTG monitoring if appropriate
- Large-bore IV access
- Consider supplemental oxygen if fetal compromise
- Fluid infusion
- Aseptic technique
- Neuraxial blockade
- Tilt (uterine displacement)—table tilt or wedge
- Urinary catheter—bladder emptying
- Testing for block adequacy
- Antibiotics prior to skin incision
- WHO surgical checklist 'time out' before skin incision
- Oxytocin at delivery to encourage uterine contraction and minimize blood loss
- Postoperative analgesia and thromboprophylaxis
- Complete anaesthetic documentation
- WHO surgical checklist "sign out" before leaving operating theatre
- Handover to recovery staff
- Follow-up within 24 hours

## WHO surgical safety checklist

The worldwide implementation of the WHO surgical safety checklist has reduced death rates and complications during surgery and is now established in safe theatre practice in the United Kingdom following an alert from the National Patient Safety Agency in 2009.[50,51]

The checklist has changed practice by prompting checking of routine interventions and improving team communication and dynamics. The original version can be adapted for use according to specialty requirements and is successfully being used in obstetrics for planned and emergency CD (Figure 20.2).

The components of the checklist are read out aloud while the woman is awake.

Initially there was concern that the patient may suffer unnecessary anxiety as a result of the checklist. A questionnaire-based study found that, on the contrary, patients experienced lower levels of anxiety and were reassured by its use.[52]

## Aseptic technique

Serious central nervous system (CNS) infections (vertebral canal abscess, meningitis) are rare in the obstetric population; however, potentially devastating morbidity and mortality can occur[49] (see Chapter 28). Although firm evidence is lacking for some of the components of the aseptic technique, the potential consequences from CNS infection warrants thorough attempts to reduce this risk.[53]

A series of precautions are recommended to reduce the risk of infection. These include:

- removal of jewellery, clean short fingernails, and complying with the 'bare below the elbows' policy[54]
- pre-procedural hand washing with an alcohol-based antiseptic solution
- wearing single-use sterile gloves, hat and mask, and a sterile surgical gown. It should be noted that this recommendation is common in the United Kingdom and Australia but not worldwide[55,56]
- skin disinfection with 0.5% chlorhexidine in alcohol
- maintaining a sterile field and performing the procedure with an aseptic technique using sterile equipment
- application of a sterile dressing and regular inspection
- safe disposal of sharps

### Skin disinfection

Skin disinfection is performed with an alcohol-based chlorhexidine solution. Chlorhexidine is superior to iodine in onset time, its efficacy in eradicating skin flora, and in duration of action and is recommended for disinfection by the RCoA in the United Kingdom and the American Society of Anesthesiologists. Currently chlorhexidine is available as 0.5% chlorhexidine with ethanol or 2% chlorhexidine in isopropyl alcohol.[57] Malhotra et al. compared the application of a single spray of 0.5% chlorhexidine spray with double spraying.[58] The single spray rendered skin sterile and a further spray was considered unnecessary. The original application should be thorough and allowed to dry properly.[58] Given that a single application of 0.5% chlorhexidine effectively

disinfects the skin there is currently no evidence to support the use of the 2% solution for neuraxial procedures.[59]

Excessive use of chlorhexidine is not without risk. It is a known neurotoxic agent and epidural injection of chlorhexidine solution or contamination of equipment used in central neuraxial block procedures has been implicated in causing severe adhesive arachnoiditis.[60] Precautions should be taken to prevent accidental contamination of any equipment with the antiseptic. The antiseptic should not be poured or applied in the vicinity of block equipment.[61] This can be avoided by using spray compared to liquid from a bottle and spraying the patient's back before the anaesthetic pack is opened. Colourless solutions should be avoided to prevent being mistaken for saline.[59] After application the antiseptic fluid should be allowed to dry in order for it to exert its effect and to prevent contaminating gloves when palpating the skin. Gloves should be checked for contamination and changed if necessary.[59] (See also Chapter 28.)

### Antibiotics

Up to 8% of women are known to suffer from a wound, urinary, or endometrial infection after CD and antibiotic prophylaxis is routinely administered to prevent these postoperative infective complications. Recent guidance suggests this risk of infection can be reduced by administering maternal IV antibiotics prior to skin incision without causing undue harm to the baby.[7] Nonetheless, the use of co-amoxiclav has been discouraged due to an increased risk of necrotizing enterocolitis in the neonate, particularly in preterm deliveries or in women with premature rupture of membranes.[62,63] The current recommendation is to use cephalosporins despite deficient data on the safety profile of these in neonates.[64]

## Identifying the correct vertebral interspace

In the majority of people the spinal cord tapers and ends at the level of the L1/2 interspace (Figure 20.3). In a small but significant proportion of the population the position of the conus medullaris varies and may extend down to L3. Accidental insertion of a needle into the spinal cord can result in permanent neurological injury and most anaesthetists opt to perform neuraxial anaesthesia at the L3/4 interspace or below.[65]

Tuffier's line is a radiological line and anatomical landmark used to orientate the anaesthetist. A virtual line is drawn between the patients' iliac crests and generally this crosses the spinous process of the fourth lumbar vertebra. The L3/4 interspace is palpated one space above Tuffier's line and L4/5 one below. Radiologically this line is neither affected by the position of the patient nor BMI (Figure 20.4).

Palpation and estimation of the intervertebral space using Tuffier's line are inaccurate even when performed by experienced anaesthetists. Broadbent et al. demonstrated that in over 50% of cases the interspace identified on magnetic resonance imaging (MRI) was one space higher than previously estimated on palpation and only a third of anaesthetists correctly located a specific vertebral level.[66] These discrepancies were more likely to occur in obese patients. A decade later, Lee at al. published a similar assessment of vertebral level accuracy, this time using ultrasound scanning.[67] Only 14% of ultrasound findings correlated with the findings on clinical palpation. It is apparent that what is palpated on the patient's back does not correspond to Tuffier's line as seen on ultrasound or MRI. Palpation often identifies a line that may be up to three spaces higher than anticipated.[68]

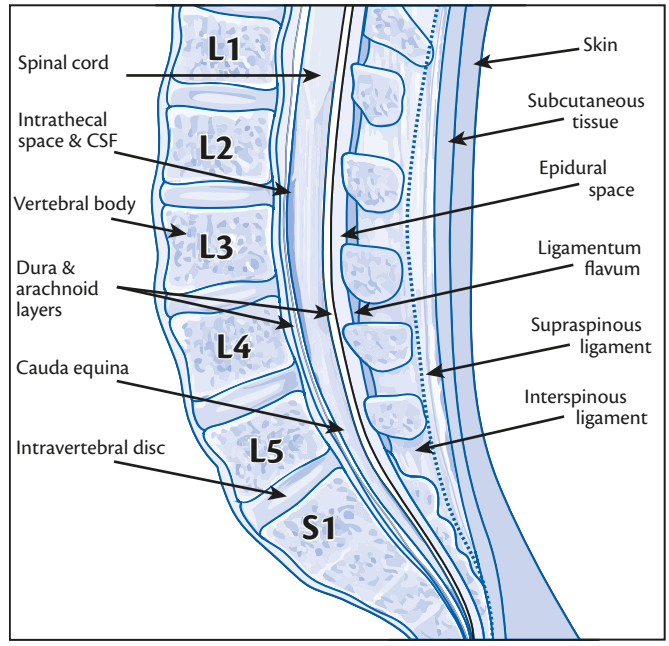

**Figure 20.3** The spinal cord generally tapers and ends at the conus medullaris at L1/2. Nerve roots known as the cauda equine continue to S2 and are surrounded by cerebrospinal fluid (CSF) within the intrathecal space.

In addition to identifying the iliac crests and correct vertebral level, ultrasound has been shown to accurately calculate the distance from skin to epidural space, identify the best point and angle of needle insertion, and reduce risk of failed or traumatic lumbar punctures and epidural catheterizations[69] (see Chapter 54).

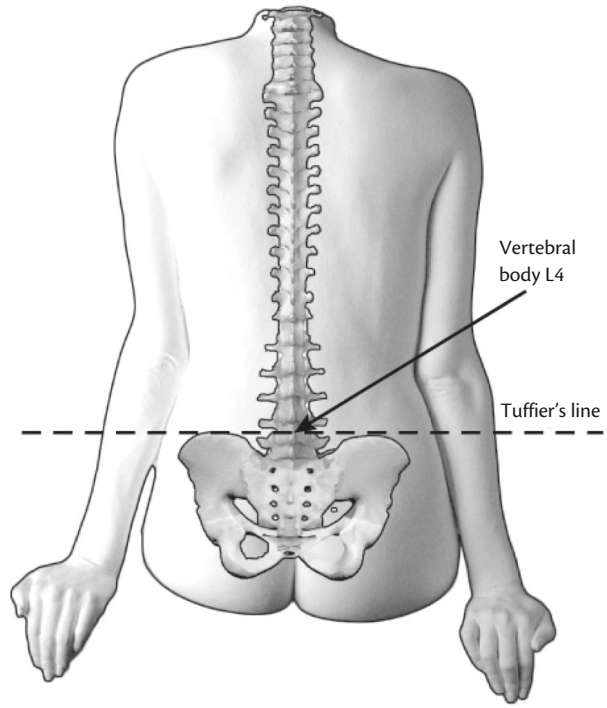

**Figure 20.4** Tuffier's line is drawn between the highest points of the iliac crests and intersects L4.

## Block testing

Pain or discomfort during CD is the leading cause of complaint against obstetric anaesthetists.[70] Prior to surgery it is necessary to perform an assessment of the neuraxial block to confirm block adequacy and so avoid intraoperative pain (see Chapter 21). Autonomic innervation of the abdominal viscera and peritoneum is conveyed by splanchnic nerves that descend from the thoracolumbar sympathetic trunk and spinal cord from levels as high as T5. A sensory block from sacral dermatomes to at least T4 is considered necessary for CD.

The different modalities used to test the block include temperature, pinprick, light touch, and presence of motor block. Depending on the modality used to test, the block detected may vary by several dermatomes. In the United Kingdom, practice is variable, the majority of obstetric anaesthetists aiming for a sensory block to cold up to a level of T4.[71] Nevertheless, Russell suggests that testing for an adequate block to light touch to T5 (without intrathecal opioids) or T6 (with intrathecal opioids) is the necessary standard of care.[72]

The stimulus used to test the block height is also considered to be very important. Ethyl chloride is the most common method used in the United Kingdom to test for both touch and cold;[71] however, the application (full force spray versus passive drop of the liquid) will vary according to the operator. A newer device, the Neuropen® monofilament (Owen Mumford, Oxford, UK) assesses response to touch and is not operator dependent. The Neuropen® has been well validated as accurate test of touch. Walsh et al. compared both equipment methods to assess neuraxial block to touch.[73] Findings between both were equivalent to within one dermatome; however, occasional wide individual differences were found. The height of block detected by the Neuropen® was lower than that of ethyl chloride. Despite a block to touch lower than T5, no increase in intraoperative discomfort was noted, raising the possibility that the gold standard block to touch to T5 is stimulus dependent or requires further validation.[73]

Findings from testing the block should be documented on the anaesthetic chart and include mode of testing, laterality (left or right side) and relevant timings. The use of dermatome maps is encouraged to standardize documentation.[74]

## Effects of positioning

Women are either positioned sitting or lateral for neuraxial anaesthesia. Choice of position depends on patient circumstances, preference of the anaesthetist, and baricity of the local anaesthetic agent. Anaesthetists should be competent with both positions. The sitting position is more widely used and helps to locate the midline and interspace, particularly in obese patients.[75] The lateral position is preferential in emergency CD to minimize disturbances to uteroplacental blood flow with a distressed fetus.[76] However, as the sitting position may help locate the midline making neuraxial anaesthesia quicker it may be beneficial in an emergency situation.[77]

Studies investigating the influence of posture on block adequacy and incidence of hypotension vary in design, making comparisons difficult.[78] Anaesthetists may perceive increased difficulty in the position they have less experience in. Spinal or CSE anaesthesia initiated with hyperbaric bupivacaine in the lateral position may take longer to perform, however this is offset by a faster onset sensory block. Studies comparing positions using epidural anaesthesia report a higher incidence of hypotension in patients in the lateral position.[77,79] Procedural delays occurring in the sitting position (e.g. due to difficulty inserting the epidural catheter), may lead to a shorter effective duration of anaesthesia due to sacral pooling.[75] It has been hypothesized that due to a lower venous hydrostatic pressure the epidural venous plexus is less engorged and 'bloody taps' are less likely in the lateral position.[80,81]

When lying supine, all women require left uterine displacement to reduce aortocaval compression. A wedge can be applied under the right hip or the table tilted a minimum of 15° to the left. Even with these manoeuvres it is important to remember there will still be an element of aortocaval compression.[82]

The use of the head-elevated ramp position using blankets or commercially available pillows may be beneficial once anaesthesia has been established. The time of adequate surgical anaesthesia may be delayed but the incidence of hypotension following spinal anaesthesia may be reduced.[83,84] Cheesman et al. looked at 60 women undergoing elective CD under CSE and randomized them to one of three head positions following a CSE: horizontal with a small pillow under the head; head-elevated ramped position with the torso on a special elevation pillow; head-elevated ramped position, after initially being positioned horizontally (giving time for the block to be established). The authors measured the block height and time to onset of adequate block as well as maternal comfort and need for epidural supplementation. They found no significant difference in the time to establish an adequate height of block and that the women found the head-elevated positions more comfortable. However, the need for epidural supplementation was greater in the intervention groups.[83] The ramped position is useful if conversion to emergency general anaesthesia is needed as it provides optimal airway position for intubation. The arms should not be folded across the chest as this may impede airway access particularly in the obese patient.

## Temperature control

Intrathecal and epidural anaesthesia for CD can cause significant decreases in core body temperature.[85] This is most likely due to the onset of sympathetic block and a mixing of warm blood in the body core with the cooler blood in the lower limbs.[86] Horn et al. evaluated whether newborns develop hypothermia during intraoperative bonding while positioned on their mothers' chests and investigated the effects of active forced air-warming of the mothers and babies during a 20-minute intraoperative bonding period.[87] They found a decreased incidence of neonatal hypothermia, an increase in the maternal core temperature and increase in the mean skin temperatures of both mother and infant, Maternal thermal comfort was improved, and maternal perioperative shivering reduced.

There is good evidence in non-obstetric patients that hypothermia leads to increased wound infection rates, length of hospital stay, and blood loss, all of which are highly relevant to obstetric practice.[88,89] Temperature management for CD is challenging due to limited body surface available for warming, peripheral vasodilatation, and exposure of the peritoneum. As the risk for major postpartum haemorrhage is greater in emergency CD, active temperature management is important; however, only 16% of UK maternity units routinely actively manage patient temperature.

The majority only initiate active warming after blood loss of over 1 L, prolonged surgery, or measured patient hypothermia.[90]

As with non-obstetric surgery, temperature should be recorded at the start of the operation, every 30 minutes until the end of the operation, and continued into the recovery period.[7]

There are limited numbers of studies that have investigated active patient warming during elective CD; the most consistently effective method of warming patients is by fluid warming either by an in-line device or by infusing fluids taken from a warming cabinet maintained at 41°C.[90,91]

There is weak evidence for maintaining theatre temperature above 21°C.[92] However, there is some evidence of benefit for higher theatre temperatures improving core temperature of premature infants delivered by CD.[93] This needs to be balanced with the environmental comfort of the surgical team.[92]

## Intravenous fluids

Prior to neuraxial blockade, large-bore IV access is established to allow rapid administration of medication and fluids. Counteracting the sympathetic-mediated spinal-induced hypotension requires a combination of strategies including the administration of IV fluids. Co-loading with fluid while performing the neuraxial anaesthetic reduces vasopressor requirements and limits hypotension.[94,95] A Cochrane review identified colloid fluids to be more effective than crystalloids, regardless of timing and rate of administration; however, colloids are used with caution in daily clinical practice due to an increasingly adverse side effect profile that includes anaphylaxis, coagulation abnormalities, and renal impairment.[96] (See also Chapter 23.)

## Spinal anaesthesia

Spinal anaesthesia is the technique of choice worldwide for elective CDs and emergencies where there is not an epidural already in place. Over the last 50 years the development of small-gauge pencil-point needles such as the Sprotte® and Whitacre needles has enabled a widespread change in practice in providing anaesthesia for CD.[97] Whereas previously epidural or general anaesthesia were favoured, spinal anaesthesia has been the predominant technique for planned CD since the 1990s. By the new millennium, anaesthetic departments in the United Kingdom were performing up to 95% of planned CD under neuraxial anaesthesia and up to 87% of these were single-shot spinal techniques.[25,98] Compared to epidural anaesthesia, spinal anaesthesia is simple, cheap, has a rapid onset, and provides a more effective and denser block with less breakthrough pain.[99] The use of smaller, non-cutting pencil-point needles has reduced the incidence of PDPH from up to 25% to 0.5–1%.[100] The advantages and disadvantages of spinal anaesthesia are summarized in Table 20.2.

**Table 20.2** Advantages and disadvantages of spinal anaesthesia

| Advantages | Disadvantages |
|---|---|
| Single injection | Limited duration, no ability to extend block |
| Quick to perform | Rapid-onset sympathetic blockade leading to hypotension |
| Endpoint with visualization of CSF | |
| Rapid-onset surgical anaesthesia | |
| Dense, predictable anaesthesia | |
| Less breakthrough pain, less likely to require supplemental analgesia | |
| Reduced incidence PDPH | |
| More cost-effective | |
| Only small amount local anaesthetic used, reduced toxicity risk | |
| Predictable recovery | |

## Local anaesthetic dose for spinal anaesthesia

The most commonly used local anaesthetic in obstetric spinal anaesthesia is hyperbaric (heavy) bupivacaine. Europeans and North Americans tend to use the 0.5% and 0.75% concentrations respectively. Effects are dose dependent and therefore in Europe larger volumes are used than in the United States but with the same effect. Diluting the local anaesthetic to increase the volume will not affect the intensity or the height of the block.[101,102]

Bupivacaine in dextrose or glucose 8% is a hyperbaric solution with a density greater than cerebrospinal fluid (CSF). Compared to isobaric or hypobaric bupivacaine, the hyperbaric formulation produces a more predictable and reliable block with a lower incidence of spinal-induced hypotension.[103] The baricity of the solution can be used to manipulate block height, for example, a head-down position encourages the block to spread in a cephalad direction if hyperbaric bupivacaine is used.

A key consideration with spinal anaesthesia is the dose-dependent incidence of hypotension. Without preventative measures (such as fluid and vasopressor administration) this can occur in up to three-quarters of women and result in maternal and neonatal morbidity.[104]

A spinal block to cold to dermatome T4 and light touch to T6 are considered necessary predictors for a painless CD.[72] There is controversy over the dose of local anaesthetic required to achieve this block and which lasts for the duration of a CD. Textbooks recommend 12–15 mg of hyperbaric bupivacaine in combination with an opioid; however, in contemporary practice a conventional dose is usually 10–12.5 mg and a low dose is considered less than 8 mg.[105]

Ginosar et al. carried out logistic regression analysis to determine the effective dose in 95% of subjects ($ED_{95}$) of intrathecal hyperbaric bupivacaine with 10 mcg fentanyl and 200 mcg morphine for planned CD.[106] Block success was defined as a bilateral sensory block to pinprick at T6 level within 10 minutes of intrathecal injection with no subsequent requirement to supplement the block during surgery. The $ED_{95}$ was 11.2 mg hyperbaric bupivacaine. A subsequent study of intrathecal plain (hypobaric) bupivacaine calculated the $ED_{95}$ at 13 mg.[107] Despite fluid administration and preloading, the patients in these studies with 'conventional' doses experienced significant hypotension with systolic blood pressures dropping 20–30% from baseline. Compared to the non-pregnant population, pregnant women require reduced doses of intrathecal anaesthetic as the gravid uterus compresses the inferior vena cava causing epidural vein engorgement and a relative reduction in the volume of the dural sac.

Once sited, apart from repositioning the patient and taking advantage of the baricity of hyperbaric bupivacaine, there is no facility to extend or manipulate the spinal anaesthetic block. Inadequate or failed block, perioperative discomfort, or prolonged surgery will require the use of Entonox®, IV analgesic supplementation, or conversion to general anaesthesia. This situation is a risk factor for both maternal morbidity and mortality and may result in dissatisfaction. In the United Kingdom, the recommended conversion rate from regional to general anaesthesia during planned CD is less than 1%.[72]

## Intrathecal dose adjustments according to patient characteristics

The literature suggests that no patient variables affect block level or merit a dose alteration when using conventional intrathecal doses. Norris injected a relatively large dose (15 mg) of hyperbaric bupivacaine into 52 women and found no correlation of the sensory spread with age, height, weight, BMI, or vertebral column length.[108]

Harten et al. compared a fixed dose regimen (hyperbaric bupivacaine 12 mg with diamorphine 0.4 mg) with smaller doses adjusted to the patient's height and weight (median dose hyperbaric bupivacaine 9.5 mg with diamorphine 0.4 mg) and found no significant difference in block adequacy; however, the adjusted-dose group were less likely to have a high block spreading to cervical dermatomes and suffered less hypotension.[109]

In Caravalho's dose–response study of morbidly obese patients (BMI > 40) no dose reduction was found necessary. Lower doses (<10 mg hyperbaric bupivacaine) were able to attain the necessary block but were seldom adequate for the duration of surgery. Large confidence intervals suggests that those at the extreme end of the BMI scale demonstrate greater variability in response and a CSE technique rather than a single-shot spinal would be more suitable due to the unpredictability.[107]

Results from optimal dose-finding studies may not be generalizable or comparable.[26] Obstetric patients are a heterogeneous population and practice varies widely both between institutions and countries. Western women are taller and have a larger body weight compared to Asian women and raised BMI can result in a technically challenging surgical procedure, requiring a denser and longer-acting anaesthetic block.

Anaesthetists vary in practice and experience and perform neuraxial anaesthesia with the patient in different positions, with the needle orifice in different directions, and injecting at different lumbar interspaces with variable speed.[110] Opioids are usually added to the intrathecal local anaesthetic; however, the dose and type is variable and polymorphism in the mu-opioid receptor might cause populations of different genetic profiles to respond differently. Surgical technique, for example, incision site, application of fundal pressure, and exteriorization of the uterus can influence anaesthetic requirements. Patient expectations and pain thresholds vary individually. It is therefore clear that many factors need to be considered when selecting the optimal intrathecal dose and anaesthetic technique, and what works well in one institution may be different in another.[26]

## Rapid sequence spinal for category 1 caesarean delivery

Kinsella and Scrutton described the 'rapid sequence spinal' in order to dramatically minimize anaesthetic time in the face of category 1 CD. The principles consist of a 'no-touch' spinal technique (only sterile gloves and skin prepared with a single wipe of chlorhexidine solution) with preoxygenation occurring during the attempt. Other components of the technique include consideration of omission of the spinal opioid, limiting spinal attempts to just one, allowing the start of surgery before full establishment of the spinal block, and being prepared for conversion to general anaesthesia if there are delays or problems.

Their case series of 25 rapid sequence spinals for category 1 CD demonstrated a technique that provided an anaesthetic block that was adequate to start surgery in 6–8 minutes. The authors stress that this technique should not be used by novices and not for cases where the spinal is predicted to be difficult or if the woman is not compliant. Staff teamwork is crucial, for example, in siting the cannula, attaching monitoring, and ensuring equipment is ready for general anaesthesia. There are no large trials validating this technique and it has been criticized primarily for compromising sterility, although while the wearing of a sterile gown is considered necessary in the United Kingdom and Australia, it is not common practice in the United States, Canada, and many parts of Europe.[55,56]

## Epidural anaesthesia

Epidural anaesthesia was the mainstay neuraxial technique for CD prior to the introduction of small-gauge pencil-point spinal needles. It is now used infrequently for planned CD as the slow-onset incremental block limits use in current high-turnover planned CD lists. Epidural anaesthesia remains frequently used in emergency CD due to the rising number of woman having epidurals sited for labour analgesia subsequently requiring CD. Disadvantages of the epidural anaesthetic include a less dense block compared to spinals with increased rates of block failure or missed segments which may potentially put women at risk of perioperative discomfort.[99] The OAA epidural information leaflet states that 1 in 8–10 epidurals are not adequate for CD and require conversion to spinal or general anaesthesia (http://www.oaa-anaes.ac.uk).

However, there are some desirable components to the technique. The gradual onset sympathetic block may be more haemodynamically stable and beneficial in patients with cardiovascular morbidity.[33,111–113] The presence of the epidural catheter also allows perioperative top-ups or can be used to prolong the block in lengthy procedures. Nevertheless these advantages have now been combined with the advantages of spinals in CSE procedures and has further eliminated the need for stand-alone epidural anaesthesia for elective CD. The advantages and disadvantages of epidural anaesthesia are summarized in Table 20.3.

## Topping-up a labour epidural for emergency caesarean delivery

The practice of 'topping-up' in the delivery room is contentious; the desire for rapid onset of surgical anaesthesia must be balanced with safety, but as any adverse outcome can be blamed on delays it is understandable that 80.5% of anaesthetists working on UK units initiate the top-up in the delivery room.[114] Once the top-up has started, the anaesthetist must not leave the patient under any circumstances and monitoring should be established as soon as is practical. Many anaesthetists give a 5 mL 'test dose' in the room and then give the full dose when in the safety of the operating theatre. Top-up of an existing epidural should lead to adequate

**Table 20.3** Advantages and disadvantages of epidural anaesthesia

| Advantages | Disadvantages |
|---|---|
| Titratable level of anaesthesia | Longer time to insert than spinal |
| Haemodynamic stability | Potential for catheter to be intravenous or intrathecal |
| Ability to prolong block | Administration and onset takes longer |
| Epidural postoperative analgesia | Less dense, less reliable, missed segments more likely, variable sacral spread |
| Labour analgesia epidurals can be 'topped-up' to provide anaesthesia for emergency CD | Large volumes of local anaesthetic required, systemic absorption increased, with potential for local anaesthetic toxicity |

anaesthesia for CD within 10–12 minutes.[115] The properties of the local anaesthetic drug combinations often used for epidural top-ups for CD are summarized in Table 20.4.

## Local anaesthetic agents used for epidural anaesthesia

- Lidocaine 2% with 1:200,000 epinephrine
- Bupivacaine 0.5%
- Levobupivacaine 0.5%
- Ropivacaine 0.75%
- 2-Chloroprocaine 3%.

Compared to the intrathecal space, the epidural space is larger. Greater volumes of local anaesthetic are required to achieve adequate block height and nerve root penetration. The volume of local anaesthetic necessary is usually 15–25 mL.

Engorged epidural venous plexuses mean that systemic absorption is more likely and may put the patient at risk of local anaesthetic toxicity or opioid-induced respiratory depression.

There is controversy over the superiority of various regimens for urgent top-up of a previously sited epidural for surgical delivery. The ideal agent should provide a rapid, predictable onset, require little preparation, provide cardiovascular stability, and have a low risk of intraoperative failure. Lidocaine, plain racemic bupivacaine, the single isomer levobupivacaine, and ropivacaine have been frequently studied when topping-up epidurals in labour for emergency CD. Hillyard et al.'s 2011 meta-analysis could not find evidence to support any one particular epidural top-up solution and highlighted the need for a large multicentre trial due to the heterogeneity of studies.[115]

### Lidocaine 2%

Lidocaine 2% with epinephrine produces the fastest onset of surgical block to T4 within 7–11 minutes.[116–119] Concentrations of less than 2% can result in inadequate surgical anaesthesia and are not recommended.[120] The pKa of 7.7 means it is less ionized and therefore has a faster onset of action. The large dose (20–25 mL) given necessitates the co-administration with epinephrine to minimize systemic adsorption (0.1 mL of 1:1000 or 1 mL of 1:10,000) added to the 20 mL 2% lidocaine solution which produces a 1:200,000 = 5 mcg/ mL epinephrine solution). Epinephrine itself can also affect block as it acts both as a vasoconstrictor, limiting absorption and increasing block density, and as an independent analgesic via alpha-adrenergic blockade. These doses of epinephrine given epidurally do not appear to reduce uterine or fetal umbilical blood flow.[121] It is an easy solution to prepare in an emergency and can remain stable for up to 6 hours if kept in a fridge and protected from light. There does not appear any significant difference in the need for intraoperative supplementation when compared with bupivacaine 0.5%.[115]

Commercial preparations of lidocaine are acidic, alkalinization of lidocaine towards its pKa value increases the unionized fraction of drug thereby increasing the amount of lipid-soluble base available to cross the neuronal membrane and theoretically increase the speed of onset. Adding 2 mL of sodium bicarbonate (8.4%) to the 20 mL lidocaine/epinephrine mixture can increase the onset of block to T4 to within 5.2–7 minutes.[116] The drawback of this technique is the additional preparation time required which may offset

**Table 20.4** Drugs used for epidural anaesthesia for caesarean delivery

| Drug combination | Epidural dose range (mg) | Speed of onset (min) | Duration (min) | Special considerations |
|---|---|---|---|---|
| 2% lidocaine + NaHCO3 + 5 mcg/ mL epinephrine | 300–500 | 5.2–7 | 75–100 | Delay in preparing mixture<br>Potential for drug error |
| 2% lidocaine + 5 mcg/mL epinephrine | 300–500 | 7–11 | 75–100 | Easy to mix<br>Stable for 6 h<br>Potential for drug error |
| Bupivacaine 0.5% or L-bupivacaine 0.5% | 75–125 | 7.5–15 | 120–180 | Stable at room temperature<br>Mixing unnecessary<br>Intraoperative failure more frequent |
| Ropivacaine 0.75% | 75–125 | 7.5–15 | 120–180 | less dense motor block<br>Reduced intraoperative supplementation vs bupivacaine or L-bupivacaine |
| 2-chloroprocaine, 3% | 450–750 | 2–10 | 40–50 | Unavailable in the UK<br>Short duration of action |

the benefit of speed of onset and the additional steps increase the risk of a drug error.[117]

### Levobupivacaine/bupivacaine 0.5%

Levobupivacaine (L-bupivacaine) and bupivacaine have similar potencies, providing anaesthesia to T4 in 7.5–15 minutes. Both drugs can cause cardiovascular and CNS toxicity, but higher doses of L-bupivacaine are required to cause ventricular arrhythmias.[122,123] They have the same pKa of 8.2 which means they are more ionized than lidocaine and therefore have a slower onset of action than lidocaine (pKa 7.7). In the United Kingdom, 65% of anaesthetic departments have used bupivacaine or L-bupivacaine as their main agent for emergency CD either as a sole agent or combined with lidocaine 2%.[114] L-bupivacaine and bupivacaine are stable at room temperature and easily prepared.[117] Hillyard's meta-analysis showed that block onset requires 4.5 minutes longer that the lidocaine/epinephrine mixture but a similar incidence of need for intraoperative supplementation.[115] There was a higher incidence of intraoperative supplementation with L-bupivacaine and bupivacaine when compared to ropivacaine 0.75%.

### Ropivacaine 0.75%

Ropivacaine has a similar structure to bupivacaine and the same pKa but is less lipid-soluble so penetrates the myelin sheath less readily and produces a reduced blockade of motor fibres. Ropivacaine 0.75% has similar onset time to bupivacaine when topping-up for an epidural for emergency CD requiring around 4.5 minutes longer than a lidocaine/epinephrine mixture.[124,125] The potency ratio of ropivacaine to bupivacaine has been reported to be between 1:1 and 1:2,[126,127] so a more concentrated preparation of 0.75% would account for its superiority with a reduced need for intraoperative supplementation when compared to levobupivacaine and bupivacaine and less cardiotoxicity.[115]

### 2-Chloroprocaine 3%

2-Chlorprocaine (2-CP) 3% is an ester local anaesthetic is not currently licensed for use in Europe but widely used in the United States. Due to high lipid-solubility it has a rapid onset of action of 6–12 minutes making it an ideal solution for emergency CD. It is hydrolysed by plasma pseudocholinesterase more rapidly than the hepatic metabolism of the amide local anaesthetics. The half-life of 2-CP in maternal plasma is less than 60 seconds therefore an unexpected IV injection would be rapidly metabolized making 2-CP extremely safe. A dose of 15–20 mL (up to 25 mL) of 3% 2-CP will provide rapid anaesthesia within 10 minutes, but its duration of action is short and will require a top-up of 10 mL after 30 minutes or there will be a rapid onset of patient discomfort, which may be difficult to control. The short duration of action may be beneficial in reducing the recovery room stay and shortening time to mobilization. 2-CP may act as a mu-receptor antagonist thereby interfering with the quality and duration of pain relief produced by epidural morphine or fentanyl and additional epidural or IV opioids may be required.[128] Unlike the amide local anaesthetics there is no fetal ion trapping so it may become the local anaesthetic of choice for delivery when the fetus is acidotic.

## Opioid adjuvants in epidural top-ups

Opioids such as fentanyl (50–100 mcg) and sufentanil (10–20 mcg) are commonly added to improve the quality of anaesthesia. Malhotra and Yentis compared epidural top-up of 20 mL levobupivacaine 0.5% with or without fentanyl 75 mcg and found no difference in the speed of onset of block or the need for intraoperative supplementation.[129] Since these patients already had an epidural in labour and were being prepared for emergency CD, it was thought that the fentanyl in the labour epidural solution may have already saturated spinal opioid receptors. Interestingly, those receiving additional epidural fentanyl had a significantly higher proportion of nausea and vomiting.

Both morphine and diamorphine (2.5–3 mg) are frequently administered epidurally for postoperative CD analgesia. Pruritus and nausea and vomiting are common side effects. (See also Chapter 17 and Chapter 24.)

## Rates of conversion to general anaesthesia

Unfortunately failure to convert a labour epidural to provide adequate anaesthesia for emergency CD can vary from 3% to 25%.[130] Guidance from the RCoA in the United Kingdom suggests that for planned CD the conversion rate from neuraxial anaesthesia to general anaesthesia should be less than 1% for elective CD and less than 5% for emergency CD.[131]

There are a number of factors which are thought to influence the success rates of epidural top-ups. An increasing number of unscheduled clinician-administered boluses during labour to maintain effective analgesics is a risk factor for failed epidural anaesthesia and even a single clinician top-up is an independent risk factor for failure.[132,133] The urgency of CD is also a predictor with Kinsella reporting a 25% (18/72) failure and conversion to general anaesthesia in category 1 CDs compared to a 7% (35/505) for category 2 CDs.[30] Fetal heart rate (FHR) abnormalities have not been shown to be an independent risk factor for failed conversion of epidural anaesthesia.[133]

The rate of conversion from epidural analgesia to general anaesthesia was found to be significantly increased when a non-obstetric anaesthetist was managing the anaesthetic compared to an obstetric anaesthetist (7.2% vs 1.6%).[132,134] This may be due to a number of factors including teamwork, communication, familiarity with the delivery suite operating theatre, as well as the ability to determine the urgency of the CD and to assess the quality of the labour epidural analgesia. There may be higher numbers of maternal requests for general anaesthesia, particularly in certain ethnic minorities.

A high BMI does not appear to be an independent risk factor for unsuccessful top-up but this may be due to a low tolerance for a poorly functioning labour epidural in obese mothers because of the high incidence of operative delivery and the desire to prevent a general anaesthetic.[135]

The different effects of general and neuraxial anaesthesia on the fetus also require further evaluation. Drugs used in general anaesthesia may have effects on the developing fetal brain and neuraxial anaesthesia has traditionally been considered more preferable for both mother and neonate. Nevertheless it is important to note that neuraxial anaesthesia is not entirely benign for the fetus. Spinal-induced hypotension, impaired uteroplacental perfusion, and ephedrine use have been associated with fetal umbilical artery acidosis and in recent years the vasopressor of choice has moved towards phenylephrine, which has improved fetal acid–base status compared to ephedrine.[136,137] (See also Chapter 21 and Chapter 23.)

## Combined spinal–epidural anaesthesia

The CSE is a procedure combining both a spinal and an epidural block. Although considered more complex and time-consuming to perform than either block alone, a CSE offers significant advantages and is a popular technique for planned CD. The advantages and disadvantages of the CSE technique are summarized in Table 20.5.

The spinal component of the CSE enables a rapid onset dense and predictable block, whereas the additional epidural catheter enables intraoperative supplementation, block prolongation and postoperative analgesic administration. Conversion rates to general anaesthesia may be reduced when compared to stand alone spinal or epidural anaesthetics for CD.[138,139] Additionally, the presence of the epidural catheter allows the subarachnoid dose to be lowered or an incremental technique to be used. These techniques are associated with improved haemodynamic stability, reduced nausea and vomiting, and quicker recovery and are discussed further below.[140,141]

Made up of two components, the CSE procedure is seen as a more complex, lengthy and costly procedure. All complications of both spinals and epidurals may occur, including PDPH.

Technical difficulties are said to be more common with CSE than with either block alone.[75,142] The spinal component may fail if the long narrow-gauge spinal needle is displaced during the needle through needle technique (see below). If not advanced far enough to pierce the dura, fluid (epidural saline) seen in the hub of the spinal needle may be mistaken for CSF and any injection of the local anaesthetic mixture into this space will naturally fail to produce a block.[75]

The epidural catheter is usually inserted after the intrathecal injection. At this time there may already be an ascending subarachnoid block and paraesthesia or warning signs of nerve irritation while threading of the epidural catheter can theoretically be masked.[75] Also, the presence of the subarachnoid block doesn't allow for testing of the epidural catheter, so there is potential for a misplaced epidural catheter to go unnoticed until it is required perioperatively. On the other hand, it has been argued that the epidural catheter is more likely to be in the correct position when sited as part of the CSE procedure.[143]

If difficulties are encountered inserting the epidural catheter (e.g. intravascular catheter or severe paraesthesia) and the patient is in the sitting position for a prolonged length of time then a (spinal) saddle block (lumbosacral anaesthesia) may occur with hyperbaric bupivacaine.[144] This can often be remedied by repositioning the patient in a head-down position after completion of the CSE procedure, or by administering a local anaesthetic epidural top-up or epidural volume extension (EVE), as discussed in a later section in this chapter.

