produced from rice and is used with rice mashes, whereas barley-koji (containing *Aspergillus kawachii*) is made with barley and is used in the production of barley shochu. Barley-koji is made by taking pearl barley (70% pearling rate) steeping it in water and then steaming it. The cooled, cooked barley is then inoculated with *Aspergillus kawachii* and incubated at 30–40 °C for about 48 h (Iwami *et al.*, 2005). Fermentation is carried out in a similar manner to that described for sake (Section 2.7.1), but the flavor of the resulting wine, and hence the final spirit, depends on the concentration of precursors in the koji and therefore in the prefermentation mash. In particular, concentrations of aroma and flavor compounds (such as higher alcohols) in the spirit will be relatively high if high levels of precursors (such as amino acids) exist in the mash (Iwami *et al.*, 2005). Additionally, higher levels amino acids, such as alanine, glycine and phenylalanine will produce higher levels of Maillard products by reaction with sugars at higher temperatures (e.g. during nonvacuum distillation).

The levels of a number of amino acids in barley koji depended largely on the barley variety and the pearling rate (Equation 3.4.1), especially with regard to lysine, proline, histidine, threonine and lysine, phosphoserine (respectively).

$$\text{Pearling rate} = \frac{\text{Weight of 1000 pearled barley kernels}}{\text{Weight of 1000 barley grains}} \times 100 \tag{3.4.1}$$

In particular, the total concentration of amino acids is generally higher at higher pearling rates (say 80%), irrespective of barley variety, which means the resulting shochu is likely to be rather more highly flavored, with higher levels of congeners (all other things being equal). Besides the above considerations, the presence of high levels of amino acids is conducive to a good, trouble free fermentation. In the above respects, koji from the Japanese barley variety Nishinohoshi and the Australian malting variety Schooner have been judged to be suitable varieties for barley shochu produced in the traditional way (Iwami *et al.*, 2005). Additionally, these two varieties gave koji with higher acidities, higher levels of α-amylase and glucoamylase and higher levels of glucose and maltose than several other varieties; factors that give wines of high ethanol content.

The current trend (2009) in Japan is toward milder, less flavorful, lower strength spirits, but many of the older generation still prefer all round more powerful shochu. Competition has become fierce as the big breweries have diversified their interests to include shochu, as beer and sake sales continue to fall. Distillers of traditional shochu are striving to enhance the brand value of their products by modifying the production process in order to eliminate undesirable flavors and to moderate the intensity of desirable flavors (Minabe, 2004). Modifications have included use of high grade starting materials, reduced pressure distillation, filtration and maturation in wooden casks. Much shochu was once made from low quality ingredients (not fit for human consumption), which led to undesirable flavors. Reduced pressure distillation leads to a spirit that is lighter in body, having fewer congeners than shochu made by normal pressure distillation. Likewise, various filtration processes (activated carbon, ion exchange or chill filtration) that can be carried out before bottling generally lower the levels of congeners, as well as removing undesirable aroma components, such as certain organosulfur compounds (Minabe, 2004).

However, although much modern traditional shochu is lighter in body and flavor than in former times, it is still much more flavorful than the type A (kuo-rui) shochu, which is still produced in greater quantity than the traditional spirit. It can also be made from a single ingredient (e.g. maize), but is more likely to come from several ingredients. The saccharification process is more likely to be carried out on the cooked grains by the addition of fungal α-amylase, glucoamylase and other enzymes, rather by the use of koji, and fermentation is promoted by added yeast (*Saccharomyces cerevisiae*). The wine is distilled in continuous column stills to give a high strength (95% ABV) spirit, which after a short storage in bulk tanks is diluted with deionized water to around 30% ABV (or lower) before filtration and bottling. Like its Western counterparts, grain neutral spirits, vodka and others, type A shochu is clear and clean on the palate and is good for premixes ('ready to drink' beverages), but can also be enjoyed in cocktails or supped cooled or iced, with food.

Although Ohita prefecture is famous for barley shochu and Kagoshima prefecture for sweet potato shochu, it is probable that the first shochu (known as awamori), from rice, was made in the Ryukyu group of islands (Okinawa prefecture) prior to the sixteenth century (the first written record of Kagoshima shochu dates from 1559). The production of awamori is similar to that of traditional shochu, except that the major microbiological constituent of the rice koji is *Aspergillus awamori*, which gives a high concentration of citric acid, thus offering considerable protection from bacterial infection during koji manufacture and fermentation. Also, sometimes long grain rice from Thailand and western Asia is used in the brew, rather than the indigenous short grain japonica rice, perhaps a legacy of the possible Thai origin of the awamori production methods, although this is uncertain, since China and Korea probably exerted considerable influence in the fifteenth century. Awamori is distilled once in pot stills and is collected at 45–50% ABV, although like shochu, it is often diluted to 25–30% ABV with pure water before bottling. Because of the use of koji and single distillation, new make awamori is high in congeners, which can give it an earthy, pungent, even medicinal character. Consequently, awamori has traditionally undergone lengthy aging periods, often 10 years and more.

Aged awamori, matured in earthenware containers, is known as kuusu. The aging process is usually conducted over three years, but can be extended up to 25 years, during which time many reactions occur to give a smoother, more harmonious palate, as with other spirits. By law, a three year old awamori need only contain 51% spirit of that age, the remainder possibly being made up of younger spirit (compare this with the law regarding Scotch whisky age statements – see Section 3.2.5). However, a bottle labeled kuusu, 100% 10 year aged (or similar statement) will be entirely of 10 year old spirit.

The traditional method of aging awamori was known as shitsugi, and was a kind of simplified solera system. The household or restaurant would have several large covered earthenware pots of awamori lined up outside, with the pot containing the oldest spirit closest to the door and pots containing progressively younger spirit at greater distances from the house. As a sample was taken from the nearest pot, it was replaced by a sample from the second pot. This in turn was refilled from the third pot and so on. New make spirit was placed in the last pot, when available.

Phenolic substances play an important role in both undesirable and desirable aroma characteristics of awamori and shochu, the undesirable aromas receding with aging. Studies on the fate of ferulic acid in model shochu suggested that conversion of ferulic acid to the less desirable 4-vinylguaiacol and the more desirable vanillin and vanillic acid could involve chemical processes during distillation and aging, as well as biochemical processes during fermentation (Koseki *et al.*, 1996). The suggested processes are outlined in Figure 3.4.9, where the ferulic acid is derived originally from hydrolysis of ferulate ester linkages to arabinose residues of the arabinoxylans in rice cell walls.

Korean Soju and Related Spirits

The most famous and most popular Korean spirit is soju, which is similar in many ways to Japanese shochu. Like shochu, it can be subdivided into two major types, according to the ingredients, the method of fermentation and the method of distillation: hiseoksik soju, the everyday drink made by diluting rectified spirit and jeungryusik soju, a more traditional drink made by single distillation of (usually) rice wine (Section 2.7.1). The development of soju manufacture into the present situation, is not unlike the development of shochu in Japan, except the economic and political backgrounds are rather different (see Sections 1.2.3 and 1.2.4).

In either case, however, economic and political circumstances led to the domination of the markets by inexpensive, mildly flavored drinks made by relatively modern methods from a variety of materials. Thus, both the younger generations and some of the older generation acquired a taste for the mild, relatively low alcohol (20–25% ABV) products. The traditional products survived, used mainly for special occasions, but

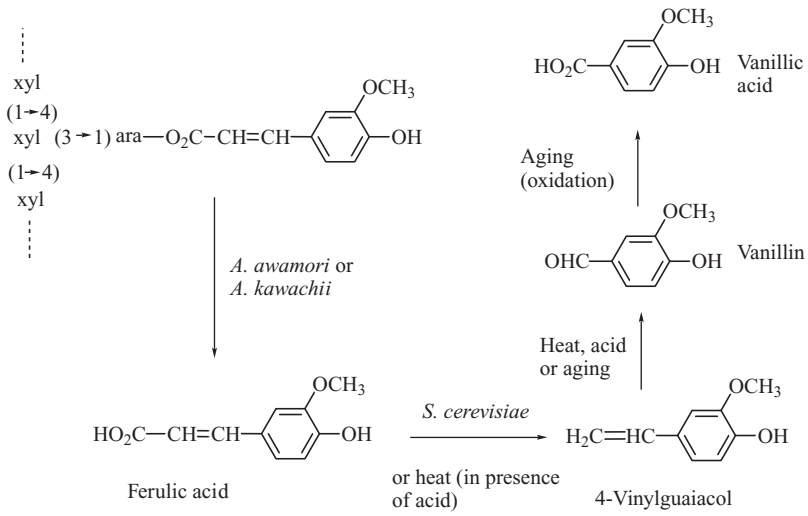

Figure 3.4.9 *Mechanism for the conversion of ferulic acid in awamori and shochu. Koseki* et al. *(1996)*

were seen by the younger generations as old fashioned, both in the their presentation (e.g. decorated porcelain bottles with Chinese inscriptions), flavor (very pronounced, often malty flavors) and alcoholic strengths (sometimes in excess of 45% ABV; double the strength of hiseoksik soju).

During the 1990s, distillers attempted to increase the market share of more traditional soju (premium soju), but these products were invariably more expensive than the standard drink, so that they were not a success. Additionally, their stronger flavors and higher ethanol contents were bucking the trend towards lighter drinks. However, during the past decade, Korean consumers have become more aware of the virtues of the traditional spirit and distillers are responding by producing milder premium versions by traditional methods and presenting them in modern, but attractive bottles (Cho, 2005).

The most popular type of soju is hiseoksik soju, produced by the fermentation of sugars from a wide variety of sources, including barley, maize, potato, rice, sweet potato, tapioca (dangmil in Korean) and wheat. The wine is distilled using continuous columns to give a highly ethanolic, mildly flavored spirit, which is then diluted to 20–25% ABV and sweetened with various ingredients before filtering and bottling, as described below. Because the undiluted spirit is highly rectified and has few congeners, like vodka and gin, aging is not required. A wide range of sweeteners is used, including natural ones such as honey and maple syrup to noncarbohydrate sweeteners such as aspartame, stevioside and xylitol. Stevioside is a carbohydrate free, natural sweetener derived from *Stevia Rebaudiana*, a South American plant, whereas xylitol, a sugar alcohol, is produced by the reduction of the carbohydrate xylose.

Traditional soju is basically yakju (makkoli) or takju (Section 2.7.1), made using the traditional nuruk starter and yeast, and singly distilled in pot stills, like the one shown in Figure 3.4.10. The most famous traditional soju is that of Andong, a city in North Gyeongsang. It is sold at 40% or more alcohol by volume, giving it a pungent introductory character, which broadens out into a fine malty palate that slowly disappears to leave a warm, clean finish.

In recent years, several distilleries (or brewery companies as they call themselves in Korea) have introduced lighter brands of traditional soju, including Andong Soju Ilpum and Sipguse, described below. Other companies have repackaged some of their traditional brands to attract the younger generation, an example being Cheongdam soju of the Sunyang Brewery Co.

Figure 3.4.10 *Traditional Korean soju still*

Jinro, based in Seoul, is the largest manufacturer of soju, controlling around 50% of the market and selling 72 million cases in 2007. The most popular variety of soju is currently Jinro's Chamisul (참 이슬 - 'real dew') brand, a quadruple filtered soju, but recently Cheoum Cheoreom (처음처럼 – 'like the first time') of Doosan (두산), based in Gangwon province, has become very popular in recent years. Because of government legislation and reorganization of the soju industry (Section 1.2.4) into one large distillery in each province, the market for a particular distillery company tends to be rather localized. That company can sell its products freely in its own province, but only in a few outlets in other provinces. The major distillery companies, apart from Jinro, are Bohae of South Jeolla province, Daesun of Busan, Doosan of Gangwon province, Hallasan of Jeju Island, Hite of North Gyeongsang province, Kumbokju of North Gyeongsang province, Muhak of South Gyeongsang province and Sunyang of Chungcheong province.

A brief description of some products of the major distillery companies is given next, based on Cho (2005).

Andong Soju

This is the 40–45% ABV jeungryusik soju from Andong, North Gyeongsang province, famous for its traditional soju. A powerful, pungent early palate, gives way to a long, malty flavor and finally a clean aftertaste.

Andong Soju Ilpum

This relatively new premium soju, made in North Gyeongsang province, is mildly malty, with a clean aftertaste. It is made using 51% rice and contains 21% alcohol (v:v).

C1 Soju

It has a pungent aroma and character, with a clean, but bitter aftertaste. This soju comes from the Daesan company in Pusan and can easily found only in southern Korea.

Chamsoon

This soju has a bland start, but with a sharp plate and slightly bitter aftertaste. It contains an extract from Japanese Raisins (*Hovenia dulcis* Thumb.), which is rich in both sugar and minerals.

Charm

From the Kumbokju company in North Gyeongsang province. It has a sweet, rounded palate, with a clean farewell.

Jinro Gold

This brand has a mild start, opening into a powerful, pungent palate (25% ABV).

Green

At 29% ABV, this is one of the stronger hiseoksik types of soju, leaving a heavy, sweet aftertaste.

Ipsaeju

From Bohae in South Jolla province, it is light and sweet, being sweetened by maple syrup (24% ABV).

Hallasanmul Sunhan Soju

This soju from Jeju island has a slightly pungent introduction, leading to a mild, sweet palate. It contains 21% alcohol (v:v) and is made with weakly alkaline water and aspartame as additive.

Hite Soju

From North Jeolla province, it has 21% ABV and added aspartame. It has a mild, sweet flavor.

Malgeul Linn

Made in the Chungcheong region by Sunyang Brewery Co., it has 23% ABV, is light and floral, leaving a slightly bitter, but clean aftertaste.

San

This new soju, introduced last year by the Doosan Company in Dongwang province, is made with mineral water from Daegwallyeong mountains, with green tea extract and aspartame additives.

Sipguse

This is new and with only 19% alcohol. It is a pure (jeungryusik) soju made in Andong, North Gyeongsang province. It has a mild, malty palate, creamy texture and soft, clean farewell.

White

This soju is made by Muhak in South Gyeongsang province. It contains 21% alcohol (v:v) and contains contains aspartame, honey and xylitol additives. It has a pungent introduction, with mild, sweet flavor and soft farewell.

Other Korean distilled liquors include goryangju made from sorghum and similar to Chinese gaoliang jiu and okroju. Another variety, called munbaeju (문 배 주), has the distinction of being South Korea's Important Intangible Cultural Property Number 86-1. Munbaeju is a traditional aged distilled liquor made of malted millet, sorghum, wheat, rice and nuruk (fermentation starter), with a strength of 40% alcohol by volume. It originates in the Pyongyang region of North Korea and is noted for its fragrance, which is said to resemble the flower of the munbae tree (similar to a pear).

3.5

Cane Spirits, Vegetable Based Spirits and Aniseed Flavored Spirits

A Martinique rum is the perfect antidote for a rainy day.
—Ernest Hemingway

3.5.1 Overview and Scope

This section describes aspects of the production and character of a number of spirits that are distilled from various fermented vegetable and fruit juices. Principal amongst these spirits are sugar cane spirits rum and cachaça, produced mainly in the Americas. The corresponding spirits of Indonesia and southeast Asia are often known as arrack, rather than rum, giving rise to a certain amount of confusion of nomenclature, since arak is a word used to name often quite different spirits of western Asia.

Both arrack and arak are derived from the same Arabic word araq (عدق), whose meaning is sweat, referring to the beads of distillate in a still, but now is used for distilled alcoholic beverages. Arrack spelling tends to be reserved for spirits of southern and southeastern Asia; it is made by distillation of wine made from a range of vegetable or fruit sources, including, sugar cane, palm sap, dates, figs and plums. On the other hand, the word arak tends to be reserved for spirits of the Middle East derived from (grape) wine or pomace and anise – in essence, aniseed flavored brandies or pomace spirits. These beverages are made in countries in eastern Europe/western Asia: Bulgaria, Greece, Israel, Jordan, Lebanon, Palestine and Syria, although in the European countries non-Arabic names, such as ouzo and mastika are used. Further west, similar drinks are made in France (pastis), Italy (anesone) and Spain (ojén).

For the purposes of this book, arak is included in the number of aniseed flavored spirits, in Section 3.5.6, along with anesone, ouzo, pastis and others, despite the fact that some Egyptian and other Middle Eastern beverages named arak are produced from dates, figs or other sources. Likewise, arrack is the name used in Section 3.5.5 to describe the distilled wine of any vegetable or fruit origin (other than sugar cane) and is discussed alongside mezcal, tequila and related drinks. The sugar cane spirits of Indonesia (e.g. of Bali and Batavia) (often also known as arrack) are discussed as rum in Sections 3.5.2–3.5.4, even though some of them include rice in their production (Cooper, 1982).