It has been suggested that the CSE procedure and ensuing pressure rise (from negative to atmospheric) within the epidural space could affect the flow of injected local anaesthetic within the intrathecal space and increase cephalad block spread in the CSE technique as compared to a single-shot spinal technique in elective CD.[145] Subsequent studies have not been able to replicate these findings and found that intrathecal dose requirements are the same for both single-shot spinal and CSE.[146]

**Table 20.5** Advantages and disadvantages of CSE

| Advantages | Disadvantages |
|---|---|
| Rapid-onset dense predictable block from spinal component | Increased failure rate of spinal component by:<br>◆ Wrong identification of saline for CSF<br>◆ Spinal needle movement<br>◆ Failure to obtain CSF if insertion has been paramedian |
| Epidural catheter *in situ* for increased flexibility:<br>◆ Prolong anaesthesia<br>◆ Perioperative supplementation<br>◆ Rescue inadequate block<br>◆ Epidural volume extension (EVE)<br>◆ Reduce conversion rate to general anaesthetic | Untested epidural catheter, may be intrathecal or incorrect position<br>Paraesthesia on threading epidural catheter may be masked by ascending subarachnoid block |
| Epidural catheter may be used for postoperative analgesia | Risk of saddle block if delayed epidural catheter placement |
| Possibility to reduce intrathecal dose and perform incremental block with increased haemodynamic stability | Patient at risk of complications from both spinal and epidural procedures, e.g. postdural puncture headache |

### Needle-through-needle technique

A CSE can be performed either using a needle-through-needle technique using the same vertebral interspace or as two separate procedures in different vertebral interspaces—the double-spaced technique. Some centres report a higher failure rate of the spinal component with the needle through-needle-technique, however it remains the more commonly used method.[147]

With the needle-through-needle technique the epidural space is identified by a loss of resistance using a 16–18 G epidural needle and a spinal needle is subsequently passed through the epidural needle to pierce the dura. The operator may sense a dural 'click' or 'pop' during dural puncture, although the long and narrow (27–29 G) spinal needle sometimes make this difficult to feel which may contribute to the higher failure rate of the spinal component. CSF is then observed flowing through the spinal needle and an intrathecal dose of local anaesthetic and opioid is administered. During the intrathecal injection the epidural needle acts as the introducer to the spinal needle, however the spinal needle can be difficult to anchor unless specific CSE locking kits are used (see below).[148] Relatively large forces are required for the spinal fluid injection and the poorly anchored spinal needle may be subject to manual displacement which can also result in failure of the technique.[75] An alternative method when using the needle-through-needle technique is to advance the spinal needle slowly through the Tuohy needle without the spinal stillette/introducer. CSF will be seen as soon as the needle tip pierces the dura and the likelihood of advancing the spinal needle too far and causing paraesthesia may be reduced.

Standard epidural needles can be used for CSE but a longer spinal needle is needed compared to those used when performing single-shot spinals. CSE-specific commercial packs exist that may feature an epidural needle with a small hole in the greater curvature of the Huber tip to facilitate direct passage of the spinal needle through the dura and reduce friction between both needles.

Following injection the spinal needle is withdrawn and the epidural catheter is threaded through the epidural needle.

## Double-space technique

The double-space technique is less popular and is made up of two separate procedures at different vertebral interspaces. If the epidural catheter is sited first then there is a theoretical risk of the spinal needle subsequently causing trauma to the catheter. Maternal satisfaction is reduced with this technique due to the need for two separate injections; however, this method allows the placement of the epidural catheter in an unhurried fashion compared to the needle-through-needle technique and if the catheter is intravascular, it can be replaced which is not the case in the latter technique. The double-space technique may also have a lower failure rate and therefore a lower conversion rate to general anaesthesia.[149]

## Low-dose combined spinal–epidural

Low-dose CSE is a modified approach to anaesthesia for CD. The aim is to reduce the incidence of spinal-induced hypotension while still maintaining adequate anaesthesia. No exact definition exists for a 'low dose'. The $ED_{95}$ of hyperbaric bupivacaine with opioid to produce a successful block without intraoperative discomfort is 11.0 ± 0.95 mg.[150] It would make sense to define a dose below this value as a 'low dose'; however, the literature tends to refer to 'low dose' as less than 8 mg hyperbaric bupivacaine.[105,151] The advantages of low-dose CSEs are summarized in Table 20.6.

The main advantage of low-dose anaesthesia is the reduction in spinal-induced hypotension. Adverse consequences of hypotension can be mild (e.g. maternal nausea and vomiting) or more serious such as circulatory collapse and cardiac arrest in already compromised patients who cannot tolerate a sudden sympathetic block.[150] Uteroplacental hypoperfusion secondary to spinal-induced hypotension can also lead to fetal acidosis and hypoxia. Reynolds and Seed carried out a meta-analysis of umbilical artery acid–base status in over 2000 subjects and found cord pH to be significantly lower and base-deficit significantly higher with spinal anaesthesia compared to epidural or general anaesthesia. Larger doses of ephedrine were administered in the spinal group.[136]

Studies lowering the dose of intrathecal anaesthetic have consistently demonstrated a reduction in the incidence of hypotension. Leo et al. compared 7, 8, and 9 mg hyperbaric bupivacaine in combination with intrathecal morphine and reported hypotension requiring vasopressor use in 30% versus 70% in the 7 mg and 9 mg groups respectively. No patient had inadequate anaesthesia.[152] Similarly, Van de Velde et al. compared 6.5 mg hyperbaric bupivacaine with 9.5 mg in combination with sufentanil.[140] A significant decrease in the systolic blood pressure greater than 20% from baseline was found in 16% versus 68% in the 6.5 mg and 9.5 mg groups respectively. A systematic review by Arzola and Wieczorek reported a risk reduction (RR) in hypotension with doses less than 8 mg to be RR 0.78.[105] It is now widely acknowledged that low doses of spinal anaesthetic are associated with less hypotension with reduced sympathetic blockade. In keeping with this, the block is also of shorter duration and the patient is at increased risk of perioperative discomfort. Subsequently low-dose techniques are only recommended for use as a part of a CSE technique where the epidural catheter can be used to top-up a regressing block, prevent discomfort, and prolong the duration of anaesthesia. Opioids are added to the intrathecal injection to intensify the sensory block without adding to the sympatholytic effect.

Opponents of low-dose spinal anaesthesia argue that current strategies to limit hypotension are much improved and therefore intrathecal dose reductions are unnecessary and put the patient at risk of intraoperative discomfort. Indeed, with tailored fluid administration and phenylephrine infusion regimens blood pressure can be maintained at near baseline values.[153] However, excessive vasopressor use has been associated with maternal morbidity.[154] Phenylephrine infusions reduce cardiac output in healthy elective parturients, but this has not yet been associated with any detrimental maternal or fetal effects.[155] It is unknown what the impact of reducing maternal cardiac output is on a compromised fetus in a high-risk pregnancy. Low-dose CSE techniques may counteract the haemodynamic derangement in the first instance and avoid effects of excessive vasopressor use.[140] Apart from the reduction in hypotension and nausea and vomiting, further advantages of a low-dose CSE may include faster recovery from motor blockade and discharge from the post-anaesthetic care unit.[156]

The lower intrathecal dose requires modification of standard techniques to provide an anaesthetic block adequate for the duration of surgery and to prevent intraoperative discomfort. Arzola and Wieczorek calculated the risk of intraoperative analgesic supplementation in low-dose anaesthetic techniques to be more than three times higher than in conventional dose groups.[105] This meta-analysis excluded studies that used mixed interventions such EVE or pre-emptive epidural top-up and advocates of low-dose anaesthesia emphasize that it is these interventions that are integral to improving outcomes.[157] Nevertheless, the increased risk of intraoperative discomfort and potential for complaint and litigation is a valid concern and has limited the widespread use of low doses.[158]

Modifications for low-dose CSE may include an initial steep Trendelenburg position and/or EVE to improve the spread of the small spinal dose and obtain a satisfactory sensory block level.

**Table 20.6** Advantages and disadvantages of low-dose combined spinal epidural anaesthesia

| Advantages | Disadvantages |
|---|---|
| Less sympathetic block therefore less hypotension and preserved uteroplacental perfusion | Risk of inadequate anaesthesia and perioperative discomfort, litigation potential |
| Reduced vasopressor requirements | Less dense block |
| Reduced nausea and vomiting | Faster block regression |
| Quicker recovery from motor block | Increased supplementation required |
| Safer technique in patients with respiratory or cardiovascular morbidity | Specialized technique—degree of experience necessary |
| Facility to extend or prolong block with epidural catheter | Pruritus may occur if using increased opioid instead of local anaesthetic |
| Administer postoperative pain relief with epidural catheter | Maternal satisfaction may be low if discomfort experienced |

Hyperbaric bupivacaine is recommended. The resulting block is less dense and a block to touch may not be detected. A shorter duration of effective anaesthesia necessitates prudent time keeping, checking for block regression, and pre-emptive epidural top-up to avoid intraoperative discomfort.[157] Experience with the technique and good communication between patient, anaesthetist, and obstetrician has been associated with good outcomes,[55] but above all the dose reduction must not be at expense of patient discomfort.

### Low-dose sequential or incremental combined spinal–epidural

Low-dose incremental or sequential CSE comprises an intrathecal injection of a small dose of local anaesthetic (4–8 mg hyperbaric bupivacaine), with or without a dose of opioid, followed by gradual epidural top-ups. The resulting initial sensory block is deliberately not adequate for proceeding with surgery and further incremental boluses of epidural local anaesthetic are administered until satisfactory anaesthesia is achieved.

The aim of this technique is to avoid any haemodynamic instability caused by a rapid onset spinal block and may be beneficial in women with severe cardiac or respiratory morbidity in whom it is desirable to avoid sudden precipitant drops in blood pressure or changes to systemic vascular resistance and cardiac output.

Traditionally these high-risk CDs have been carried out under general anaesthesia following a modified rapid sequence induction. The sequential CSE may provide a safe alternative in appropriate circumstances.[33]

A low-dose sequential CSE is also useful when the dose of spinal is in question, for example, in patients with very short stature or in the morbidly obese parturients. In short women, a small spinal dose can be used and then if block height not achieved, the epidural is used. In the very obese woman, a standard spinal dose may result in a high block and necessitate a general anaesthetic, which one has tried to avoid in the first place. A smaller spinal dose in these challenging patients may produce the requisite block height but if surgery is prolonged, then the epidural can be brought into play.

Stand-alone epidurals are also used for incremental anaesthesia but compared to sequential CSE are more likely to be associated with inadequate anaesthesia.

## Epidural volume extension

EVE is occasionally used in low-dose CSE to increase block height after intrathecal injection. In studies, 5–10 mL saline is injected either through the epidural catheter into the extradural space or directly through the epidural needle after the spinal injection.[144] Evidence suggests this causes compression of the dural sac and cephalad spread of intrathecal local anaesthetic. EVE may work if given within 20 minutes of the spinal injection but is unlikely to have an effect afterwards as the local anaesthetic becomes fixed at its site of action and block regression commences. Effects should last up to 30 minutes.[159]

Blumgart et al. injected 10 mL saline or 10 mL 0.5% bupivacaine into the epidural space in pregnant patients undergoing planned CD under CSE and demonstrated an extension in sensory block height of up to four dermatomes and significantly faster onset compared to a control group who received no EVE.[160] Since there was no significant difference between the bupivacaine and saline groups they concluded that the block spread was a volume effect and using bupivacaine for EVE had no advantage over saline. Myelographic studies in non-pregnant patients undergoing CSE anaesthesia for elective surgery have shown a 75% reduction in subarachnoid space diameter together with cephalad spread of intrathecal contrast after 10 mL epidural saline injection.[161] Beale et al. found that the median effective dose ($ED_{50}$) of hyperbaric bupivacaine for CD could not be significantly reduced with the addition of 7 mL of saline during EVE; however, if sustaining a block to a minimum of 45 minutes were to be removed from the study criteria then the $ED_{50}$ could have been significantly lower in the EVE group. This confirms the ability of EVE to increase intrathecal local anaesthetic spread to an adequate block height but acknowledges that the duration of this block is reduced.[162] Loubert et al. did not demonstrate any increase in sensory block height after using 5 mL saline EVE (in the sitting position, via the epidural needle immediately after the spinal injection) following a low-dose CSE technique.[144]

## Continuous spinal anaesthesia

Continuous spinal anaesthesia involves using a microcatheter (28 G) or small-gauge catheter into the intrathecal space to provide analgesia and anaesthesia. Theoretically this technique offers many advantages—an accurate, continuous, titratable, dense spinal block of rapid onset and the ability to use low doses and minimize haemodynamic instability. However, the technique remains underutilized due to unavailability and unfamiliarity with the necessary equipment, technical difficulty, high failure rates, and an increase in PDPH rates.[163,164] In addition there are currently no randomized studies and a lack of consensus regarding choice and dose of local anaesthetic in continuous spinal anaesthesia. The advantages and disadvantages of continuous spinal anaesthesia are summarized in Table 20.7.

In the early 1990s, Rigler et al. reported a small case series of cauda equina syndrome and permanent neurological injury following the use of 28–32 G spinal microcatheters with hyperbaric 5% lidocaine in general surgical and orthopaedic patients.[165] It was hypothesized that the narrow internal diameter of the microcatheters encouraged slow laminar flow of local anaesthetic resulting in nerve roots being exposed to very high concentrations as opposed to a more widespread distribution of the solution

**Table 20.7** Advantages and disadvantages of continuous spinal anaesthesia

| Advantages | Disadvantages |
|---|---|
| Rapid onset | Lack of available equipment |
| Titratable dense block, haemodynamic stability | Technical insertion difficulties, high failure rate |
| Continuous | Increased risk of postdural puncture headache |
| Advantages in women after spinal surgery with scarred epidural space | Risk of being mistaken for epidural catheter and dosing errors |
| | Care required when dosing, calculation of catheter dead-space needed |

throughout the CSF.[165] The US Food and Drug Administration subsequently withdrew licensing of catheters smaller than 24 G.

A subsequent study of 28 G catheters for continuous labour analgesia found no incidence of permanent neurological injury. However, the primary medication administered was an opioid, with bupivacaine added only for breakthrough pain.[164] More recently in Spain, Alonso et al. trialled 22–24 G spinal catheters for women undergoing planned CD but concluded that the unacceptably high failure rate (20%) and PDPH rate (29%) currently limited the use of this technique in the obstetric population.[163]

A UK study of 24 G microcatheters (Spinocath® B. Braun, Melsungen AG, Germany) in high-risk parturients for elective CD found it a useful technique to maintain haemodynamic stability. Only one procedure failed but nearly 25% of women required IV analgesic supplementation in the intraoperative period and 9% of patients experienced PDPH.[166]

At present the complications of continuous spinal techniques outweigh the potential benefits and in most circumstances using a CSE is more appropriate. However, possible useful indications include patients with previous spinal surgery and scarring of the epidural space (restricting epidural local anaesthetic flow), high-risk cardiac patients, and those in whom epidural placement is difficult or more likely to fail, for example, in morbid obesity.[167]

More commonly a continuous spinal is encountered as a result of inadvertent dural tap with an epidural needle or after a 'catheter tap' while threading the epidural catheter epidurally. Following an inadvertent dural tap, the 18–20 G epidural catheter can subsequently be deliberately inserted into the intrathecal space and used as a spinal catheter. The practice of leaving the epidural catheter in the intrathecal space may reduce the requirement for an epidural blood patch should a PDPH arise following the dural tap.[168] While providing excellent anaesthesia, care must be taken not to mistake the spinal catheter for an epidural one and putting the patient at risk of a high block or total spinal anaesthesia after inadvertent large volume injection. It is important to remember the epidural catheter and filter has more than l mL of dead-space so a continuous spinal catheter should be flushed with 2 mL of saline after each bolus dose.[167]

Although spinal catheters placed after accidental dural puncture may work well in labour, they are often problematic when attempting to use them for CD. There is the dead-space issue raised previously. In addition, the spread of the local anaesthetic depends on which orifice the local anaesthetic exits from. This varies depending on the pressure used to inject—a large pressure will force the injectate through the distal holes with further spread, less force will result in exit through the proximal holes with less spread. As a result, the spinal catheter top-up for CD is not reliable and many operators would prefer to abandon the spinal catheter and perform a single-shot spinal with more consistency instead.

## Adjuvants

The addition of adjuvants to the intrathecal local anaesthetic injection can prolong anaesthesia and increase the time until additional analgesia is required. Safety data on several potential agents (e.g. neostigmine, midazolam, and magnesium) is lacking and these should not be used in routine clinical practice until further evidence is available.[169] (See also Chapter 17.)

## Intrauterine resuscitation

Obstetricians use antepartum fetal assessment to make decisions about the timing and method of delivery. This is important for anaesthetists, as lack of familiarity with fetal assessment tools and their significance can lead to poor communication delaying delivery or a suboptimal choice of anaesthetic technique. Fetal assessment and decisions related to it may also have significant medicolegal implications[170] (see Chapter 6).

When electronic FHR monitoring shows suspicious or pathological traces, it may be possible to instigate intrauterine neonatal resuscitation measures with the aim to reverse any hypoxia that might lead to further deterioration. It should start as soon as the obstetrician/midwife makes the diagnosis of fetal compromise and continued into the operating theatre. Any resultant improvement in FHR may eliminate the need for an operative delivery or allow time for neuraxial anaesthesia for a vaginal or CD. Thurlow and Kinsella provide a good acronym for fetal resuscitation, 'SPOILT' (see Box 20.6).[171]

1. Discontinuing oxytocin: uterine blood flow is minimal at the peak of uterine contractions, which may lead to disruption of gas exchange. In normal conditions the fetus has adaptive mechanisms to compensate for this but when there is excessive uterine activity and insufficient time between contractions, fetal hypoxia and acidaemia can occur. Excessive contractions can be the result of iatrogenic oxytocin or prostaglandin and are associated with prolonged decelerations, bradycardias, or late decelerations; therefore stopping the oxytocin is warranted. Reduction in uterine activity does not happen immediately and may warrant use of a tocolytic drug.[172]
2. Position change: the first action should be to move the mother into the left or right lateral position to avoid aortocaval compression, so maximizing venous return, cardiac output, and ultimately uteroplacental perfusion.
3. Oxygen supplementation: intuitively the obvious way to improve oxygenation of the fetus would be to administer supplemental oxygen to the mother, but the data supporting its benefits to the fetus have been inconsistent. Early studies showed that maternal oxygen reduced late decelerations within

**Box 20.6** 'SPOILT'—intrauterine resuscitation

6. Tocolysis: terbutaline 250 mcg (SC), glyceryl trinitrate 400 mcg (metered aerosol doses)

a few minutes,[173] but then this may only be beneficial if given for a short period of time and may precipitate fetal acidosis if given for extended periods.[174] Maternal oxygen administration during labour has gone out of vogue since the 2003 Cochrane meta-analysis which concluded that there was not sufficient evidence that maternal oxygen administration improved fetal oxygenation in labour, although most of the studies in this review excluded women with non-reassuring FHR patterns.[175] The recent use of fetal pulse oximetry has been used to determine the effects of maternal oxygenation during labour; administration of 100% oxygen (using a non-rebreathing facemask) has been shown to improve fetal oxygen saturation, with the greatest increase seen in those fetuses with an initial fetal oxygen saturation of less than 40%.[176,177] However, these studies have been too small to show any difference in neonatal outcome. Studies by Khaw et al. and Noh et al. have reported that high inspired oxygen fraction can cause an increase in oxygen free radical activity in maternal blood and that lipid peroxidation levels and antioxidant capacity in umbilical venous blood were higher in patients delivering by planned CD.[178,179] They suggested that both the mother and fetus are exposed to higher oxidative stress during CD. Clearly this is a balance of risks and it would seem sensible to give oxygen if maternal saturations were less than 95% and on balance oxygen should be given at high flow for a short period of time to see if there is improvement in fetal status.

4. Increased IV hydration: as oxygenation of the fetus is highly dependent on uterine blood flow and placenta perfusion, an optimal intravascular volume is necessary. Fluid restriction policies may result in maternal dehydration, which may be precipitated in women in prolonged labour. A bolus of 1000 mL of lactated Ringer's solution over 20 minutes significantly increases fetal oxygen saturation, which can last for more than 30 minutes.[176,180] Boluses of IV crystalloids also appear to have a mild tocolytic effect thought to be mediated by atrial natriuretic peptide release by distention of the atrium as well as some benefits due to reduced blood viscosity.[176] Caution should be observed in giving repeated boluses of IV fluids in pre-eclamptic woman and those on corticosteroids and beta-mimetic agents as these women are at increased risk of pulmonary oedema.
5. Avoidance of hypotension: similar to increasing intravascular volume by fluid, maintenance of blood pressure and placental blood flow is vital. Initiation of neuraxial blockade can result in hypotension, particularly if the woman is dehydrated. Vasopressors, such as phenylephrine, should be used to maintain blood pressure and placental perfusion.
6. Administration of tocolytics: excessive contractions can cause placental hypoperfusion. It can occur with or without the administration of synthetic oxytocin but it is important to exclude underlying serious pathology such as an abruption. Administration of a tocolytic agent can decrease the uterine activity and improve the FHR allowing labour to continue or to allow time for staff utilization, that is, getting a second anaesthetist/obstetrician or opening a second operating theatre.[181] The optimal tocolytic agent has not been found and individual departments should have protocols for their preferred drugs. Beta-agonists drugs such as terbutaline 250 mcg administered subcutaneously or IV salbutamol 100 mcg is the most commonly used drug for this purpose in the United Kingdom. Ritodrine is no longer recommended due to its high side effect profile. Glycerol trinitrate, although not licensed as a tocolytic, has a fast onset of action and can be given as a 400 mcg metered dose sublingually or 100–400 mcg IV. Maternal hypotension is a major side effect but can be treated easily with vasopressors.[182] Magnesium sulphate (4 g IV over 20 minutes) can also provide emergency tocolysis.[183]

## A woman with a poorly working labour epidural requiring emergency caesarean delivery

Complications during CD such as pain and discomfort that may necessitate conversion to general anaesthesia can often be predicted with knowledge of how the epidural worked during labour—a golden rule should be that a poorly working labour epidural should not be used to top-up for a surgical delivery. This again emphasizes the importance of regular ward rounds and assurance that all labour epidurals are working effectively, a poorly working labour epidural should be removed and replaced.

A dilemma occurs when a top-up has been given and there is no or only a partially adequate block. Perhaps the best option is to do a sequential epidural top-up (injecting small doses, e.g. 5 mL of local anaesthetic epidurally, assessing the block height after a few minutes). If after 10 mL of local anaesthetic there is no cephalad spread and the patient is still feeling her contractions or the block is not bilateral, the epidural should be abandoned and an alternative method used. If time allows, manipulation of an epidural (i.e. by withdrawing the catheter 1 cm) can improve successful conversion to surgical anaesthesia in up 80% of poorly working epidurals.[133]

The concern is that performing an intrathecal injection following a long-standing epidural could result in a high spinal. This may occur in a number of ways; the large volume within the epidural space could cause sac compression resulting in a higher intrathecal block. Alternatively, a high spinal may arise from diffusing local anaesthetic in the epidural space or leakage of it into the CSF via the hole in the dural sac.[184–186] In some units, it is standard practice to remove a poorly functioning epidural and use a CSE or a single-shot spinal technique. Furst looked retrospectively at 1393 operative deliveries in a 2-year period; 672 (48%) received epidural blockade, of these 32 (5%) were identified as providing inadequate anaesthesia and an alternate mode required.[186] Twenty-seven of these 32 patients (84%) received subsequent spinal block, while the rest underwent induction of general anaesthesia. Of those patients who received both epidural and subarachnoid anaesthesia, three cases of high spinal anaesthesia were recorded making an incidence of 11%. They found the incidence in the same population having spinal anaesthesia alone (i.e. those that did not have an *in situ* epidural) was 0.2%. During the data collection period they did not have a standard dose of intrathecal bupivacaine; the mean dose used was approximately 12.0 mg of heavy bupivacaine, this did not differ greatly in patients in whom high spinal anaesthesia did or did not occur. In their discussion they recommended that a

reduced dose of local anaesthesia is used (20% less) and allowing the local anaesthesia to 'set' for 60–90 seconds prior to placing the patient supine. However, this runs the risk of a low block. Other units use a standard intrathecal dose with no incidence of high block. High blocks can be avoided with the an Oxford pillow technique where the head is ramped much higher than the shoulders or tilting the table head-up once the desired block height is achieved.

At present there are no studies to recommend the safest intrathecal dose of bupivacaine following an inadequate labour epidural. Many would advocate the use of a CSE technique with reduced dose of intrathecal local anaesthetic and then using the epidural catheter component to titrate to achieve an adequate block. Full resuscitation facilities should be available to manage a high spinal block or provide a rapid and safe conversion to general anaesthesia. (See also Chapter 21.)

**Table 20.8** Troubleshooting neuraxial blockade for caesarean delivery

| | |
|---|---|
| **Spinal-induced hypotension** | *Causes*<br>◆ Rapid cephalic spread of anaesthesia<br>◆ Drop in systemic vascular resistance<br>◆ Sympathetic blockade<br>◆ Aortocaval compression |
| | *Consequences*<br>◆ Maternal nausea and vomiting, dizziness<br>◆ Loss of consciousness or death if limited cardiovascular reserve or pre-existing morbidity<br>◆ Reduced uteroplacental perfusion<br>◆ Fetal compromise and asphyxia<br>◆ Neonatal acidosis, poor outcome |
| | *Management*<br>◆ Multimodal approach, aim to keep systolic blood pressure within 10% of baseline<br>◆ Left lateral positioning and uterine displacement<br>◆ Crystalloid or colloid pre- and/or co-loading<br>◆ Low-dose CSE or incremental anaesthesia, epidural volume extension<br>◆ Vasopressor use, e.g. phenylephrine (α-adrenergic receptor agonist) bolus 50–100 mcg or infusion 25–100 mcg/min |
| **Intraoperative nausea and vomiting** | *Causes*<br>◆ Multifactorial<br>◆ Stimulation of area postrema in chemoreceptor trigger zone<br>◆ Stimulation of vomiting zone in medullary lateral reticular formation<br>◆ Vagal input from exteriorization of uterus, organ manipulation, visceral pain, peritoneal stimulation<br>◆ Cerebral hypoperfusion secondary to spinal-induced hypotension, bleeding or aortocaval compression<br>◆ Dopaminergic, muscarinic, tryptaminergic, histaminic, and opioid receptor stimulation<br>◆ IV opioids<br>◆ Entonox®<br>◆ Uterotonic agents: ergometrine (dopaminergic and serotoninergic stimulation), oxytocin (hypotension via nitric oxide and atrial natriuretic peptide release), and carboprost (prostaglandin $F_2$-α gastrointestinal tract stimulation) |
| | *Consequences*<br>◆ Maternal discomfort and reduced maternal satisfaction<br>◆ Pulmonary aspiration<br>◆ Difficult operating conditions |
| | *Management*<br>◆ Prevention and prompt treatment of hypotension<br>◆ Use of neuraxial opioids (analgesic, improve block quality, anxiolytic, dose-sparing)<br>◆ Reduce surgical stimuli<br>◆ Cautious use of uterotonic agents<br>◆ Pharmacological antiemetic prophylaxis not routine<br>◆ Antiemetics to treat existing nausea and vomiting (e.g. metoclopramide, antihistamines, 5-$HT_3$ antagonists)—used in practice; however, not enough data available to support efficacy |

*continued*

**Table 20.8** Continued

| | |
|---|---|
| **Pruritus** | *Cause*<br>◆ Caused by neuraxial opioids, exact mechanism unclear, likely interaction between diamorphine and 5-$HT_3$ receptors in spinal cord and medulla<br>◆ Particularly common following intrathecal or epidural morphine<br>◆ Always exclude allergic reaction |
| | *Management*<br>◆ Serotonin 5-$HT_3$ antagonists, e.g. ondansetron, reduce incidence of severe pruritus and number of patients requiring treatment<br>◆ Opioid antagonists, e.g. naloxone (50–100 mcg), disadvantage is antanalgesic effect and patient should be warned<br>◆ Propofol (subhypnotic doses)—conflicting evidence of efficacy<br>◆ Antihistamines (e.g. chlorpheniramine) unlikely to be of use as neuraxial opioid-induced pruritus is not related to histamine release |
| **Managing a high block** | *Cause*<br>◆ Individual variation in response<br>◆ Anatomical abnormalities<br>◆ Subdural injection<br>◆ Intrathecal administration of epidural intended solution |
| | *Features*<br>◆ Weak upper limb function and hand paraesthesia<br>◆ Altered voice<br>◆ intercostal muscle paralysis<br>◆ Respiratory failure (total spinal)<br>◆ Profound hypotension and bradycardia<br>◆ Loss of consciousness |
| | *Management*<br>◆ Reassurance, explanation of events to patient, their partner, and team<br>◆ Change in position, head-up tilt<br>◆ Supplemental oxygen<br>◆ Circulatory support with fluids and vasopressors<br>◆ General anaesthesia and endotracheal intubation if required |
| **Intraoperative discomfort** | *Causes*<br>◆ Inadequate neuraxial anaesthesia, block failure<br>◆ Prolonged surgery, neuraxial block regression<br>◆ Increased surgical stimulation, e.g. uterine exteriorization<br>◆ Different patient expectations |
| | *Actions*<br>◆ Temporarily stop surgery<br>◆ Communicate with patient to establish nature of pain or discomfort<br>◆ Assess level of sensory block<br>◆ Reassure and offer prompt management<br>◆ Document events |
| | *Management*<br>Will depend on timing (i.e. at incision, during delivery, skin closure, etc.), degree of discomfort and patient preference:<br>◆ Reassurance<br>◆ IV opioid analgesia, e.g. fentanyl, alfentanil, remifentanil<br>◆ Epidural top-up with local anaesthesia and/or opioid<br>◆ Entonox®<br>◆ Local anaesthetic infiltration of surgical field but beware of local anaesthetic toxicity if epidural top-up has been given as maximum doses may already have been achieved<br>◆ Repeatedly offer general anaesthesia as alternative strategy<br>◆ General anaesthesia<br>◆ Documentation of events<br>◆ Follow-up |

*continued*

**Table 20.8** Continued

|---|---|
| **Failed regional technique** | *Causes*<br>◆ Injection into the wrong space, e.g. following a false loss of resistance or needle displacement<br>◆ Anatomical deviations, e.g. scoliosis, presence of an epidural or dural septum or distorted anatomy following back surgery<br>◆ Technical difficulty due to patient positioning, patient discomfort, obesity or anaesthetic inexperience |
| | *Action*<br>◆ Sensory block testing and identification if any block present<br>◆ Seek help if necessary<br>◆ Devise an alternate strategy<br>◆ Explain events and plan to the patient<br>◆ Document |
| | *Management*<br>Alternative management will depend on the difficulty previously encountered, the patient, and any current degree of anaesthesia.<br>For elective CD there is no urgency and plan B should not compromise patient safety. Consider:<br>◆ Repeating the procedure<br>◆ Alternative regional technique, e.g. CSE—particularly useful if patient has existing partial block and incremental anaesthesia will avoid a high block<br>◆ General anaesthesia |

## Troubleshooting

See Table 20.8.

## Recovery

Following CD, specific observations are carried out to monitor recovery from anaesthesia, manage postoperative discomfort, and check for obstetric complications such as uterine atony and postpartum haemorrhage.

Basic observations such as blood pressure, heart rate, respiratory rate, urine output, and pain and sedation scores should be carried out half-hourly for 2 hours and hourly for 4 hours provided all is well.[7] Most obstetric units now record observations on 'early warning score' charts to guide midwifery and nursing staff when to seek help should any observations deviate from the norm. (See Figure 35.3 in Chapter 35 for an example of an early warning chart used in obstetrics.)

Due to the potential risks of delayed respiratory depression, it is recommended that following intrathecal diamorphine or morphine the woman should be monitored as above for 12 or 24 hours respectively.[7] Women with pre-existing comorbidities or perioperative anaesthetic or obstetric complications may be at increased risk and a more intensively monitored environment such as an obstetric high dependency unit may be appropriate.

Pregnancy and surgery increase the risk of venous thromboembolism and each woman should undergo a risk assessment for thrombosis. The method of thromboprophylaxis required may include hydration, early mobilization, graduated stockings, pneumatic compression devices, and/or low-molecular-weight heparin.

All women who undergo CD should have a follow-up within 24 hours by anaesthetic staff to check for signs or symptoms of complications from neuraxial blockade such as PDPH or epidural haematoma. It is also an opportunity to assess maternal satisfaction, answer questions, or explain any untoward events that may have occurred, for example, perioperative discomfort or the need for a general anaesthetic compared to neuraxial block.

## Enhanced recovery

Increasingly popular is the concept known as 'enhanced recovery'. Well established in other specialities (e.g. orthopaedics), the programme has yet to become widespread in obstetric services.[187]

A recent UK survey found that only 6% of maternity departments had an enhanced recovery programme, were implementing one, or considering doing so and a French questionnaire found that although the concept is feasible, the majority of patients remain hospitalized for more than 72 hours.[188,189]

The principle underpinning enhanced recovery is that right from the point of booking a planned CD the woman enters a pathway designed to minimize physical and emotional stress responses and encourage a swift recovery to normality postoperatively. Multidisciplinary staff and the patient themselves have proactive roles in delivering this service. With regard to CD, this may include preoperative education on analgesia and breastfeeding, an increasing awareness of 'what to expect', and haemoglobin optimization. Starvation times should be kept to a minimum, preoperative antibiotics administered, neuraxial opioids used for postoperative analgesia, surgery kept as minimally invasive as possible (smallest possible incision and avoidance of postoperative drains), and thromboprophylaxis undertaken. Following surgery, the patient should be allowed to eat and drink, the urinary catheter removed once anaesthesia has worn off to allow early mobilization, and regular analgesia commenced. If all postoperative observations are satisfactory with mother and baby, the length of hospital stay may be able to be reduced from 3–4 nights to 1–2 nights. Implementation and success of enhanced recovery relies on regular follow-up and support from community healthcare professionals and a safety net for when problems are encountered.[190]

## Conclusion

CD should be a safe and rewarding experience for the parturient. While neuraxial or general anaesthesia are both acceptable,

neuraxial anaesthesia is preferable in order to minimize the risks of a general anaesthetic and to allow the mother to participate in the birth. While this is possible in the majority of elective CDs with a range of techniques being successfully employed, there is still debate as to the optimal neuraxial technique in the emergency situation. Guidelines for obstetric units should strive to organize services to minimize the time taken to deliver the baby while maximizing the analgesia, safety, and positive experience for the mother.

# CHAPTER 21

# Intraoperative management of inadequate neuraxial anaesthesia

Tauqeer Husain and Roshan Fernando

## Introduction

Neuraxial anaesthesia (NA), in the form of neuraxial blockade, is increasingly seen as the preferred method of anaesthesia for elective and emergency caesarean delivery (CD). Within the United Kingdom, a number of studies have shown NA rates for CD of approximately 80%, or more (Figure 21.1). Shibli and Russell[1] conducted a prospective survey of 129 maternity hospitals, obtaining data on anaesthesia for 60,455 CDs. They found that 78% were performed under NA, with 47% under single-shot spinal, 22% epidural, and 9% with combined spinal–epidural (CSE). In elective procedures, NA was used in 87% of cases, whilst 72% of emergencies were performed under NA. The National Sentinel Caesarean Section Audit Report,[2] presented the findings of an audit of CD rates in England, Wales, and Northern Ireland between 2000 and 2001. It found that 77% of emergency and 91% of elective CDs were performed with NA. Rafi et al. demonstrated the use of continuous prospective audit increased the NA rates in both elective and emergency CD. In their study, NA rates for elective CDs increased from 95.3% to 98.2%, whilst rates in emergency deliveries increased from 82.3% to 85.7%, between 2004 and 2007.[3]

However, the increasing use of NA for CD is not just limited to the United Kingdom. Similar rates of NA use for CDs have been demonstrated in other European countries, such as France,[4,5] Germany,[6,7] and Belgium,[8] and further afield, in the United States,[9] Israel,[10] the West Indies,[11] and Nigeria.[12]

Many factors have driven the increasing use of NA in obstetric surgery. Most markedly, there has been an appreciation of the prominent role of general anaesthesia (GA) in the causes of anaesthetic mortality and morbidity in obstetrics. The MBRRACE-UK project (Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the UK; formerly the Centre for Maternal and Child Enquires (CMACE), and the Confidential Enquiry into Maternal and Child Health) publishes triennial reports on the results of what has become the longest running audit in medicine. In the first report, covering 1952–54,[13] 49 deaths were attributed to anaesthesia, and there were at least 20 more where anaesthesia was thought to be contributory. By the 2009–12 report, published in 2014,[14] only four deaths were directly related to anaesthesia. It has been suggested that this trend of decreasing anaesthetic mortality (anaesthesia being 30 times safer than it was in the 1960s) is at least partly due to the increasing use of NA, since the 1960s.[15,16]

The predominant causes of anaesthetic death, as shown in previous reports, have either been related to failed oxygenation during intubation, or aspiration of gastric contents causing early asphyxia or late respiratory failure.

## Medicolegal implications of inadequate anaesthesia

Whilst the use of NA over GA undoubtedly provides a favourable balance of risks and benefits for most pregnant women, the employment of NA does not abolish risk altogether. Along with the risk of morbidity from the actual neuraxial procedure, the risk of failed NA and potential conversion to GA also exists. A prospective audit of over 5000 CDs in a single UK hospital showed a GA conversion rate of 0.8% for elective and 4.9% for emergency cases.[17] In a US retrospective analysis of nearly 20,000 deliveries, over a 3-year period, the rate of conversion from spinal anaesthesia was 1.2%, while 4.3% of GAs occurred after conversion of epidural anaesthesia.[18]

The risk of inadequate NA has medicolegal and clinical consequences. The American Society of Anesthesiologists' Closed Claims Database (which collects detailed case summaries from malpractice insurance organization claim files) found that of the 1541 claims made between 1985 and 1990, 12% involved obstetrics, and 33% of these were associated with NA.[19] Eight per cent of obstetric claims involved pain during anaesthesia, resulting in a median payment of $17,000 (ranging from $5000 to $305,000). In a more recent study, 13% of perioperative claims made between 1990 and 2003 were related to obstetric anaesthesia.[20] The median litigation payment was $222,000, although these claims were not exclusively related to intraoperative pain. A study of the Canadian Medical Protective Association closed claims between 1990 and 1997 demonstrated 13 obstetric claims out of 61.[21] Pain during anaesthesia made up 15% (2/13) of obstetric claims. Within the United Kingdom, the Clinical Negligence Scheme for Trusts (which handles all clinical negligence claims against Nation Health Service bodies) managed 841 cases relating to any form of anaesthesia, between 1995 and 2007.[22] Of these, 245 (29%) were

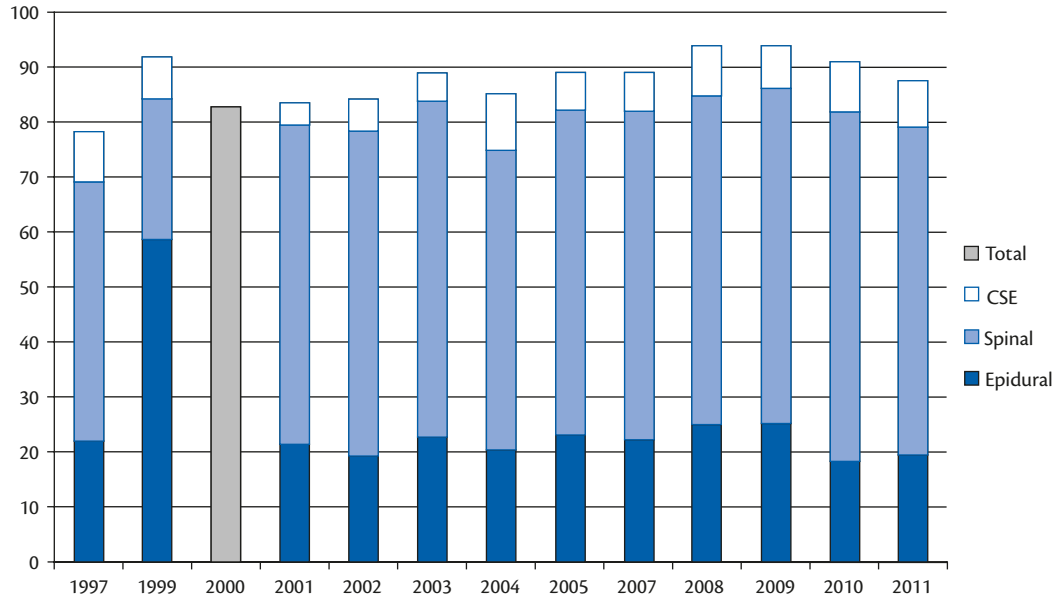

**Figure 21.1** Neuraxial anaesthesia use in the UK between 1997 and 2011.
Data from Shibli KU, Russell IF, A survey of anaesthetic techniques used for caesarean section in the UK in 1997, *International Journal of Obstetric Anesthesia*, volume 9, pp. 160–7, Copyright © 2000 Elsevier and OAA National obstetric anaesthetic database (http://www.oaa-anaes.ac.uk/content.asp?ContentID=241).

classified as relating to obstetric anaesthesia. The total value of claims was £7.5 million. An examination of litigation specifically related to NA within the same period demonstrated that 186 out of 366 claims were associated with obstetric anaesthesia.[23] Of the 326 neuraxial claims, inadequate block with resulting pain accounted for 24 claims. Fifty-seven of the obstetric claims (31%) were due to inadequate block, resulting in pain during CD or labour.

# Epidural anaesthesia

## Risk factors for failed conversion of epidural analgesia to anaesthesia

Epidural analgesia in labour has become increasingly popular, not just for the excellent pain relief that is normally provided in labour, but also for the ability to convert labour analgesia to operative anaesthesia by the addition of higher concentrations of local anaesthetic (LA) and opioid. Reported rates of failed epidural conversion (defined as failure to induce adequate anaesthesia or to provide adequate anaesthesia throughout the procedure, requiring analgesic supplementation, an alternative regional technique or GA) for CD, varies between 7.1% and 24%.[17,18] A number of factors that may predict the risk of failed epidural conversion have been identified (Box 21.1).

**Box 21.1** Factors associated with an increased risk of failed epidural conversion

- Supplementary clinician boluses in labour
- Non-obstetric anaesthetist providing care
- Urgency of caesarean delivery
- High maternal weight or height.

### Clinician boluses in labour

The likelihood of successful epidural anaesthesia is related to the effectiveness of epidural labour analgesia. This has most commonly been represented by the requirement of clinician-initiated boluses to manage breakthrough pain during labour. Riley and Papasin investigated the clinical factors associated with catheter failure in a retrospective case note review of 246 patients that had continuous epidural infusions of 0.0625% bupivacaine with 0.33 mcg/mL sufentanil, for labour analgesia.[24] The authors found that failure to obtain adequate surgical anaesthesia correlated to the number of times the patient required extra clinician boluses during labour. Successful catheters required a mean (range) of 1 (0–8) clinician boluses, while the unsuccessful catheters required a mean (range) of 3 (0–10) clinician top-ups. They concluded that although additional clinician boluses had classically been attributed to 'especially painful' labours, it is equally probable that this actually reflects suboptimal catheter placement in the epidural space. Further studies have demonstrated a correlation between the need for any,[25] or more than one additional labour bolus,[26] and an increased risk of inadequate epidural anaesthesia. With this in mind, it would be reasonable to consider a patient requiring multiple clinician boluses in labour to be at high risk of failed epidural anaesthesia, if CD were required. It may therefore be prudent to have a low threshold to replace the epidural catheter in a patient where analgesia is not adequately maintained without additional clinician interventions. Additional caution should be used when patient-controlled epidural analgesia is used, as the need for additional boluses may not be as readily evident, necessitating increased vigilance and more frequent reviews.

### Obstetric anaesthesia specialists

It has also been hypothesized that anaesthetists who have undergone specialist training, or are specialists, in obstetric anaesthesia may have a higher success rate at managing epidural anaesthesia.

This may be the result of them having more confidence and patience in waiting for an epidural to provide adequate anaesthesia, or in them being more likely to actively manage a suboptimal epidural by withdrawing the catheter or giving additional LA.[25] Specialists may, therefore, be less likely to convert to an alternate method of anaesthesia. These differences may result in different clinical decision-making, which may allow less time for adequate epidural block to work before it is abandoned for an alternative method. Riley and Papasin showed that non-specialists have a failed epidural anaesthesia rate of almost four times that of obstetric anaesthesia specialists, in one study.[24] However, this has not been consistently found in other studies.[26,27]

### Maternal size

It has also been argued that increased maternal weight may be a risk factor for failed epidural anaesthesia; the suggestion being that maternal obesity may result in increased catheter displacement as the distance between the skin and the epidural space changes with patient movement.[24] This, again, has not been consistently demonstrated in the literature. Interestingly, Halpern et al.[26] identified increased maternal height, but not body mass index (BMI), as a factor leading to failed epidural anaesthesia. The authors hypothesized that the lack of difference in failure rate between patients with a BMI higher than 35 compared to those with a BMI lower than 35 might be due to a low tolerance of suboptimal labour analgesia by anaesthetists in this high-risk group, and therefore early replacement of inadequate epidural catheters in labour.

## Local anaesthetic solutions for epidural anaesthesia

### Local anaesthetic

The characteristics of LAs used to 'top-up' epidural analgesia for operative anaesthesia are numerous. High on the list of desired features are the onset and duration of anaesthesia. Epidural conversion from analgesia to anaesthesia is most commonly needed in urgent or emergency cases. In the most extreme situations, delayed anaesthesia maybe associated with maternal or fetal mortality. In such a scenario, a rapid onset of epidural anaesthesia is needed to avoid the alternatives, general or spinal anaesthesia. Additionally, the quality and duration of anaesthesia are clearly important to avoid breakthrough pain, supplementation and potential conversion to GA during the procedure.

Hillyard et al.[28] performed a meta-analysis to find if significant differences in time of onset and incidence of intraoperative supplementation exist between three LA solutions (0.5% bupivacaine or levobupivacaine (Bup/Levo), 0.2% lidocaine + 1:200 000 epinephrine ± fentanyl (LE ± F), and 0.75% ropivacaine (Ropi)) used for epidural top-up in labouring women undergoing non-elective CD. Analysis indicated that the time of onset of anaesthesia was significantly reduced by over 1.5 minutes with LE ± F, compared to either Bup/Levo or Ropi (Figure 21.2). By excluding studies with markedly different protocols, the heterogeneity of the meta-analysis was reduced, and the mean difference in onset time was further increased to 4.5 minutes. Intraoperative supplementation of anaesthesia was significantly increased with the use of Bup/Levo. The increased risk of supplementation was highest when Bup/Levo was compared to Ropi (Figure 21.3).

There are several limitations to the Hillyard et al. meta-analysis.[28] The addition of bicarbonate and opioids were not included and this is discussed in a later section. Another limitation of the meta-analysis is that it did not consider the use of 2-chloroprocaine for top-up epidural anaesthesia. As an ester-linked LA, it is rapidly hydrolysed by plasma cholinesterases to inactive metabolites, has a maternal plasma mean half-life of 3.1 ± 1. 6 minutes, after epidural anaesthesia,[29] and an approximate duration of action of 40–50 minutes. Chloroprocaine also has a rapid onset of action. Compared to 0.5% bupivacaine, 3% chloroprocaine resulted in significantly shorter injection-to-anaesthesia and injection-to-delivery times when *de novo* epidural anaesthesia was administered for CD.[30] When 3% chloroprocaine has been compared to lidocaine with epinephrine for CD, onset of block has been equal,[31] or significantly faster with chloroprocaine, and a non-significant increase in the need for supplemental analgesia has been noted in the lidocaine group.[32] Additionally, when administered via a *de novo* epidural in order to provide anaesthesia for CD, 3% 2-chloroprocaine was found to cause similar incidences of maternal and fetal side effects to 2% lidocaine and 0.75% bupivacaine.[33]

Some studies have found that the rapid onset of anaesthesia accompanying administration of chloroprocaine is associated with greater maternal hypotension, when compared to 0.5% bupivacaine.[30] However, the hypotension was not associated with adverse maternal or fetal effects when corrected rapidly. The use of chloroprocaine has also been associated with cases of neurological damage after epidural or inadvertent intrathecal administration.[34,35] Sodium bisulphite, a preservative contained within earlier commercially available preparations, was implicated in the pathogenesis of this neurotoxicity,[36] and has led to the development of bisulphite-free preparations. However, some work has questioned whether neurotoxicity might occur as a direct effect of the anaesthetic, rather than the preservative.[37] Furthermore,

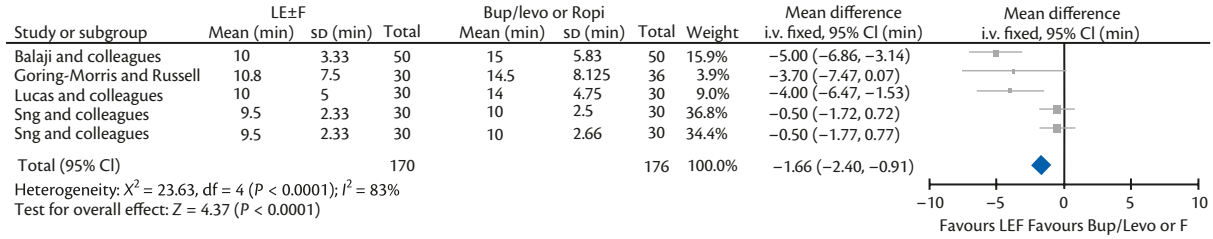

**Figure 21.2** The onset time of a block suitable to allow surgery, comparing LE+F (2% lidocaine, epinephrine, and fentanyl) top-up solutions with either Bup/Levo (0.5% bupivacaine, 0.5% levobupivacaine), or Ropi (0.75% ropivacaine) solutions.

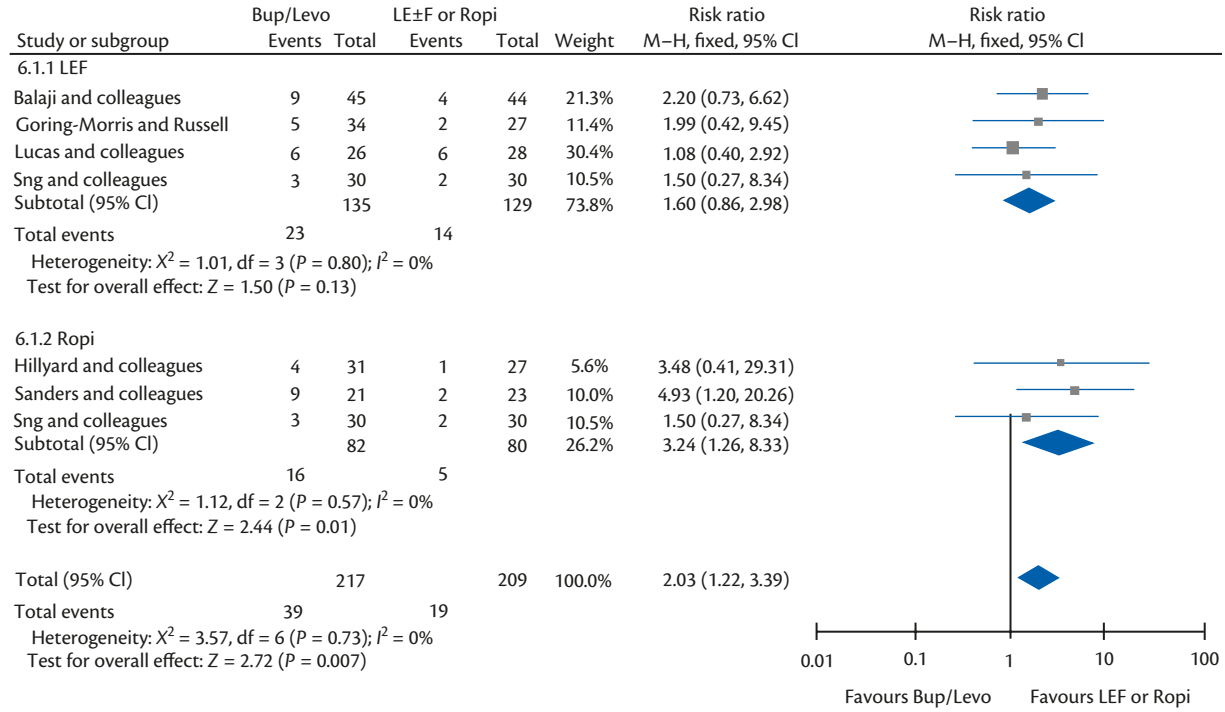

**Figure 21.3** The need for intraoperative supplementation, comparing Bup/Levo (0.5% bupivacaine or 0.5% levobupivacaine) top-up solutions to LE+F (2% lidocaine, epinephrine, and fentanyl), or Ropi (0.75% ropivacaine) solutions.

Hillyard S *et al.*, Extending epidural analgesia for emergency Caesarean section: a meta-analysis. *British Journal of Anaesthesia*, 2011 volume 107, issue 5, pp. 668–78, by permission of Oxford University Press.

2-chloroprocaine has also been implicated in the antagonism of opioid receptors, resulting in a decreased duration of epidural morphine analgesia following CD.[38] Finally, although it is licensed for use in anaesthesia for short surgical procedures in parts of Europe, 2-chloroprocaine is not currently licensed in some countries, such as the United Kingdom.

As well as the type of LA solution used for epidural anaesthesia, it is also worth considering ways in which LA solutions may be modified to enhance desirable characteristics.

## Opioids

The addition of a lipophilic opioid to epidural LA solution has been demonstrated to decrease the likelihood of pain during elective surgery.[39] However, this has not been supported by the meta-analysis of epidural anaesthesia for emergency CD, by Hillyard et al.[28] Although the addition of 50–75 mcg of fentanyl to the LA solution decreased the mean onset time to anaesthesia by 2 minutes, no difference in intraoperative supplementation was seen. The authors suggested that the difference observed in emergency situations may be due to the fact that opioids used in labour analgesic LA solutions may have already produced a near-maximal effect. However, these findings were generated from pooling only two trials with conflicting results.

Unlike other countries where it is not available commercially, most obstetric units in the United Kingdom use diamorphine as the opioid of choice for neuraxial anaesthesia. Indeed, the National Institute of Health and Care Excellence (NICE) has made the evidence-based recommendation that women should be offered intrathecal or epidural diamorphine, in order to reduce the need for postoperative supplemental analgesia.[40] Caranza et al. showed that administration of 3 mg epidural diamorphine at the end of CD, followed by a further 3 mg bolus at the first request for supplemental analgesia, supplied equivalent post-caesarean analgesia to 0.2 mg intrathecal morphine.[41] Hallworth et al. found that 0.25 mg diamorphine produced the same duration and quality of postoperative analgesia as 5 mg epidural diamorphine.[42] The NICE guidance recommends 0.3–0.4 mg intrathecal or 2.5–5 mg epidural diamorphine as suitable doses.[40] However, the guidance does not make any reference to the dose required to reduce intraoperative pain. In a dose finding study of women undergoing elective CD under CSE using an intrathecal dose of 0.5% 12.5 mg hyperbaric bupivacaine and diamorphine, the effective dose in 95% of subjects ($ED_{95}$) of diamorphine required to prevent intraoperative supplementation was 0.39 mg.[43] Although the time until the first request for supplemental postoperative analgesia increased with higher doses, so did the incidence of nausea, vomiting, and pruritus.

## Alkalinization

A further limitation of the meta-analysis by Hillyard et al.[28] is that it did not consider the use of alkalinizing agents in epidural top-up solutions. LAs are weak bases. Therefore, an increase in pH would increase the extraneural amount of the lipophilic, unionized form of the LA, which diffuses through the nerve cell membrane to block nerve impulses. Since the addition of sodium bicarbonate has been found to potentiate the effect of LA on peripheral nerves *in vitro*,[44] alkalinization of LA may enhance the depth of epidural anaesthesia. The addition of 2 mL 8.4% sodium bicarbonate to either 2% lidocaine alone,[45] or in combination with 0.5% bupivacaine,[46] has been shown to significantly speed up the onset of

action, and improve pain threshold and density of motor block. Furthermore, Allam et al. compared pH-adjusted 1.8% lidocaine and 1 in 200,000 epinephrine to 0.5% levobupivacaine for conversion of epidurals for emergency CD.[47] The authors found that the median onset of a block to touch to T5 was reduced from 14 minutes with levobupivacaine, to 7 minutes with the pH-adjusted lidocaine/epinephrine solution.

### Temperature

Similar to alkalinization, warming LA increases the proportion of uncharged molecules available to cross the neural cell membrane. The use of epidural LA solution warmed to body temperature (37–38°C) has been demonstrated to produce a more rapid onset of anaesthesia for elective CD,[48] and faster onset and improved visual analogue scores in epidural labour analgesia.[49] However, currently this practice would involve storing LA outside the conditions recommended by manufacturers, which many clinicians may be reluctant to do.

### Single solutions versus multiple drug mixtures

Although the addition of drugs, such as epinephrine and sodium bicarbonate, speed up the onset of epidural anaesthesia, there are concerns over the time delays that may result from drug mixing. Lucas et al. compared the time taken to prepare three solutions commonly used for epidural top-up in CD: (a) 0.5% bupivacaine 20 mL, (b) 2% lidocaine 20 mL with 1:200,000 epinephrine, and (c) 0.5% bupivacaine 10 mL and 2% lidocaine 10 mL with 1:200,000 epinephrine and 8.4% sodium bicarbonate 2 mL.[50] They found that preparing bupivacaine by itself took half the time required for lidocaine/epinephrine, which in turn took half the time needed to prepare the bupivacaine/lidocaine/epinephrine/bicarbonate solution. The increased time required to prepare complex solutions led the authors to conclude that if they were prepared immediately before administration, any reduction in onset time may be offset by the additional preparation time. Additionally, the speed of onset is most important in the context of fetal distress. It may be argued that there is increased potential for drug errors when mixing complex solutions in stressful, emergency situations, when compared to single-solution LA.

Some anaesthetists may prepare epidural top-up solutions in advance, in order to minimize delays and potential errors when mixing multiple drugs. The solutions are then often stored for up to 24 hours before use. Robinson et al. investigated the stability of pH-adjusted solutions containing bupivacaine, lidocaine, and epinephrine, which had been stored at room temperature for 24 hours.[51] They found that epinephrine was chemically unstable in solutions which had been alkalinized with sodium bicarbonate, but concentrations did not change in non-alkalinized solutions. Additionally, although none of the solutions demonstrated a decrease in LA concentration, the pH in all the solutions decreased with storage at room temperature. In a subsequent study, Tuleu et al. found that the epinephrine concentration in a pH-adjusted lidocaine–epinephrine solution fell by 30% after 6 hours of storage at room temperature, unprotected from light.[52] It has therefore been concluded that epinephrine should not be used with pH-adjusted solutions of LA that are to be stored, but should be added immediately before administration.[51]

Concerns also exist over the use of preservative-containing drugs within the epidural solutions. Epinephrine is sensitive to oxidative degradation and is combined with sulphites, which are preferentially oxidized, to prolong its shelf-life.[52] Sulphite preservatives have also been implicated in various reports of chronic adhesive arachnoiditis (CAA; a progressive inflammation of the arachnoid mater) after administration into the epidural space.[53,54] However, in the context of epidural anaesthesia, epinephrine is usually diluted as a dose of either 0.1 mL of 1 in 1000, or 1 mL of 1 in 10,000, in 20 mL LA solution. Additionally, the exact relationship between neuraxial sulphites and CAA remains unclear, with reports of intrathecal sulphite administration resulting in no neurological complications.[55] Alkalinization of LA solution is normally performed using 8.4% sodium bicarbonate. This is done using preservative-free solutions, as there is also a worry of neurological injury related to EDTA within alternative preparations of sodium bicarbonate.[56]

Although the risk of neurotoxicity related to neuraxial preservatives is uncertain, it would appear a sensible precaution to avoid the use of preservative-containing drugs with epidural LA solutions. If preservative-containing drugs must be administered (as in the case of epinephrine), maximal dilution of the drug should be used.

In summary, although there is no single LA solution of choice for minimizing the risk of failed epidural anaesthesia, the evidence suggests that bupivacaine or levobupivacaine 0.5% has a slower onset of anaesthesia and lower quality of block, compared to lidocaine with epinephrine or ropivacaine. Ropivacaine 0.75% may offer the lowest risk of intraoperative supplementation, whilst 2% lignocaine with epinephrine produces the fastest onset of anaesthesia. Chloroprocaine may be considered in situations where rapid conversion of epidural analgesia to anaesthesia is required, although concerns over neurotoxicity, opioid antagonism, and availability may limit its use. Lipophilic opioids, such as fentanyl, may be considered to speed the onset of anaesthesia, whilst alkalization with preservative-free 8.4% sodium bicarbonate may also be employed to enhance onset and quality of anaesthesia. Warming LA solution may increase the speed of onset.

## Spinal anaesthesia

When considering the management of failed spinal anaesthesia for CD, the first step must be to consider the causes, and therefore ways to minimize the risk of pre- or intraoperative anaesthetic failure.

### Causes of inadequate spinal anaesthesia

The causes of inadequate or failed spinal anaesthesia are not always clear. In a review of mechanisms of failed spinal anaesthesia, Fettes et al. described five phases of an individual intrathecal anaesthetic.[57] Each phase contains a variety of factors which might render the intrathecal anaesthetic inadequate (Box 21.2).[57]

Assuming lumbar puncture is adequately performed, a major determinate of successful intrathecal anaesthesia is the choice of an effective dose of anaesthetic. Although, it is important to appreciate that within the clinical range normally used, changes of dose have small effect on the spread of the block, but a more significant association on the duration of anaesthesia.[58]

### Local anaesthetic dose for spinal anaesthesia

The choice of LA dose administered can be represented by the proportion of the population where a given effect is produced.

Common descriptions of this include the effective dose in 50% and 90% of the population ($ED_{50}$ and $ED_{90}$).

Carvalho et al.[59] found the $ED_{50}$ and $ED_{90}$ values for intrathecal 'isobaric' bupivacaine (actually hypobaric in relation to cerebrospinal fluid) with fentanyl and morphine were 7.25 and 13.0 mg, respectively, for overall anaesthetic success. Success was defined as a bilateral T6 sensory block to pinprick within 10 minutes, and no additional epidural intraoperative supplementation. Using a similar methodology, the same group also found that the equivalent values for hyperbaric bupivacaine with fentanyl and morphine were 7.6 and 11.2 mg, respectively.[60] In a study using levobupivacaine with sufentanil and morphine, the $ED_{50}$ and $ED_{90}$ values for operative success (defined as T6 sensory block to pinprick, and no epidural supplementation intraoperatively) were 6.2 and 12.9 mg, respectively.[61] A number of studies that have examined dosing for intrathecal anaesthesia have found little correlation between successful induction of anaesthesia (i.e. establishment of a given sensory level by a predetermined time) and operative success. This would further support the suggestion that an intrathecal dose may have a greater effect on the duration of anaesthesia, and so an adequate block at incision is not always indicative of operative success.

However, the doses stated above may be considered by some to be unnecessarily high. It has been argued that although the primary goal of intrathecal anaesthesia is to allow a painless CD to take place, this should be done while also avoiding maternal and neonatal side effects. The use of lower doses in spinal anaesthesia aims to decrease maternal hypotension, nausea, and vomiting, allow earlier discharge from post-anaesthesia care units, and improve maternal satisfaction.[62] On the other hand, this approach may also increase the risk of failed anaesthesia, increase the need for intraoperative supplementation, or conversion to GA.

A systematic review and meta-analysis by Arzola and Wieczorek,[63] compared the efficacy of 'low'-dose spinal bupivacaine with 'conventional' dose for CD. The authors defined a 'low' dose as 8 mg of bupivacaine or less, whilst a 'conventional' dose was greater than 8 mg. They found that low-dose spinal anaesthesia was associated with a lower risk of hypotension (relative risk (RR) = 0.78) and nausea/vomiting (RR = 0.71), but a significantly higher need for intraoperative analgesic supplementation (RR = 3.76). Additionally, the only cases where conversion to GA were required occurred in two out of 21 participants in the low-dose group.

The ideal dose of intrathecal LA for CD is a balance between the need to avoid patient discomfort, and to minimize maternal side effects. If successful operative anaesthesia is the primary goal, it is advisable to consider the use of 'conventional' dose anaesthetic techniques, complemented by strategies to minimize maternal side effects. If low-dose spinal anaesthesia is used, it would be better to do this as part of a CSE technique.[64,65]

**Box 21.2** Causes of inadequate spinal anaesthesia

**Failed lumbar puncture**

- Positioning: maximal separation of lumbar laminae and spines by flexion of whole spine, hips, and knees
- Needle insertion: knowledge of spinal anatomy and landmarks; adequate insertion level and angle
- Pseudo-successful lumbar puncture: aspiration of injected LA solution after failed epidural top-up; congenital arachnoid cysts (Tarlov cysts).

**Errors in preparation and injection of solution**

- Dose selection
- Loss of injectate: leakage from the syringe–hub interface
- Misplaced injection, for example, into epidural space.

**Inadequate spread of drugs in cerebrospinal fluid**

- Anatomical abnormalities: curvature abnormalities; spinal stenosis; previous vertebral canal surgery; intrathecal chemotherapy
- Solution density.

**Failure of drug action**

- Errors in identification of LA
- Chemical incompatibility
- Inactive LA solution
- LA resistance: very rare, reports tend to be anecdotal.

**Failure of subsequent management**

- Testing block
- Catheter and combined techniques.

## Testing the adequacy of neuraxial blockade prior to operative delivery

Checking to ensure adequacy of a neuraxial block prior to surgery must be considered gold standard practice within obstetric anaesthesia. However, methods of assessment vary widely. Historically, some anaesthetists have used a technique of ensuring that the right dose of drug is injected in to the right place with complete confidence.[66] The assessment of sensory block has more recently been variably assessed by loss of pinprick,[59,61,50] cold,[46] and light touch sensation.[67]

In a prospective observational study, Russell examined the difference in level of analgesia (defined as loss of sharp pinprick sensation) and anaesthesia (loss of touch sensation), and the relationship between the level of anaesthesia and occurrence of pain in women undergoing CD under NA without opioids.[68] He found that the levels of analgesia at delivery that were associated with pain varied from T1 to T9, and that the corresponding range of anaesthesia was T4 to T10. Of the women who experienced pain, 25% had a level of analgesia at T3–T4. No women that experienced pain had a level of anaesthesia above T5. He concluded that assessing readiness for surgery by testing level of analgesia (i.e. loss of

pinprick sensation) may be misleading, and that in the absence of neuraxial opioid, a level of anaesthesia up to and including T5 is required to prevent intraoperative pain. In a subsequent study, Russell assessed pinprick, cold, and touch modalities in 102 women undergoing CD under spinal anaesthesia including intrathecal diamorphine.[69] The findings indicated that there was a median difference of approximately two dermatomes between the level of block by pinprick or cold, and touch, and that there was no constant relationship between these levels of block. Additionally, using 100 mcg/mL diamorphine in 0.5% bupivacaine, no patient experienced intraoperative pain when anaesthesia provided a loss of touch sensation including T6 or above.

In a study of sensory testing and variability for spinal anaesthesia, Kocarev et al. compared cold (ethyl chloride), sharp (calibrated Neuropen®), pressure (standardized monofilament), and light touch (Neuropen® stroking, monofilament stroking, and cotton wool).[70] The median differences between the four modalities were significant, while multiple comparisons of medians showed no significant difference between the tests of light touch. The authors also noted the cost of each method of testing. When cost was also factored into the evaluation, they suggested that testing light touch with cotton wool appeared to be the cheapest method of testing. Additionally, as well as being more expensive, ethyl chloride spray, Neurotip® and monofilament use did not appear to offer any advantages. The distributions of data for each sensory test are displayed as violin plots (Figure 21.4). These show the least dermatomal spread in the tests with least variability, such as the tests of light touch. Additionally, tests that stimulate more than one sensory modality are represented by a bimodal distribution. This can be observed in the violin plot of cold sensation. Ethyl chloride spray causes stimulation which is conducted by cold-specific Aδ fibres. However, nociceptor C fibres may participate in the transmission of painful cold sensation, while the contact of the spray with skin would illicit stimulation via Aβ fibres.

There are currently no formal guidelines for the assessment of NA prior to CD. The available evidence has led to some expert opinion suggesting that intraoperative failure of NA in the absence of an assessed loss of touch sensation may result in difficulties for the anaesthetist, if litigation were to be pursued.[71] However, it should be considered that clinical conduct may not mirror expert opinion in this matter. A national survey of obstetric anaesthesia practice in the United Kingdom demonstrated that only 60% of all respondents assessed light touch prior to starting surgery, compared to 92% who assess cold.[72] Where only a single sensory modality was assessed, this went down to 26% for light touch and 69% for cold. Furthermore, only 26% of respondents ensured a block to light touch up to T5 prior to delivery. If this is to be considered the requirement to reduce the risk of intraoperative pain, it seems inconceivable that 74% of obstetric anaesthetists in the United Kingdom expose their patients to NA which may result in painful CD. The difference between the evidence and the practice may be explained by the variable course of visceral pain fibres to the upper thoracic cord, and may be why a patient with an apparently 'low' block experiences no intraoperative discomfort.[73] Alternatively, it may be that although the anaesthetist is targeting a particular level of block, they may actually inadvertently be achieving a higher level. This may be because the level of anaesthesia has continued to ascend between testing, and when

the procedure begins, or due to variability or inaccuracies with the actual assessment of the block.

Congreve et al. found in a survey of anaesthetists that identification of the T5 dermatomal level showed marked inaccuracy.[74] Of the 73 anaesthetists surveyed, only 63% identified the dermatome correctly on an anatomical picture. There is also a marked variability when considering the true upper level of NA. In a study of his practice, compared to anaesthetic trainees, Yentis found that he consistently recorded higher levels of anaesthesia compared to the trainees, for the same block.[75] The differences were explained by the fact that most trainees recorded the level of anaesthesia to be where the patient first experienced any sensation from the cold or light touch stimulus. It was argued that the true upper level of anaesthesia should actually be where sensory perception returns completely to normal. Finally, it is clear that in describing NA nomenclature may also vary. Where one anaesthetist may consider the perception of sensation at T4 to be 'a block to T4', another may refer to this as 'the upper level of block being T5'.[76]

In summary, there remains much debate as to what should be considered the gold standard for adequate NA for CD. The variable nature of the assessment of neuraxial blocks, along with the differences between expert opinion and actual clinical practice, makes the evaluation of evidence difficult. Until the presentation of high-quality prospective evidence to the contrary, it might be simpler to follow the suggestion that a documented block up to and including T5 to light touch may be the best way to avoid intraoperative pain during CD. On the other hand, due to the inconsistencies and difficulties with the assessment of light touch, particularly concerning what constitutes a complete absence of touch, compared to other modalities, anaesthetists may choose to vary their method of testing according to their own clinical experience. Either way, care should be taken when checking the block to ensure the assessment is performed with an adequate and consistent degree of accuracy. Whatever modality is chosen it is important to record the first dermatomal level where initial

change in that modality occurs and the dermatomal level in which complete absence of sensation of that modality occurs.

## Managing inadequate neuraxial anaesthesia

Although very few formal, evidence-based guidelines exist for the management of inadequate NA in obstetrics, it is clear that management depends on the clinical context of the situation. Decision-making should take into account when inadequacy of NA is recognized in relation to the beginning of surgery, and to delivery. Additionally, consideration must be given to how urgently delivery needs to occur. Because of the numerous factors affecting the decision-making process, as well as concerns for maternal and fetal well-being, recognition of inadequate NA can prove to be a particularly stressful time for the anaesthetists, but is one which necessitates rapid formulation of a clear plan of management.

### Before the start of surgery

Neuraxial anaesthetic techniques for CD can take the form of a single-shot spinal, CSE, epidural top-up, or rarely a *de novo* epidural. However, when NA has been identified as being inadequate before the start of surgery, this is broadly a failure of either spinal or epidural anaesthesia. A decision must then be made regarding whether there is sufficient time to attempt an alternative NA technique (Figure 21.5). This usually means the use of spinal anaesthesia after a previously failed spinal, or after a failed epidural top-up. A CSE may be of particular benefit in this situation, as it allows reduction of the spinal dose administered in order to manage the apparent increased risk of a high spinal block. The epidural catheter can therefore be used if the spinal component proves to be inadequate. If it is not possible to provide alternate NA, GA must be provided.

The use of spinal anaesthesia after failed epidural anaesthesia is a controversial issue. Case reports describe spinal administration of LA after failed epidural anaesthesia resulting in an unintentionally high spinal block, and the need for emergency intubation and ventilation.[77,78] The apparent unpredictable nature of spinal anaesthesia after epidural injection has even lead to some suggesting that 'the rule should be to avoid spinal anaesthesia in pregnant women who already have an epidural block or in whom an epidural block has been attempted'.[79] However, some institutions routinely perform spinal anaesthesia after inadequate epidural block, and have reported low complication rates when using both reduced,[80] and normal doses of spinal LA.[81] The role of spinal anaesthesia after failed epidural injection remain unclear, as does the spinal dose that should be used to avoid unintended high blocks. The use of a low-dose spinal component of a CSE technique with the fallback of the epidural should the block still be too low, is valuable in this situation.

There have been many hypotheses to explain the possible risk of high block.[82] The most commonly cited, and most intuitive, is that there is expansion of the dural sac by the epidural injection of LA, which causes compression of the intrathecal compartment, and results in greater spread of spinal anaesthetic. Alternative theories include leakage of epidural LA into the intrathecal space via the dural puncture, uncovering of subclinical epidural anaesthesia by the spinal dose, or incremental continuing spread of intrathecal LA.