3.5.2 History and Basic Description of Rum and Cachaça

Rum is the distillate of fermented sugar cane products, principally molasses, but some rum is made from sugar cane juice. It is produced wherever sugar cane is grown, in subtropical climates, like those of the numerous islands of and the many countries surrounding the Caribbean Sea. Figure 3.5.1 shows the main rum producing Caribbean countries, along with a selection of well known distilleries or distillery companies in certain countries. Although the best known rums are from the Caribbean countries, rum is also made in Australia, Fiji, India, Indonesia, Mauritius, Reunion, Sri Lanka and other countries. Cachaça is the Brazilian spirit made from fermented sugar cane juice. Similar drinks to rum and cachaça are made in the Central American countries of Mexico (aguadiente de caña and chasanda) and Panama (seco), as well as cane juice in Liberia and tafia in the Caribbean islands. Additionally, sugar beet spirit, known as tuzemák or tuzemský rum (domestic rum) is made in the Czech Republic.

The origin of the word rum is uncertain; the Spanish and French equivalents, ron and rhum respectively, appear to based on this word, although in Spanish and French, rum is often known as aguadiente (aguadente in Portuguese) and eau-de-vie de molasses, respectively. Two claims of origin (and there are others) are 'rumbullion' (a Cornish word meaning an uproar – no doubt a drunken one) and 'rummer,' from roemer, a drinking glass used by Dutch sailors (Blue, 2004). It is also possible, however, that the name rum is derived

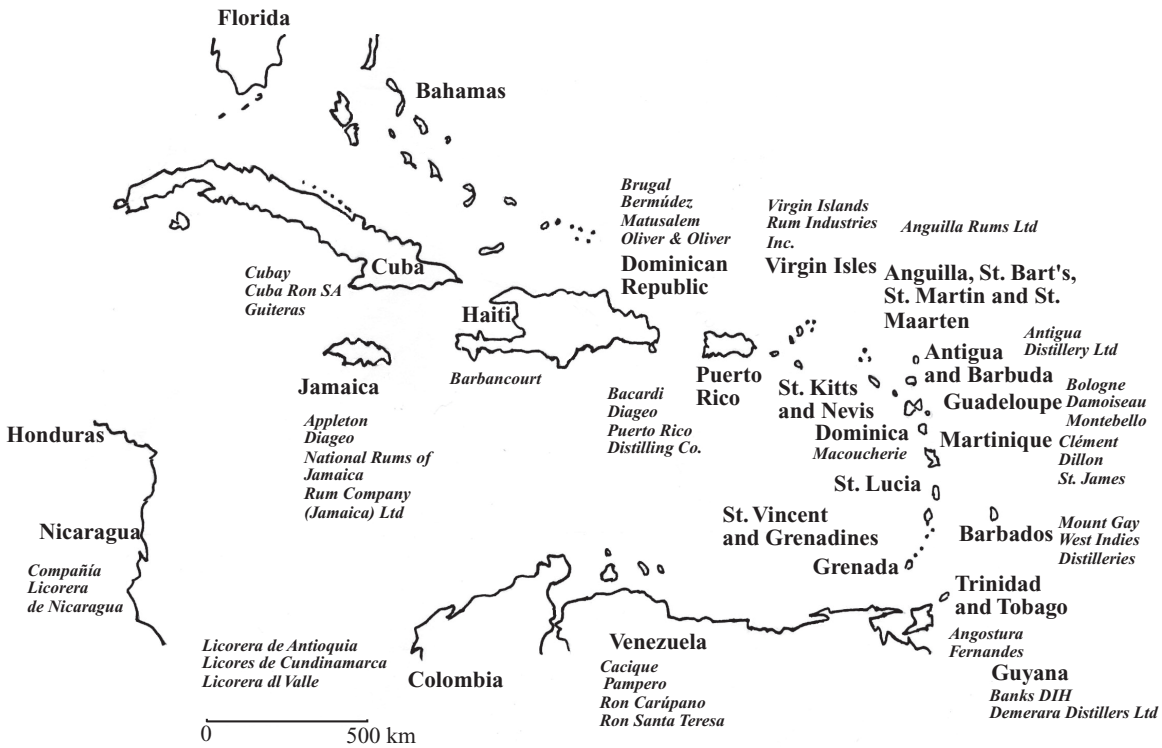

Figure 3.5.1 *The heart of rum production in the Caribbean area. Representative distilleries or companies only are indicated: the list is by no means exhaustive*

from 'brum', an ancient fermented drink made from sugar cane juice by Indonesian and Malay peoples (Blue, 2004).

The original home of sugar cane is probably Indonesia, where rum is still made. The Chinese introduced sugar cane to Arab merchants, who in turn traded plants with Europeans, where it was planted on subtropical islands such as the Azores and the Canary Islands. Sugar cane plants were taken by Christopher Columbus on his second trip to the Americas (1493), where he planted them on the island of Hispaniola (now Dominican Republic/Haïti). Later, Portuguese explorers started sugar cane plantations in northeastern Brazil, so that sugar production was well underway in the sixteenth century and it is probable that the first cachaça was distilled from fermented cane sugar waste ('borra') around the middle of the sixteenth century.

In the Caribbean area, sugar plantations sprung up on most of the islands and in most of the countries of the surrounding landmass, particularly those to the south and west. The first rums distilled from fermented molasses were probably made in Barbados around 1600, although there are reports of rum being produced in Puerto Rico as early as 1526. However, the Mount Gay Distillery on Barbados claims to be the oldest surviving Caribbean rum distillery (Figure 3.5.1) (Lichine, 1982).

The early Portuguese colonizers of Brazil soon began trading sugar and cachaça for west African slaves who were put to work in the sugar plantations, refineries and distilleries (Faria *et al.*, 2004a). It wasn't long before the colonizers of the Caribbean islands and countries (the British, Dutch, French and Spanish) involved sugar and rum in a similar trade, that later became known as the 'Triangle Trade.' It is not within the scope of this book to discuss the slave trade in detail; suffice it to say that rum and cachaça are unique among spirits in the roles that they played in the slave trade. They are also unique in that in the two modern centers of production, the Caribbean region and Brazil, cane sugar spirit is not indigenous; this claim most likely goes to Indonesia.

It was probable that the above situation, along with increasing colonization, accounted for the early popularity of rum and cachaça. Rum was, along with applejack (see Section 3.8.2 and also 3.1.1), a popular spirit of the early American colonists, whiskey not becoming popular until the influx of Irish and Scottish immigrants in the early to mid nineteenth century (Section 3.3.1). Indeed, New England rum was probably of the best quality available in the seventeenth and eighteenth centuries, because of superior technology. Rum was the basis of the early Colonial New England's largest industry and the Sugar Act of 1764 (imposing a sugar tax) did nothing to increase the Colonialists' love of the British (House of Hannover) monarchy.

Cachaça has increased its popularity in Brazil over the past few decades, so that today (2009) more than 1.5 billion litres are produced annually. Although only about 40 million liters per annum were exported in the last few years, this is growing steadily and there have been signs for many years that the drink is becoming more popular outside Brazil. The Brazilian government has been making concerted efforts for some time to regularize the quality of cachaça, in order to make it more attractive for export. See Faria *et al.* (2003) for an account of cachaça.

Rum, on the other hand, although popular where it is distilled, has always been exported, originally to the American colonies via the ports of New England (such as Boston) and to Britain via the western ports (such as Whitehaven – see Section 1.2.2) and to France via the Atlantic ports. When the United States obtained Puerto Rico from Spain (1898), that country became the major importer of Puerto Rican rum, so that today more than 70% of rum consumed in the USA today comes from Puerto Rico. Puerto Rico is presently the biggest producer of rum, exporting all over the world, but principally to the USA. Cuba, a large producer of light rum (like Puerto Rico) is the major exporter of rum to Russia.

The most popular rums of the seventeenth and eighteenth centuries were dark, full bodied types, derived from molasses and colored with caramel. In the twentieth century tastes began to change toward rums lighter in both body and color; these were (and still are) usually consumed in cocktails such as Daiquiri, rather than drunk neat. Initially, the lighter rums were produced largely by Cuba and Puerto Rico, with Bacardi, originally based in Cuba, becoming predominant. Nowadays, light rum is distilled from either cane juice or molasses in

most of the Caribbean area, although those of Puerto Rico and Cuba dominate. Likewise, darker or heavier rums are produced more or less all over the Caribbean area, but those of Barbados, Dominica, Guadeloupe, Guyana (Demerara), Haïti, Jamaica and Martinique are probably the best known. The major styles of rum and how they are made are discussed more fully in Section 3.5.3.