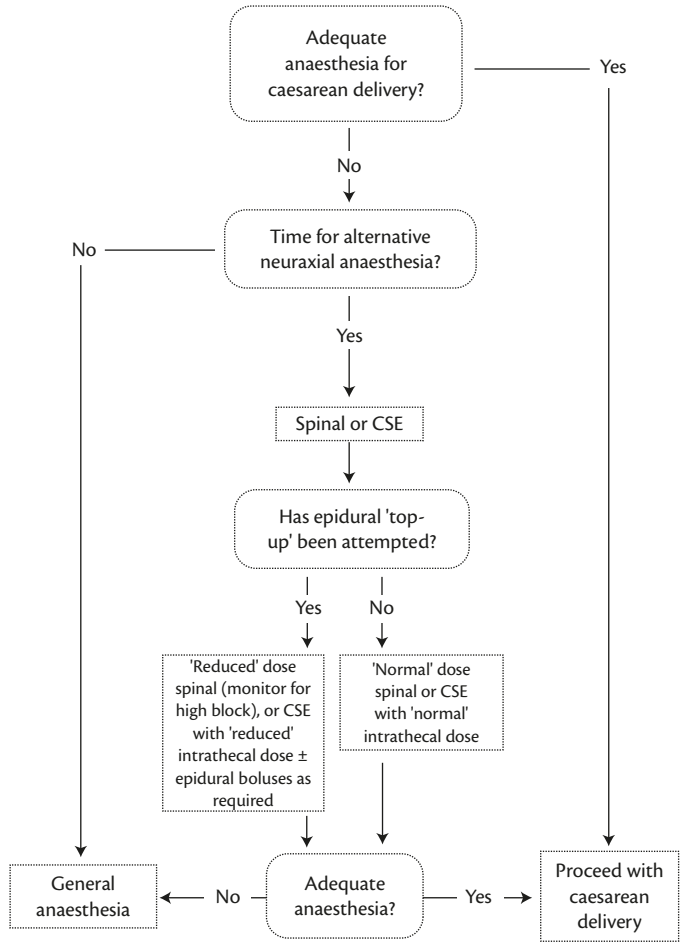

**Figure 21.5** Management of inadequate neuraxial anaesthesia before the start of surgery.

Advocates of a reduced spinal dose (typically a reduction of 20–30%)[80] after failed epidural anaesthesia cite the fact that epidural volume extension (EVE) has been demonstrated in both pregnant[83] and non-pregnant[84] patients to cause a median dermatomal level rise. Since EVE acts as a volume effect in reverse (i.e. spinal, then epidural), it seems reasonable that compression of the dural sac preceding a normal dose of spinal LA might result in a high block. However, some studies have questioned the effect of EVE on LA sparing[85] and level of sensory block.[86] This has led to those in favour of normal spinal doses arguing that there is a lack of prospective, randomized evidence, and that reducing the dose of spinal LA exposes the patient to the risk of a second inadequate block, the risks of a second procedure, and possibly of a subsequent GA.

At a national obstetric anaesthetic conference, having heard the arguments for and against reduced spinal doses after failed epidural anaesthesia, 60% of delegates voted for the use of normal spinal doses.[81] It would therefore seem reasonable to perform a normal dose of spinal when an epidural has failed prior to surgery. However, if a normal spinal dose is to be used, care must be taken to minimize high spinal effects, with the careful use of positioning (head-up after the desired block level reached), intravenous (IV) fluid, and vasopressors in order to reduce maternal and fetal risk.

The use of repeat spinal LA after failed spinal anaesthesia appears far less controversial, which may be due to the differing causes of failure in spinal anaesthesia, compared to epidurals. Whilst there are isolated case reports of repeat spinals with 'normal' doses being successfully used,[87] a retrospective study of 1197 women undergoing CD under spinal, using 12 mg 0.5% heavy bupivacaine, found that there was a failure rate of 1.5%.[88] When spinal anaesthesia was repeated in these women, using 9 mg of the same LA, 33% experienced either hypotension, bradycardia, or both. Additionally, 5.5% of women experienced a 'high block', whilst the failure rate for the second spinal injection was also 5.5%.

The dosing for spinal anaesthesia after either failure of previous NA remains a balance between the need to provide adequate anaesthesia, and therefore avoid the need for an additional GA, and the need to avoid potentially life-threatening complications to either maternal or fetal health. An alternative, if time allows, may be to use a CSE. This allows a lower dose of spinal to be injected, in order to avoid excessive hypotension or high block, but also the relative security of an epidural catheter, so that further epidural LA may be given if required to pre-empt, or in response to intraoperative discomfort.

## Intraoperatively: before delivery

Once surgery has been commenced, management of inadequate NA has classically been divided into those measures that can be undertaken prior to delivery, and those that are undertaken after delivery. One reason for this could be concern that some interventions may result in a delay in delivery of the fetus (e.g. obtaining, drawing up, and titrating IV analgesia). In situations of an emergency CD, this may add to fetal morbidity and mortality. A more probable reason for the restricted range of management options available to anaesthetists before delivery may be concerns over unintentional neonatal side effects from maternal drug administration (Figure 21.6).

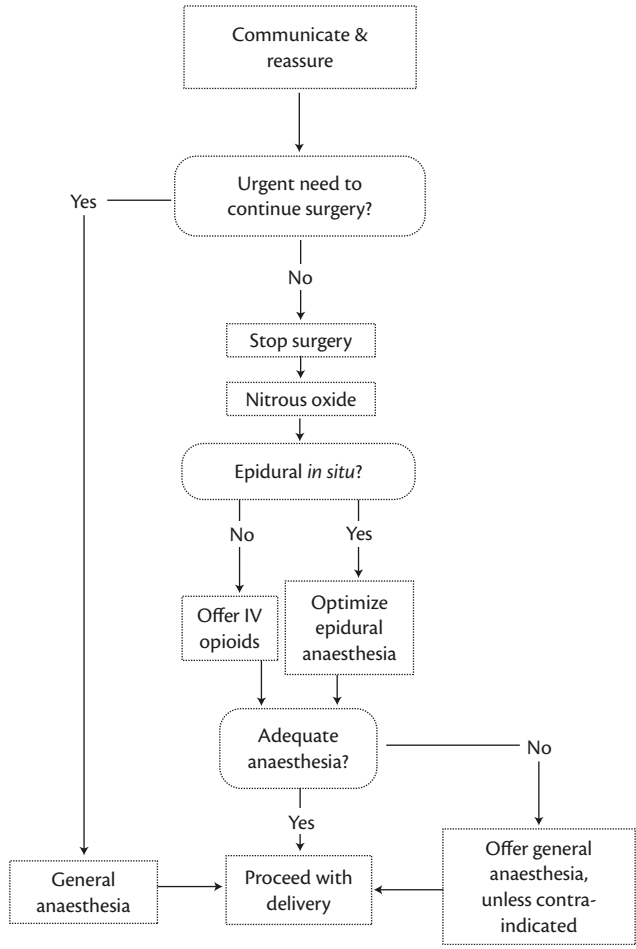

**Figure 21.6** Management of inadequate neuraxial anaesthesia before delivery. With permission of Sunderland Royal Hospital.

Extrapolating from the use of IV opioids in labour, it is clear that the use of IV fentanyl-based patient-controlled analgesia (PCA) during labour can result in lower Apgar scores at 1 minute, and increased rates of naloxone use and active resuscitation.[89] However, it may not be altogether accurate to base operative management on labour data. Firstly, the overall dose of IV fentanyl used (940 mcg) is far higher than would be expected to be used for operative supplementation. Furthermore, although active resuscitation and naloxone were more commonly used, this may just be a product of bias on the part of the unblinded clinicians that were caring for the neonates. And finally, although Apgar scores at 1 minute were significantly different, the effect was short lived, and not present at 5 minutes.

Looking specifically at the use of IV opioid analgesia intraoperatively, data is conflicting. Studies comparing the effects of IV and intrathecal sufentanil[90] and fentanyl[91] found no differences in Apgar scores where opioids were administered intravenously, compared to controls. Indeed, in a study designed to assess the safety of premedication doses of IV midazolam with fentanyl in women having elective CD, there were no significant differences in Apgar scores, arterial cord blood gases, nor newborn neurobehavioural scores compared to controls receiving saline.[92] However, the use of the ultra-short-acting opioid, remifentanil, during elective CD under GA, has been associated with significantly lower Apgar scores at 1 and 5 minutes, and lower umbilical vein pH (although this remained within the normal range).[93] Alfentanil may allow a better compromise between the depth of analgesia and length of action, compared to other IV opioids. An *in vitro* study of alfentanil pharmacokinetics suggested that it is rapidly transferred across the human placenta, with transfer occurring within 5 minutes and peaking at approximately 30 minutes.[94] However, alfentanil did not accumulate in placental tissue, and was readily washed out. Purdie et al. assessed the use and safety of an alfentanil PCA device to relieve visceral pain during elective CD.[95] There were similar incidences of sedation and nausea and respiratory changes between the PCA users and the non-PCA users. Only 2 out of 24 women used the PCA before cord clamping. However, in this small group, the Apgar scores and umbilical venous pH were similar to those observed in all the neonates.

Considering the conflicting evidence regarding neonatal side effects, it would seem sensible to attempt to avoid IV supplementation with either opioid analgesia or anxiolytics, such as midazolam, before umbilical cord clamping. If pre-delivery supplementation is to be used, short-acting opioids should be considered, and the personnel and equipment required to perform neonatal resuscitation should be immediately on hand.

Avoiding IV supplementation before delivery leaves a limited number of options available in the event of inadequate NA.

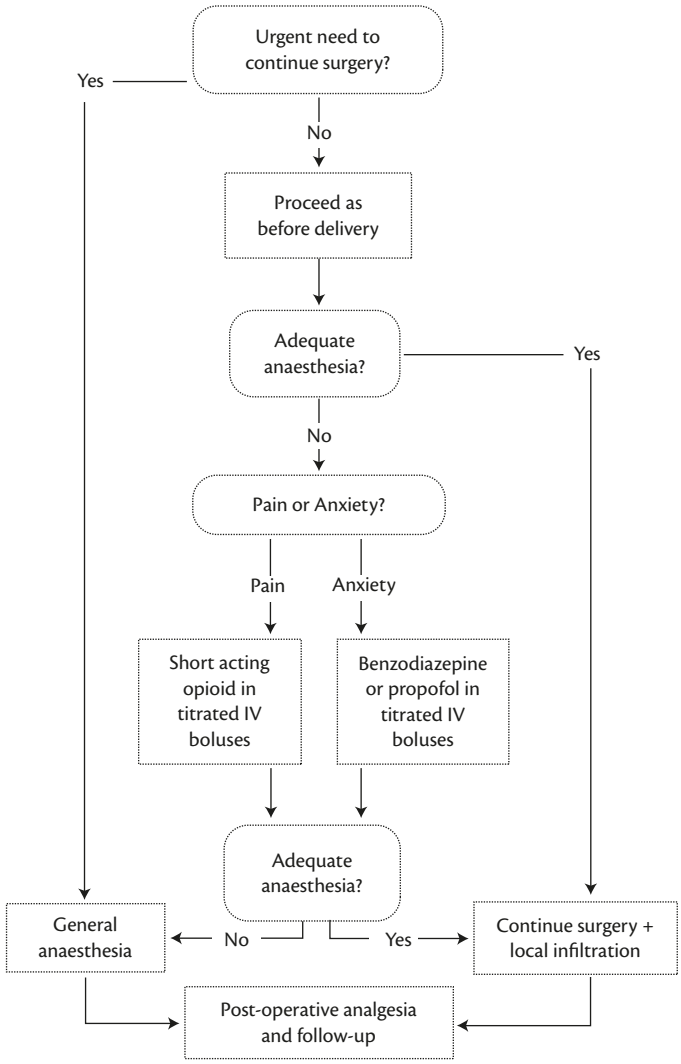

**Figure 21.7** Management of inadequate neuraxial anaesthesia after delivery.

Importantly, a clear pre- and intraoperative explanation of the causes of any residual sensation may reassure some patients.[96] Not only might this help recruit the birth partner to distract the woman from the sensations, but also may allow discussion of a management plan that is acceptable to both the patient and clinician. Some authors recommend playing music in the background, to help relaxation and distraction.[97] However, a review of the use of music during CD found that the magnitude of improvement in maternal heart rate and satisfaction scores were low, and that the methodological quality of some studies were questionable.[98] It would therefore appear wise not to rely on musical distraction as the sole means of managing inadequate NA.

Fifty per cent nitrous oxide has long been used for labour analgesia,[99,100] and its anaesthetic-sparing effects during CD under GA.[101] Its use in situations of inadequate NA therefore seems intuitive, due to its easy availability on anaesthetic machines, the ease of administration, and the familiarity that most pregnant women have with it. However, nitrous oxide use is not without its disadvantages. Acute side effects that may be experienced include dose-dependent depression in ventilatory function and control of upper airway patency, dysphoria, and vomiting. Additionally, although it can be effective in minor procedures, it is generally less effective in severely painful procedures.[102] As a result, the use of nitrous oxide should only be considered a short-term solution, allowing time for either GA to be induced, or delivery of the fetus followed by a more definitive form of management.

Every effort should also be made to optimize pre-existing epidural anaesthesia, if a catheter has been maintained *in situ*. The use of faster-acting LA, such as 2% lidocaine with 1 in 200,000 epinephrine, and epidural opioids are ideal, although care must be taken to avoid administering doses above the upper safe limit. Furthermore, unless there is a specific contraindication to GA, this option should always be discussed with the patient, regardless of when the NA has become inadequate, along with the risks and benefits in the specific situation.

## Intraoperatively: after delivery

If inadequate NA becomes apparent after delivery, more management options are generally available, as concerns over fetal transfer of drug are removed (Figure 21.7). Also, any concerns about the

need to rapidly deliver the baby have also been resolved. However, the approach to management should mirror what has already been described, namely reassurance, communication, the use of nitrous oxide as a temporary analgesic, optimization of epidural anaesthesia, if an epidural catheter is *in situ*, and consideration of GA. Where possible, surgery should be halted until definitive management of the inadequate anaesthesia has occurred. This is clearly not possible in emergent situations, such as maternal haemorrhage, where the transition to GA will need to be done rapidly, but safely.

In a retrospective case notes review of 2471 women undergoing CD under NA, Garry and Davies examined the causes and management of inadequate NA.[103] Sixty-five women received GA, whilst 175 required some form of supplementation at some point during the procedure. Common post-delivery causes of supplementation or conversion to GA included pain on uterine exteriorization, bleeding, and prolonged surgery. Types of supplementation included nitrous oxide, short-acting opioids such as alfentanil or fentanyl, nitrous oxide and opioids in combination, or alternatives such as morphine, ketamine, midazolam, or propofol. Only 13 of the patients requiring supplementation also received a GA. However, the review did not present data regarding maternal or fetal side effects of IV supplementation with opioids or anxiolytics, such as benzodiazepines.

In situations where pain is the main complaint, supplementary agents of choice should undoubtedly have an analgesic effect. Short-acting opioids, such as fentanyl or alfentanil, provide the balance between a rapid onset of action, ease of titration and avoidance of side effects, such as respiratory depression. Ketamine provides a good alternative to opioid analgesia for mild to moderate pain. Although little prospective evidence is available regarding the effectiveness of ketamine at supplementing intraoperatively inadequate NA, in combination with spinal bupivacaine, 0.15 mg/kg IV ketamine has been associated with significantly lower postoperative pain scores from 60 minutes, and reduced postoperative analgesia usage up to day 2.[104] However, ketamine use is also associated with unpleasant emergence phenomenon, which may be unacceptable to the patient. Additionally, ketamine should be avoided in patients with hypertension.

If pain is localized within the surgical field, supplementation of NA with local infiltration by the surgeon should also be considered. However, many obstetricians are untrained at administering local infiltration, and perform this rarely, due to the relative reliability of NA. Therefore, it is likely that infiltration will not be effective. Surgical administration of LA within the peritoneal cavity has also been advocated where peritoneal stimulation is the major source of discomfort.[105] If supplemental LA administration is considered, attention should be given to avoiding toxic doses, when combined with NA administered within the last 4 hours.

Exteriorization of the uterus was regularly done in the past but this is no longer advocated unless there is a definite surgical indication, for example, if there is a lateral tear to optimize surgical repair. Warning should be given by the surgeon as peritoneal tugging at this time will cause discomfort particularly if done under epidural top-up.

Garry and Davies found that a cause of conversion to GA or need for supplementation was maternal anxiety, or the dislike of paraesthesia associated with established NA.[103] In cases where anxiety is the primary cause of maternal distress, and is not associated with pain, an anxiolytic may be considered. Titrated dosing of a benzodiazepine, such as midazolam, is familiar to most anaesthetists, although some have suggested that diazepam may be superior to midazolam, as it produces less amnesia during the birth period.[104] Propofol, as an alternative anxiolytic, allows for a shorter duration of action, but at the expense of greater cardiovascular side effects. Care should be taken when administering such drugs, due to the risk of respiratory and cardiovascular depression, and the potential for central nervous depression, regurgitation, and aspiration. Furthermore, if maternal distress is associated with pain, analgesia or anaesthesia should be considered the solution, rather than anxiolysis.

When all possibilities in optimizing pre-existing NA and supplementation have been unsuccessful, the only remaining option should be GA. Where possible, induction should be preceded by clear communication with the patient, partner, and surgeons, a temporary halt of surgical manipulation, adequate antacid premedication, and pre-oxygenation prior to rapid sequence induction. Once anaesthesia has been induced, endotracheal intubation has been performed, and the patient is being adequately ventilated and anaesthetized, attention should be given to intra- and postoperative analgesia, as discussed in the chapters covering GA for CD (Chapter 22) and postoperative analgesia after CD (Chapter 24).

## Postoperative care

Undoubtedly, childbirth can be stressful for the parents, especially if unexpected events occur. In some cases, childbirth can be such a traumatic experience, as to precipitate, in extreme cases, post-traumatic stress disorder (PTSD). A survey of pain during labour, by Melzack,[106] found that 60% of primiparous, and 45% of multiparous women had severe or extremely severe pain during labour, whilst most reported that labour was the most intense pain they had ever experienced. A traumatic event, during which the patient feels threatened by death or serious injury, and has feelings of fear or helplessness, is the first diagnostic criteria of PTSD. It is therefore important for clinicians to be aware of when women perceive their experience of childbirth as traumatic, the risk factors for development of post-delivery complications, such as PTSD, and their impact within this.

A number of risk factors for the development of PTSD after child birth have been described. These include having a more negative experience than expected,[107] unplanned CD, obstetric or pregnancy complications,[108] and experiencing intense pain or distress during labour.[109] It is easy to see that any of these factors could be experienced during inadequate anaesthesia for CD. However, management of the spectrum from traumatic childbirth to PTSD is less well described, with limited evidence relating to the management of women with PTSD after childbirth. There is some consensus with non-childbirth-related literature that debriefing and counselling are inconclusively effective, whilst cognitive behavioural therapy may improve PTSD status.[110] That said, it has also been suggested that offering women an opportunity to discuss their experience and to differentiate this from a formal debrief, may also be appropriate.[111]

Considering all the above, it would seem reasonable to perform a postoperative visit to the patient, in the days following delivery. Not only does this give the anaesthetist a chance to review for complications of NA, but also allows an opportunity to explain

the possible reasons for, and the management of, the inadequate NA. Additionally, the patient will have the opportunity to gain answers to any questions that they may still have, in a more relaxed environment. Furthermore, arrangements can be made at this point, if further discussion is required regarding the childbirth experience. Documentation should also be meticulous, as this not only supplies a record of events for subsequent discussion of the experience, but also supplies the basis of a medicolegal defence, if required.

## Conclusion

NA is the preferred method of providing anaesthesia for CD. This has been primarily driven by the prominent role of GA in the morbidity and mortality related to anaesthesia in obstetrics. However, the effects of failed NA, both to the short- and long-term health of the woman, and also the medicolegal consequences, mean that clinicians need to have ways of predicting such situations. Careful choice of LA, neuraxial technique, and recognition of risk factors can reduce the risk of inadequate NA. Furthermore, if NA were to fail, clinicians need to have strategies for effective management of intraoperative pain or anxiety, whilst minimizing the risk to both the mother and newborn. Management options, such as repeating or attempting another neuraxial technique, IV analgesic, or conversion to GA could all be considered, depending on the individual situation.

# CHAPTER 22

# General anaesthesia for caesarean delivery

David M. Levy and Ieva Saule

## Introduction

In this chapter we shall review key aspects of the history of general anaesthesia (GA) and rapid sequence induction (RSI) for caesarean delivery (CD), and make comparisons with the latest concepts. The indications and contraindications to GA will be outlined and the following discussed: preoperative assessment, positioning, monitoring, intravenous (IV) access, preoxygenation, and airway management. Anaesthetic pharmacology will be summarized with a focus on neuromuscular blockade (NMB). Specific GA issues in the management of pre-eclampsia and haemorrhage will be detailed.

## History of rapid sequence induction

Inhalation anaesthesia by facemask was used until a technique of IV induction, NMB, and tracheal intubation for CD was described by Hamer Hodges et al. in 1959.[1] Compared with anaesthetic techniques in which women received trichloroethylene, cyclopropane, or diethyl ether, the regimen of thiopental, succinylcholine, and nitrous oxide/oxygen resulted in the shortest times to babies' sustained respiration and crying. Certain elements of contemporary RSI were absent: cricoid pressure wasn't applied (Sellick had yet to describe his manoeuvre) and there was a period of bag and mask ventilation between induction and intubation. The novel use of succinylcholine for CD was advocated on the grounds that its rapid maternal offset reduced the chance of neonatal curarization compared with the only two alternative neuromuscular blocking drugs, gallamine and tubocurarine. The notion that recovery from succinylcholine might conceivably be advantageous for the woman in the event of airway problems did not appear to have been considered.

The salient characteristics of RSI were set out by Stept and Safar in 1970:[2]

- Preoxygenation
- Predetermined doses of thiopental and succinylcholine
- Cricoid pressure
- Avoidance of ventilation by bag and mask
- Tracheal intubation.

It has been noted that the number of maternal deaths attributable to anaesthesia in the Confidential Enquiries into Maternal Deaths in the United Kingdom virtually doubled in the period corresponding to the widespread replacement of mask and ether by RSI in the early 1960s.[3] Scott highlighted the apparent increased incidence of death due to Mendelson's syndrome and failed intubation secondary to succinylcholine and RSI.[4]

A rigorous Canadian evidence-based clinical update has analysed, in non-obstetric practice, the components of RSI. No evidence was found for decreased incidence of aspiration with RSI—the primary reason for continuing to practise the technique.[5] Despite a conspicuous lack of supportive evidence, the technique is endorsed for CD by the UK National Institute for Health and Care Excellence (NICE).[6]

## Indications and contraindications to general anaesthesia

The most recent (2012) UK data from the Obstetric Anaesthetists' Association (OAA) National Obstetric Anaesthesia Database (http://www.oaa-anaes.ac.uk) revealed a median CD rate of 25.2% (range 13.4–51.3%). GA was induced in 10594 recorded cases (7.6% of CD), of which 43.1% represented conversions from neuraxial anaesthesia. These data are broadly in line with published surveys from elsewhere.

In the United Kingdom, the degree of urgency of CD is classified according to the presence of fetal or maternal compromise.[7] Category 1 denotes an immediate threat to life of woman or fetus. Category 2 indicates maternal or fetal compromise but no immediate threat to life. Category 3 describes a requirement for expedited delivery by CD in the absence of maternal or fetal compromise. Category 4 CD means that delivery can be planned to suit the woman and maternity services. The only absolute contraindication to GA is maternal refusal. GA is ideally avoided if there is predicted airway difficulty or malignant hyperthermia susceptibility. In morbid obesity, awake fibreoptic intubation can be considered (see Chapter 26 and Chapter 39). The UK Royal College of Anaesthetists has published a 'proposed standard or target for best practice'.[8] GA should be used in fewer than 5% of category 4 CD, and in fewer than 15% of Categories 1–3 combined. Fewer than half of category 1 CD should require GA. The most common indications for GA are listed in Box 22.1.

Placental abruption with significant haemorrhage is a contraindication to neuraxial anaesthesia on account of the very real risk of maternal cardiovascular collapse secondary to sympathetic blockade and not infrequent disseminated intravascular

**Box 22.1** Common indications for general anaesthesia in obstetrics

- Category 1 CD for women without a working labour epidural
- Contraindications to a neuraxial technique, for example:
  - lumbar spinal abnormality (e.g. instrumented fusion)
  - coagulopathy
  - hypovolaemia
  - local sepsis
  - cardiac disease (e.g. aortic stenosis) in which abrupt sympathetic blockade would risk decompensation
- Failed neuraxial technique: uncontrollable breakthrough pain at CD
- Maternal refusal of neuraxial technique.

coagulopathy. In contrast, *elective* CD for placenta praevia, when surgery is started with a normal circulating blood volume, is not necessarily a contraindication to a neuraxial block. It is important to plan for major haemorrhage and ensure large-gauge vascular access and availability of rapid infusion devices to keep up with blood loss and maintain intravascular volume. Homologous blood must be available in theatre and, ideally, the facility for intraoperative cell salvage provided.

Although traditionally regarded as an absolute indication for GA, umbilical cord prolapse does not mandate GA. Provided that the fetus is continuously monitored and signs of compromise are not observed, a labour epidural can be topped up or spinal anaesthesia instituted in a left-lateral position.

## Preparation for general anaesthesia

### Preoperative assessment

The conduct of maternal preoperative assessment differs in elective and emergency settings.

Women scheduled for elective CD should ideally be reviewed before the day of surgery either on a ward or pre-assessment suite. Past medical and anaesthetic history, drug allergies and intolerances, gestation, parity, and placental site should be noted. Careful assessment of the airway is essential. Antacid premedication should be prescribed (see 'Aspiration prophylaxis: antacids'). Recent blood antibody screen (to determine ABO and Rhesus D types and detect other red cell antibodies that could haemolyse transfused red cells) and availability of matched blood must be reviewed in association with recent maternal haemoglobin concentration and platelet count. Although NICE advises that pregnant women who are healthy and have uncomplicated pregnancies do not require routine grouping and saving of serum or cross-matching of blood before CD, confirmation of a recent 'group and save' remains routine practice in many units. However, cross-matched blood must be available for women with anaemia, coagulopathy, or abnormal placentation.[6] A preoperative visit should include full informed consent and explanation of the respective risks and benefits of RSI, blood transfusion, patient-controlled analgesia, rectal medication, and transversus abdominis plane (TAP) blocks if applicable.

In an emergency, there can be a significant time limitation and assessment is often necessarily brief and limited to the following:

- Co-morbidities and anaesthetic history
- Drug allergies
- Fasting status
- Airway assessment: a minimum assessment comprises evaluation of mouth opening, Mallampati score, mandibular protrusion, neck extension, and a check for loose dentition.
- Evaluation of haemodynamic status (pallor, heart rate, and blood pressure) and respiratory rate.

A swift explanation of the procedure is offered and verbal consent elicited. Translators should ideally be employed for foreign language speakers or women with hearing impairment. Use of family members to translate can lead to omission of important and sensitive clinical information.

### Consent

In the United Kingdom, for a woman to give valid consent she must have capacity, which is presumed unless there is an impairment of, or disturbance in, the functioning of her mind. Labour pain, opioid medication, or anxiety can diminish capacity. Women must be appropriately informed, and give consent voluntarily. Current practice in the United Kingdom entails discussion with the woman and provision of written information leaflets, but no separate written consent for anaesthesia. Information about anaesthesia should be offered well in advance of an elective procedure, before the preoperative meeting with the anaesthetist. New information should not be imparted after the woman has arrived in theatre.

In an emergency, the consent process is much more concise. In our experience, women will typically indicate just how much information they would like to receive. Risks will be explained and issues explored in detail only in response to an explicit request for more information. Risks and benefits discussed should be carefully documented. A pregnant woman with capacity can refuse any procedure, even if refusal jeopardizes her own life or that of the fetus. GA can be induced in a woman judged to lack capacity if it is deemed to be in her best interests (i.e. to save her life, but not that of the fetus). These issues are explored in detail in Chapter 29.

### Aspiration prophylaxis: antacids

Changes in gastrointestinal physiology in pregnancy have been reviewed in Chapter 2. The numerous factors that potentially increase the chances of pulmonary aspiration of gastric contents are summarized in Figure 22.1. Decreased lower oesophageal sphincter tone and increased intra-abdominal pressure secondary to the gravid uterus predispose to reflux in a majority of women. Although gastric emptying is not delayed in pregnancy, administration of opioids in labour causes gastric stasis. In Mendelson's classic series[9] published in 1946, nitrous oxide and ether anaesthesia by facemask for operative delivery was complicated by aspiration in 66 women from 44,016 maternities (0.15%) between 1932 and 1945. The only two deaths were from airway obstruction by solid, undigested food, in two of five women who aspirated solid

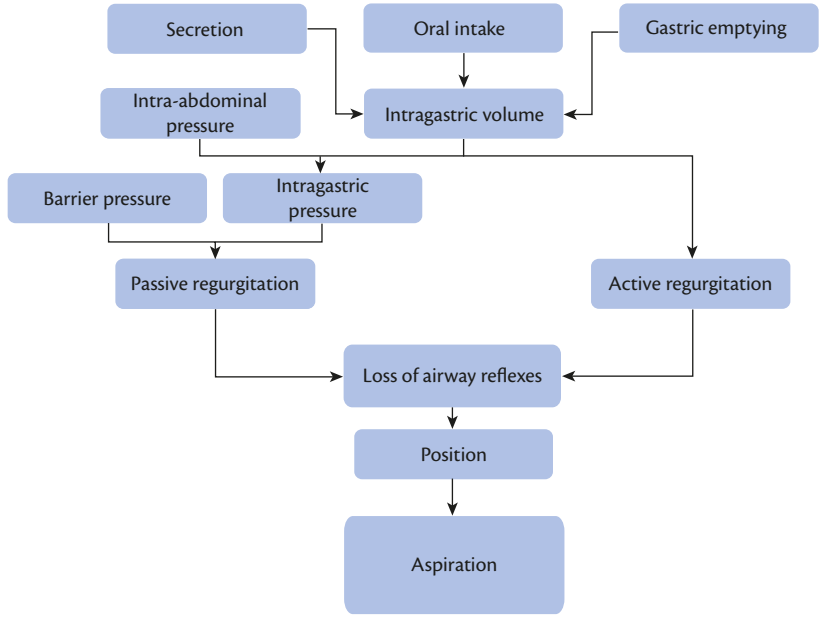

**Figure 22.1** Factors contributing to pulmonary aspiration of gastric contents.
Reproduced with permission from Dr James Eldridge.

material. In those who aspirated liquid, a syndrome of dyspnoea, cyanosis, and tachycardia was observed. Recovery after 24–36 hours was universal—many decades before respiratory intensive therapy became available. Respiratory failure secondary to aspiration pneumonitis during anaesthesia became synonymous with Mendelson's syndrome, and its prevention a cornerstone of anaesthetic practice.

Prolonged fasting is distressing and can affect maternal and fetal physiology adversely by causing dehydration and ketosis. In the United Kingdom, women are typically allowed to consume a low-residue diet during labour unless they have identifiable risk factors for CD, in which case ranitidine 150 mg should be prescribed 6-hourly. Recommended fasting times before elective surgery are *2 hours for fluid* and *6 hours for food*, although every pregnant woman from late in the second trimester is deemed to have a 'full' stomach, despite notional fasting times. The risk and potential severity of the consequences of aspiration are increased if emergency GA is required in a parturient who has recently consumed solid food. Emptying the stomach before induction of anaesthesia is extremely unpleasant and rarely practised in the United Kingdom. Most obstetric units in the United Kingdom administer non-particulate antacid such as 0.3 M sodium citrate (30 mL) before all GA CDs. Ranitidine is the $H_2$-receptor antagonist of choice in most UK hospitals and should be prescribed for 12 and 2 hours before the anticipated time of an elective operation. Proton pump inhibitors are acceptable alternative agents. A non-particulate antacid, $H_2$-receptor antagonist, and/or metoclopramide are recommended in practice guidelines published by the American Society of Anesthesiologists.[10]

The risk of aspiration is high not only during induction but also emergence from GA. The eighth report of the Confidential Enquiries into Maternal Deaths in the United Kingdom[11] has suggested that consideration should be given for a gentle 'in and out' insertion of a wide-bore orogastric tube before extubation in women with a known full stomach (e.g. recent ingestion of a meal).

### Location of induction

In the United Kingdom, most anaesthetic procedures are performed in an anaesthetic room—an area separate from but adjacent to the operating theatre. However, obstetric anaesthesia is an exception. GA should be induced in the operating theatre, to avoid the risks related to transporting and repositioning the woman. Monitoring will be uninterrupted, and the induction–delivery interval minimized. The woman's abdomen usually can be prepared and draped during preoxygenation. The anaesthetist can allow surgery to start as soon as the airway has been secured and ventilation of the lungs confirmed.

## Process of general anaesthesia

The key steps in RSI of GA for CD are detailed in Box 22.2. Waveform capnography, the most sensitive indicator of tracheal tube position, has arguably contributed most to maternal safety over the last 30 years by allowing identification of oesophageal intubation. Given that mean maternal arterial $CO_2$ tension is 3.87 (standard deviation ± 0.24) kPa at 38 weeks' gestation, end-tidal $CO_2$ should be maintained below 4 kPa in order to maintain the gradient for fetal $CO_2$ elimination.[12] It has been shown that 100% oxygen in the maintenance inspired anaesthetic gas mixture increases fetal oxygenation, although it remains uncertain whether clinical outcome for the neonate is improved. Isoprostane, generated during free radical oxidation of arachidonic acid in membrane phospholipids, is a highly specific marker for *in vivo* oxidative stress. No differences were found in isoprostane concentrations resulting from 30%, 50%, or 100% oxygen in equivalent minimum alveolar concentrations of sevoflurane and nitrous oxide during elective CD under GA.[13]

The WHO's patient safety culture should be adopted in every obstetric operating environment. Team briefing, sign in, time out, sign out, and debriefing should be observed. A locally adapted sign in/time out and sign out checklist should be articulated and completed before embarking upon every case (see Figure 20.2 in Chapter 20).

**Box 22.2** Key steps in rapid sequence induction of general anaesthesia for caesarean delivery

- WHO surgical safety checklist
- Left lateral table tilt to reduce aortocaval compression in association with (~25°) head-up ('reverse Trendelenburg') position to ensure stomach is below the level of the head
- Graduated compression stockings fitted, and (if used) pneumatic calf-compression system functional
- Large gauge IV access secured and patency verified
- Suction device immediately available and suction system working
- Physiological monitoring systems functioning
- Preoxygenation (denitrogenation)
- IV antimicrobial prophylaxis—ideally should be administered before skin incision
- IV induction of anaesthesia: precalculated doses of (traditionally) thiopental 7 mg/kg (maximum 500 mg) and succinylcholine (maximum 150 mg)
- Application of cricoid pressure (still taught to UK trainees) 10 N awake, increased to 30 N on loss of consciousness
- Intubation of the trachea with a cuffed tube, usually one size smaller than in the non-pregnant population (i.e. 7.0 mm internal diameter)
- Delivery of volatile agent (initially with overpressure) in nitrous oxide or air and oxygen
- Permission to obstetrician to start surgery
- After delivery: oxytocic agent, IV opioid, and antiemetic
- Emergence and tracheal extubation: woman positioned semi-recumbent/upright and awake

## Intravenous access

Large-gauge IV access (16 or 14 G) is desirable for all parturients undergoing CD, to allow rapid blood transfusion if required. In women at significant risk of major obstetric haemorrhage, *two* cannulae are required. In parturients with poor peripheral venous access (e.g. morbidly obese women or IV drug users), central venous access might be necessary. A Vascath™ or Swan–Ganz sheath (7 Fr) should be inserted under ultrasound guidance into an internal jugular vein if a woman's peripheral venous access is inadequate and there is a high risk of major haemorrhage. Use of the humeral intraosseous route (EZ-IO® driver, Vidacare, San Antonio, TX, USA) (see Chapter 35) has been described in obstetric haemorrhage.[14] Familiarity with the device is essential before an obstetric anaesthetist contemplates its use in an emergency.

## Positioning

When positioning a parturient on the operating table the anaesthetist must consider three key issues: avoidance of aortocaval compression, optimal conditions for securing the airway, and care of pressure points to avoid soft tissue and nerve damage.

### Aortocaval compression

Compression of the aorta and/or inferior vena cava by the pregnant uterus can lead to supine hypotension in the second half of pregnancy. A 15° lateral tilt of the theatre table is generally recommended to minimize maternal hypotension. A Cochrane review examined maternal position during CD and its effects on maternal and neonatal outcome. Most studies had very small numbers and authors concluded that there was limited evidence to support or disprove the value of left or right lateral tilt, head-up or head-down positions, or use of manual displacement of the uterus.[15] When applying operating table tilt the anaesthetist has to ensure that side supports are fitted and belts secure the parturient's legs to prevent the woman falling.

In the event of maternal cardiac arrest, UK Resuscitation Council adult life support guidelines[16] recommend manual uterine displacement combined with up to 30° left tilt of the operating table to provide optimal conditions for restoration of maternal cardiac output.

### Positioning for intubation

The incidence of difficult and failed intubation is higher in the obstetric as opposed to general population on account of pregnancy-induced soft tissue changes as well as the circumstances under which GA is often performed (see Box 26.3 in Chapter 26). Weight gain during pregnancy and development of airway oedema in labour or secondary to pre-eclampsia can alter airway anatomy. Changes in Mallampati score in labour and pregnancy are discussed in Chapter 26. Pregnancy-induced breast enlargement can make insertion of the laryngoscope particularly difficult; left lateral tilt and cricoid pressure complicate positioning for intubation.

The neck is extended at the atlanto-occipital joint until the external auditory meatus is in a horizontal plane with the sternal notch ('sniffing the morning air'). Ramping of shoulders and upper back by using folded blankets can help to align the neck to allow optimal laryngeal visualization (see Chapter 39 for further information and illustrations). In obese women, a reverse Trendelenburg position is all the more important in order to increase the functional residual capacity (FRC) and delay the onset of hypoxaemia after induction of anaesthesia. A number of devices and pillows such as the Oxford Head Elevating Laryngoscopy Pillow (HELP™, Alma Medical, Oxford) are available to assist with achieving the ramped position.

### Pressure points

Avoidance of soft tissue, nerve, and eye damage is as important as in any speciality. The eyes should be closed and the lids taped, with careful attention to ensure no wires or tubing are in contact. Soft tissues and nerves should be protected by padding and careful positioning. The arms should not be abducted beyond 90°; the ulnar nerve must be protected at the elbow.

## Monitoring

### Maternal monitoring

The following monitoring modalities are essential:

- Electrocardiogram (ECG)
- Non-invasive blood pressure (NIBP)

- Peripheral arterial oxygen saturation ($SpO_2$)
- Gas analysis: capnography/oxygraphy/vapour concentration
- Airway pressure
- Peripheral nerve stimulator.

Means of measuring temperature (e.g. oesophageal thermistor) must be available for a case in which major haemorrhage is anticipated.

Electroencephalography-based depth of anaesthesia monitors are used by only a very small fraction (2%) of anaesthetists and are unavailable in one-third of UK hospitals.[17]

Direct arterial pressure monitoring (an arterial line) should be considered before induction of GA in the following conditions:

- Severe pre-eclampsia (to help ensure that the pressor response to laryngoscopy is obtunded—see 'General anaesthesia and pre-eclampsia')
- Morbid obesity where NIBP measurement is unreliable
- Sepsis
- Anticipated major haemorrhage (e.g. placenta praevia)
- Any systemic illness—when postoperative critical care is anticipated.

Measurement of cardiac output may be useful in women with haemodynamic instability attributable to critical illness or cardiac disease. However, there is no evidence of clinical utility of minimally invasive cardiac output monitors utilizing oesophageal Doppler velocimetry or arterial pulse waveform analysis at CD. None of the various devices has been formally validated in pregnancy.[18] The only evidence is from case reports, such as a Canadian description of data derived from a NICOM® thoracic bioreactance monitor in a woman with aortic stenosis.[19]

A real-time non-invasive haemoglobin (SpHb) monitor (the Masimo Rainbow SET® Pulse co-oximeter) has been evaluated at elective CD[20] and in five women undergoing caesarean hysterectomy.[21] A significant correlation was found between laboratory haemoglobin values and SpHb measurements, although median SpHb values were higher than laboratory Hb values. The HemoCue® point-of-care photometric cuvette system (which requires a drop of blood) provides a more accurate approximation of laboratory haemoglobin measurement.[22]

Maternal bladder catheterization is necessary at every CD to prevent surgical injury to the bladder. Urine output can therefore be measured.

### Fetal monitoring

In emergency cases, fetal heart rate monitoring should be by continuous cardiotocography or intermittent Doppler ultrasound during preparation for induction of GA. Change in the fetal status (e.g. in response to intrauterine resuscitation) can influence anaesthetic management. Resolution of a fetal bradycardia might allow a change of plan from GA to neuraxial block.

## Preoxygenation

Replacement of the nitrogen in the FRC of the lungs by oxygen is essential before inducing GA. The progressive reduction in FRC during pregnancy (further reduced by morbid obesity and multiple gestation) and increased oxygen consumption by the fetoplacental unit mean that arterial oxygen desaturation following apnoea is predictably accelerated.[23] Preoxygenation should be undertaken with the woman in a head-up position,[24] and the process guided by oxygraphy, as opposed to a predetermined number of breaths or duration of tidal breathing. Care should be taken to eliminate any leak between the woman's face and the face mask, to avoid entrainment of room air and impairment of the (exponential) denitrogenation process. The target end-tidal oxygen concentration is 90%.

In obstetric practice, 100% oxygen should be administered. The argument in non-obstetric anaesthesia for lower fractional inspired oxygen concentrations (in the interests of prevention of atelectasis) is outweighed by the FRC reduction/increase in oxygen consumption.[25] Following preoxygenation, time to arterial oxygen desaturation during apnoea is shorter after succinylcholine compared with rocuronium. This phenomenon is explicable by the additional skeletal muscle oxygen consumption incurred by fasciculations[26,27] (Figure 22.2).

## Airway management

### Laryngoscopy and intubation

The following devices can prove invaluable aids to successful intubation:

- McCoy 'levering' laryngoscope (with hinged tip)
- Polio Macintosh blade (mounted at 135° to the handle)
- A short-handled laryngoscope is particularly useful in obese women with large breasts
- Gum-elastic bougie.

In obstetric practice, a tracheal tube one size smaller than that typically used for adult females (i.e. 7.0 mm internal diameter) is recommended.

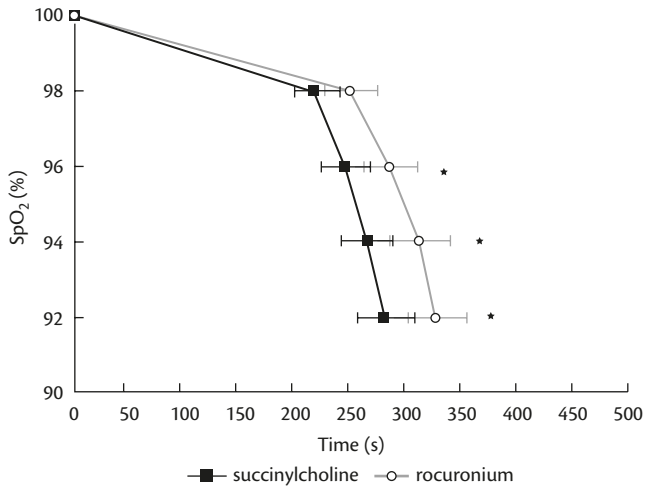

**Figure 22.2** Decrement in peripheral arterial oxygen saturation ($SpO_2$) after succinylcholine or rocuronium. Mean (95% confidence interval) times for decrease in $SpO_2$ to 98%, 96%, 94%, and 92% in patients with body mass index 25–30 kg/m$^2$ receiving succinylcholine or rocuronium after 3 minutes' pre-oxygenation.

*P < 0.05.

Some authors advocate video laryngoscopy as the laryngoscopic technique of first choice, as opposed to a rescue strategy.[28] In an emergency situation, it is important to use the equipment that is most familiar to the individual anaesthetist. An emergency CD is not the right time to try out a laryngoscope for the first time. Trainees should be encouraged to familiarize themselves with various laryngoscopes in the high-fidelity simulator and in the elective setting before use in obstetrics.

## Failed intubation

Every anaesthetist should have a rehearsed plan for a difficult or failed intubation. The UK incidence at CD has been reported at around 1/300 in most series. The most commonly used rescue airway in the United Kingdom appears to be the original (marketed as Classic™) laryngeal mask airway (LMA).[29] 'Secondary' tracheal intubation via LMA and exchange catheter is not recommended at emergency CD (see the UK Difficult Airway Society website, http://www.das.uk.com/).

Management of unanticipated difficult tracheal intubation is focused on 'oxygenation without aspiration'[30] and prevention of airway trauma, which can insidiously precipitate a 'can't ventilate' scenario on account of airway oedema.

Harmer's system (Table 22.1) for grading the clinical urgency to proceed with surgery remains most useful in aiding decision-making as regards whether or not to discontinue anaesthesia in the event of failure to intubate the trachea at CD.[31]

### Supraglottic airway devices

Many reports have accrued of successful use of supraglottic devices as rescue airways. Mushambi and Pandey have reviewed in detail the findings of the UK National Audit Project 4 (NAP4)[32] (see Chapter 26). Details of major airway management complications (death, brain damage, emergency surgical airway, and unanticipated intensive care unit admission) in the course of anaesthesia were collected from all UK National Health Service hospitals over 1 year. There were four obstetric cases, all of whom survived. In one, an Intubating LMA® Airway (ILMA®) was used successfully. In contrast, the concurrent UK Confidential Enquiries into Maternal Deaths[11] highlighted a case of oesophageal intubation through an ILMA®.

The LMA Classic™ has been studied at elective CD in 1067 fasted Korean women of low body mass index (BMI) who received succinylcholine 1.5 mg/kg for NMB.[33] There were no data on the frequency with which cricoid pressure was relaxed or removed to facilitate LMA insertion. No instances of regurgitation or aspiration were reported. The second-generation LMA ProSeal™ (PLMA; see Figure 26.5 in Chapter 26) was studied in 3000 elective CD cases in Jordan.[34] The PLMA provides an improved seal for positive pressure ventilation, separation of the respiratory and gastrointestinal tracts, and venting of gas or liquid via a drain port. All women had BMI < 30 $kg.m^{-2}$ and were given rocuronium 0.9 mg/kg; cricoid pressure was applied. A 14 Fr orogastric tube was preloaded on the PLMA—its distal tip extended 10 cm beyond the drain port and was guided into the oesophagus with the aid of Magill forceps before subsequent 'railroading' of the PLMA (during which cricoid force was released). The only incidence of regurgitation was during fundal pressure, at delivery of the neonate. Gastric contents reached the mouth, but not the lungs. As indicated in Figure 22.1, intragastric pressure is an important factor in the overall risk of aspiration. In an accompanying editorial, Paech concluded that there is now, arguably, clinical equipoise between tracheal intubation and use of an LMA after RSI with cricoid pressure.[35] A Chinese study examined the LMA Supreme™, a disposable version of the PLMA, in 700 fasted women with BMI less than 35 $kg/m^2$ with no history of gastro-oesophageal reflux.[36] Again, rocuronium was used for NMB and there was no clinical evidence of regurgitation or aspiration. Habib[37] has commented that the Supreme™ might be considered for slim, fasted parturients with no reflux scheduled for elective CD. Insertion of an LMA at an early stage after failed tracheal intubation might reduce the trauma of repeated intubation attempts whilst providing adequate oxygenation and ventilation.[37] In a review of the array of new supraglottic airways,[38] it was pointed out that a distinction must be made between clinical evidence relating to efficacy, and safety of performance. Although small clinical evaluations can determine the efficacy of particular devices in absolute and relative terms, safety evaluations (e.g. ventilation failure rates or the risk of aspiration) may need many thousands of cases before concerns are identified. In reality, this means that the risk profile of a new device is unlikely to be established until several years after introduction.

**Table 22.1** Suggested actions in the event of failed tracheal intubation, according to five graded maternal/fetal clinical scenarios

| Grade | Scenario | Action |
|---|---|---|
| Grade 1 | Woman's life depends upon the completion of surgery (e.g. cardiac arrest, massive haemorrhage) | No alternative but to continue with maintenance of GA to facilitate haemostasis |
| Grade 2 | Maternal pathology makes alternative neuraxial techniques unsuitable (e.g. decompensated heart disease, coagulopathy) | Either continue GA if supraglottic airway securely placed or discontinue anaesthesia and proceed to awake fibreoptic intubation |
| Grade 3 | Sudden and severe fetal compromise not recovering between contractions (e.g. placental abruption, prolapsed cord) | Although abandoning GA could lead to fetal demise, maternal well-being is paramount. Unless airway is secure with a supraglottic airway, awakening the woman and institution of a neuraxial technique is appropriate |
| Grade 4 | Long-standing fetal compromise of varying severity (e.g. showing good recovery between contractions) | GA should be abandoned: in a majority of cases the fetus will be delivered under neuraxial anaesthesia without detriment |
| Grade 5 | Elective procedure | Woman should be woken up and awake fibreoptic intubation or neuraxial anaesthesia instituted |

### Videolaryngoscopes and fibreoptic intubation

Examples of current videolaryngoscopes are illustrated in Chapter 26. McGuire and Younger have explained the distinctions between rigid indirect laryngoscopes and optical stylets.[39] Awake fibreoptic intubation is the gold standard for management of the anticipated difficult airway. NAP4 pointed out that a flexible fibrescope may have several roles in the obstetric setting, and that anaesthetic departments should provide a service where the skills and equipment are available to deliver awake fibreoptic intubation whenever it is indicated. The Ambu® aScope™ is a single-use flexible intubation scope that is suitable for an obstetric theatre that might be distant from a hospital's main theatre complex. Following a difficult or failed intubation the anaesthetist must remember to inform the woman afterwards and impart verbal and written information about the airway difficulty and its importance for future anaesthetics. It should be emphasized that the woman must impart this information to future anaesthetists.

## Cricoid pressure

Cricoid pressure can distort the view at laryngoscopy especially if applied with left lateral tilt of the operating table, for which the assistant has not accounted (NB The term cricoid 'pressure' is strictly incorrect—force (measured in Newtons, N) is applied, rather than pressure (force per unit area)). Priebe has summarized the case against continued use of cricoid pressure.[40] A 30 N force can cause complete loss of the glottic view;[41] the risk of occlusion of the cricoid ring and airway obstruction is greater in females.[42] Although a Canadian study concluded that cricoid pressure applied by trained assistants did not increase the rate of failed intubation in elective non-obstetric patients,[43] a risk:benefit analysis of cricoid pressure in the emergency department questioned its universal application, and recommended immediate consideration of its removal in the event of difficult intubation or ventilation.[44] Anaesthetic assistants' training is of crucial importance.[45] The anaesthetist must be assured that the assistant can discern individual patients' cricoid cartilages and apply the appropriate level of pressure.

## Intravenous anaesthetics and analgesics

### Induction agents

Ninety-three per cent of UK consultants who responded to an OAA survey in 2011 used thiopental for induction of GA for CD.[46] The motion 'Propofol should be the induction agent of choice for caesarean section under general anaesthesia' was debated in 2003.[47] Although a majority opposed the motion before and after the debate, the arguments highlighted minimal evidence upon which to reject propofol as a reasonable alternative in the event of non-availability of thiopental. There is a lack of clarity as to what constitute truly equipotent doses of thiopental and propofol. Reynolds has stressed that all anaesthetic agents cross the placenta readily. Even if drug concentrations are high in umbilical venous blood, these are not the concentrations in the blood reaching the fetal brain.[48] GA and the developing fetal brain is discussed in a later section.

The following should be done to minimize harm to the fetus:

- Maintenance of maternal oxygenation
- Maintenance of normocapnia for pregnancy
- Aortocaval compression minimized
- Uterine incision–delivery interval minimized
- Obligatory presence of a neonatologist to offer neonatal ventilatory support.

### Opioids

Remifentanil or alfentanil are necessary adjuncts to any IV induction agent at RSI for women in whom a hypertensive response to intubation is particularly undesirable (see 'General anaesthesia and pre-eclampsia'). A review of studies evaluating remifentanil at CD concluded that remifentanil reduced the maternal circulatory response to intubation and surgery, although the incidence of brief neonatal respiratory depression was increased compared to an opioid-free induction regimen.[49] In women with cardiac disease, the chosen anaesthetic regimen should not depart from whatever would be judged best for a non-pregnant woman with similar cardiovascular compromise.[50] An opioid-based cardiac anaesthetic regimen should not be avoided on account of fetal concerns, provided that a neonatologist is present in anticipation of neonatal respiratory depression

### Total intravenous anaesthesia

A propofol-remifentanil total intravenous anaesthetic regimen has been described,[51] which might prove useful when volatile agents are contraindicated (e.g. malignant hyperthermia susceptibility). A 0.5 mcg/kg remifentanil bolus was followed by an infusion at 0.20 mcg/kg/min and an induction dose of propofol (blood concentration of 5 mcg/mL by target-controlled IV infusion) reduced to 2.5 mcg/mL after the trachea was intubated. Mean arterial blood pressure remained stable. Cord umbilical artery pH was universally greater than 7.20, although 1-minute Apgar scores ranged from 1 to 9 and a brief period of bag-mask ventilation was required in half of the neonates.

## Volatile agents

Historically, it was not possible to discern the respective effects on the fetus of GA and asphyxia, and the contribution of supine maternal position to impaired uteroplacental perfusion was not appreciated. Forty years ago, Crawford advocated maintenance of anaesthesia with only $N_2O$ and $O_2$. He regarded uterine relaxation as the only indication for halothane.[52] Moir demonstrated improved Apgar scores with a $N_2O/O_2$ 50:50 mixture with halothane 0.5% (inspired) compared to $N_2O/O_2$ 70:30 without halothane.[53] He concluded that it was the higher fractional inspired oxygen concentration permitted by the use of halothane that was responsible for the improved neonatal condition. Whereas two of 50 women who received unsupplemented $N_2O/O_2$ had clear recall, halothane ensured lack of awareness and did not cause increased blood loss. Moir's paper was reproduced as a *British Journal of Anaesthesia* 'citation classic' in 1998.[54] Uterine relaxation conferred by a volatile agent might actually improve fetal compromise to which uterine hyperstimulation has been contributory.[55] A maternal stress response to excessively light GA might compromise uteroplacental blood flow.

In the recent survey of UK practice, 85% of respondents still used nitrous oxide and sevoflurane was the most popular vapour for maintenance.[46] Compared with isoflurane, sevoflurane[56] and

desflurane[57] offer the advantage of more rapid approximation of alveolar to inspired tensions as the effect of the IV induction dose declines. However, maternal recovery was not demonstrably faster with either of the newer agents (sevoflurane was compared with isoflurane; desflurane with enflurane). Isoflurane is an entirely satisfactory agent for maintenance, provided attention is paid to end-tidal vapour concentration during the phase of overpressure after IV induction. Desflurane is contraindicated in the hypertensive disorders on account of the risk of sympathetic activation during rapid increases in inspired tension.[58]

End-tidal vapour concentration must be monitored to avoid awareness. Data support maintenance of end-tidal vapour concentration greater than 0.75 MAC (in addition to 50% $N_2O$) to maintain bispectral index (BIS) values less than 60 for 'adequate' depth of anaesthesia at CD.[59] BIS values have been compared between women presenting for elective CD and a group requiring CD who had previously laboured for a mean duration of 5.4 hours.[60] A fixed anaesthetic regimen was administered: induction with thiopental 4 mg/kg and maintenance with sevoflurane (end-tidal concentration 1.0%) and nitrous oxide 50%. Baseline BIS mean values were similar between the groups. After induction, from the time of tracheal intubation until 10 minutes after delivery of the neonate, BIS values were significantly greater in the elective group. In addition, more IV postoperative analgesia was self-administered by women who had undergone elective CD. The authors' explanation was that labour pain might induce release of β-endorphin by the pituitary. This study provides insufficient justification upon which to decrease vapour concentrations in women who have been labouring.

Inhalation agent monitoring is now universally available in the developed world, and the incidence of awareness should be negligible. In a prospective Australasian survey of over 1000 CDs, 70% of women were interviewed about awareness and dreaming. In the two cases of definite explicit awareness, administered drug doses were manifestly insufficient (in one case water was administered without the intended diluted thiopental). BIS or entropy monitoring was used in one-third of cases.[61]

The Fifth National Audit Project (NAP5) of the Royal College of Anaesthetists of Great Britain and Ireland was published in 2014 and looked at 3 million GAs delivered over 1 year in public hospitals in these countries.[62] NAP5 reported an overall incidence of awareness during GA of 1/19,000, much lower than previously reported. However, as previously recognized, the incidence was considerably higher in the obstetric population (1/670). Most cases were at caesarean delivery—at induction or an early stage of surgery. A key message was to 'mind the gap' between waning concentrations of intravenous induction agent and attainment of adequate vapour tension following traditional RSI.

### Inhalation induction

There is neither historical nor contemporary evidence upon which to declare inhalation induction with sevoflurane as inherently unsafe. Sevoflurane causes minimal airway irritation and has been used successfully for inhalation induction of anaesthesia for CD in the absence of vascular access and in acute severe asthma. The smooth, rapid onset and lack of coughing or vomiting suggest that the technique does not necessarily cause an increased risk of aspiration. Tidal breathing of 8% sevoflurane in $N_2O/O_2$ 66:33 can induce anaesthesia as rapidly as an IV bolus.[63] The following approach is suggested:

- 20–30° head-up tilt
- Breathing system primed with sevoflurane 8% in $N_2O/O_2$ (2:1)
- Tidal respiration
- Avoid cricoid pressure
- IV cannulation after loss of consciousness
- NMB, tracheal intubation.

### Uterine tone

Maintenance of uterine tone is crucial in reducing intraoperative blood loss. A dose-dependent reduction in uterine muscle contractility has been shown *in vitro* with sevoflurane and desflurane[64]—a finding that agrees with earlier studies of halothane, enflurane, and isoflurane. However, myometrial responsiveness to Syntocinon® at different end-tidal volatile tensions has never been studied *in vivo*. Whereas recent work has found that adequate uterine tone can be attained with small bolus doses (0.5–3 IU) of Syntocinon® in patients undergoing elective CD under spinal anaesthesia, there is no evidence to support reducing the magnitude of the bolus dose from 5 IU in GA cases.[65]

## Neuromuscular blockade

There are many diverse risks associated with the administration of succinylcholine, including anaphylaxis, increased masseter tone, malignant hyperthermia, hyperkalaemia, vagal arrest, myotonic crisis, and myalgia. Belief that spontaneous recovery will necessarily be sufficiently rapid to allow retrieval of a failed ventilation scenario is incorrect.[66]

Rocuronium is licensed for CD at 0.6 mg/kg. In its original evaluation for CD, conditions for tracheal intubation were good or excellent at 90 seconds or disappearance of the third twitch of a train of four (TOF) only after the thiopental dose had been increased from 4 to 6 mg/kg.[67] Mean duration of NMB (time to reappearance of the second TOF twitch) was 32.7 minutes. The ratio of umbilical venous:maternal venous rocuronium concentrations was 0.16, similar to other fully ionized and water-soluble quaternary ammonium compounds.

A comparison of rocuronium 0.6 mg/kg and succinylcholine 1.0 mg/kg for non-obstetric RSI found that intubation scores were superior after succinylcholine—although limb movement/coughing in response to intubation rather than inferior conditions for laryngoscopy (jaw relaxation/resistance to the blade) or vocal cord adduction/movement accounted for the difference.[68] The median time to completion of intubation was shorter after succinylcholine than rocuronium 0.6 mg/kg.

There is a body of evidence that rocuronium becomes an increasingly acceptable alternative to succinylcholine for RSI as doses are increased to 0.9 mg/kg or greater.[69] The onset time of rocuronium is inversely related to the intubating dose; histamine release remains insignificant after rocuronium 1.2 mg/kg.[70] The duration of action of this dose (at least an hour until sufficient spontaneous recovery for evoked reversal with neostigmine) precluded its use at CD until the advent of sugammadex.

The incidence of anaphylaxis to different neuromuscular blocking drugs varies according to geographical location. A recent analysis from Western Australia found that rocuronium and succinylcholine were responsible for 56% and 21%, respectively, of cases of anaphylaxis to neuromuscular blocking drugs. The study estimated the number of patients exposed to neuromuscular blocking drugs from ampoule sales data.[71]

### Reversal of rocuronium with sugammadex

Sugammadex is a cyclodextrin that can chelate or encapsulate rocuronium and (to a lesser extent) vecuronium. Sugammadex has a dose-dependent speed of onset. Unlike neostigmine, there is neither acetylcholinesterase inhibition nor simultaneous requirement for (antimuscarinic) anticholinergic agents.

Reversal of rocuronium 0.6 mg/kg with sugammadex at 2–4 mg/kg has been studied at CD.[72] In an evaluation of rocuronium 1.2 mg/kg at CD, tracheal intubation was undertaken at 60 seconds. Intubating conditions were 'excellent' in two-thirds and 'good' in one-third of women. The three neonates who were admitted for neonatal intensive care were all delivered after intervention for pre-existing fetal compromise. Umbilical cord venous blood was not sampled for rocuronium assay. All women received sugammadex 4 mg/kg at the end of surgery.[73]

It might be expected that the mass of rocuronium transferred across the placenta will be broadly proportional to the maternal dose. It is uncertain whether the fraction of 1.2 mg/kg transferred in the event of prolonged surgical delivery would impair neonatal respiratory effort. Emergency reversal of rocuronium 1.2 mg/kg with sugammadex 16 mg/kg has not been reported in obstetrics. Figure 22.3 represents data from two subjects recruited to a non-obstetric study which found that spontaneous recovery of succinylcholine 1.0 mg/kg to TOF greater than 0.9 was slower than recovery evoked by sugammadex 16 mg/kg 3 minutes after rocuronium 1.2 mg/kg.[74]

## Role of rocuronium/sugammadex after failed intubation

When the original failed intubation drill was conceived in the mid 1970s,[75] GA was undertaken for a much greater proportion of CD and succinylcholine was used for NMB almost exclusively. The key principle of the drill[30] was that in the event of failed intubation, either a woman could be allowed to wake up and a neuraxial technique used, or surgery could proceed with facemask and spontaneous ventilation. Nowadays, the indications for the vast majority of GA CD are immediate threat to life of the mother or fetus, or failure of neuraxial blockade.

If maternal compromise is life-threatening (e.g. massive haemorrhage), surgery must proceed to secure haemostasis, even if a definitive airway (tracheal tube) has not been secured and there is difficulty ventilating the lungs effectively. The usefulness of the emergency reversal dose of sugammadex is therefore limited. Moreover, sustained profound rocuronium blockade might be expected to offer conditions for airway management that are superior to those offered by succinylcholine. The period of initial recovery from succinylcholine increases maternal oxygen consumption and, as muscle tone increases and the patient begins to move, can make ventilation of the lungs difficult on account of decreased thoracic compliance. There is a distinct possibility of retching/vomiting and a heightened risk of aspiration of gastric contents. Proceeding to rapid reversal of profound rocuronium blockade in the event of 'can't intubate, can't ventilate' at category 1 CD would be more likely if fetal as opposed to maternal compromise was the indication for operation (see Table 22.1).

Data on placental transfer of sugammadex are sparse, and limited to animals. The manufacturer has indicated that less than 2–6% is transferred in rat and rabbit populations. There is no information about placental transfer of the sugammadex–rocuronium complex. However, adverse fetal effects of sugammadex-encapsulated rocuronium are unlikely.

## General anaesthesia and the developing fetal brain

There is accumulating evidence from primate studies that neurotoxicity (a pathological increase in apoptosis—programmed cell death) can follow fetal exposure to general anaesthetics.[76] However, the induction dose of ketamine administered to pregnant Rhesus macaque females at 120 days' gestation (full term 165 days) in one prominent study was 10 mg/kg, which was followed by a continuous infusion at 10–85 mg/kg/h for 5 hours.[77] The relative dose of GA transferred to a human fetus at CD, particularly in an emergency case with impaired uteroplacental perfusion, would be inevitably smaller by many orders of magnitude. Concerns about the impact of GAs on the developing fetal brain should therefore be focused on *in utero* fetal surgical procedures (see Chapter 7), where volatile agents might be administered at high doses many weeks before term to facilitate uterine relaxation, for significant durations.

## Postoperative analgesia

IV opioids such as morphine or diamorphine should be administered after delivery of the neonate, supplemented by IV paracetamol 1 g and a non-steroidal inflammatory drug (NSAID) such as diclofenac, provided there are no contraindications. Armstrong and Stocks describe detailed strategies for postoperative analgesia, including wound infiltration and TAP blocks, in Chapter 24.

## General anaesthesia and obstetric haemorrhage

If there are signs of significant blood loss such as pallor and tachycardia—which can develop before significant hypotension—the approach to IV induction of anaesthesia must be particularly careful. Options include decreasing the dose of thiopental or using ketamine (1.5–2 mg/kg) or etomidate (0.2–0.3 mg/kg). The sympathomimetic effect of ketamine is a contradiction to its use in hypertensive disorders of pregnancy. It is uncertain whether concern about etomidate-induced adrenal insufficiency[78] is warranted in obstetric haemorrhage. Although there is little evidence that small doses of volatile agents in the presence of Syntocinon® exacerbate uterine atony, substitution of volatile agent by IV agent(s) (e.g. increments of ketamine 50 mg) for maintenance of anaesthesia might be considered. NSAIDs are absolutely contraindicated in women whose kidneys might have sustained hypoperfusion secondary to haemorrhage. The risk of acute kidney injury will be compounded by pre-eclampsia.

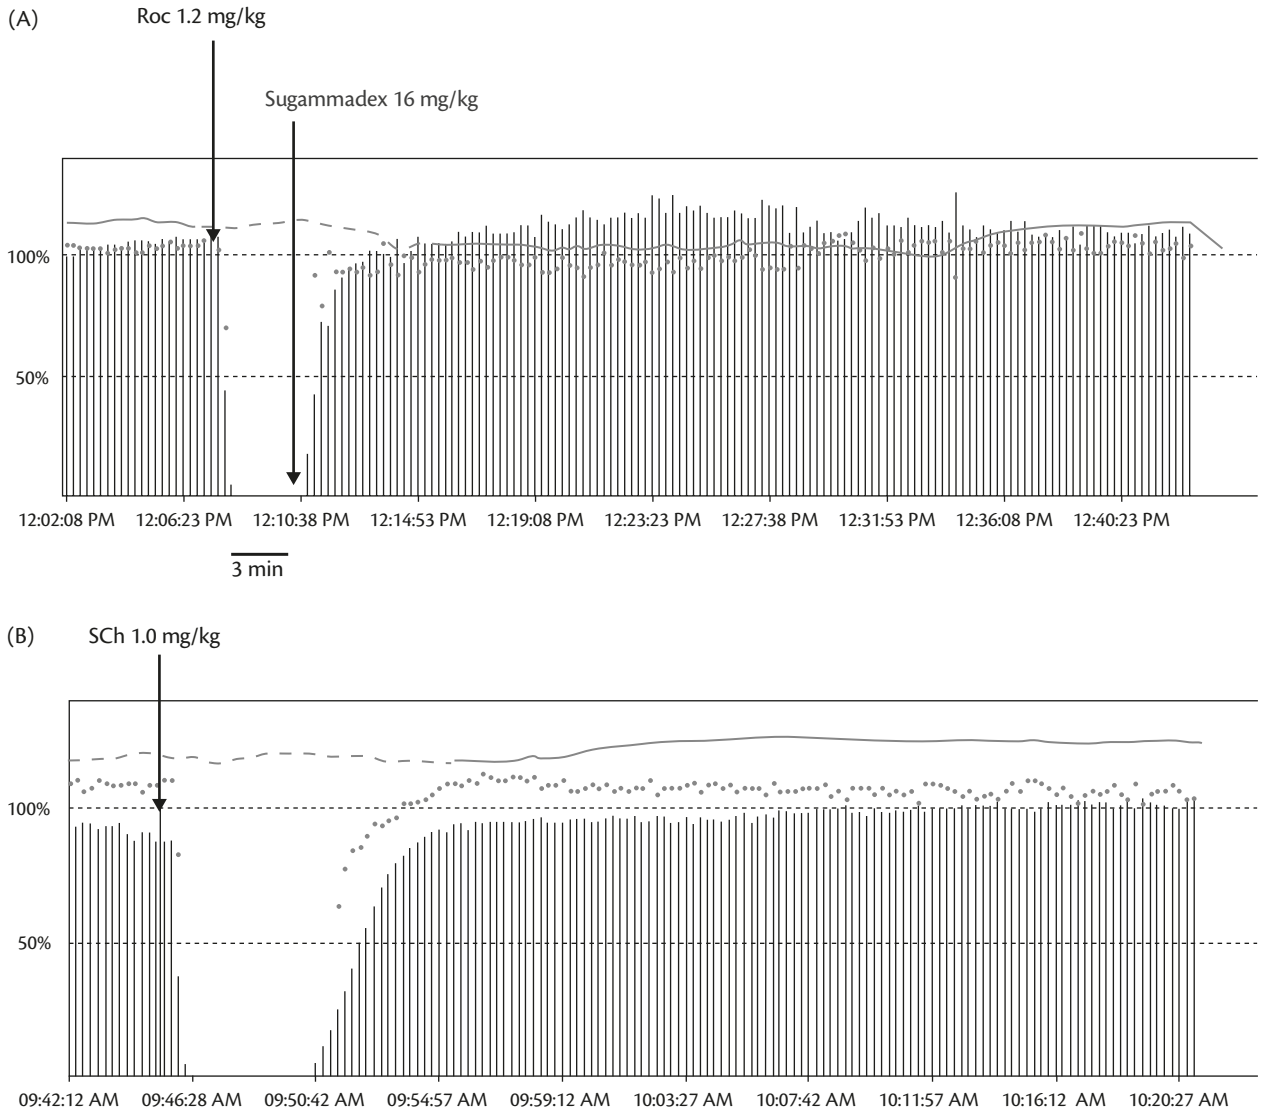

**Figure 22.3** Acceleromyographic comparison of onset and offset of neuromuscular blockade with Succinylcholine and a rocuronium/sugammadex combination. (A) Recovery of the train-of-four (TOF) ratio after administration of rocuronium 1.2 mg/kg followed 3 minutes later by sugammadex 16 mg/kg. Recovery to first twitch height (T1) 90% and TOF ratio 0.94 took 110 seconds. The onset–offset time with this sequence (i.e. the time from the end of the injection of rocuronium to T1 recovery to 90%) was 4 minutes 47 seconds. (B) Effects of administering 1.0 mg/kg succinylcholine with spontaneous recovery to T1 90% after 9 minutes 23 seconds.

## General anaesthesia and pre-eclampsia

There are very few comparative studies of anaesthetic techniques in women with pre-eclampsia. A study that randomized pre-eclamptic women with a 'non-reassuring' fetal heart trace to spinal or GA found that 1-minute Apgar scores were lower after GA—explicable by the transient, reversible effects of residual anaesthetic agents. However, GA was associated with increased mean umbilical cord arterial pH compared with the spinal group.[79] When uteroplacental perfusion is compromised, GA might predispose to a better neonatal acid–base outcome compared to spinal anaesthesia.

In pre-eclampsia, obtunding the dangerously exaggerated maternal hypertensive response to laryngoscopy and tracheal intubation is of critical importance. A death described in the 'Pre-eclampsia and eclampsia' chapter of the 2003–2005 UK Confidential Enquiries was attributable to lack of supplementation of a 'standard' GA induction regimen.[80] A woman suffered prolonged systolic hypertension secondary to difficult intubation, and was subsequently found to have sustained a massive intracranial haemorrhage. The $ED_{95}$ for remifentanil in women with severe pre-eclampsia has been defined as 1.34 mcg/kg (the 'effective' dose was defined as that which prevented systolic arterial pressure increasing to > 160 mmHg for > 1 minute). Women were pretreated with a loading dose of magnesium sulphate and received thiopental 5 mg/kg.[81] Alfentanil 10 mcg/kg (1 mg maximum) is a suitable alternative.

Although the duration of action of all non-depolarizing neuromuscular blocking agents is significantly prolonged by therapeutic serum concentrations of magnesium, the onset and duration of succinylcholine is unaffected.[82]

A population-based study of 303,862 Taiwanese women identified an increased risk of stroke over a 1–6-year follow-up period following GA (compared to neuraxial anaesthesia) for CD in the presence of pre-eclampsia.[83] Speculative mechanisms include the neuroendocrine stress response to CD, increased incidence of thromboembolism after GA, and endothelial cell dysfunction mediated by nitrous oxide. There was no increased risk of stroke associated with GA in women without pre-eclampsia.

Before extubation, additional antihypertensive therapy (e.g. labetalol in 10–20 mg increments) should be considered in order to avert a dangerous pressor response.

Any woman whose larynx is noted to be swollen at laryngoscopy for GA, or in whom intubation is traumatic, will be at particular risk of laryngeal oedema. Postoperative care must therefore be undertaken in a critical care area with an anaesthetist immediately available. Midwives should be vigilant for the development of stridor, which signifies airway obstruction and a possible need for re-intubation.

## Antibacterial prophylaxis

A further analysis of the Taiwanese population in which incidence of stroke was studied revealed an increased 30-day surgical site infection rate when GA was compared with neuraxial anaesthesia (odds ratio of infection 3.7).[84] It is unclear if this difference reflected greater immunosuppression and impairment of host defences associated with GA or vasodilatation and better surgical site tissue oxygenation mediated by neuraxial anaesthesia.

The recent UK NICE guideline suggests administration of antibiotics with efficacy against endometritis, urinary tract infections, and wound infections.[6] Although NICE in the United Kingdom and the American College of Obstetricians and Gynaecologists[85] recommend that antibiotic administration should precede skin incision, administration after delivery in a category 1 emergency is more realistic.

## Conclusion

In many obstetric units, the regimen for GA for CD has changed little in 50 years—apart from use of increased doses of volatile agents. Thiopental can be replaced with propofol; the rocuronium/sugammadex combination is an acceptable alternative to succinylcholine. Diverse new devices have been developed to aid conventional tracheal intubation and offer an alternative means of airway management in the event of difficulty.

Recognition of the importance of human factors and universal implementation of the WHO surgical safety checklist have the potential to make a significant contribution to the safety of women undergoing CD under GA around the world.

CHAPTER 23

# The aetiology and management of hypotension during spinal anaesthesia for caesarean delivery

Robert A. Dyer, Michelle J. Arcache, and Eldrid Langesaeter

## Background

The benefits of neuraxial anaesthesia in obstetrics were first recognized in July 1900, when the obstetrician Oscar Kreis administered spinal cocaine to six parturients in labour. Cleland's classic experiments on anaesthetized dogs provided the anatomical basis for neuraxial anaesthesia in obstetrics in 1933.[1] However, these pain relief methods in obstetrics were initially to fall into disrepute, since inadequate training and monitoring led to a high morbidity and mortality; an editorial points out that the mortality after spinal anaesthesia (SA) was 1/1000 surgical patients prior to 1944, and as high as 1/139 in obstetrics.[2]

As understanding of maternal and fetal physiology developed, outcomes improved. Of particular importance was the early work on aortocaval compression in the third trimester.[3] A major advance in SA in obstetrics was the introduction of atraumatic pencil-point needles by Hart and Whitacre in 1951, which reduced the incidence of significant postdural puncture headache to less than 1%.[4]

Since the first Confidential Enquiry into Maternal Deaths was performed (1952–1954), the decreasing mortality associated with obstetric anaesthesia in the United Kingdom has been due both to the adoption of SA for caesarean delivery (CD) as the preferred method, and to safer general anaesthesia. Although recent literature reports a lower incidence of failed intubation[5] than an earlier study (1/250),[6] this complication continues to contribute significantly to maternal deaths.[7,8] The development of obstetric anaesthesia as a subspecialty, and the introduction of strict supervision of junior anaesthetists have also influenced obstetric anaesthesia safety.