As with other alcoholic beverage industries, the rum industry has been influenced at various times by changing economic and political conditions, including wars and periods of prohibition. Most commercial rum nowadays is made in large distilleries owned by big international beverage companies, such as Bacardi, Banks DIH, Demerara Distillers, Diageo, Edrington Group and Pernod-Ricard. Many smaller distiller companies still exist in the Caribbean area, especially on the French West Indies islands, such as Guadeloup and Martinique, and on smaller, less well known islands such as Grenada, the Grenadines, St Kitts and Nevis, and St. Vincent. The larger companies have more than one rum distillery in the Caribbean region and some, like Diageo, have rum or other distilleries elsewhere. Rum producers often possess bottling, distribution and transport companies as subsidiaries. The larger producers also have diversified interests, owning (apart from sugar plantations and refineries), fruit juice companies (e.g. Demerara Distillers Ltd) and breweries (e.g. Banks DIH), for example.

Until the 1960s, production of rum was not particularly profitable and the industry was in a state of stability or slow growth. Interest at that time had shifted away from dark, full rum to lighter rum for use in cocktails and punch. The Cuban revolution in 1959 forced many rum distillers to other countries, notably Puerto Rico and the USA. Stimulated by a preferential status regarding rum imports into the USA (the 'Caribbean Basin Initiative,' which includes the US Virgin Islands as well as Puerto Rico, in which the US Treasury returned $10.50 excise tax for every proof gallon of imported rum from those two countries), there followed a period of rapid growth of Puerto Rican rum production, which fueled keener competition between distilleries all over the Caribbean area. Within 10 years or so, the industry had become dominated by a small number of relatively large distilleries. Demand for rum continued to grow into the 1970s and beyond, so that these days, rum, if cachaça and rum liqueurs are included, shows the greatest growth of all distilled spirits (Delevante, 2004).

Free trade agreements, or economic Partnership Agreements as they are known now (like that mentioned above for USA and Puerto Rico/Virgin Islands), also existed between the former European colonies in or around the Caribbean Sea (CARICOM) and the European Union, whereby selected imports from both partners were given preferential status, such as zero duty quotas. For the Caribbean countries, the duty free quotas included rum. Originally, the economic partnership between the EU and ACP (African, Caribbean and Pacific countries) was embodied in the Lome agreement, but pressure from the World Trade Organization has forced renegotiations of this agreement between the European Commission (EC) of the EU and CARIFORUM (= CARICOM + Dominican Republic), so that the new (2007) trade agreement (EPA) covers substantially all trade (involving goods, services, investment, government procurement and intellectual rights), and not just selected items, such as rum (Berridge, 2008). Rum from the CARIFORUM countries exported to Europe thus is free of duty and hence can be sold at more competitive prices in the EU market.

In Brazil, it was estimated that in 2004, there were more than 2500 small producers of cachaça (Faria *et al.*, 2004a). Although the larger distillers actually buy much of their spirit from small producers (in order to give consistent blended products), it is felt in government and trade circles that there are too many small producers and too great a range of products, particularly with regard to competing in international markets.

India is the biggest consumer of rum (followed by the USA) (2008). Distilled in the northern states of Bihar, Haryana and Uttar Pradesh, as well as in the Punjab, from fermented sugar cane molasses, Indian rum ranges from the rough and pungent tharra to sophisticated, aged dark beverages such as Old Monk. Tharra is distilled in countryside locations using small pot stills, often illegally. It is never aged and tends to be sold and consumed locally. The major distillery companies of Gilbey, Herbertson, McDowell, Simpson and others are now part of larger conglomerates, such as SOM and UB (Mumbai). The latter is India's largest

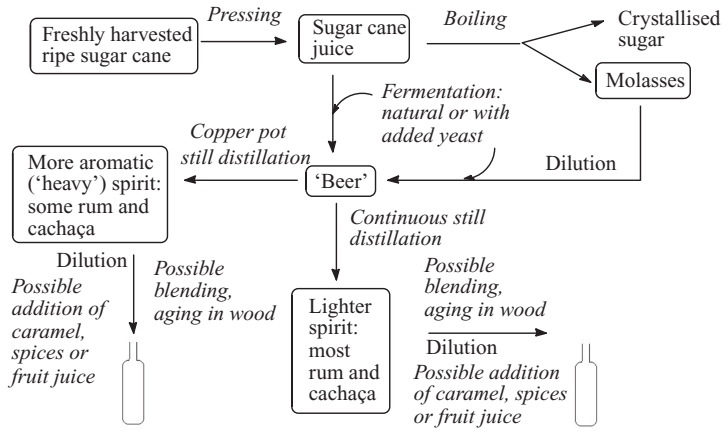

Figure 3.5.2 *General scheme for the production of rum and cachaça. Special distillation and other procedures are described in the text and in Figure 3.5.3*

distiller and probably amongst the world's top three distillers. India also produces whisky (including single malts) (Section 3.3.6) and other spirits, and at present (2009) India is the fourth largest producer of alcohol in the world. If one includes Mauritius and Sri Lanka, the countries of the Indian Ocean produce quite an impressive portfolio of distinctive rums: Old Monk, McDowell's No. 1 Celebration, Old Cascade (all India), Green Island (Mauritius), Rockland and White Diamond (both Sri Lanka).

Other rum producing countries include Fiji (e.g. Bounty rum), Hawaii (e.g. Maui dark rum) and the Philippines (Tanduay and Tondeña rum). Rum is also manufactured in Indonesia, the best known being Bali rum and Batavia rum. The latter is made by distillation of fermented molasses, although red rice is also used in the fermentation. Distillation is carried out in pot stills, originally of Chinese design, and the rums are aged in wood.

The basic processes (simplified) for the production of rum are shown in Figure 3.5.2. Ripe sugar cane is harvested, crushed and the resulting juice can be fermented directly (or somewhat diluted or even concentrated and then diluted) to give a liquor for distillation of *ca.* 7–8% ABV, called 'beer' in the rum industry. Much cachaça and some rum, especially from the French West Indies islands, are made in this way. However, most rum is made from molasses, the dark, viscous mass remaining after refinement of sugar cane juice. Refinement refers to the process of obtaining sugar crystals from cane juice. The juice is firstly clarified by the addition of slaked lime (calcium hydroxide), after which the clear juice is pumped off the deposit and boiled under pressure. Sugar crystals form on cooling and the molasses remaining after separation should contain around 50–60% by weight of total sugars. The reader is referred to Nicol (2003) for a detailed description of sugar cane processing. Dilution of the molasses with stream or rainwater (see Section 3.5.3) gives a substrate capable of producing a beer of around 7% ABV after fermentation, usually with specially cultured yeasts (Section 3.5.3). Fermentation can take from 24 h to 12 days, depending on the style of rum desired (Sections 3.5.3 and 3.5.4).

Distillation is carried out either in pot stills (Section 3.1.2), as with malt whisky (Section 3.2.4) and Cognac (Section 3.6.2) or in Coffey or continuous (columnar) stills (Section 3.1.3), as with many other spirits, including grain whisky (Section 3.2.4) and most Bourbon (Section 3.3.4). The former gives a spirit of around 65% ABV (for double distillation) with higher concentrations of congeners (flavor compounds), whereas the latter gives a more pure, lighter and less overtly flavored spirit containing close to 95% ethanol (v:v). Both types of distillation systems are open to modifications and a variety of operating options (Section 3.5.3).

Following distillation much cachaça and rum is not aged in oak casks, but usually spends some time ageing in stainless steel tanks. However, most cachaça and rum is blended, diluted and chill filtered before bottling. These spirits are naturally colorless (as are all freshly distilled or 'new make' spirits), but caramel can be used to give a golden or darker color. More usually, all traces of color may be removed by charcoal filtration prior to bottling, as with much cachaça, Cuban and Puerto Rican rum. Cachaça and rum can be aged in stainless steel tanks, wooden vats or smaller casks, such as ex-Bourbon casks, in which case color is acquired according to the length of ageing and the extent of charring of the cask interior (Section 3.3.4). This color can be further deepened or removed by the processes mentioned above. Charcoal filtration also removes certain aroma/flavor constituents, as observed in the depleted ester profile of white Brazilian rum, compared with the rich ester profiles of typical cachaca samples (Nascimento *et al.*, 2008).