In the United States, general anaesthesia for CD was shown to be associated with a 16.7 times higher case fatality rate than neuraxial anaesthesia for the period 1985–1990.[9] More recently, the case fatality rate for general anaesthesia has decreased, and the fatality rate has increased from 2.5 (1991–1996) to 3.8 (1997–2002) per million neuraxial anaesthetics, so that the risk ratio for general versus neuraxial anaesthesia has decreased during this period from 6.7 to 1.7.[10] This shows that SA does have an associated morbidity and mortality, although mortality is rare.

The Eighth Report on Confidential Enquiries into Maternal Deaths in the United Kingdom, published in 2011, showed that mortality as a direct result of anaesthesia remains low. For the triennium 2003–2005 there were only 6/132 deaths directly attributable to anaesthesia and in 2006–2008, there were 7/107 deaths. On analysis of the seven deaths, it was felt that substandard care was delivered to six (86%) of the women, with half of them receiving 'major' substandard care which significantly contributed to the death of the mother; different treatment may well have altered the outcome.[11]

South Africa is the only country with predominantly limited resources in which an extensive audit of maternal mortality has been in progress for many years. During the triennium 2005–2007, the report of the National Committee for the Confidential Enquiries into Maternal Deaths showed that there were 74 direct anaesthesia deaths, of which 53 were associated with spinal and 18 with general anaesthesia. For the triennium 2008–2010, 73/92(79%) of direct anaesthesia deaths were associated with SA.[12] Two-thirds of these fatalities were due to poor management of spinal hypotension or high motor block, and most were assessed as avoidable. This shows the importance of the provision of detailed recommendations for the management of haemodynamic instability during SA for CD. Such recommendations, as well as ongoing research into this important subject, should contribute to improved maternal and neonatal safety and greater maternal comfort during and after the procedure.

## Haemodynamic consequences of spinal anaesthesia

Haemodynamic instability during single-shot SA for CD is the result, first and foremost, of the effects of SA in a pregnant patient predisposed to aortocaval compression.

The splanchnic vasculature provides a major reservoir for venous return in the parturient. This blood returns to the inferior vena cava via the hepatic vein, above the level of potential aortocaval compression. During a state of hypovolaemia, typically after blood loss in obstetrics, the transmural pressure of the compliant

splanchnic veins is predominantly above zero,[13] due to activation of the sympathetic nervous system. The sympathectomy associated with SA would inhibit these compensatory changes, resulting in a marked decrease in venous return, due to a precipitous decrease in mean circulatory filling pressure. This may result in cardiovascular collapse. SA is thus absolutely contraindicated in this situation.

Even in the healthy parturient with her expanded blood volume, SA for CD is associated with hypotension, due to a combination of increased venous capacitance and decreased systemic vascular resistance (SVR). Since uterine blood flow is pressure dependent, hypotension results in a decrease in uterine blood flow and potential compromise to fetal oxygenation. Hypotension is commonly associated with unpleasant symptoms such as maternal nausea and vomiting, and cardiovascular collapse may rarely occur.

The definition of hypotension varies considerably between practitioners. A literature search examined 63 publications between 1999 and 2009. The two commonest definitions were a decrease in systolic blood pressure below 80% of baseline and a systolic blood pressure below 100 mmHg, or simply a decrease of 20% from baseline.[14]

Predicting hypotension in the individual case remains difficult, although the use of a supine stress test,[15] preoperative positional blood pressure change,[16] correlation between baseline heart rate (HR) and vasopressor requirements,[17] or preoperative assessment of sympathovagal balance by analysing HR variability may be useful.[18–20] Intraoperative assessment tools have included maternal symptoms, non-invasive measures such as HR and manual or oscillometric blood pressure readings, as well as central venous pressure and cardiac output (CO) measurements, including non-invasive, minimally invasive, and invasive methods.[21,22] Short-term neonatal outcome has most commonly been assessed by umbilical arterial and venous blood gas values and Apgar scores.[23]

Potential haemodynamic responses to SA are:

- hypotension and increase in HR
- hypotension and bradycardia
- persistent refractory hypotension
- high motor block with cardiorespiratory failure

These responses will be influenced by:

- aortocaval compression
- baricity and dose of local anaesthetic and opioid employed
- rational use of fluids
- goal-directed use of vasopressors.

This chapter will describe these scenarios and the mechanisms involved, and conclude with a management strategy for each one. Special considerations apply in the management of SA for patients with severe pre-eclampsia and cardiac disease.

## Haemodynamic effects of aortocaval compression and spinal anaesthesia

### Aortocaval compression

The association between arterial hypotension and the supine position in late pregnancy was first recognized by the Swedish obstetrician Gideon Ahltorp in 1931, as described in a review of the subject.[24] The correct aetiology was described in 1951, and classic case reports alerted anaesthetists to the importance of avoiding this complication.[25] Early studies demonstrated both vena caval and aortic compression in late pregnancy. The methodology included the measurement of right heart filling and inferior vena caval pressures, CO, differences in brachial arterial and femoral arterial pressures in the supine and the lateral or lateral tilt position, and abdominal angiography.[3] Aortic compression, shown by a decrease in femoral artery pressure, occurs earlier in pregnancy than inferior vena caval compression, as indicated by a decreased femoral artery pressure in the supine position.[26] Whilst CO may be reduced in the supine position, most women respond with compensatory increases in SVR and HR. The result is that less than 20% of women experience arterial hypotension and the 'supine hypotensive syndrome', and the quoted incidence varies greatly between studies.[24] However, the fetus may be subjected to diminished intervillous blood flow because of a rise in uterine vascular resistance secondary to aortic compression. Fetal bradycardia has been shown to occur when hypotension occurs with the mother in the supine position,[27] and HR decelerations can be reversed by turning the mother into the lateral position.

### Positioning during spinal anaesthesia

During SA for CD, CO has been shown to be greatly improved by a change from the supine to the left lateral position.[28] Umbilical venous and arterial saturation was demonstrated to improve during SA in patients receiving lateral tilt.[29] A recent investigation suggests that CO is 5% higher if the patient is tilted by more than 15°.[30] However, as much as 34° of lateral tilt may be necessary to completely eliminate the effects of aortocaval compression,[31] and some investigators have recommended the performance of SA for CD in the lateral or modified lateral position.[32] It may be that the position of the parturient prior to tilting is important. One investigation showed that when women were tilted from a previous fully supine position, there was evidence of aortocaval compression. However, if they were tilted from a previously fully left lateral position, there was no evidence of aortocaval compression.[33] Interestingly, in the only published study comparing hypotension during CD in multiple gestation pregnancy with singleton pregnancy, there were no differences detectable in haemodynamic instability.[34] However, aortocaval compression may be of greater concern in patients with multiple or a large singleton pregnancy.

The effects of maternal position on the human fetal circulation have been studied using umbilical artery scanning with real-time Doppler signals during epidural anaesthesia. The results showed a higher umbilical artery vascular resistance in the supine position.[35]

### Effects of spinal anaesthesia

#### *The typical response: hypotension and an increased heart rate*

During SA, sympathetic blockade diminishes the compensatory mechanisms and results in a high incidence of clinically significant hypotension. An early study of intermittent CO measurement during SA for CD, using indicator dilution, showed that SA was associated with a significant depression of CO in 10/12 patients.[28] A further study employing intermittent suprasternal Doppler flow measurements, showed that SA employing a median dose of 11 mg hyperbaric bupivacaine was associated with a decrease in CO of greater than 1 L/min in 9/16 patients.[36] By contrast, a further investigation employing lower doses of local anaesthetic

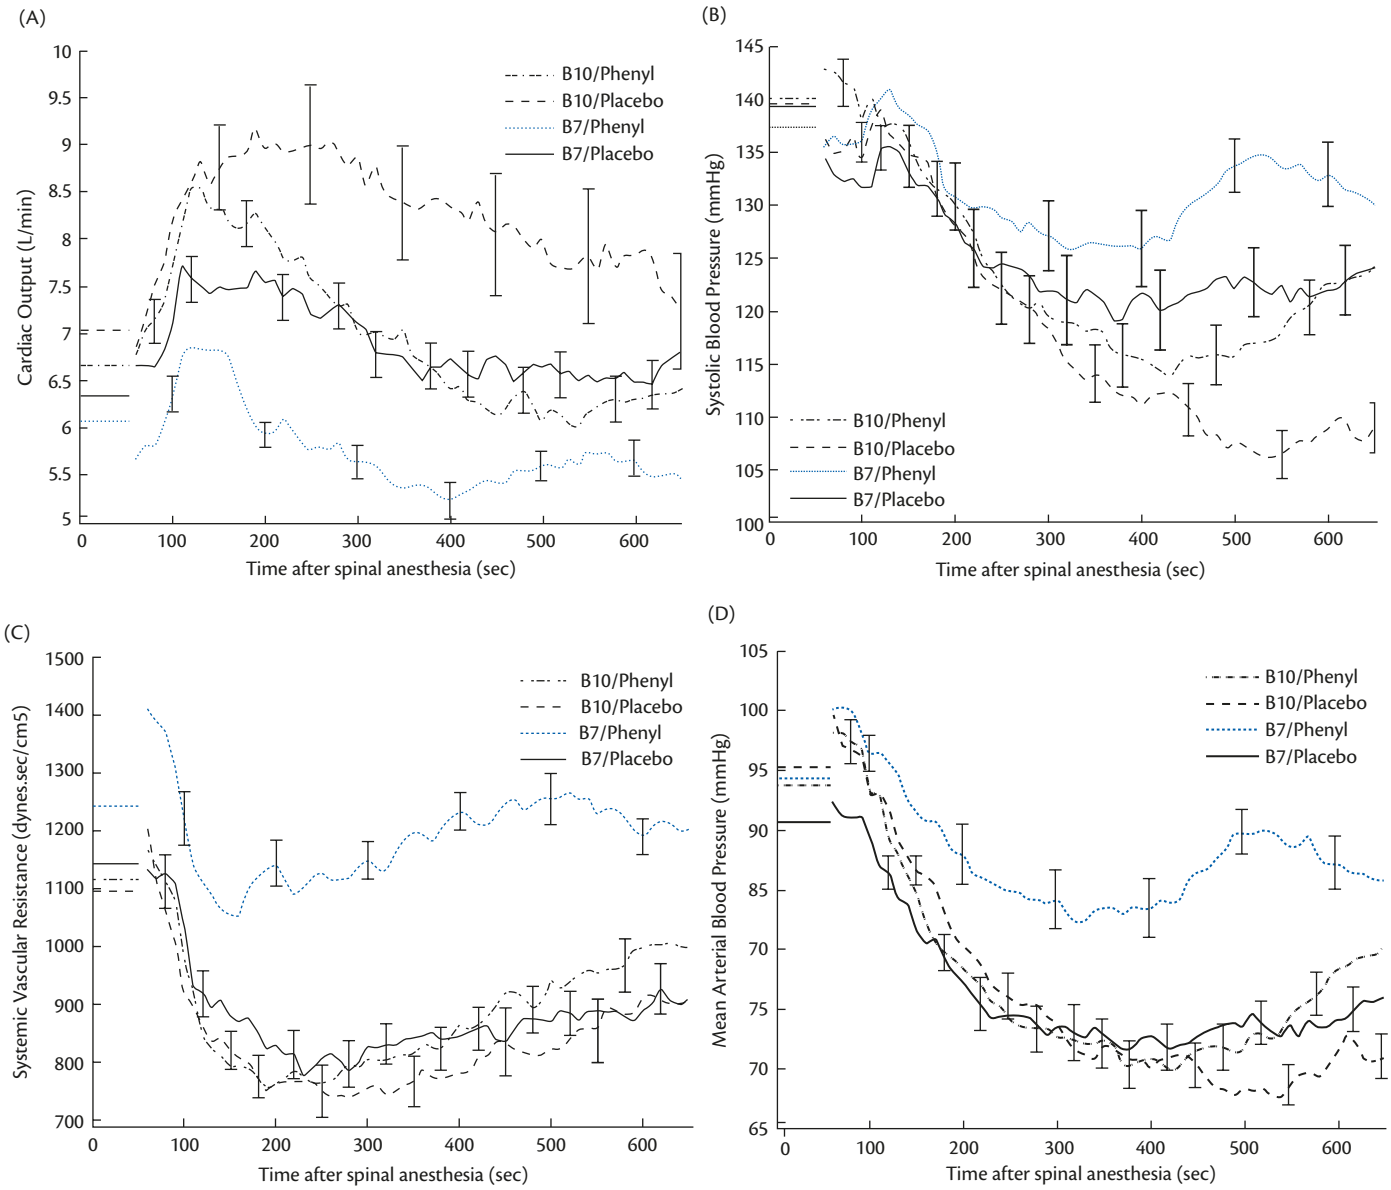

**Figure 23.1** Mean differences in haemodynamic variables between the four treatment groups. (A) Cardiac output. (B) Systolic blood pressure. (C) Systemic vascular resistance. (D) Mean arterial pressure. Baseline is marked on the y-axis. Standard error (SE) for each group is marked as error bars.

(7 mg and 10 mg hypobaric bupivacaine) in conjunction with subarachnoid sufentanil, demonstrated a marked decrease in SVR and an *increase* in CO following SA, using pulse waveform analysis[37] (Figure 23.1).

Another study, employing both pulse waveform analysis and bioimpedance changes in the same patient, confirmed that the typical response to SA for elective CD is a decrease in SVR, which causes hypotension and a partially compensatory increase in CO, mediated by increases in both stroke volume (SV) and HR.[38] The important difference in findings between the old studies[28,36] and the more recent studies[37,38] is the methods applied. The older studies using intermittent measurements of CO 5, 10, and 15 minutes after SA, would not be able to detect the initial effects of SA as shown in the two more recent studies using continuous monitoring of CO. In addition, the modern practice of using lower doses of spinal bupivacaine, together with the recognition of the importance of patient positioning and the judicious use of fluids and vasopressors, may contribute to more stable haemodynamics once SA is established. In most women, the baroreceptor response is well preserved soon after induction of SA, despite sympathetic blockade. In the non-obstetric population, sympathovagal balance usually does not alter to complete vagal dominance during the sympathetic block associated with SA, and sinus bradycardia is therefore infrequent.[39]

### *Hypotension and bradycardia*

Sudden severe bradycardia may occur in approximately 7% of patients,[40] and occasional cardiac arrest has been described.[41–44]

In many of the cases describing cardiac arrest, high doses of local anaesthetics were used, some with inadvertent spinal placement of an intended epidural top-up. The cause of the profound vagal activity that occurs in a small proportion of women is unknown, but it may be triggered by several different causes such as aortocaval compression, high block, emotional stress, peritoneal manipulation, or sudden haemorrhage.[45] Reflex phenomena such as the pacemaker stretch reflex,[46] Bezold–Jarisch reflex (BJR),[47] and the 'reverse' Bainbridge reflex[48,49] may be causatory, but there is no strong evidence to support this theory.

The BJR was initially described as a chemoreflex: precipitous bradycardia followed the injection of toxic steroidal alkaloids into dogs' coronary arteries. More recently, it has been postulated that there may be mechanical stretching during contraction of the poorly filled left ventricle, which results from a sudden decrease in venous return following induction of SA for CD, or in severe hypovolaemia. This may result in increased afferent input into the vasomotor centre via C-fibres in the inferoposterior wall of the left ventricle. This is followed by profound bradycardia and peripheral vasodilatation. A review supports the possibility of the involvement of the BJR in acute bradycardia during neuraxial anaesthesia, but states that there is probably more than one physiological precipitating factor or mechanism.[50] The Bainbridge reflex was described in 1915. An infusion of saline into anaesthetized dogs produced tachycardia, on the basis of activation of stretch receptors in the atria. The 'reverse' Bainbridge reflex has been proposed to explain slowing of the HR when venous return decreases.[49] Whatever the mechanism, the final common efferent pathway is the vagus nerve, and the result is occasional profound bradycardia.

### *Persistent refractory hypotension*

Having ensured adequate uterine displacement, hypotension resistant to vasopressors should raise the suspicion that either an error has been made concerning the volume status of the patient, or there is undiagnosed cardiac pathology. In low-resourced areas,[51] the diagnosis of valvular heart disease and cardiomyopathy may be missed in patients presenting close to term.

### *High motor block*

This scenario is fortunately rare, of the order of 1/3000.[44] The doses are not mentioned in this study. If the currently recommended doses of spinal local anaesthetic and details of technique are employed, this incidence is likely to be much lower. Therefore, when teaching SA for CD, it should be emphasized that cardiovascular instability requires immediate treatment, and is by far the more common scenario than high spinal block.[52] SA for CD is associated with a reduction in respiratory function of approximately 25%, which may impair cough strength in some patients.[53,54] High motor block results in increasing dyspnoea and weak respiratory effort, followed by apnoea. Concomitant sympathetic block may result in cardiovascular collapse.

Overall, maternal and fetal morbidity have been greatly reduced by the recognition of the effects and the avoidance of aortocaval compression during SA for CD. However, an editorial discusses the relative contribution of the venous and arterial circulation to spinal hypotension during CD.[55] The point is made that despite careful attention to fluid management and positioning in order to minimize aortocaval compression, significant hypotension still occurs in a large percentage of patients, due to the effects of SA on the *arterial* circulation. This thought-provoking editorial suggests that there is a 'lesson' to be learned 'from pre-eclampsia', in that one would expect greater haemodynamic instability in these patients if intravascular depletion and decreased venous return were the predominant contributor to spinal hypotension. Research employing continuous pulse waveform analysis (previously discussed) supports the contention that spinal hypotension is usually in large part due to effects on the *arterial* circulation during SA for elective CD.

## Baricity, dose, and volume of spinal local anaesthetic, and combination with an opioid

Currently, most anaesthetists employ hyperbaric bupivacaine for SA for CD. In support of this practice, a randomized trial suggested that isobaric and hypobaric solutions were associated with more motor block, as well as more hypotension and a higher number of cervical level blocks than hyperbaric bupivacaine, if SA was performed in the sitting position.[56] A study comparing the effects of 7 and 10 mg hypobaric bupivacaine, with and without a prophylactic phenylephrine infusion during elective CD, showed that greater haemodynamic instability occurred in the higher-dose group (Figure 23.1).[37]

Since the early adoption of 0.5% bupivacaine for SA for CD, interest has focused on the optimal local anaesthetic/opioid combination and dose to achieve the goals of effective surgical anaesthesia and postoperative analgesia, with minimal maternal and neonatal side effects. This is particularly important in view of the fact that maternal pain is the commonest reason for failure of technique, particularly if the uterus is exteriorized. Pain is also the most commonly cited anaesthetic cause of litigation in obstetric practice.[57] Despite several studies on dose response and efficacy, currently there seems no advantage of either levobupivacaine or ropivacaine over bupivacaine. Most anaesthetists employ hyperbaric 0.5% bupivacaine in a dose of 7.5–15.0 mg (1.5–3.0 mL). The incidence of visceral pain has been shown to be related to the dose of spinal bupivacaine. The use of less than 10 mg alone or 8 mg in combination with an opioid is considered 'low dose'. Some investigators have examined the lower dose range, with a view to reducing side effects such as hypotension, nausea and vomiting, and prolonged motor blockade. In a comparative study of three different doses of hyperbaric bupivacaine, the use of 7.5 mg of bupivacaine was advocated in the interests of haemodynamic stability; however, many patients rated analgesia as poor.[58] Furthermore, a study employing a suprasternal Doppler flow technique was unable to demonstrate improved haemodynamic stability when comparing the initiation of SA for CD with a standard local anaesthetic dose versus a smaller dose as part of a combined spinal–epidural (CSE) technique.[59]

The addition of various doses of different intrathecal opioids may allow the reduction of the local anaesthetic dose, with an equivalent success rate and less severe side effects. Adequate surgical anaesthesia has been reported in parturients receiving only 5 mg hyperbaric bupivacaine, to which 25 mcg fentanyl was added, with less hypotension, and less nausea and vomiting than the group receiving 10 mg of bupivacaine only.[60] Other investigators reported that 8 mg of bupivacaine was sufficient if 10 mcg fentanyl was added.[61] All studies suggest that a combination of local anaesthetic and opioid allows for a reduction in local anaesthetic dose. Most studies investigating low local anaesthetic doses

have employed hyperbaric bupivacaine, which allows the use of positioning to manipulate dermatomal spread. In this regard, low-dose (6.6 mg) hyperbaric bupivacaine has been shown to produce more reliable cephalad spread of anaesthesia, with less hypotension and nausea, than the hypobaric solution.[62]

When the effects of low-dose SA are studied, a CSE technique is often employed, since this allows for epidural supplementation should analgesia be inadequate. It should be noted that the interpretation of the results of these studies may, however, be influenced by the fact that single-shot SA may result in less sensorimotor anaesthesia than an identical dose administered as part of a CSE technique for elective CD.[63]

One recent investigation into the dose–response relationship for intrathecal hyperbaric bupivacaine co-administered with intrathecal fentanyl and morphine, demonstrated an $ED_{50}$ of 7.6 mg and an $ED_{95}$ of 11.2 mg for bupivacaine.[64] In addition, a recent meta-analysis suggests that if less than 8 mg bupivacaine is employed, there is an increased requirement for intraoperative analgesic supplementation (risk ratio 3.76; 95% confidence interval (CI) 2.38–5.92).[65] There is good evidence that a dose of less than 10 mg should also not be used in morbidly obese patients, since the $ED_{95}$ was estimated at 15 and 12 mg respectively in two papers.[66,67] In view of the fact that the patient's experience of pain is by far the most important outcome, low-dose single-shot SA can no longer be recommended, and such low doses should only be administered as part of a CSE technique.[68]

In summary, surgical anaesthesia during single-shot SA should not be compromised due to concerns about the management of cardiovascular instability.[65,69] A dose of no less than 8 mg hyperbaric bupivacaine combined with an opioid, or 10 mg of hyperbaric bupivacaine alone, would seem appropriate. If doses lower than these are envisaged, SA should only be performed as part of a CSE technique. The use of a long-acting opioid as part of a single-shot SA technique depends upon facilities available for postoperative monitoring. Having selected the optimal combination of local anaesthetic and opioid for SA in this manner, with a view to attaining ideal surgical anaesthesia and a minimal requirement for intraoperative supplementation of analgesia, haemodynamic instability will still occur in a significant percentage of patients, despite positioning the mother in left lateral tilt. This requires careful attention to fluid and vasopressor therapy.

## Fluid management

Considerable controversy exists as to the most appropriate IV fluid regimen for SA for elective CD. Widespread use of crystalloid preload was initiated by the demonstration of improvements in uterine blood flow in pregnant ewes in response to rapid fluid administration after SA-induced hypotension.[70] The rationale for 'preload' was that SA-induced venodilatation results in a decrease in SV which more than offsets the increase due to afterload reduction, and thus CO may decrease precipitously. Early promising results[71,72] may have been due to the inclusion of patients in labour, an inadequate understanding of the importance of prevention of aortocaval compression, and other aspects of study design such as blinding, randomization, and local anaesthetic dose. Patients in labour may be less susceptible to hypotension during CD, possibly due to autotransfusion during contractions.[73]

A qualitative systematic review evaluated the efficacy of increasing blood volume in reducing the incidence of hypotension during elective SA for CD.[74] Secondary outcomes were maternal nausea, vasopressor use, and umbilical cord pH and Apgar scores. The studies fell into four categories: large versus small volumes of crystalloid, colloid versus crystalloid, different colloid regimens, and mechanical methods for increasing blood volume (total N = 1504). Crystalloid solutions were ineffective as a preload. Of the nine studies examining crystalloids, only three showed a significant reduction in the incidence of hypotension in the group receiving a higher volume of preload.[71,75,76] There were considerable differences in the study protocols, which probably accounts for the heterogeneity of the results.[74] Colloids were effective in reducing, but not eliminating, hypotension in all but one of a total of 23 randomized controlled trials. Of the seven studies comparing crystalloid and colloid (albumin, hetastarch, gelatin, pentastarch, or dextran), five showed a decreased incidence of hypotension in the colloid relative to the crystalloid group.[77–81] Only one study showed a better neonatal outcome in the colloid group.[79] A limitation of the results was the variability in the volumes of colloids chosen in the studies, as well as differing definitions of hypotension and ephedrine protocols. Due to variation in study design, it was also not possible to determine whether prophylactic fluid administration affected vasopressor requirements. Some small studies have shown that wrapping the legs consistently reduced the incidence of hypotension compared with leg elevation or controls.[82] However, this is not a method that is easy to apply in routine clinical practice.

The latest update of the Cochrane Database in this field includes 75 studies with only eight trials reporting adequate allocation concealment methods, and blinding was reported in 28 trials. This review is in general agreement with findings from the above-mentioned systematic review,[74] reporting that 'Crystalloids were more effective than no fluids (relative risk 0.78, 95% confidence interval 0.60 to 1.00; one trial, 140 women, sequential analysis) and colloids were more effective than crystalloids (relative risk 0.68, 95% confidence interval 0.52 to 0.89; 11 trials, 698 women) in preventing hypotension following SA at CD. No differences were detected for different doses, rates or methods of administering colloids or crystalloids'.[83] Despite the proven advantages of colloids in terms of reducing hypotension, colloids have not been uniformly adopted for fluid management for elective CD. This is partly because of their expense, as well as the risk of anaphylactic reactions, albeit very low with most available solutions.

Many studies have therefore investigated the timing of administration of crystalloid. The relevance of the duration and timing of infusion of a crystalloid preload prior to SA for CD, has been evaluated.[84] This study demonstrated that there was no difference in the incidence of hypotension whether 20 mL/kg of crystalloid was given over 10 or 20 minutes prior to induction of SA. Central venous pressure increases were greater, but increases in HR were less, and HR returned to baseline in a shorter period in the 10-minute group than in the 20-minute group, suggesting a benefit in administering the fluid closer to the time of induction of SA. In a subsequent investigation, the authors hypothesized that in order for a fluid bolus to effectively reduce post-spinal hypotension, the administration of the fluid should produce a sustained increase in CO. Patients were preloaded with 1.5 L Ringer's lactate, or 0.5 L or 1.0 L hydroxyethyl starch. CO and blood volume were assessed before and 30 minutes after fluid loading, using a non-invasive pulse spectrophotometric technique for detecting

indocyanine green. All groups had an increase in blood volume after fluid loading, but only 28% of the Ringer's lactate solution remained in the intravascular space after 30 minutes, compared with 100% of the hydroxyethyl starch solution. CO was only increased in the hydroxyethyl starch groups, and only in the 1.0 L hydroxyethyl starch group was spinal hypotension statistically and clinically significantly reduced, with an incidence of 17%, versus 75% in the Ringer's and 58% in the 0.5 L hydroxyethyl starch group.[81]

In the non-obstetric population, a sustained rise in CO has been demonstrated in a group of patients given lactated Ringer's solution after the initiation of SA.[85] A kinetic analysis of an IV infusion of Ringer's solution as preload suggested that a rapid fluid load given over 2 minutes after induction of both spinal and general anaesthesia for non-obstetric surgery, might prevent hypotension caused by central hypovolaemia.[86] These findings prompted a study of crystalloid administration after initiation of SA for CD ('co-load' or co-hydration), to overcome the problem of rapid redistribution of crystalloid fluid. The co-load group (20 mL/kg) required a lower median dose of ephedrine for the treatment of maternal hypotension prior to delivery.[87] Subsequent to this study, crystalloid co-loading has been employed in combination with phenylephrine infusion, in an attempt to obtain optimal haemodynamic stability during SA for CD.[88] Patients receiving rapid co-loading in combination with phenylephrine had an almost zero incidence of hypotension, which was an improvement on the use of phenylephrine infusions alone. This paper forms the basis for current practice, with the reservation that most practitioners use lower doses of phenylephrine than in this investigation (see 'Vasopressor Use').

Several studies have also examined the optimal volume and timing of colloid administration. In this regard, a pentastarch preload of 10 mL/kg has been found to be more effective than 5 mL/kg at preventing hypotension following SA.[89] As might be expected, colloid co-loading with 6% hydroxyethyl starch was found to be similarly effective in reducing hypotension compared with preloading.[90] Similar results were shown using hetastarch.[91] There was no difference in CO or vasopressor requirements in women randomized to colloid or crystalloid co-load.[92] However, interpretation is difficult, since a prophylactic phenylephrine infusion was used. There have been no studies comparing crystalloid co-load with colloid preload.[93]

In summary:

- Crystalloid preload is not effective.[76]
- Preload with crystalloid or colloid increases CO but this does not reduce the incidence of arterial hypotension.[94,95]
- Crystalloid co-load is partially effective and superior to crystalloid preload, however the benefit most likely depends on the volume of fluid infused (higher volume best) and the rapid administration of the fluid over the first 5–10 minutes after induction of SA, timed with the onset of the sympathectomy.[96,97]
- Colloid co-load is as effective as colloid preload.[98]
- Colloid co-load is equally effective—and possibly more effective—than crystalloid co-load.[92,97]

To conclude, colloids are more effective than crystalloids in preventing hypotension during SA for elective CD, particularly in women who have a positive preoperative supine stress test.[15] Routine use of colloids is not uniformly accepted in view of the expense, the potential for anaphylactic reactions, and the efficacy of rapid, high-volume crystalloid co-loading,[97] in combination with appropriate use of vasopressors.

## Vasopressor use

Fluids alone are inadequate to treat spinal hypotension in 40–60% of cases.[99] The most commonly used vasopressors worldwide are ephedrine and phenylephrine; this discussion is therefore limited to the intravenous administration of these agents, since prophylactic intramuscular administration may cause hypertension[100] or inadequate reduction of hypotensive episodes,[101] depending on the exact timing. The choice of vasopressor should be based upon a knowledge of the maternal haemodynamic effects of the agent, efficacy (preferably rapid onset and short duration), maternal and fetal side effects.

Ephedrine is a slow onset and relatively long-acting, non-catecholamine, direct-acting β-receptor agonist, with indirect α-effects via norepinephrine release. However, the exact mechanism of action remains controversial; one study in a rat model suggested mainly indirect effects via norepinephrine release,[102] and another supported direct α-effects.[103] In either case, the fact that the uteroplacental circulation is relatively devoid of sympathetic innervation, suggests a resistance to uterine arterial vasoconstrictive effects of this agent.[102] In support of this finding, ephedrine has been found to cause relatively more femoral than uterine artery vasoconstriction in pregnant ewes.[104] The vasodilatory effects of increased nitric oxide synthase activity in the uterine artery endothelium of pregnant ewes[105] suggests that ephedrine might preferentially shunt blood to the uterus in pregnancy.[99] A dose response meta-analysis of prophylactic IV ephedrine for the prevention of spinal hypotension, suggested a dose of 12 mg as a balance between benefit as a vasopressor and risk of causing hypertension.[106] Clinical disadvantages in terms of haemodynamic effects include a low efficacy for vasopressor effect,[106] the development of tachyphylaxis to the pressor effects,[107] and tachycardia and arrhythmias.[108] The rapid onset $\alpha_1$ agonist phenylephrine may be more effective for the reduction of nausea and vomiting during SA.[109]

The basis for the long-established use of ephedrine as a first-line drug for the management of spinal hypotension in obstetrics was a paper showing reductions of uterine blood flow in pregnant ewes following administration of α-agonists.[110] However an elegant subsequent study comparing pregnant with non-pregnant ewes, has shown that the pregnant uterine artery is less responsive to $\alpha_1$ agonist stimulation than the non-pregnant artery.[111] In the human haemochorial placental system, flow is very dependent upon pressure in the uterine arteries; thus phenylephrine maintains flow by its predominant effect on the systemic arterial pressure, while causing relatively little uterine arterial constriction.

One of the further chief objections to ephedrine is the fetal acidosis associated with its use. The decreased umbilical arterial pH and increased base deficit have been attributed to an ephedrine-generated increase in fetal metabolic rate, evidenced by an increase in an umbilical arteriovenous $PCO_2$ difference in patients receiving ephedrine when compared with phenylephrine.[109] Ephedrine also increases fetal catecholamine concentrations.[112] Transplacental transfer of ephedrine is more efficient than that of phenylephrine. When large doses are used (median

dose 60 mg ephedrine and 1.3 mg phenylephrine by infusion), umbilical arterial pH is lower (7.25 vs 7.34), and base deficit and lactate significantly higher (4.8 vs 1.9, and 4.2 vs 2.2 mmol/L respectively) in the ephedrine group.[113] Some neonates may have a genetic predisposition to fetal acidosis, based upon their $\beta_2$ adrenoreceptor haplotype.[114] Overall, both ephedrine and phenylephrine have been demonstrated to be safe for the fetus when used in healthy pregnant women in normal clinical doses.[115]. Minor increases in fetal metabolic rate may even be beneficial to the normal fetus; one investigation showed that neonatal respiratory rates were higher in patients randomized to placebo than the β-agonist terbutaline prior to elective CD. Neonates in the treated group also had lower airways resistance and higher pulmonary compliance.[116]

In the only published paper involving non-elective CDs, there were no significant differences in fetal acid–base status after randomization to phenylephrine or ephedrine.[117] It is, however, possible that in compromised infants already at risk of acidosis and intrapartum hypoxia, large doses of ephedrine may have a clinically deleterious effect, particularly by virtue of increased fetal oxygen consumption.

Phenylephrine is a potent direct-acting $\alpha_1$ agonist which has a rapid onset and is shorter acting by virtue of metabolism by monoamine oxidase. Two excellent reviews discuss the overall effects of phenylephrine on the human circulation, and specifically during obstetric SA.[118,119] A study comparing infusions of phenylephrine and ephedrine suggested a potency ratio of 81.2 (95% CI 73.0–89.7).[120] The time to peak pressor effect has been studied employing beat-by-beat finger arterial pressure. Phenylephrine has a significantly shorter time to peak effect than ephedrine (median 27 vs 78 seconds, P-value = 0.006).[121] A further study employing the LiDCO pulse waveform analysis system showed that baseline MAP was restored in approximately 40 and 90 seconds by phenylephrine and ephedrine IV boluses respectively.[38] Two investigations employing non-invasive blood pressure monitoring have examined the $ED_{95}$ and $ED_{90}$, respectively, of bolus phenylephrine, using up-down sequential allocation. The $ED_{95}$ of phenylephrine has been found to be 137 and 159 mcg for preventing hypotension and nausea, respectively.[122] However, the authors comment that a bolus of 120 mcg was effective and safe in all of the 50 patients. Another investigation estimated the $ED_{90}$ of phenylephrine to be approximately 150 mcg for the prevention of hypotension.[123] In view of the finding of a 75% increase in SVR after a bolus of 80 mcg phenylephrine,[37] the estimated $ED_{90}$ and $ED_{95}$ are too high for recommendation in routine clinical practice.

Overall, the selection and method of administration of a vasopressor to prevent hypotension should therefore be based on the efficacy in preventing *maternal symptoms*, and the maternal *haemodynamic changes in response to SA*.[124]

There are few available data comparing maternal CO responses to ephedrine and phenylephrine during SA for elective CD. Three published investigations have employed intermittent suprasternal Doppler flow measurements. In the first study, comparing bolus doses of the vasopressors, overall CO changes were not different between groups; however, bradycardia in the phenylephrine group was treated with atropine, which make the results difficult to interpret.[125] The primary outcome variable in this study was umbilical artery pH, and not maternal haemodynamic changes. Two further studies, employing infusions of vasopressors, suggested that phenylephrine may depress maternal CO.[126,127] Two studies employing beat-by-beat CO changes using the LiDCO monitor, have demonstrated the effects of phenylephrine on CO during elective CD.[37,38] In the latter investigation, the haemodynamic effects of boluses of phenylephrine (80 mcg) and ephedrine (10 mg), were studied using minimally invasive CO monitoring (both LiDCO*plus* and transthoracic bioimpedance measurements).[38] Vasopressor was administered in response to a 20% decrease in mean arterial pressure, at which point SVR had decreased by 35% and HR and CO had increased from baseline pre-SA values (~12% and 20% respectively). Figure 23.2 shows that phenylephrine reduced CO and HR to values approximating pre-SA baseline measurements, by reversing the SA-induced decrease in SVR and increase in CO. The study suggested that HR could guide phenylephrine dosing, in that HR correlated strongly with CO. In most cases, simply titrating phenylephrine to maintain the baseline HR will thus restore blood pressure and CO. When this typical response to SA is observed, it is not logical to use ephedrine to further increase CO, which in most cases is already elevated as a response to SA. A further disadvantage of ephedrine is that the peak pressor effect occurs later than in the case of phenylephrine (Figure 23.2).

Several investigators have examined the advantages of bolus versus infusion or a combination of these methods of administration of phenylephrine.[88,128,129] A comparison of a prophylactic infusion of 100 mcg/min phenylephrine with the administration of 100 mcg boluses in response to a decrease in blood pressure to less than 80% of baseline, showed a greater number of hypotensive episodes in the latter group, with no benefit in terms of cord blood gases. The prophylaxis group received approximately three times the dose of phenylephrine.[128] A subsequent investigation, using phenylephrine infusions to control blood pressure at 80%, 90%, or 100% of baseline values, suggested that tight control of blood pressure was associated with a lower incidence of nausea and vomiting, and a significantly higher umbilical arterial pH, which was, however, not clinically relevant.[129] A closed-loop feedback computer-controlled infusion has been used to maintain baseline blood pressure, using an on–off algorithm for a phenylephrine infusion at 100 mcg/min.[130] No patients were symptomatic, and umbilical arterial pH was above 7.2 in all 53 cases. Hypertension occurred in 38% of patients. Closed-loop feedback computer-controlled phenylephrine infusion has been shown to provide better arterial pressure control with fewer interventions required than with manual controlled infusion.[131] This is, however, not a readily practicable method in most units. The well-preserved cord gas values after high-dose phenylephrine,[129] suggest that phenylephrine is effective in sustaining uterine blood flow during SA by its effects on uterine artery perfusion pressure.

Initiation of a phenylephrine infusion immediately after induction of SA, rather than treating established hypotension, may be beneficial.[128] This was supported by a study in which 120 healthy women were randomized to a low-dose phenylephrine infusion (0.15 mcg/kg/min), an initial bolus of phenylephrine (50 mcg), or treatment of hypotension with phenylephrine (50 mcg).[132] In a further study using a suprasternal Doppler flow technique to measure changes in CO, three different phenylephrine infusion rates (25, 50, or 100 mcg/min) were administered after crystalloid preload in 75 patients.[127] An infusion rate of 100 mcg/min resulted in a clinically significant reduction in both HR and CO. Larger

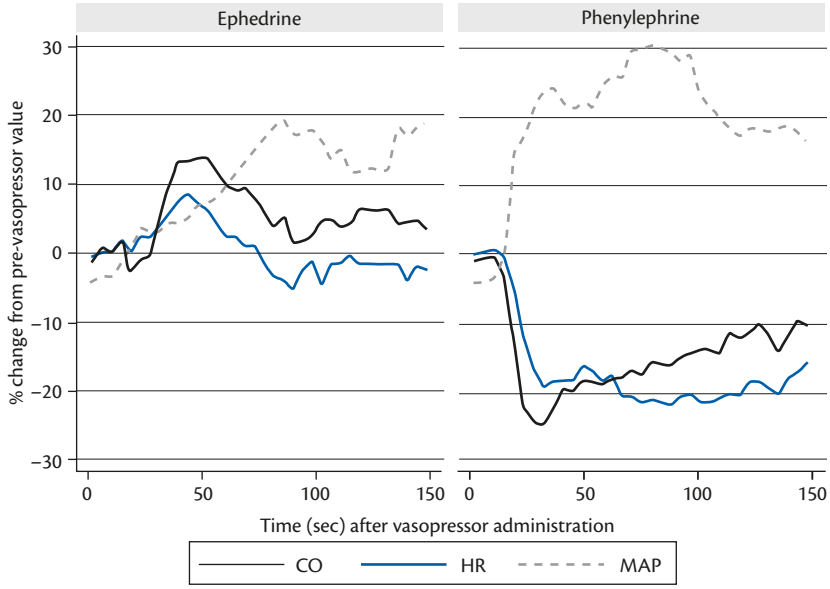

**Figure 23.2** Percentage changes, from pre-vasopressor values, in cardiac output (CO, as measured by LiDCO*plus* monitor), heart rate (HR) and mean arterial pressure (MAP) following the administration of vasopressor. Note that pre-vasopressor CO was 22% higher than baseline pre-spinal anaesthesia CO.

total doses of phenylephrine were required to maintain equivalent control of the blood pressure when the infusion rate was 100 mcg/min, suggesting a dose-related decrease in venous return. A further investigation compared placebo with four different fixed rates of phenylephrine infusion (25, 50, 75, and 100 mcg/min) in combination with a crystalloid co-load, using non-invasive blood pressure measurements in 101 patients.[133] There was no hypotension in the high-dose infusion group (100 mcg/min), but the incidence of hypertension in this group was 82%, and 32% of the patients developed bradycardia. There were no differences in the mean changes in systolic blood pressure when comparing the 50 and 100 cg/min groups. None of the patients in the 50 mcg/min group developed bradycardia, suggesting that the lower dose range of phenylephrine should be used. The authors also suggested that variable rate infusions would be more effective. The studies reviewed above provide valuable information on the dosing of phenylephrine when administered by bolus or infusion. However, research protocols follow a strict setup. Interpatient variability in response to SA and vasopressors require that treatment is guided both by the individual response and published recommendations.

Combinations of ephedrine and phenylephrine have also been studied. Phenylephrine added to an infusion of ephedrine halved the incidence of hypotension and increased umbilical cord pH,[134] but there is no apparent benefit over phenylephrine alone. In a study employing varying proportions of the two vasopressors by infusion, increasing proportions of ephedrine resulted in less favourable haemodynamic control as assessed by HR and blood pressure, and decreasing umbilical arterial pH and base excess.[135]

Overall, the studies confirm the finding from research pioneered by Ngan Kee et al.[108] that phenylephrine is the first line drug for the prevention or treatment of spinal hypotension. A potential disadvantage of *prophylactic* administration of phenylephrine is that the individual response, particularly in terms of HR, may be difficult to interpret. Many investigations suggest that the dose should be tailored to prevent hypertension and bradycardia. A review on vasopressor use during CD points out that the increase in blood pressure due to excessive doses of phenylephrine, is to some extent limited by a baroreceptor-mediated slowing of the HR.[136] Blocking the vagus nerve by the use of anticholinergic agents in this situation may therefore result in dangerous hypertension, as shown in two case reports.[136–138] This practice should thus be avoided.[139] In addition, administration of glycopyrrolate prior to induction of SA for CD, does not reduce the severity of hypotension, or vasopressor requirements.[140]

Despite documentation and recommendations for the use of phenylephrine and co-load,[88] a recent survey of practice amongst obstetric anaesthetists showed that the use of preload and ephedrine for prevention and treatment of spinal hypotension is still common practice.[141] This apparent reluctance of obstetric anaesthetists to change practice in response to convincing evidence from randomized trials, is highlighted in an editorial.[142]

In summary:

- *Hypotension and an increased HR is the typical response*. This response reflects a decrease in SVR, and a partial compensatory increase in CO, via an increase in HR and SV. Therefore, appropriate management is left lateral tilt, rapid crystalloid or colloid co-load, and the administration of IV phenylephrine. Given that this haemodynamic response is so common, good practice is to administer the vasopressor prophylactically. Since the haemodynamic response varies between patients, it is also reasonable to administer phenylephrine in immediate response to an increase in the HR. Current evidence is that the best approach is to titrate the rate of phenylephrine administration in order to maintain the baseline *HR*, since this restores SVR, CO, and blood pressure to baseline values. The initial dose should be a 50 mcg bolus, followed by intermittent 50 mcg boluses or infusion (25–50 mcg/min), or both as required. There is no evidence to

support the use of anticholinergic agents in the setting of a normal or raised blood pressure and a decreased HR in response to phenylephrine. This can cause tachycardia and hypertension.

- *Hypotension and bradycardia*. Since the final common pathway is the vagus nerve, anticholinergics should be administered, preferably atropine 0.5 mg if bradycardia is severe, together with attention to maternal position and accelerated fluid administration. Ephedrine may also be used in conjunction with anticholinergic agents, but theoretically it may worsen bradycardia if the BJR is involved, since $\beta_1$ agonist-induced mechanical stretch of an empty left ventricle may initiate the reflex.
- *Persistent refractory hypotension*. Since a possible misdiagnosis has been made with respect to fluid balance or underlying cardiac pathology, adequate uterine displacement should be ensured, larger doses of vasopressor and/or small bolus doses of positive inotropes such as adrenaline (10 mcg) may then be necessary, together with close attention to fluid balance.
- *High motor block*. This results in increasing dyspnoea and weak respiratory effort, followed by apnoea. Concomitant sympathetic block may result in cardiovascular collapse, requiring full cardiopulmonary resuscitation.

## Special considerations in pre-eclampsia

When one considers the cardiovascular pathophysiology of severe pre-eclampsia, including decreased intravascular volume and markedly raised SVR,[143] there has been an understandable caution as regards neuraxial anaesthesia in these patients, due to the theoretical possibility of precipitous hypotension, decreased CO, and associated placental hypoperfusion. Epidural anaesthesia for labour has been found to be associated with remarkable haemodynamic stability, as demonstrated by the use of pulmonary artery catheterization, in patients with severe pre-eclampsia who were receiving magnesium therapy.[144] SA has only recently been recognized to have a place in operative management in pre-eclampsia. In 1995, three groups of patients with severe pre-eclampsia were randomized to receive epidural, CSE, or general anaesthesia for CD, with similar haemodynamic stability (as assessed by HR and blood pressure) and fetal outcome in each group. Patients with non-reassuring fetal heart traces were excluded from this study.[145] Subsequently an editorial highlighted a study which showed that haemodynamic stability was equivalent in patients receiving spinal or epidural anaesthesia for non-emergency CD.[146,147] Fluid requirements were, however, higher in the spinal group. Despite the gradually emerging evidence that SA was safe in pre-eclampsia, at least one editorial called for caution, and stressed the value of epidural anaesthesia.[148] In a randomized multicentre study, SA was associated with a higher incidence of hypotension and a higher ephedrine requirement than epidural anaesthesia for CD for pre-eclampsia, but these differences were not of clinical significance.[149]

Early investigations showed that withdrawal of sympathetic activity, both by SA and by autonomic ganglion blockade, has less effect in pre-eclamptic women than in healthy pregnant and non-pregnant women.[150,151] More recently, several authors have confirmed that SA for CD in severe pre-eclampsia is associated with less hypotension and/or vasopressor requirements than in healthy parturients.[152–155] One such study used a control group consisting of healthy patients having a preterm CD, in whom the neonatal weights were similar to those in the pre-eclampsia group. This ensured that observed differences in blood pressure were not due to varying degrees of aortocaval compression in the two groups, as might have been the case in a previous study by the same authors.[153]

There are no definitive data on fluid management during SA for CD in patients with severe pre-eclampsia. Mean central venous pressure has been shown to increase significantly after a preload of 1 L of crystalloid, but returned to normal shortly after induction of anaesthesia.[156] Atrial natriuretic peptide release after a crystalloid preload is exaggerated in patients with pre-eclampsia relative to healthy parturients, and this may aid in the adaptation of maternal circulation to a volume load at elective CD.[157]

There are limited CO data in the setting of SA for CD in severe pre-eclampsia. Owing to a significant incidence of complications using the pulmonary artery catheter, the research focus has moved to non-invasive technologies. In only a few studies has CO been monitored during SA for CD. Whole-body impedance cardiography was used in a study to evaluate maternal CO changes in ten pre-eclamptic women, of whom six had severe disease, undergoing CD with SA.[158] After recovery from SA, stroke index and cardiac index in the pre-eclamptic group were significantly lower than pre-surgery levels. By contrast, using the LiDCO*plus* monitor in 15 women with severe pre-eclampsia, CO was shown to be stable during SA, suggesting that SA is well tolerated in these patients.[159] The main effect was a modest afterload reduction. On first principles this is desirable in severe pre-eclampsia, since SVR is often raised. This suggests that vasopressor therapy during SA should be conservative in patients with severe pre-eclampsia, and a modest lowering of blood pressure should be allowed before treatment is initiated. There are no randomized trials comparing the maternal or fetal effects of phenylephrine and ephedrine in this patient population. In this study, phenylephrine 50 mcg effectively raised SVR in cases in whom hypotension required treatment.

Detailed investigations employing transthoracic echocardiography have shown that the cardiac abnormality in patients with severe pre-eclampsia is diastolic dysfunction.[160,161] This work confirms and clarifies earlier findings using pulmonary artery catheterization.[162] Inotropy is usually well preserved or increased, and an 'inovasoconstrictor' state is accepted as the usual response in severe disease. Early-onset disease may be associated with greater myocardial impairment,[163,164] as well as a higher SVR at an early stage.[165] The resistance to hypotension during neuraxial anaesthesia may thus be due to a combination of factors. Firstly, there is an imbalance between pro- and anti-angiogenic factors in pre-eclampsia, due to vascular endothelial damage caused by the release of proteins derived from the placenta.[166,167] This results in vasoconstriction. Secondly, the increased inotropic state of the myocardium[161] results in adequate compensation for any decrease in SVR induced by SA. In complicated cases with established pulmonary oedema and hypoxia, neuraxial anaesthesia may be relatively contraindicated. There are no good data in these cases concerning the concomitant development of systolic hypofunction. An interesting laboratory study postulates that there may be a link between peripartum cardiomyopathy and severe pre-eclampsia. Peripartum cardiomyopathy may be due to an imbalance of angiogenesis in pregnancy, and markedly raised levels of soluble tyrosine kinase in severe pre-eclampsia may also

be associated with antiangiogenic effects, with resultant systolic hypofunction.[168]

## Neuraxial anaesthesia in patients with cardiac disease

Due to improved cardiac surgical techniques and follow-up, more patients with congenital heart disease reach fertile age.[169] Increasing numbers of women with congenital and acquired heart disease require operative delivery. Pregnant women with cardiac disease should be managed by a multidisciplinary team including an obstetrician, a cardiologist, and an anaesthesiologist.[148–150] Patients at high risk for cardiac instability should have a planned delivery at a tertiary centre with specialized cardiac services, including options like the intra-aortic balloon pump, and high-quality critical care.

Several case reports describe the use of titrated neuraxial anaesthesia in high-risk patients with cardiac disease.[170,171] Favourable outcomes have also been documented in case series using neuraxial anaesthesia for elective CD in high-risk patients,[172–174] despite recommendations to the contrary.[175]

One of these papers describes the management of ten pregnancies in nine women with pulmonary hypertension, all delivered by an elective CD, using an epidural or a CSE technique with perioperative CO monitoring, including admission to a critical care unit postpartum. This paper highlights the importance of antepartum treatment, an early elective CD using neuraxial anaesthesia, and postoperative monitoring in a critical care unit.[173] Another survey from the United Kingdom described continuous spinal anaesthesia in 34 women with congenital or acquired cardiac disease. Patients had continuous invasive arterial monitoring. Using a mean dose of spinal bupivacaine of approximately 10 mg, the mean dose of phenylephrine required was 550 mcg, and 18% had transient symptomatic hypotension with no adverse effects.[172] A third survey from Norway reported favourable outcomes in moderate- and high-risk patients receiving SA or CSE, with spinal bupivacaine doses of 8–10 mg (combined with opioids).[174] One patient with severe peripartum cardiomyopathy (ejection fraction 15%, HR 150) had continuous spinal anaesthesia. The anaesthesia was well tolerated by all patients. The patients were monitored with continuous arterial blood pressure and pulse waveform-derived CO. Haemodynamic changes were prevented and treated with carefully titrated phenylephrine infusion and boluses.

Anaesthetists should understand both the cardiovascular pathophysiology and potential risks of neuraxial anaesthesia in the individual patient. A favourable outcome is dependent upon careful haemodynamic monitoring and close control of fluid balance. Patients with high risk for morbidity and mortality during pregnancy are those with Eisenmenger's syndrome, pulmonary hypertension, severe aortic and mitral stenosis, hypertrophic obstructive cardiomyopathy (HOCM), and poor ventricular function with New York Heart Association (NYHA) functional class greater than II independent of underlying cause.[176]

The same principles as described above in healthy patients can be applied in cardiac compromised women. These are the avoidance of aortocaval compression, the use of judicious doses and volumes of combinations of spinal local anaesthetic and opioids, co-loading, and the use of phenylephrine to counteract the initial vasodilatation and avoid tachycardia. A focus on the maternal circulation, both in terms of pressure *and* flow is mandatory in high-risk patients.[177]

In summary:

- Pregnant women with cardiac disease should be managed by a dedicated multidisciplinary team, and high-risk patients should have a planned elective delivery during daytime hours in a tertiary centre with specialized expertise in the peripartum management of these patients.
- A suggested approach to prevent haemodynamic instability and tachycardia during neuraxial anaesthesia in pregnant women with moderate and high-risk cardiac disease, is as follows:
  - Position: cardiac compromised pregnant women are more vulnerable to aortocaval compression and must be placed in left lateral tilt.
  - Monitoring: an arterial line is mandatory to detect rapid haemodynamic changes, and minimally invasive CO-monitoring is recommended. A pulmonary artery catheter may be indicated postoperatively in women with severe pulmonary hypertension in need of controlled ventilation.
  - Titrated anaesthesia:
    - Single-shot spinal, CSE, epidural, or continuous spinal anaesthesia should be chosen according to the specific lesion and NYHA classification. NYHA class III–IV patients with severe ventricular failure are especially vulnerable to rapid haemodynamic changes and tachycardia, and continuous spinal anaesthesia is recommended with small titrated doses of IV phenylephrine to counteract vasodilatation. In cases with moderate/severe mitral or aortic stenosis or HOCM, single-shot spinal (or CSE) anaesthesia may be tolerated, with co-load and initial more aggressive use of phenylephrine to compensate for the SA-induced induced vasodilatation.
    - General anaesthesia still has a significant role to play, especially in complex urgent or emergency cases.
  - Small titrated doses of oxytocin (0.1 IU) should be used, to avoid haemodynamic instability.
  - Postoperative monitoring is crucial to ensure a negative fluid balance during the first 72 hours after delivery.

# Conclusion

An improved understanding of maternal physiology, and of the haemodynamic changes associated with SA for CD, has made single-shot SA a safer and more comfortable experience for millions of mothers.

Key recommendations are as follows:

- Appropriate case selection (SA contraindicated in hypovolaemia).
- Left lateral tilt greater than 15°.
- Reducing the dose of spinal local anaesthetic reduces the incidence and severity of hypotension. However, the primary consideration is adequate maternal anaesthesia, and the dose of a single-shot spinal local anaesthetic should be not less than 10 mg bupivacaine alone or 8 mg with opioid. It can be reduced if CSE anaesthesia is used. There is no convincing evidence that the dose should be reduced in obese patients.

- Combination of crystalloid co-load 20 mL/kg (or occasionally colloid preload), and phenylephrine to prevent hypotension.
- The appropriate use of vasopressors and/or anticholinergics (see 'Vasopressor use').
- Co-morbidities:
  - In pre-eclampsia, single-shot SA is recommended, using at least as high a dose as employed in healthy term patients, if there is no epidural catheter in place.
  - CSE, and to a limited extent continuous spinal anaesthesia, appear to have a significant role to play in the management of CD in patients with cardiac disease.

Prevention is better than cure, but should spinal hypotension occur, rapid intervention is essential, based upon the exact clinical scenario and individual haemodynamic response. Thus future research in healthy patients should include the prediction and prevention of patients at risk of hypotension; for example, the development of a simple test of sympathovagal balance would be useful. In addition, for research purposes, haemodynamic monitoring during CD should be continuous—either minimally invasive, which allows for CO monitoring, or non-invasive, in which case beat-by-beat blood pressure can be measured. This would inform clinicians as to how to reduce the incidence and severity of hypotension.

The incidence of obesity is increasing in the pregnant population, and more work is required on the haemodynamic effects of SA and the correct doses of spinal local anaesthetic in women with a high body mass index. In patients with cardiac disease, the increasing sophistication of transthoracic echocardiography allows for more accurate preoperative diagnosis, which can be followed by the intraoperative use of minimally invasive monitors and reduction of spinal hypotension by careful titration of vasopressors. Further echocardiographic investigation of the haemodynamics of patients with complicated severe pre-eclampsia could identify patients with both diastolic and systolic dysfunction, and who are therefore at high risk of spinal hypotension.

# CHAPTER 24

# Postoperative analgesia after caesarean delivery

Sarah L. Armstrong and Gary M. Stocks

## Introduction

In 1985, the World Health Organization stated that there was no justification for any region to have caesarean delivery (CD) rates higher than 10–15%, but it is recognized that in many countries around the world CD rates continue to escalate.[1] It is estimated that 18.5 million CDs are performed yearly worldwide with some South American countries reporting CD rates as high as 45% and many countries in Europe quoting rates of between 20% and 30%.[2] Postoperative pain after CD is therefore a problem affecting many millions of women each year.

Providing good quality postoperative analgesia is important not only for humanitarian reasons. It is well documented that effective pain relief after any type of surgery leads to earlier mobilization, fewer pulmonary and cardiac complications, a reduced risk of deep vein thrombosis, an earlier return of gastrointestinal function, and faster recovery.[3] Specifically for mothers after CD there are further benefits. Poor analgesia can impair the ability to look after the newborn infant and pain and/or anxiety can reduce effective breastfeeding. Furthermore inadequate treatment of acute pain can lead to chronic pain.[4] In a multicentre, prospective study of 1288 women hospitalized after CD or vaginal delivery, 10.9% experienced severe pain and women with severe acute postpartum pain had a 2.5-fold increased risk of persistent pain and a 3.0-fold increased risk of depression 8 weeks after delivery.[5]

Quite apart from the advantages of good pain relief for mothers we must increasingly respond to maternal demands and expectations. What do women think are the most important aspects of a good quality anaesthetic? Using written questionnaires Carvalho et al. asked patients to rank various anaesthetic outcomes and showed that pain during and after CD were the two most feared outcomes with minor side effects such as shivering and itching thought to be of only moderate concern.[6]

Both anaesthetists and patients therefore appreciate the importance of effective postoperative analgesia but there is evidence to suggest that provision of analgesia may not be as good as it could be. There are several ways to objectively measure pain intensity. One way is to use a visual analogue pain scale (VAPS) score, which is a unidimensional measure of pain intensity. When using a numerical VAPS score where 'no pain' is given a score of 0 and 'worst pain imaginable' scores 10, then by convention a VAPS score of greater than 3/10 is regarded as moderate to severe pain. Dolin et al. reviewed studies examining the incidence of pain (VAPS score > 3) after major surgery including CD and reported an incidence of 20.9% in patients with epidural analgesia, 35.8% for patient-controlled analgesia (PCA), and 67.2% for intramuscular (IM) analgesia.[7] Results from a US national survey suggest that a patient has a 50–71% chance of experiencing moderate to severe pain after surgery.[8] For CD there is little definitive evidence regarding achievable parameters in best practice.[9] Good practice guidelines from the United Kingdom have in the past suggested that over 90% of women after CD should have a worst pain score of less than 3/10,[10] but Wrench et al., using a multimodal analgesic approach for CD, reported that only 37.9% of their patients achieved a pain score of 3 or less and suggested, along with others, that this target was unachievable.[11] Subsequently the target for best practice has been revised, aspiring to 95% of women being 'satisfied' with analgesia the day after CD, but it would appear that there is still room for improvement.

A better understanding of the neurophysiology of pain transmission and pharmacology of analgesics has led to the realization that postoperative pain relief is best provided by using a variety of different analgesic techniques and drugs as part of a multimodal approach. This chapter will first look at the physiological basis for pain after CD before examining and evaluating the methods used for managing pain such as neuraxial, systemic, and regional techniques.

## Pain pathways

### Anatomy and physiology of pain transmission

In a healthy individual, pain is a complex sensory experience associated with actual or potential tissue damage. Noxious inputs stimulate the unspecialized, peripheral nociceptors which transmit signals to the dorsal horn of the spinal cord via small unmyelinated C fibres and medium A delta fibres[12] At the molecular level, pain stimulates the release of many mediators from keratinocytes and blood vessels in the dermis, including prostaglandins, substance P, and calcitonin gene-related peptide (CGRP) which depolarize nociceptive fibres and cause neurotransmitter release from the nerve itself into the periphery. This phenomenon, called axon reflex, causes vasodilation and inflammation. It results in a positive feedback loop that begins to recruit silent nociceptors and pain fibres in close proximity to the initially activated nerve.[12]

Pain fibres synapse with their secondary fibres at the superficial laminae (Rexed's I and II) of the dorsal horn where neuropeptides such as tachykinins (substance P and neurokinin A) and

glutamate are released at the presynaptic level. Opioid receptors and their ligands are present on the superficial dorsal horn, particularly on Rexed's lamina II (substantia gelatinosa).

The current nomenclature (approved by the International Union of Pharmacology) for identification of the opioid receptors is that of MOP, KOP, DOP, and NOP receptors. Opioids have both presynaptic (indirect) and postsynaptic (direct) facilitatory and inhibitory actions on synaptic transmission in many regions of the nervous system via G-protein coupled receptors. These effector systems can be divided into two categories: short-term effectors involving potassium and calcium channels and longer-term effects involving second messengers such as cyclic adenosine monophosphate (cAMP). Spinal opioids exert their analgesic effects by reducing neurotransmitter release at the presynaptic level, and by hyperpolarizing the membrane of dorsal horn neurons at the postsynaptic level.[13]

Opioid receptor activation can inhibit the release of CGRP, glutamate, and substance P from nerves, thereby preventing the forward-feeding mechanism of pain that typically results in sensitization at the site of injury.[14] These injury-induced neuromodifications (which may include microglial cell activation) can be perceived as allodynia (pain due to a stimulus which does not normally provoke pain) or hyperalgesia (an increased response to a normally painful stimulus). Moreover, peripheral sensitization drives the repeated release of molecular mediators at the dorsal horn, causing secondary hyperalgesia.

Descending pathways from the somatosensory cortex also modulate the perception of pain. Opioids exerting their effect at the supraspinal level promote descending pain modulation by increasing the release of inhibitory gamma-aminobutyric acid (GABA) from the periaqueductal grey and rostral ventral medulla.[15] This opioid disinhibition activates descending inhibitory pathways and increases the concentrations of serotonin and norepinephrine at the presynaptic level thereby modulating pain signals at the spinal cord.

## Pain pathways after caesarean delivery

Post-CD pain has both somatic and visceral components. Somatic pain arises from cutaneous and deep nociceptors within the abdominal wound which are transmitted within the anterior divisions of the spinal segmental nerves, usually T10–L1. These nerve fibres run laterally in the abdominal wall between the layers of the transversus abdominis and internal oblique muscles.[16] Visceral uterine nociceptive stimuli return via afferent nerve fibres that ascend through the inferior hypogastric plexus and enter the spinal cord via the T10–L1 spinal nerves.[17,18]

An ideal post-CD analgesic regimen would be one that is cost-effective and simple to implement providing high-quality pain relief despite wide interpatient variability with a low incidence of side effects and complications. This ideal regimen would not interfere with the maternal care of the newborn or breastfeeding, with minimal drug transfer into the breast milk. Achieving these goals requires a multimodal approach.[19,20]

## Multimodal analgesia

An appreciation of the complexity of the neurophysiology of pain transmission and the numerous potential sites of action for analgesics to work has resulted in many different ways of providing analgesia after CD. Approaches can be divided into opioid-based techniques using intrathecal, epidural, or systemic routes with or without the use of adjuvant agents, wound infiltration, and nerve blocks and the use of oral analgesics such as paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs). It is unlikely that utilization of one method alone will be effective and so the concept of multimodal analgesia is now well established in clinical practice. This is a technique intended to improve analgesia and to reduce the incidence of unpleasant opioid-related side effects. It is achieved by combining analgesics which work by different mechanisms and at different sites in the nervous system and results in an additive or even synergistic effect whilst at the same time reducing side effects (Figure 24.1). For CD, many of the techniques described in this chapter should be used as part of a multimodal approach to analgesia. A growing number of studies seem to support a multimodal approach for post-CD analgesia.[20] For example, NSAID medications combined with intravenous (IV) patient-controlled morphine administration may decrease nausea and sedation in patients when compared with those using patient-controlled morphine alone.[21] However, only NSAIDs (in combination with morphine) reduce pain intensity and the incidence of morphine-related side effects. Neither paracetamol nor the selective COX-2 inhibitors have been shown to affect the incidence of opioid-induced nausea, vomiting, or sedation when used in combination with these agents. Different classes of analgesics with different routes of administration (i.e. IV versus epidural methods) are used to produce fewer side effects such as sedation, nausea, vomiting, pruritus, and constipation, and also improve pain relief.

## Neuraxial techniques for postoperative pain relief

### Benefits

Most CDs are performed using spinal, epidural, or combined spinal–epidural (CSE) anaesthesia techniques. Data from the United Kingdom shows that neuraxial anaesthesia is used for 94.9% of elective and 86.7% of emergent CDs.[22] The safety benefits of neuraxial anaesthesia over general anaesthesia in the pregnant patient are well documented, and neuraxial opioid administration augments intraoperative anaesthesia and optimizes postoperative analgesia.[23,24]

In the non-obstetric population, the MASTER (Multicentre Australian Study of Epidural Anaesthesia and Analgesia in Major Surgery) trial was the largest prospective study to date comparing epidural and intravenous patient-controlled opioid analgesia (PCA) for postoperative analgesia. The study used random sampling to evaluate mortality and major morbidity outcomes in high-risk patients undergoing non-obstetric surgery.[25] Of the seven predefined major morbidity complications assessed in this study, respiratory failure was the only outcome with a lower incidence in the epidural infusion group than in the PCA group.

Administration of subarachnoid or epidural opioids to parturients, however, offers several advantages when recovering from CD. These include excellent postoperative analgesia with a decrease in total dose of opioid required, a low level of sedation, minimal accumulation of the drug in breast milk and facilitation of early ambulation. Neuraxial analgesic techniques appear more likely to reduce perioperative morbidity in high-risk obstetric patients than systemic analgesic techniques. The benefits include a lower rate of perioperative cardiovascular complications, a lowered incidence of pulmonary infections and pulmonary embolism, a faster return of gastrointestinal function, fewer coagulation disturbances, and reduction in inflammatory and stress responses to surgery.[26] Potency, onset, duration of action, and side effects vary depending on the opioid used and the route of its administration with pruritus, nausea, and vomiting being the most common side effects of these agents, resulting in a decrease in maternal satisfaction.

### Pharmacology of neuraxial opioids

Neuraxial opioids have the advantage of producing analgesia without motor or sympathetic blockade. Opioids, especially diamorphine and preservative-free morphine, are central to many neuraxial post-CD analgesic regimens. They appear to act principally on MOP receptors in the substantia gelatinosa of the dorsal horn by suppressing the release of excitatory neuropeptides from C fibres.[27] Lipid solubility of the individual drug determines the degree of uptake from the cerebrospinal fluid (CSF) by the dorsal horn. Lipid soluble drugs like fentanyl or sufentanil have better direct diffusion into neural tissue as well as greater delivery to the dorsal horn by spinal segmental arteries. Highly soluble fentanyl, for instance, has a relatively rapid uptake into the lipid-rich dorsal horn and consequently has a rapid onset of action but a short duration. Studies that measure 24-hour opioid consumption confirm its limitations for adequate postoperative analgesia.[28] Conversely, lipid-insoluble opioids, such as morphine, are retained in the CSF, providing a longer supply to the spinal cord and consequently a slower onset, but longer duration of analgesia after the administration of a single dose.[29] As morphine resides for a longer period of time in the CSF it may spread rostrally, from which complications such as respiratory depression may arise.[30]

Lipophilicity, as assessed by octanol:buffer distribution coefficient, correlates with the meningeal permeability coefficient but in a non-linear fashion. After a drug is deposited in the epidural space but before it reaches the spinal cord, it must first cross a hydrophilic zone (extracellular and intracellular fluids) and then a hydrophobic zone (cell membrane lipids) of the arachnoid membrane.[29] Lipophilic drugs (i.e. those with high octanol:buffer partition coefficients, e.g. fentanyl and sufentanil) readily dissolve in the lipophilic component of arachnoid mater and can cross the region easily. Conversely, they penetrate the hydrophilic zone with difficulty creating the rate-limiting factor in their diffusion through the arachnoid membrane. Drugs with intermediate lipophilicity move more readily between the lipid and the aqueous zones, and their meningeal permeability coefficients are correspondingly greater (e.g. alfentanil, hydromorphone, and pethidine).[29] These physical and chemical properties of the opioids will also determine vascular permeability. Lipophilic opioids such as fentanyl and sufentanil move more easily to the intravascular compartment than to the subarachnoid compartment. In this way spinal cord concentrations of an opioid following epidural administration are the result of the net difference between the rate of uptake and distribution to the vascular and subarachnoid spaces. These differences explain why morphine, despite having a meningeal permeability coefficient similar to fentanyl and sufentanil, which are well below the optimal range of meningeal penetration, is a useful agent for epidural analgesia.

There has been some debate in the past concerning the site of action of epidurally administered opioids with some studies suggesting that epidural fentanyl produces analgesia by systemic absorption and redistribution to the brain rather than by acting through a spinal mechanism. It would appear that the site of action depends on firstly whether the epidural fentanyl is given as a bolus or infusion, and secondly whether it is co-administered with local anaesthetic. Several studies have shown that when given as a bolus, epidural fentanyl has a spinal effect but when given as an infusion, without local anaesthetic, others have shown a systemic mechanism of action.[31–33] This is probably because low concentrations of lipophilic opioid are subject to rapid vascular uptake. However, when given as an infusion in the presence of epidural bupivacaine fentanyl appears to act spinally rather than systemically. Ginosar et al. performed a prospective, randomized, double-blinded study in which women in active labour received epidural bupivacaine until pain free. The women were then randomized to receive either IV or epidural fentanyl infusions. It was found that an equivalent dose of fentanyl was more than three times as potent when administered epidurally than by the IV route, suggesting a predominantly spinal mechanism of opioid action.[34]

## Intrathecal opioids

### Intrathecal morphine

Morphine is highly ionized and hydrophilic and does not penetrate lipid-rich tissues as rapidly as fentanyl. Morphine remains within the CSF for a prolonged period of time, spreading rostrally and reaching the trigeminal nerve distribution 3 hours after

intrathecal injection in healthy volunteers.[35] Morphine requires 45–60 minutes to achieve a peak effect, and the duration of analgesia is 14-36 hours. This duration may be dose dependent.

A variety of intrathecal morphine doses have been investigated. Palmer et al. studied patients receiving intrathecal doses from 25 to 500 mcg and found a ceiling effect with doses greater than 75 mcg, as measured by patient-controlled IV morphine consumption with no clear dose–response relationship demonstrated using doses greater than 100 mcg.[36] Higher doses conferred no additional analgesic benefit but caused a dose-dependent increase in side effects, particularly pruritus. It was also noted that despite high doses of intrathecal morphine, most parturients continued to administer additional opioid analgesia at a low but constant rate, possibly explaining the interaction between spinal and supraspinal sites of action. Yang et al. administered 100 or 250 mcg of morphine as a component of spinal anaesthesia to 60 women undergoing elective CD. Women also received 20 mcg of intrathecal fentanyl and perioperative and postoperative NSAIDs routinely. There was no significant difference between the small and larger-dose morphine groups in pain relief, as measured by a VAPS.[37] In a systematic review of intrathecal opioid usage in patients undergoing CD, Dahl et al. reported a median time to first analgesic request of 27 hours (range 11–29 hours) and recommended an intrathecal dose of 100 mcg.