Rum can be spiced or flavored with fruits or coconut before bottling (Section 3.5.4). Most cachaça and rums are diluted with rainwater, mountain stream water or distilled water (Section 3.5.3) to give beverages of around 40% ethanol (v:v), but 'overproof' rums can possess alcohol contents of 75% (v:v) and beyond (Section 3.5.4)

3.5.3 Fermentation and Distillation Practices in the Production of Cachaça and Rum

Most cachaça and rum distilleries are linked to or are situated close to sugar plantations and refineries, often owned by the same parent companies as the distilleries. Some distilleries (like some on the islands of the French West Indies and the Macoucherie distillery on Dominica, producing 60 000 bottles of rum per annum) are entirely self-sufficient in this respect, using only their own estate grown sugar cane. The majority, however, rely on imported sugar cane or molasses, as well as local products, so that import and export of molasses is a very important trade. Brazil is a major exporter of molasses to the Caribbean area, where the biggest producer, Puerto Rico, is a net molasses importer.

The quality of the molasses is dependent on the quality (ripeness) of the sugar cane and also on the quality of the slaked lime and water used in its preparation. Molasses should have close to 60% of its mass composed of total sugars, with a high sugar to ash ratio (>7), a low gum to sugar ration (<0.05) and a low acetic acid content (<5 g/l) (Delevante, 2004). If the last mentioned is too high, fermentation may not be satisfactory.

As is the case with most other spirits, the solution to be fermented (the beer, wine or wash, according to the industry) should contain enough sugar to produce 7–8% ethanol (v:v) when fermented right out; it should have an original gravity of around 50–60 °Oe ($\sim$12.5–15.0 °Brix). To achieve this, both sugar cane juice and molasses must be diluted with pure, clean water – rainwater, as in the case of Cruzan rum (US Virgin Islands), mountain spring water, as in the case of many Jamaican distilleries, or distilled water. Both cane juice and (diluted) molasses may be treated by boiling or pasteurization prior to further processing, in order to reduce populations of microorganisms.

Most cachaça is made from sugar cane juice, but most rum is made from molasses, although some rum made in Martinique ('rhum agricôle'), Haïti and a few others are derived from sugar cane juice. In many cases, distilleries that are located close to or are associated with sugar refineries use molasses, although imported molasses are also important.

Larger cachaça and rum distillers use special cultivated yeasts for fermentation, but smaller concerns may still use baker's yeast (e.g. in Brazil), wild yeasts or yeasts cultivated from generations of previous fermentations (e.g. Rhum Barbancourt, Haïti). Some fermentations are conducted with the lees (yeast residue) of previous fermentations (called 'dunder' or 'fermento-caipira'); certain aromatic rums from Jamaica and Martinique are typical of those using this type of fermentation.

The speed of fermentation has a considerable influence on the classification or style of the finished rum. Slow fermentations, taking up to 12 days, give beer that is rich in esters and higher alcohols (congeners). Such

beer, if double distilled in pot stills, results in the more 'aromatic' or 'heavy' rums of Demerara (Guyana), Jamaica, Martinique and certain other Caribbean islands. Rather more typical are rapid fermentations taking two days or less. These give a beer with fewer congeners, which if distilled in continuous (Coffey) stills, produces a more neutral or 'light' rum, spirit, typical of Brazil, Colombia, Cuba, the Dominican Republic, Puerto Rico and Venezuela. In general, wild yeasts and lees (dunder) conduct slower fermentations, while baker's yeasts or cultivated yeasts tend to ferment more rapidly.

Most fermentations are performed in temperature controlled carbon or stainless steel cylindrical vessels whose height is about twice the diameter, although other materials such as wood (as in former days), glass or plastic may be used, especially by small-scale distillers. Whatever the shape or material of the fermenter, its volume should be compatible with the distillation facilities.

The distillation process is also of high importance in deciding the style or character of the cachaça or rum, as with other spirits (see, for example, Scotch whisky, Chapter 3.2) The original method is double distillation using pot stills (Section 3.1.2). Rather in the style of Scotch malt whisky (Section 3.2.4), the first distillate (low wines) is mixed with the headings and tailings of a previous distillation and redistilled, whence the middle distillate, destined to become rum, comes over at about 65% alcohol (v:v). A variation on this general theme, originating in Jamaica, uses two retorts (called 'can pits') connected between the pot still and the condenser (Figure 3.5.3). This system removes one of the two distillation steps needed for double distillation and in effect is roughly equivalent to a triple distillation. The vapor leaving the still, containing around 30% alcohol (v:v), passes through the low wines in the first can pit where the aqueous part of the vapor condenses. This condensation releases heat into the low wine, which causes the vaporization, the vapors leaving the low wine retort now having around 60% alcohol (v:v). These vapors pass through the high wine in the second retort, where the above process is repeated, but this time the vapors leaving the high wine can pit contain close to 90% ABV. After collection of the headings the first fraction is collected as rum, then the following high wine (~75% ABV) and low wine (~30% ABV) fractions are collected (until the ethanol in the system is exhausted) and returned to the high wine and low wine can pits, respectively, ready for the next distillation batch (Figure 3.5.3).

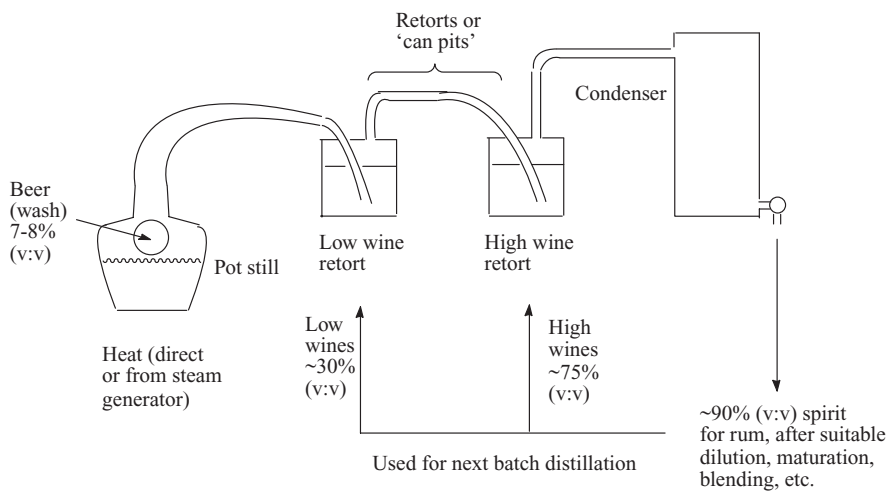

Figure 3.5.3 *Schematic representation of a twin-retort pot still distillation system. Used for certain heavy rums, originating in Jamaica. Not drawn to scale*

Pot stills, with or without double retorts, are used to make the more aromatic, heavier rums of Demerara, Jamaica and the French West Indies ('rhum arôme'). Similar rum is also made in Belize, Bermuda, Haïti, St. Kitts and other Caribbean islands. These rums all contain high ester and higher alcohol (fusel alcohol) contents. They are usually made from molasses, fermented slowly with dunder or special yeast, matured in oak casks and colored with caramel prior to bottling. These are the rums that go into the Navy and Demerara blends, although some are bottled 'straight' (e.g. 'Plummer' and 'Wedderburn' types from Jamaica and the 'Grand Arôme' types from Martinique). They are usually enjoyed neat, although they can be used to make cocktails, such as Planter's Punch. A model of a Caribbean pot still and part of a life size small Caribbean still from the eighteenth century can be seen in Figure 3.5.4.

Blending vat (1,720 gallon or 7,740 l). Bottom half of vat shown here, with two figures to give impression of size.

Life-size West Indian rum still

Figure 3.5.4 *Rum equipment at Jefferson's Rum Museum (Rum Story), Whitehaven, UK. This is effectively a museum based in Jefferson's former wine stores and warehouse. The emphasis is on rum, since the Jefferson family were involved in the import of rum into the UK via Whitehaven from the eighteenth century. (a) Vat (~1720 gallons; 7740 l) for blending or storing rum. Bottom part of vat is shown here, with two figures to give some idea of size. (b) Scale model of a small Caribbean rum pot still. (c) Life size model of small rum pot still*

Lighter rums (i.e. those that contain lower levels of congeners) and much cachaça are made using Coffey stills (Section 3.1.3), usually a two column system. The beer enters continuously at the top of the first column (the beer column), where steam entering the bottom vaporizes the ethanol (see Figure 3.1.6, Section 3.1.3). The vapors pass into the second column (the rectifier or analyzer column), where the heat of condensation of the aqueous component vaporizes more ethanol, but not the higher boiling point fusel alcohols. Thus, a relatively pure spirit containing ~95% ABV leaves the condenser (via the top of the rectifier column) to become rum, after appropriate dilution, maturation, etc. This type of rum has less volume of flavor than pot still rum and is a typical product of all the Portuguese or Spanish speaking countries of Central America, South America and the Caribbean region. These rums are often bottled after relatively short maturation times (in tanks or vats) and without coloration, although there are exceptions to this, and some is blended with darker more flavorsome rums to give medium bodied blends. The colorless versions (white rum) of Coffey still rum and cachaça are used in cocktails such as Daiquiri and long fruit drinks such as Caipirinha. In western Guyana, Coffey still spirit is matured over spices or fruit to give the popular spiced or fruit rums. A three column distillation system gives a highly rectified, almost flavorless spirit, like vodka, and indeed some molasses spirit distilled in this way can be called vodka in some countries (such as the UK) or can form base spirit of gin (Section 3.4.2).

The type of distillation system and the material from which it is made, not only has a bearing on the flavor of the resulting spirit (Section 3.1.1) but also on the levels of ethyl carbamate (urethane) (section 5.11.5) and dimethyl sulfide (DMS) and other sulfur compounds. In the latter case (a sensory defect), copper stills or aluminium stills with copper inserts were found to give cachaça with lower levels of DMS on an experimental/pilot scheme (Faria *et al.*, 2004b). Under distillation conditions, copper reacts with some of the DMS to form (as yet unknown) odorless substances.

The situation is more complex regarding ethyl carbamate (EC), a potentially carcinogenic compound found naturally in many foods and beverages. It appears that pot stills that are operated using low temperature/high reflux rate distillation (Section 3.1.2) produce cachaça with the lowest levels of urethane (Bruno *et al.*, 2007). This conclusion arises from a study of the spirits from 28 cachaça distilleries, who used a wide range of distillation systems, operations and materials. In general, pot stills produced spirit with lower EC levels than continuous stills, but the role of copper is not straightforward. The spirit with the lowest EC concentration came from a stainless steel pot still, but double distillation in a big pot still and distillation from stainless steel or copper alembics using a steam generator (rather than direct heating) and a copper serpentine (the 'worm' condenser used to make some Scotch malt whiskies – see Sections 3.2.4 and 3.2.6) gave spirits with low EC levels. This is important for cachaça producers, since the Brazilian government in 2005 put forward a five year limit for production to attain maximum EC levels of 150 μg/l, so that exports to countries such as Canada fulfill those countries' statutory limits for EC content.

Although the much rum and cachaça is not aged (much of it is consumed locally in long fruit drinks or cocktails, especially caiprinha), certain types for export are aged (in wood usually) because many countries have import regulations that stipulate a minimum ageing period for rum (usually one year). Ageing in wood is generally carried out in ex-Bourbon casks, their singed interiors imparting both flavor congeners and an amber or dark brown color, depending on the severity of singeing and on the resting time in cask. Most rum aged this way remains in the casks for no more than five years, but a few (particularly some Demerara, Jamaica and Martinique rums) are aged for longer periods – up to around 20 years. Rum aged in large wooden vats or stainless steel tanks remains almost colorless, but color can be added either by blending with dark rum or by adding caramel. On the other hand, any color acquired by a light rum during wood ageing can be removed by filtration through charcoal, a practice used extensively in Cuba. In general, casked spirits age more rapidly in subtropical climates than in cooler climates, so five years is normally sufficient to give well rounded mature rum. They also lose a greater volume of liquid (ethanol or water, depending on the cask strength of the spirit (see Sections 3.2.5 and 3.3.4): around 10%

per annum, as opposed to the 2% lost by Scotch whisky maturing in cask in the cool, damp climate of Scotland.

Most aged rum is destined for blends that are mostly medium bodied, consistent and whose bottles do not carry any indication of age. However, there is a growing market for premium rums, rather like the now well established market for malt whiskies. Premium rums are generally blends of spirits of different cask ages, whereupon the age of the youngest component is stated on the bottle label, as for Scotch whisky. Premium rums, like fine Cognacs and malt whiskies are meant to be sipped; they are usually medium to full bodied dark rums from Guyana, Haïti, Jamaica and the French West Indies, but premium rum is made elsewhere, notably Barbados, Bermuda and the US Virgin Islands. A few rums from the French West Indies are even vintage dated, like some Scotch malt whiskies (Section 3.2.6).

For rum and cachaça, like most distilled beverages, the art of blending plays an important role in maintaining consistency of product character from year to year. The blender's job is to ensure that consistency, which depends on the marriage of several distillates (or 'marks') to strike the best balance in the final product. This depends on the age and congener profile of the distillates available for blending. After ageing and blending, but before bottling, cask-aged rum is chilled and then filtered to remove flocs formed by the precipitation of fatty acids (Delevante, 2004).

The production of all alcoholic beverages involves material waste (see, for example, Sections 3.2.5 and 3.5.6). In other spirits industries the wastes can be disposed of in economically and environmentally acceptable ways. For example, spent grains from the mash used to produce whiskies make good animal feed and spent lees, pot ales, etc. from the stills are partially recycled in some distilleries. Distillation residues discharged into the environment require prior dilution because of the accumulated heavy metal salts (Section 3.2.5).

In the rum distillery, the most problematic waste is the still residue (mosto or 'rum slops'), which correspond to the residue of the rectifier Coffey still. This residue contains high levels of heavy metals and organic compounds making it both toxic and a heavy demander of biochemical oxygen, so untreated effluent is not permitted to be discharged into rivers or coastal seawater. Pretreatment (acidification) of the diluted molasses before fermentation, removal of yeast and fermenter sludge prior to distillation both help to minimize sludge build up in stills and to reduce the toxicity of distillery effluent. The sludges can be applied to the land and the still residue can be evaporated to give condensed molasses solubles (CMS), which can be used as animal feed or can be incinerated, the ashes being used as fertilizer.

3.5.4 Flavor Characteristics of Rum and Cachaça

Several studies have been performed on the flavor characteristics of rum and cachaça (e.g. Nykänen and Nykänen, 1983: Pino *et al.*, 1996; Ng, 1999; Faria *et al.*, 2004b; Faria *et al.*, 2004c; Pino, 2007; Nascimento *et al.*, 2008; Silva *et al.*, 2009). As with other spirits, the majority of volatiles fall into the categories esters, aromatic compounds, terpenoids, alcohols, acetals, aldehydes, phenols, ketones, furans, carboxylic acids and benzopyrans. In a recent detailed study (Pino, 2007), the number of compounds in each category is in the order listed above, although this may not necessarily reflect their relative contributions to the overall odor and flavor. Using a highly sensitive solid phase microextraction (SPME)/gas chromatography-mass spectrometry (GC-MS) technique (Sections 4.2.4 and 4.3.2), Pino identified 184 volatile components in unaged sugar cane spirit (aguadiente) and also in three and seven year old cask-aged rums.

In all the samples, the major volatile compounds were ethyl esters, 3-methyl-1-butanol and 2-methyl-1-butanol. The ethyl ester profiles for the samples were similar, suggesting that this particular profile may be influenced by fermentation and distillation methods, but not by maturation in oak casks. As expected, there were many differences in the concentrations of certain components in the unaged white spirit and the

cask-aged rums. In general, the aged rums had higher levels of ethyl acetate, ethyl butanoate, ethyl isobutanoate, a number of other esters, benzaldehyde and some terpenoids. On the other hand, the white sugar cane spirit had higher levels of certain esters, some hydrocarbons, (e.g. benzene and naphthalene derivatives), phenols and some edulans. Compounds normally associated with wood ageing (e.g. acetals, certain lactones, phenols and terpenoids) were present only in the aged rums. Principal component analysis based on 15 volatile components allowed discrimination between three and seven year old rums. The first principal component, contributing 69% to the total variance, was highly correlated with acetic acid, benzaldehyde, 3-*tert*-butyl-4-hydroxyanisole, (*E*)-β-damascenone, diethoxyethane, dodecanal, 2-dodecanol, ethyl butanoate, limonene and menthol.

Analysis of the ethyl esters (by direct injection GC) of 136 cachaça samples distilled in copper alembics, mixed copper/stainless steel stills or steel columnar stills revealed ethyl acetate and ethyl lactate to be the most abundant (Nascimento *et al.*, 2008). High levels of ethyl lactate in cachaça (compared with whiskeys) were suggested to be the result of greater *Lactobacillus* activity during fermentation; spontaneous fermentation at high pH and reaching temperatures of 45 °C, as opposed to the yeast culture, temperature controlled fermentations at lower pH used for whiskey production. Cachaça produced in alembics (the majority: 109/136) had higher mean levels of ethyl acetate and ethyl lactate than those produced in column stills, reflecting the greater rectifying power of the latter types of stills. Other ethyl esters (butanoate, hexanoate, octanoate, decanoate and laurate) of cachaça were present in much lower concentrations (as in whiskeys) and were slightly more abundant in column still samples.