Adverse effects of intrathecal morphine have been reported widely and include pruritus, nausea and vomiting, urinary retention, and early or delayed respiratory depression. The most common side effect, pruritus, increased in severity as morphine doses increased. If a morphine dose of 100 mcg is used, it is estimated that 43% of women will experience pruritus, and 12% will experience nausea and vomiting.[30]

## Intrathecal diamorphine

Diamorphine (3,6-diacetylmorphine, also known as morphine diacetate) is a semi-synthetic opioid produced by acetylation of morphine. The administration of neuraxial diamorphine for the treatment of pain relief after CD is a common practice in the United Kingdom even though it is not licensed for intrathecal use.[38] In contrast, in the rest of the world diamorphine is unavailable for clinical use. Diamorphine has many of the ideal physicochemical properties to provide good pain relief during and after surgery with the potential to decrease side effects. The intermediate lipid solubility of diamorphine (oil/water partition coefficient 280), increases permeability to both hydrophobic and hydrophilic tissue compartments when compared either with morphine or fentanyl. Diamorphine undergoes metabolism within spinal cord tissue, generating active compounds (6-acetyl morphine and morphine) which increases the analgesic effects. These metabolites are less lipid soluble than the parent drug, which limits their back diffusion into the CSF. Other important physicochemical characteristics of diamorphine are lower PKa (PKa 7.8), low protein binding (40%), and a high unionized fraction (27%) that increases the bioavailability for opioid receptors within the spinal cord and increases clearance from CSF, decreasing the potential for serious side effects such as respiratory depression.[39]

These physicochemical properties explain why intrathecal diamorphine is effective for both intraoperative and postoperative analgesia. Cowan et al. randomized 74 parturients undergoing elective CD to receive either 20 mcg fentanyl or 300 mcg diamorphine intrathecally with hyperbaric bupivacaine.[40] They found no difference in intraoperative analgesia requirements between the groups but also demonstrated reduced VAPS score 12 hours postoperatively in the diamorphine group compared to only 1 hour in the fentanyl group. They found no difference in pruritus postoperatively between the opioid groups. In a study of 200 women undergoing CD, Saravanan et al. concluded that the effective dose $(ED)_{95}$ for intrathecal diamorphine to prevent intraoperative supplementation was 0.4 mg and that this provided a mean time interval to first request for analgesia of 601 minutes.[41]

There have been other studies looking at intrathecal diamorphine doses for pain relief after CD. Skilton et al. and Kelly et al. looked at doses up to 0.375 mg and found improved analgesia (as determined by the amount of rescue analgesia required) as the dose increased without a ceiling effect.[42,43] Stacey et al. randomly allocated 40 women undergoing elective CD to receive either 0.5 mg or 1 mg of intrathecal diamorphine.[44] They found the time to request for rescue analgesia was significantly longer and 24-hour morphine consumption was significantly lower in the 1 mg group (45% using no opioids postoperatively at all) and that pain scores in this group tended to be lower. Minor side effects were found to be present in both groups but the incidence did not differ between groups. In the United Kingdom, the National Institute for Health and Care Excellence (NICE) recommends women should be offered diamorphine (0.3–0.4 mg intrathecally) for intra- and postoperative analgesia.[45]

## Alternative intrathecal opioids

Other less commonly used intrathecal opioids include pethidine (meperidine), buprenorphine, and nalbuphine. Pethidine is the only member of the opioid family with local anaesthetic-like effects and it has a tendency to sometimes result in motor block. It has historically been used as a sole spinal drug for CD.[46]

Fentanyl is arguably one of the most commonly administered intrathecal opioids worldwide. Its relatively high lipid solubility results in a greater restriction of segmental activity and rapid onset of action when compared to morphine. Although intrathecal fentanyl offers a relatively short duration of analgesia, it is shown to improve intraoperative analgesia, especially during uterine exteriorization, and provides the patient with a better postoperative transition to other pain medications during recovery from intrathecal anaesthesia. The short duration of action of fentanyl generally makes it an unfavourable sole choice intraoperatively to provide post-CD analgesia but one study has suggested intrathecal fentanyl may also offer a longer-term analgesic benefit when administered alongside a local anaesthetic at the time of CD.[47] In many units, intrathecal fentanyl is combined with intrathecal preservative-free morphine to give superior intraoperative analgesia combined with the benefits of analgesia extending into the second postoperative day. In contrast to morphine, intrathecal fentanyl does not appear to predispose the patient to nausea and vomiting following CD and causes less severe pruritus and respiratory depression.[30,48] Sufentanil is a thienyl derivative of fentanyl but has higher potency due to greater lipid solubility. Intrathecal sufentanil offers some theoretical advantages over fentanyl including faster onset, reduced rostral spread, and a lower level of placental transfer. Several studies have been performed comparing fentanyl and sufentanil for analgesia for CD and have found them to be equivalent but those women in the sufentanil

groups experienced more pruritus. Again, the short duration of action of intrathecal sufentanil prevents routine use for postoperative analgesia for CD.[49–51]

## Epidural opioids

When anaesthesia for CD is provided by using an epidural top-up or a CSE technique then the epidural catheter provides another useful route to administer neuraxial opioids and a number of different opioids are used in this way

### Epidural morphine

Epidural morphine is most commonly administered as a single bolus dose. Because of its low lipid solubility it has a relatively slow onset of action with its peak analgesic effect occurring after 60–90 minutes. However, its duration of action has been shown to provide pain relief for approximately 24 hours.[52] A recent systematic review of ten studies comparing analgesia efficacy and/or adverse effects of a single bolus dose of epidural morphine versus systemic opioids after elective CD proved that a single bolus of epidural morphine provides better analgesia than parenteral opioids but with an effect limited to the first postoperative day after CD and with an increase in side effects.[53]

A range of doses have been investigated. Palmer et al. performed a dose–response study looking at varying doses of epidural morphine between 0 and 5 mg for post-CD pain and found a ceiling effect in terms of analgesia. They found no difference in cumulative systemic morphine use above 3.75 mg used epidurally while 3 mg of morphine epidurally appeared equivalent to 100 mcg intrathecally and was found to provide analgesia for 12–24 hours.[36,54] Based on this study and a systematic review, the general practice is to use 3 mg of preservative-free morphine in the epidural space.[53]

Due to its prolonged analgesic effects, epidural morphine can be administered as an intermittent bolus or as a continuous infusion. It appears that some clinical advantages exist using continuous epidural morphine infusions over intermittent bolus for epidural analgesia. Studies in the non-obstetric population evaluating morphine's cephalad migration after a lumbar epidural bolus suggest that respiratory depression may occur as a result of significant amount of the drug reaching the respiratory centre in the brainstem after the administration of a bolus dose in the lumbar epidural area.[29,55] In fact, large-scale studies suggest that respiratory depression requiring treatment may be higher with intermittent bolus than with continuous infusions.[56,57] When mean doses between 7 and 13 mg/day were utilized in the intermittent bolus group and mean doses of 6–14 mg/day were used in the continuous infusion group, the incidence of respiratory depression was different. In the bolus study group, the incidence of respiratory depression was 1/500.[56] In contrast, in the continuous infusion group, the incidence was 1/1500. Based on these data, in the non-obstetric population the maximum risk of respiratory depression within the 95% confidence intervals are 1/100 versus 1/5000 respectively. Moreover, the concurrent use of parenteral opioids for breakthrough pain, a practice which has been discouraged when intermittent dosing of epidural morphine is used, may be administered without an increased risk of delayed respiratory depression even on the surgical wards.[56]

Interestingly, the quality of analgesia appears to be more complete when utilizing continuous infusions compared with an intermittent bolus. A study in the non-obstetric population evaluating the quality of analgesia produced by epidural morphine administered either as bolus doses or via continuous infusion demonstrated that patients who received continuous infusion of epidural morphine experienced a higher quality of analgesia than those who received intermittent bolus injections.[58] Based on apparent greater clinical efficacy and a lower incidence of respiratory depression it would appear that patients would derive a greater benefit from receiving epidural morphine via a continuous infusion.

### Epidural diamorphine

Diamorphine is commonly administered epidurally in the United Kingdom because its high lipid solubility provides rapid onset of action and its main metabolite (morphine) provides a prolonged duration of action. Doses have been used in the range of 2.5–5 mg and have demonstrated prolonged duration of analgesia with 5 mg doses expected to provide analgesia for a mean duration of 14 hours.[39,59] However smaller epidural doses are associated with a lower incidence of nausea and vomiting suggesting that 3 mg is the optimum dose of diamorphine to administer epidurally.[59–61]

### Single-dose extended-release epidural morphine

The goal of current postoperative pain research and development is to find a medication that can work locally to give long-lasting pain relief at the site of surgical focus with as little negative impact as possible. Single-dose, extended-release epidural morphine (EREM) (DepoDur®, Endo Pharmaceuticals, Chadds Ford, PA) is a recently developed drug that delivers conventional morphine sulphate using DepoFoam® (SkypePharma, San Diego, CA) technology. DepoFoam® is a revolutionary drug delivery system containing multivesicular lipid particles comprised of non-concentric aqueous chambers that fully encapsulate the active drug. These naturally occurring lipids are broken down by erosion and reorganization, resulting in a locally contained morphine depository for up to 48 hours after a single administration.[62]

Clinical studies within the obstetric population show EREM's postoperative analgesia consistently extending into the second day with no significant side effects. This is of notable benefit as a single dose of neuraxial morphine would lose its efficacy in this time frame and peak post-CD pain levels are not typically reached until 24–48 hours following surgery.[63] When an EREM dosage of 10 mg was compared to that of a standard 4 mg dose of epidural morphine, the supplemental opioid dose usage during the 24–48 hours postoperatively was significantly decreased by 60% in patients receiving EREM. Additionally, no significant differences in the occurrence of nausea, pruritus, sedation, respiratory depression, or hypoxic events were observed between these two groups.

Clinical trials have demonstrated the efficacy of EREM for postoperative pain relief following hip arthroplasty and elective CD.[64,65] Recent pharmacokinetic data obtained by Gambling et al. have described the effective use of EREM in a controlled, dose-ranging study of 114 patients following lower abdominal surgery.[66] The authors observed that the best balance of maximum analgesia with the lowest occurrence of side effects was achieved by administration of 15 mg of EREM and as such recommended

that a multimodal pain management approach—such as the addition of a NSAID to the regimen—could further reduce the dose required to provide effective analgesia and reduce concomitantly the occurrence of adverse side effects.

While the prolonged analgesic effect during the first 48 hours using EREM is quite attractive, this advantage must be weighed against the potential disadvantages. One of these includes the instability of the formulation in the presence of local anaesthetics. Local anaesthetics other than a test dose cannot be administered immediately before or after the administration of EREM which has obvious implications when topping-up an existing epidural for CD. An in-line epidural filter cannot be used due to the viscosity of the preparation. No clinical studies have evaluated the safety of administration of EREM into the intrathecal space. In cases of accidental intrathecal injection, in post-marketing experience there were signs of prolonged respiratory depression requiring naloxone administration or ventilatory support. In terms of safety, there is the need for prolonged monitoring of patients following its administration, and the cost of the formulation may be prohibitive.[67] In September 2009, the US Food and Drug Administration (FDA) approved safety labelling revisions for EREM to emphasize the need for individualized dosing adjustments, as well as the need for monitoring capabilities, resuscitative equipment, and opioid antagonist availability. When EREM is given correctly in the epidural space, monitoring should be continued for up to 48 hours.

### Alternative epidural opioids

The quality of analgesia experienced after hydromorphone administration appears to be similar to that produced by morphine.[68] Based on unpublished clinical observations, a ratio of 5:1 between morphine and hydromorphone has been utilized when administering the drug in a bolus form, and a ratio of 3:1 has been recommended for continuous infusions. Hydromorphone appears to have a faster onset and shorter duration of action than morphine with a lower incidence of pruritus.

Fentanyl, which has a high octanol:buffer coefficient, appears to undergo preferential vascular absorption rather than meningeal penetration after epidural administration. In fact, the value of utilizing fentanyl for epidural analgesia is controversial. Several studies have demonstrated that the quality of analgesia, the incidence of side effects, daily fentanyl utilization, and plasma levels after 24 hours of infusion are similar between patients receiving either epidural or IV therapy after non-obstetric surgery and at CD.[69–72]

Sevarino et al. performed a double-blinded randomized study on 40 American Society of Anesthesiologists (ASA) I/II women undergoing elective CD under lidocaine epidural anaesthesia who received after delivery either saline or 100 mcg fentanyl through the epidural catheter.[73] All patients were provided with an IV pethidine PCA postoperatively and it was noted that no differences in PCA use were recorded between the groups. The authors concluded that a single bolus of epidural fentanyl does not provide an advantage for postoperative pain relief in this patient population.

## Patient-controlled epidural analgesia

The first study of patient-controlled epidural analgesia (PCEA) following CD, by Parker and White, described it as a safe, effective alternative to IV PCA with less opioid use and more rapid recovery.[74] In a follow-up study, the same investigators found that the efficacy of PCEA was not improved by adding a background infusion.[75] PCEA has been compared with IM opioid analgesia where it was found that PCEA pethidine resulted in better analgesia, earlier ambulation, and improved ability to care for the neonate.[76] PCEA has been shown to provide improved quality pain relief when compared with patient-controlled IV fentanyl, morphine, or pethidine, although no difference was found when epidural hydromorphone was also infused.[68,74,76–78] PCEA without a background infusion can provide adequate analgesia after CD, using either fentanyl or pethidine.[76,79] PCEA has been repeatedly shown to reduce opioid requirements and could potentially be an excellent method of postoperative pain relief for CD.[20,80,81] The combination of local anaesthetics and opioids in PCEA postoperatively for CD appears to have the benefit of achieving postoperative analgesia without significant motor blockade. This is extremely important to allow the mother to take care of her baby. However, the overall popularity of the technique is limited. The requirement for prolonged epidural catheterization can result in failures and interfere with thromboprophylactic low-molecular-weight heparin (LMWH) administration and removal of the urinary catheter. Furthermore, carrying an epidural infusion pump can be cumbersome whilst ambulating and caring for a newborn. In addition, Vercauteren et al. considered the cost-effectiveness of PCEA by randomizing 53 women for elective or semi-urgent CD to receive either PCEA with bupivacaine and sufentanil or intrathecal bupivacaine and morphine. They found that in the PCEA group patients had lower VAPS scores both at rest and during mobilization. Manpower and drug costs were equal in both groups. The total cost per head was more expensive in the PCEA group mainly as a result of the more costly equipment required.[82]

## Intrathecal and epidural opioids compared

When a CSE is used to provide anaesthesia for CD, longer-acting opioids could be administered either intrathecally with the initial spinal injection of local anaesthetic or epidurally towards the end of the operation. When an opioid is administered intrathecally, the analgesic effects and side effects such as respiratory depression, pruritus, and nausea and vomiting are caused by the drug gaining access to the spinal cord and brainstem via the CSF. In contrast, when an opioid is administered epidurally, a small proportion of the dose crosses the meningeal layer whilst the remainder gains access to the central nervous system via IV absorption through the epidural venous plexus, potentially leading to side effects. The rate of dural transfer of an opioid has been shown to be inversely proportional to the molecular weight of the drug with the exception of fentanyl which has a much higher rate of transfer possibly due to its linear molecular shape.[83] Deciding whether to administer an opioid intrathecally or epidurally therefore needs to balance the benefits of analgesia and the occurrence of side effects and is complicated by an incomplete understanding of equivalent intrathecal and epidural doses and the different physicochemical properties of various opioids.

There are, however, several studies in the literature comparing the use of epidural and intrathecal opioids for post-CD analgesia. Sarvela et al. performed a double-blinded, randomized controlled trial comparing 3 mg epidural morphine with either 100 mcg

or 200 mcg intrathecal morphine and found no significant differences in pain scores. However, rescue analgesia was requested more frequently in the 100 mcg group suggesting this dose was less effective for post-CD analgesia and perhaps unsurprisingly this group were shown to have less pruritus.[84] When Bloor et al. compared intrathecal diamorphine 0.3 mg with 3.0 mg epidural diamorphine they demonstrated that the duration and quality of analgesia was comparable in the two groups but the incidence of pruritus was higher and more severe in the intrathecal group.[61] In contrast, Hallworth et al. showed a high incidence of pruritus in both groups but more nausea and vomiting in the epidural group when comparing intrathecal diamorphine 0.25 mg with diamorphine 5 mg epidurally.[39] Again, duration and quality of analgesia were similar. It would appear that in terms of analgesic efficacy there is little to choose between the two routes; however, intrathecal and epidural opioids can result in significant levels of pruritus and larger epidural opioid doses produce more nausea and vomiting.

## Side effects of neuraxial opioids

There are certain side effects associated with neuraxial blockade although it is widely accepted that the benefits outweigh the risks. The main adverse effects are that of respiratory depression, nausea and vomiting, pruritus, and urinary retention and these appear to be associated with the degree of rostral migration of the opioid in the CSF. The timing for the appearance of these side effects varies between lipophilic and hydrophilic opioids after epidural administration. Morphine's rostral migration is a phenomenon which is dose dependent and follows a predictable time course.[55] Lipophilic opioids also exhibit rostral migration, but on a less predictable timescale than morphine.

### Respiratory depression

Although rare, respiratory depression is a serious concern when considering the use of neuraxial opioids. It is thought to occur through depression of the brainstem respiratory centres through either direct or indirect mechanisms.[52,85,86] Respiratory depression is an uncommon but potentially serious side effect, though the incidence in the obstetric population is difficult to determine. Lipophilic opioids such as fentanyl may cause early-onset respiratory depression due to significant vascular uptake, rostral spread within the CSF, and possibly direct transit in epidural veins although the incidence of this occurrence in obstetric patients is unknown.[86,87] Respiratory depression has been described after administration of epidural fentanyl 90–100 mcg for CD.[88] In a study by Arai et al., intrathecal fentanyl 20 mcg in combination with bupivacaine was not shown to cause a reduction in peak expiratory flow rate, or vital capacity despite improving the quality of anaesthesia.[89] These opioids have a relatively low incidence of late-onset respiratory depression in contrast to the biphasic pattern of respiratory depression seen with neuraxial morphine.[90] Abouleish et al. studied 856 parturients who received 200 mcg of intrathecal morphine during CD and found respiratory depression, as defined by $SpO_2$ less than 85% or respiratory rate of less than 10 breaths per minute, in eight patients (0.93%), all of whom were markedly obese.[91] It should be noted, however, that smaller dosages of intrathecal morphine (75 mcg) therapy may result in a reduced duration of analgesia and may therefore require an increased need for supplemental analgesics. Also, due to the variability in patient response to intrathecal morphine, some patients may additionally experience inadequate postoperative analgesia and/or opioid-related side effects. Systemic vascular absorption may lead to early-onset respiratory depression (30–90 minutes after administration) followed by rostral spread within the CSF and slow penetration into the brainstem causing delayed respiratory depression up to 18 hours after neuraxial morphine administration.[27,35] As noted previously, EREM has not been reported in small studies looking at post-CD analgesia but has been reported when used in larger doses in the non-obstetric population.[63–66] The physiological changes of pregnancy, specifically the higher respiratory rate associated with elevated progesterone levels, may provide a greater margin of safety in comparison to other patient populations.

Respiratory depression from neuraxial opioids can be prevented by the identification of high-risk patients such as those who are obese or have coexisting disease such as sleep apnoea. Caution should be particularly exercised in those women receiving sedative drugs or pre-eclamptic women receiving magnesium therapy. Several studies have demonstrated that there is a ceiling effect for analgesia and thus caution should be exercised to limit the dose used in clinical practice.[30,36,54] The ASA has formulated guidelines to address the prevention, detection, and management of respiratory depression associated with neuraxial opioid administration in non-obstetric patients but there are no specific guidelines for the parturient.[92] All patients should ideally be monitored for level of consciousness, oxygenation, and adequacy of ventilation for the duration of the opioid action and it has been suggested that vigilant hourly assessments are probably adequate in low-risk patients as long as there is anaesthetic support immediately available to manage the complications of respiratory depression. The guidelines recommend that the lowest efficacious dose of neuraxial opioids should be administered to minimize the risk of respiratory depression and that parenteral opioids or hypnotics should be carefully administered in the presence of neuraxial opioids. If there is concomitant administration of neuraxial opioids and parenteral opioids, sedatives, hypnotics, or magnesium, this requires increased monitoring (e.g. intensity, duration, or additional methods). Patients receiving EREM should be monitored for 48 hours.

### Nausea and vomiting

Nausea and vomiting are common complaints during and after CD and the causes may be multifactorial including hypotension, increased vagal activity, surgical manipulation, and the use of uterotonic agents.[93] In addition, neuraxial opioids may increase the risk of postoperative nausea and vomiting either from rostral spread of the opioids in the CSF to the brainstem or from vascular uptake and subsequent effects on the chemoreceptor trigger zone and vomiting centre.[35,94] There have been multiple studies looking at regimens to reduce postoperative nausea and vomiting after CD in those patients who have received neuraxial opioids. However, the ability to interpret comparative data in these studies is hindered by the lack of standardization of nausea and vomiting outcome measures and lack of risk stratification or predictive models for postoperative nausea and vomiting in these groups of patients.[95]

### Pruritus

Pruritus is another regular complaint from patients receiving neuraxial opioids for CD with one study reviewing almost 5000

CDs in patients receiving epidural morphine 2–5 mg reporting pruritus in 58%.[96] Approximately 40% of patients receiving epidural morphine request treatment for pruritus.[96–98] The incidence and severity is more common after increasing opioid dose and intrathecal administration although patients who have received intrathecal opioids rank pain and nausea and vomiting as more undesirable than pruritus.[6,99]

### Urinary retention

The non-specific definition of urinary retention post CD makes an assessment of the potential effects of neuraxial opioids on urinary function difficult. The mechanisms by which neuraxial opioids affect specific components of micturition are not fully understood although spinal and supraspinal sites of action are likely to be involved. Other risk factors for post-CD urinary retention include low body mass index and multiparity.[100] One observational study investigating the effects of epidural morphine and methadone in 120 women undergoing CD found a higher rate of urinary retention and catheterization in the morphine group (57% and 50% respectively).[101] Currently there is a relative lack of research in this area.

### Reactivation of oral herpes simplex

Neuraxial morphine administration has also been linked to reactivation of oral herpes simplex. In a study of women with a past history of oral herpes simplex, reactivation occurred in 38% receiving intrathecal morphine compared with 16% of those receiving IV morphine.[102]

## Local anaesthetics

### Transversus abdominis plane block

The transversus abdominis plane (TAP) block is performed by introducing local anaesthetic into the plane between the fascia of the transversus abdominis muscle and the internal oblique muscle. It is possible to block the sensory nerves of the anterior abdominal wall before they leave this plane and pierce the musculature to innervate the anterior abdominal wall (Figure 24.2). It has a high margin of safety and is technically simple to perform, especially under ultrasound guidance but despite this, TAP blocks remain overwhelmingly underutilized in both the obstetric and non-obstetric populations. Duration of action is dependent on the type of local anaesthetic used and if prolonged analgesia is needed, a catheter for continuous infusion can also be placed using ultrasound imaging.

There are a number of studies in the literature looking at TAP blocks for analgesia after CD. Baaj et al. randomized 40 women to receive either local anaesthetic or saline TAP blocks in addition to a hypobaric bupivacaine spinal block for elective CD.[103] A significant reduction in 24-hour morphine requirement was observed in the local anaesthetic TAP block group versus controls (26 vs 63 mg). Although the authors reported lower postoperative nausea and vomiting, lower 24-hour VAPS scores, and higher satisfaction in the local anaesthetic TAP block group, no statistical measures were reported.[104] McDonnell et al. randomized 50 women to receive either bilateral TAP blocks with 0.75% ropivacaine or saline placebo.[105] They found that the median time to first morphine request was extended from 90 to 220 minutes in the TAP block group. The TAP block group were also found to have lower morphine requirements in the first 48 hours postoperatively and a corresponding reduction in sedation and nausea. However, not all studies have confirmed this finding. Belavy et al. performed a similar study which showed a decrease in postoperative IV opioids use between groups but no difference in pain scores whereas Costello et al. found no difference between groups in either opioid use, satisfaction, or pain scores with the additional TAP block.[106,107] McMorrow et al. compared the TAP block to intrathecal morphine for analgesia post CD. They randomized 80 patients to one of four groups (n = 20 in each arm) to receive (in

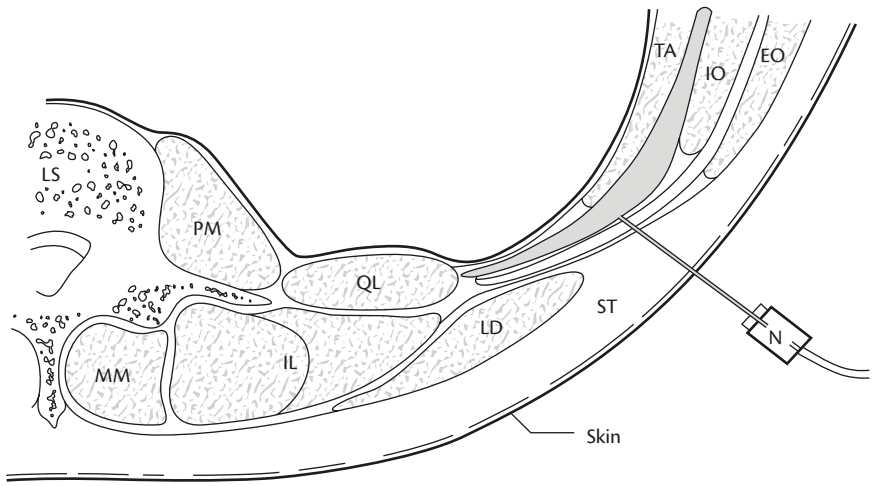

**Figure 24.2** Transversus abdominis plane block. Line drawing of a transverse section through the abdominal wall at the level of the lumbar triangle of Petit (TOP). The floor of the triangle is composed, from superficial to deep, of the fascial extensions of external oblique, internal oblique, and transversus abdominis, respectively, and the peritoneum. The needle is inserted through the triangle, using the loss-of-resistance technique. The needle is shown in the transversus abdominis plane, and the fascial layers have separated as a result of the injection of local anaesthetic.

addition to spinal anaesthesia) either spinal morphine 100 mcg, or saline and a postoperative bilateral TAP block with either 2 mg/kg bupivacaine or saline.[108] Pain on movement and early morphine consumption were lowest in the groups receiving spinal morphine and they found no incremental benefits of TAP block when intrathecal morphine was used. They also reported similar overall patient satisfaction among groups despite more frequent pruritus in the intrathecal morphine group. In a study by Singh et al., 60 women having CD under spinal anesthesia were randomized to receive ultrasound-guided TAP blocks using either high-dose ropivacaine (3 mg/kg), low-dose ropivacaine (1.5 mg/kg), or placebo. Patients received intrathecal 0.75% bupivacaine 10–12 mg, fentanyl 10 mcg, and morphine 150 mcg, and standard multimodal analgesia.[109] The primary outcome was the difference in pain with movement using a numeric rating scale at 24 hours. They found that neither high- nor low-dose TAP blocks as part of a multimodal analgesia regimen including intrathecal morphine improved pain scores with movement at 24 hours after CD when compared to placebo TAP blocks. They found that high-dose TAP blocks may improve pain scores up to 12 hours after CD.

In response to these varying studies, Abdallah et al. performed a systematic review and meta-analysis looking at TAP blocks for postoperative analgesia after CD performed under intrathecal anaesthesia.[110] They looked at five trials including 312 patients and concluded that TAP blocks provide superior analgesia compared with placebo and can reduce the first 24-hour morphine consumption in the setting of a multimodal analgesic regimen that excludes morphine.

Few studies have compared TAP blocks to epidural anaesthesia. Kadam and Moran performed a retrospective matched case–control study on 30 patients comparing continuous TAP block catheters to thoracic epidural analgesia in the non-pregnant population.[111] There were no appreciable differences in patient satisfaction between the two groups over a 3-day follow-up period. The TAP group was found to require a significantly higher amount of supplemental fentanyl for breakthrough pain over the study period. There was a higher therapeutic failure rate and rate of hypotension seen in the thoracic epidural group.

Tap blocks are not without their limitations. In non-obstetric patients, complications include visceral perforation, peritoneal injection, femoral nerve palsies, and local anaesthetic toxicity.[112] From these conflicting studies it would seem reasonable to conclude that TAP blocks should currently not be used in preference to neuraxial opioids for post-CD analgesia and should probably be reserved for a parturient undergoing general anaesthesia or where neuraxial opioids have not been used either because they are contraindicated or unavailable.

### Wound infiltration

There has been recent interest in wound infiltration using both local anaesthetic and NSAIDs. Results after general abdominal surgery are mixed, probably due to differences in the site of catheter placement, the drugs used, and the outcome with continuous versus bolus techniques. A Cochrane review in 2009 looked at 20 studies involving local anaesthetic wound infiltration during CD and found that:

- local anaesthetic infiltration and abdominal nerve blocks as adjuncts to regional and general anaesthesia are of benefit by reducing opioid consumption
- NSAIDs as an adjuvant in the local anaesthetic mixture may confer additional pain relief.[113]

Lavand'homme et al. found that diclofenac alone via a wound infusion catheter decreases 48-hour morphine requirements compared with ropivacaine infusion or IV diclofenac, suggesting that diclofenac may have peripheral analgesic properties in addition to its systemic effects.[114] Further studies are required to assess local anaesthetic infusions and NSAIDs on outcomes beyond analgesic efficacy such as wound healing and the formation of adhesions.

## Systemic opioid analgesia

In developed countries, most women will receive neuraxial opioids for post-CD pain relief. Large reviews indicate that the neuraxial approach provides superior analgesia over systemic administration but many patients will require additional systemic analgesics to further improve pain relief and to limit side effects.[30,115] Also patients who receive general anaesthesia will usually require systemic analgesics.

### Patient-controlled analgesia

PCA, which permits the patient to self-administer small doses of IV opioid analgesic at frequent intervals, often provides effective and sustained analgesia after major surgery. However, when neuraxial opioids are used, studies have shown that IV PCA is not usually required. Pain scores equivalent to mild to moderate pain are achieved using an average of only 5 mg PCA morphine in 24 hours and 15% and 32% of patients required no morphine at all when intrathecal diamorphine was used.[116,117] However, for those patients who receive no neuraxial opioids such as in CD under general anaesthesia and in whom potent analgesia via the IV route is required, different opioids can be delivered utilizing a PCA pump, including fentanyl, morphine, and hydromorphone. When comparing IV PCA with IM administration of opioid most studies conclude that the IV PCA route is preferable resulting in better analgesia, earlier ambulation, less sedation, and greater patient satisfaction regardless of which opioid is used.[118,119]

When deciding which opioid to use for PCA, most experience is reported using morphine. In a study by Howell et al. comparing PCA fentanyl with PCA morphine post CD, both analgesic solutions provided effective pain relief for a mean of 37 hours postoperatively with high levels of patient satisfaction and no differences in VAPS scores between groups.[120] However, more patients in the fentanyl group required supplementary boluses or alterations to the PCA settings and one patient in this group had to be removed from the study due to inadequate analgesia. The authors concluded that morphine PCA should be used in preference to fentanyl PCA for routine use after CD.[120] Pethidine has also been used for PCA but its use is now discouraged because of concerns about accumulation of the metabolite norpethidine in the neonate which may affect neurobehavioural scores.[121]

PCA is associated with all the usual opioid-related side effects, including potentially lethal respiratory depression, so close monitoring including continuous pulse oximetry and frequent nursing assessments is recommended.

### Common oral opioids and combinations

Once patients are tolerating an oral diet, analgesics are given via the oral route as a convenient 'step-down' after primary

management with neuraxial or IV opioids as part of a multimodal regimen.

Common regimens used worldwide include:

- hydrocodone (dihydrocodeine) + paracetamol
- oxycodone + paracetamol
- hydromorphone
- oxycodone
- oral morphine.

There are a number of studies looking at these regimens in the literature. Davis et al. performed a randomized controlled trial comparing IV patient-controlled morphine with oral oxycodone–paracetamol after CD.[122] They assessed pain at 6 and 24 hours after delivery and found that the oral group experienced less pain at both time intervals. They also found that this group had less nausea and drowsiness at 6 hours but slightly more nausea at 24 hours. Another study by Jakobi et al. assessed patient satisfaction with oral analgesia following CD and found that it provided satisfactory pain relief, was easily administered and was substantially less expensive compared to IV methods of analgesia.[123]

### Codeine

Codeine (3-methylmorphine) is a naturally occurring opioid, which is also synthesized synthetically and used for analgesia, antitussive, antidiarrhoeal, sedative, and hypnotic properties. It is used to treat mild-to-moderate pain and is marketed both as a single-ingredient drug and in combination preparations with paracetamol (as co-codamol) and NSAIDs such as aspirin and ibuprofen. Common side effects include drowsiness and constipation. Codeine is metabolized to codeine-6-glucoronide (C6G) by uridine diphosphate glucoronosyl transferase in the liver.[124] About 5% of codeine is metabolized by cytochrome P450 (CYP)-2D6 and the current evidence suggests that C6G is the primary active compound. About 0.5–2% of the population are 'extensive metabolizers' having multiple copies of the gene for CYP2D6 and producing high levels of CYP2D6 which metabolize drugs through that pathway more quickly.

CYP2D6 has been implicated in the toxicity and death of neonates when codeine is administered to lactating mothers, particularly those who are 'ultrafast metabolizers' and as a result, codeine phosphate has been withdrawn from use in many maternity units.[125,126]

### Tramadol

Tramadol is a synthetic, centrally acting analgesic, acting as a weak serotonin and norepinephrine re-uptake inhibitor, as well as a weak MOP receptor agonist. It is indicated for moderate to severe pain. It is supplied as 50 mg tablets (immediate release) and 100 mg, 200 mg, and 300 mg tablets (extended release). Side effects may include nausea/vomiting, dizziness, and constipation, amongst others. There is an increased risk of seizure in those with history of epilepsy. It should be avoided in those with anaphylactoid reactions to codeine and used with caution in those on medications that affect serotonin (risk of serotonin syndrome). There have been case reports suggesting a neonatal withdrawal including seizure activity after maternal antenatal use of tramadol but this appears rare and associated with long-term, high-dose maternal use.[127] Dosage adjustments should be made in those with renal or hepatic impairment and in those with advanced age. In severe impairment, it should be avoided. A randomized clinical trial by Ollé Fortuny et al. compared tramadol to ketorolac for postoperative pain after abdominal hysterectomy.[128] Seventy-six women were enrolled for this study and two treatment groups were formed: the TRA (tramadol) group received 100 mg of tramadol orally, while the KET (ketorolac) group received 30 mg of ketorolac IV every 6 hours. During the first 12 hours after surgery, the 100 mg dose of tramadol was shown to be more effective for pain relief compared to the 30 mg ketorolac every 6 hours. There was, however, increased incidence of postoperative vomiting in the TRA group. Epidural tramadol was evaluated in women undergoing CD with epidural anaesthesia.[47] Addition of tramadol 50 mg to 2% lidocaine with adrenaline extended the mean (SD) duration of postoperative analgesia from 2.46 (±0.45) to 15.39 (±0.54).

### Methadone

Methadone is a MOP receptor agonist more commonly used to treat opioid dependency. However, there is interest in methadone administration as an analgesic and possibly as a preventative of chronic wound pain. Shahrkai et al. performed a prospective randomized double-blinded study on 102 elective CD patients who all received spinal anaesthesia followed by a single IM dose of pethidine 50 mg in the recovery room.[129] They were then randomized to receive either 0.7 mL/kg pethidine every 6 hours or 0.07 mg/kg methadone orally every 6 hours. There was no statistical difference found in terms of analgesia, patient satisfaction, or requirements for breakthrough pain relief between the two groups. In a retrospective case–control study of parturients undergoing general anaesthesia for CD and multimodal analgesia, Russell et al. compared 25 women who had received a single IV bolus of methadone (mean dose 14 mg) at the time of delivery with 50 matched controls.[130] Women in the methadone group had lower pain scores, lower IV PCA opioid consumption, and were less likely to require IV opioid supplementation. Further work is needed in this area.

## Paracetamol and non-steroidal anti-inflammatory drugs

### Paracetamol

Paracetamol inhibits cyclooxygenase-2 (COX-2) resulting in decreased production of prostaglandin $E_2$ and the activation of descending serotonergic pathways. In the general surgical population, it has been shown to have a useful opioid-sparing effect by reducing postoperative IV PCA morphine consumption.[131,132] In patients receiving PCA morphine after CD, Alhashemi et al. compared the effects of IV paracetamol with those of oral ibuprofen with respect to pain control and morphine requirements.[133] They measured both VAPS scores and patient satisfaction. VAPS scores were found to decrease similarly in both groups over time; however, there were no differences between groups at any time. Patient satisfaction was high in both groups. They concluded that IV paracetamol was a reasonable adjunct to IV PCA morphine. There have been surprisingly few trials looking at paracetamol alone after CD. Munishankar et al. compared oral paracetamol, diclofenac, and the combination of these for pain relief after CD in a double-blind randomized controlled trial of paracetamol.[134]

Patients given the combination of diclofenac and paracetamol required 38% less morphine than patients given paracetamol alone. Morphine use in patients given diclofenac alone was not significantly different from morphine use in the other two groups. Nauta et al. performed a systematic review of randomized trials comparing a combination of codeine–paracetamol versus NSAIDs in the treatment of postoperative abdominal pain.[135] They found that none of the studies showed the codeine–paracetamol to be superior to NSAIDs in controlling post-laparotomy pain and that fewer adverse effects were reported in the NSAID group. There are currently no similar studies that have been performed in obstetric patients.

## Diclofenac sodium

NSAIDS are now widely established as a basic analgesic in the management of severe postoperative pain both in the general postoperative setting and post CD where they have been shown to potentiate opioid effect, decrease opioid consumption, and reduce side effects. They seem to be particularly effective against the visceral pain originating from the uterus and wound site and complement the somatic pain relief provided by opioids. They are usually used immediately post CD and then continued regularly for at least 48 hours postoperatively. They are thought to work by inhibiting COX, an enzyme which converts arachidonic acid to prostaglandins and thromboxane. NSAIDS are associated with side effects such as increased bleeding, renal impairment, gastrointestinal bleeding, and acute bronchospasm and should be used with caution in at-risk patients. Diclofenac sodium is commonly used to treat pain, inflammatory disorders, dysmenorrhea, endometriosis, and mild-to-moderate postoperative or post-traumatic pain. As with similar NSAIDs it predisposes to gastrointestinal bleeding but is amongst the better tolerated NSAIDs. As well as inhibiting COX there is some evidence that diclofenac inhibits lipoxygenase pathways, thus reducing leukotriene formation and may also inhibit phospholipase $A_2$. These actions may explain the high potency of diclofenac—it has a wide variety of effects including anti-inflammatory, antipyretic, and analgesic actions.[136] Approximately half of the diclofenac dose is metabolized during first-pass hepatic metabolism. Sixty per cent is excreted renally, with 1% remaining unchanged in the urine.

Diclofenac has been shown in a number of studies to have a significant opioid sparing effect. When given in the recommended dose of 150 mg daily, opioid consumption can be reduced by 35–40%.[137,138] So-called high-dose diclofenac (rectal diclofenac 200 mg daily) has also been shown to be morphine sparing without increased side effects and has been adopted by many units because of the simplicity of administration.[139] Diclofenac has been shown previously to confer significant pain relief when used in combination with paracetamol. Mitra et al. compared this combination with a diclofenac–tramadol combination when considering pain relief after CD in a randomized double-blinded parallel-group controlled trial involving 204 parturients.[140] They found both combinations to provide satisfactory postoperative pain relief after CD. The diclofenac–tramadol combination was overall more efficacious but associated with a higher incidence of postoperative nausea.

Available recent data indicate that the cardiovascular risk with diclofenac is similar to that of the selective COX-2 inhibitors and as a result is now contraindicated in those with ischaemic heart disease, peripheral arterial disease, cerebrovascular disease, or established congestive heart failure (New York Heart Association classification II–IV) and this applies to all systemic formulations including suppositories.[141] As a result, many units have switched to ibuprofen as the preferred NSAID for use after CD in doses of up to 2.4 g daily.

## Ketorolac

Ketorolac is a NSAID indicated for short-term use (5 days or less due to gastric ulceration, bleeding, and perforation risk) in managing moderate-to-severe acute pain. Routes of administration are oral, IV, or IM. When given by the IV route, usual adult dosing is 15–30 mg IV every 6 hours, with a maximum of 120 mg in 24 hours. Side effects and adverse effects are similar to other NSAIDs.