Supercritical fluid extraction (SFE) (Section 4.2.2) using CO_2 has been applied to the assessment of aroma compounds in the intermediate streams in the Cuban rum production process (Gracia *et al.*, 2007). The head alcohol fraction contained the greatest number of higher alcohols, as determined by GC-MS analysis of the CO_2 extract. This corresponded to an organoleptic (sensory) evaluation of 'fruity.' The levels of higher alcohols diminished and concentrations of carboxylic acids, esters and other compounds increased from the head alcohol fraction through crude (unaged) spirit to aged rum. Sensory evaluation correspondingly changed from fruity, through sweaty to whiskey, the last named descriptor meaning aged or mature. The head alcohol fraction was suggested as the best source of natural flavoring compounds for the food industry, extracted by supercritical CO_2. This fraction is not only rich in flavor components, but is normally used as a fuel source (as with cachaça – see Section 3.5.2), thus isolation of flavor compounds could increase the value of this fraction and contribute to increased profits.

In Brazil, since the government is pushing to optimize cachaça quality, there is much interest in the isolation and selection of yeast strains that give cachaça with high sensory value and levels of EC below those specified by current legislation. Recent experiments have evaluated 233 *Saccharomyces cerevisiae* isolates from traditional cachaça fermentations for good flocculation characteristics, high attenuation capability and nonproduction of hydrogen sulfide (Silva *et al.*, 2009). It was found that although several strains possessed these desirable characteristics and gave cachaça with good sensory evaluations, one in particular (UFMGA-1031) was recommended for use as a starter for the production of high quality cachaça. It is expected that as the industrialization and rationalization of cachaça continues, more and more use will be made of cultured yeast starters.

Wood ageing naturally contributes to the flavor of rum and cachaça, as with other alcoholic beverages. Ex-whisky or Bourbon casks are often used to age Caribbean rums (Section 3.5.3), but this practice is a relatively newcomer in the production of premium cachaça in Brazil. That country grows a wide variety of trees whose wood is capable of being made into casks and it is possible to buy cachaça aged in wood other than oak. In an experiment, the sensory values of cachaça aged for six months in specially made 15 l casks made of various indigenous woods and oak were compared (Faria *et al.*, 2004c). Sensory analysis by a panel based mainly on overall aroma and flavor suggested that amendoin (*Pterogyne nitens*), pereiro (*Hymanaea stigobocarpa*) balsámo (*Myroxylon peruifum*) and pay d'arco (*Tabebuia impetiginosa*) may be suitable for

ageing cachaça, but the remainder, amarelo (*Plathymenia reticulta*), pan d'oleo (*Copaifera langsdorfii*) and louro *Aniba parviflora*) were considered unsuitable.

Although cachaça and rum have similar origins, experienced tasters usually have little difficulty in distinguishing the two spirit types, implying that they have significant differences in aroma profiles. Gas chromatography-olfactometry (GCO) (Section 4.3.2) was used to identify the most potent aroma compounds in extracts of new make (unaged) cachaça and Puerto Rican rum, and the results were compared with the results of descriptive sensory analysis (Section 4.7.4) (De Souza *et al.*, 2006). Cachaça was found to be more intense in the grassy, spicy, sulfury and vinegar descriptors, whereas apple and caramel were about the same in cachaça and rum. This corresponded to GCO observation of spicy eugenol, 4-ethylguaiacol and 2,4-nonadienal being much more potent in cachaça, but fruity β-damascenone, ethyl butanoate, ethyl isobutanoate and ethyl 2-methylbutanoate were at about the same potency in cachaça and rum.

Application of chemometric techniques to the chemical profiles (including not only certain volatile components, but also nonvolatile components such as minerals and phenols) of various types of rum allows classification or identification, as with other beverages (e.g. see Marsala, Section 2.10.8; pomace spirit, Section 3.7.2). Sampaio *et al.* (2008) used principal component analysis (PCA), partial least square-discriminate analysis (PLS-DA) and linear discriminate analysis (LDA) of chemical descriptors derived from GC analysis of aroma compounds, atomic absorption analysis of minerals and HPLC analysis of polyphenols to discriminate between Cuban and other light rum types. In total, 23 analytes were chosen as relevant descriptors, including the aroma components acetaldehyde, acetone, 1-butanol 2-butanol, 2-butenal, cyclopentanone, ethyl acetate, isoamyl alcohol, isobutyl alcohol and vanillin.

3.5.5 Arrack, Mezcal and Tequila

As explained in Section 3.5.1, arrack (and its variants alak or arak) refers to any distilled alcoholic beverage in Asia, irrespective of the source of fermentable sugar (fruit, grain, sugar cane or vegetable. For the purposes of this book, the term arrack is used to describe the spirits of southern and southeastern Asia, particularly those derived from coconut palm sap. Arrack derived from sugar cane is also called rum and is dealt with in Section 3.5.4. The term arak is reserved for spirits of western Asia, especially those of the Middle East derived from grapes and anis or aniseed and is dealt with in Section 3.5.6.

Coconut arrack is distilled from palm wine, a beverage made by fermenting the sap (neera) tapped from the preblossom flowers (i.e. the unopened spadix) of coconut palm trees (*Cocus nucifera* L.). It is a popular alcoholic beverage of Sri Lanka, where a variety of brands are available, having alcohol contents of from ∼33% to over ∼50% (v:v). The cheaper brands are blends of arrack and neutral spirit; these are drunk with cola, ginger beer or soda water. Better quality coconut arrack tends to be consumed neat, with water or in cocktails. Sri Lanken arrack is produced by companies such as Indian Distillers Ltd, Distillers Company of Sri Lanka (DCSL), Mendis and Rockland. The brands often have sophisticated names such as VSOA ('Very Special Old Arrack') and Old Reserve. Some of these companies also produce rum.

A comparable drink to arrack, known as lambanog, is produce in the Philippines. It too is distilled from palm wine (fermented coconut palm sap: called 'tuba' in Luzon), though it is often flavored with fruit (e.g. blueberry or mango) or spices (e.g. cinnamon). At the time of writing (2009) it is just emerging from its long existence as essentially a cottage industry. Its situation is rather like that of cachaça in Brazil a few years ago.

The palm sap (called neera in southern India) is usually clarified by filtration before fermentation and distillation. As in other cases, alcoholic, lactic and other fermentations cause changes in the aroma profile, so that fermented neera (called 'toddy' in southern India) contains a greater quantity of volatile compounds. However, several aroma compounds are retained from the fresh neera, including ethyl lactate, farnesol and

2-phenylethanol (Borse *et al.*, 2007). Ethyl lactate persists through the distillation process and is considered a characteristic volatile constituent of all commercial coconut arrack (Samarajeewa *et al.*, 1981).

Mezcal and tequila are distillates of wines made by the fermentation of syrup exudates from cooked pines of *Agave* (Maguey) plants. Plants of the *Agave* family (*Agavaceae* genus) are tall succulents, although there is considerable biodiversity within the genus: various species of *Agave* grow in Mexico and other Central and South American locations. *Agave tequilana* var. Azul ('blue agave') grown mostly in west-central Mexico (especially in the states of Jalisco and Guanajuata), originally around the city of Tequila, is used for the production of Tequila, by law. Other species of *Agave* can be used for mezcal: *A. salmania* in the Mexican altiplano and *A. angustifolia* with *A. potatorum* in southern Mexico (De Léon-Rodríguez *et al.*, 2006). *Agave* plants are cultivated on farms and are harvested when between seven and nine years old, whereupon the magueyeros (maguey farmers) cut the plants from the roots and strip off the leaves to reveal the pines (piña), which can weigh up to 50 kg each.

Tequila must be made from blue agave within certain designated locations in the states of Guabajuato, Jalisco and others. Mezcal is made from Agave plants other than blue agave in a much wider range of locations. Much mezcal is produced in the state of Oaxaca, but the drink may have local names such as bacanova (Sonora region) or sotol (Chihuahua region). Both mezcal and Tequila are protected by an international Denomination of Origin: the production of Tequila is subject to the Mexican regulation NOM-006-2005 (SECOFI, 2005), whereas mezcal is subject to the regulation NOM-070-1994 (SECOFI, 1994). The annual production of Tequila in 2006 was 242.6 million litres, whilst that of mezcal was 6 million liters (Lappe-Oliveras *et al.*, 2008). They are both are consumed straight, with water, or as components of long drinks or cocktails.

The production process for traditional mezcal and Tequila are summarized in Figure 3.5.5. In all cases, the *Agave* hearts or pines are heated to ~100 °C for at least 36 h. traditionally this performed in sunken ovens (hornos) using preheated stones, but many modern distilleries use pressure cookers or autoclave-like ovens. The mean reasons for the cooking process are to hydrolyze the polymeric fructans into fermentable sugars (Waleckx *et al.*, 2008), to soften the pines so that crushing and extraction of fermentable sugars is easier, and to create a number of flavor compounds via the Maillard reaction (Chapter 2.6). The baked pines are separated

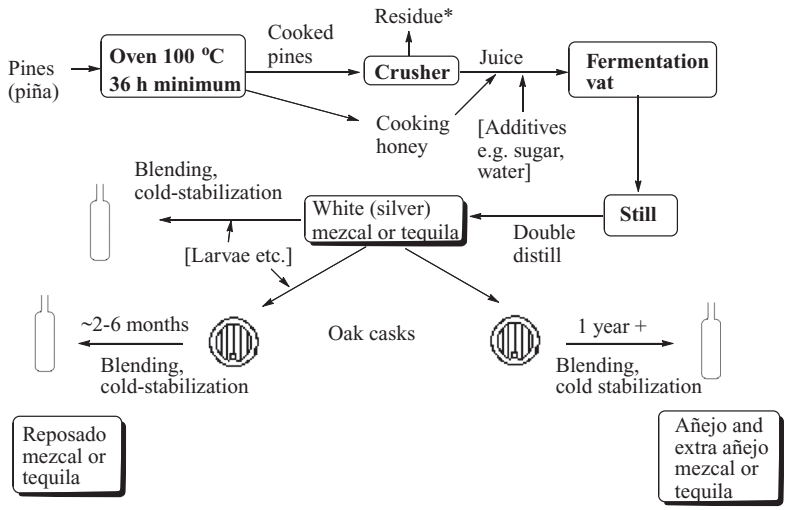

Figure 3.5.5 *Simplified scheme for the production of mezcal and tequila. *Some traditional distilleries ferment whole crushed, cooked pines and distil from this, in which case the fibers and debris have to be removed from the still before the first distillate is returned for redistillation*

from the viscous 'cooking honey' produced by the cooking process and are then crushed. This gives *Agave* juice, which is mixed with the cooking honey ready for fermentation. Additives, such as cane or corn sugar may be added at this stage. In some distilleries the whole crushed *Agave* pines (i.e. the juice plus pulp and fiber) is fermented, but in the majority of cases fermentation is carried out by microorganisms in the juice and on the distillery equipment. Fermentation takes place in vats or tanks of 500–10 000 l capacity, made of wood, stainless steel or stone, and lasts several days, depending mainly on the sugar extract of the must and local weather conditions (Lappe-Oliveras *et al.*, 2008). The resulting liquor is double distilled in metal or earthenware pot stills. As with other spirits (e.g. see Section 3.2.4), the first distillation yields a relatively crude spirit containing *ca.* 30% ethanol (v:v), which is returned to the still (after removal of residues) for a second distillation, producing a spirit of about 60–65% ABV.

Industrial mezcal and Tequila are often made by the stepwise process shown in Figure 3.5.5, but with modifications at various points (apart from scale of operation: 2000–120 000 l fermentation tanks) including the use of steam injection ovens or autoclaves for cooking, the use of a combined water extraction/milling process, the use of dried yeasts or inocula of yeast starters (∼5–10% of must volume) and the use of rectification columns on the stills. The last mentioned technique increases distillation efficiency and allows greater control of the organoleptic qualities of the final product (Prado-Ramírez *et al.*, 2005). In particular, monitoring ethanol content is a crucial factor determining how the slop cuts (the first distillate) and final distillate meet the Tequila norm for regulated compounds: ethanol, higher alcohols, methanol, acetaldehyde, ethyl acetate and furfural).

By law there are two categories of mezcal and Tequila, depending on how much of the fermentable sugars are derived from the maguey plant. For mezcal these are type I (100% Agave) and type II (80% Agave) and for Tequila, they are called Tequila 100% (100% Agave) and Tequila 51% (51% Agave). Each category is subdivided according the extent of ageing in small white oak casks: 'mezcal joven,' white or silver Tequila ('Tequila blanco') and 'Tequila joven u oro' (golden Tequila) are unaged, 'reposado' indicates 2–6 months cask ageing, 'añejo' indicates up to one year in cask and 'extra añejo' indicates at least three years of cask ageing. The most popular Tequila is the reposado type. Tequila 100% is required by law to be bottled in the region of production, but Tequila 51% can be exported in bulk and bottled outside Mexico.

Mezcal joven and reposada (but not añejo) are sometimes sold with various animal or mineral additions in the bottle. These include 'maguey worms,' scorpions and glass figurines wrapped in gold foil. The 'maguey worms' are in fact the larvae of certain insects found on *Agave* plants and up to four of these can be found in certain bottles of mezcal. For example, the well known mezcal brand 'Gusano Rojo' (Nacional Vinicola) makes use of the gusano rojo (red worm) – the larva of the *Hypopta agavis* moth.

Like other alcoholic beverages, general organoleptic characteristics, including flavor, depends on the number and type of constituents in the distillate. The presence of some Tequila and mezcal constituents (such as ethanol, acetaldehyde, higher alcohols, methanol and ethyl acetate) are regulated by Mexican law: their concentrations must fall within specified limits. However, the majority of flavor congeners, generally present in lower concentrations, are not regulated and it is these that generally contribute most to the overall character of the spirit.

As with other alcoholic beverages, the microbiota involved in fermentations play an important role in establishing the aroma/flavor profile of mezcal and Tequila. Utilization of 'spontaneous' fermentation or of starters originating from such fermentations is still widespread in the production of these spirits. These rely on the natural microorganisms already present in the *Agave* must and on distillery equipment and hence fermentation comprises of a number of phases in which successions of yeasts and bacteria dominate. In the early stages of fermentation of *Agave tequilana* to produce Tequila, *Dekkera bruxellensis*, *Hanseniaspora* spp., *K. marxianus*, *P. membranifaciens* and *T. delbrueckii* were active, but *S. cerevisiae* was the dominant yeast, whereas toward the end of fermentation the last mentioned was totally dominant (Lachance, 1995). Other workers have observed somewhat different microbiotic profiles isolated from different Tequila distilleries and

totally different ones (in which LAB and *Z. mobilis* dominate in some; *S. cerivisiae* dominating in others) from mezcal distilleries (Escalante-Minakata *et al.*, 2008; Lappe-Oliveras *et al.*, 2008).

It seems clear that different *Agave* species, locations and distillery conditions favor different microbiological populations and this will account for differences in flavor profiles amongst mezcal, Tequila and related spirits, such as raicilla. Also, if a dominant species in one must (say mezcal) is transplanted into an alien must (say, Tequila or raicilla) both biological activity and formation of flavor compounds often differ (Arrizón *et al.*, 2007). *S. cerevisiae* strains from fermenting Agave musts were found to produce β-glucosidase, whereas non-*Saccharomyces* secondary yeasts, such as *Candida*, *Kluyveromyces* and *Hanseniaspora* spp., produced both β-glucosidase and β-xylosidase enzymes, with *C. magnoliae* having the greatest β-glucosidase activity (Fiore *et al.*, 2005). These secondary yeasts could thus play an important part in the release of flavor active terpenes from their flavorless glycosides during fermentation, thereby making an important contribution to the flavor profile of the spirit. Similar relationships have been observed for natural fermentations versus inoculated yeast monoculture fermentations in the resulting flavor profiles of wine (Section 2.2.6), beer (Section 2.6.7) and cider (Section 2.8.4).

There are flavor differences between mezcal and Tequila that are made from highland or lowland plants. The highland plants give pines that are bigger and juicier, and produce liquor and spirit with more fruity notes, whereas lowland pines tend to be smaller, giving a spirit with more earthy notes. Characteristic flavor compounds of mezcal and Tequila include ethyl acetate, ethyl lactate, acetic acid, higher alcohols (major contributors), other alcohols, carbonyl compounds, carboxylic acids, ethyl esters, furans, terpenoids and hydrocarbons (De Léon-Rodríguez *et al.*, 2006; Cardeal and Marriott, 2009). In this respect, they resemble other distilled spirits. However, two dimensional GC/MS (Section 4.3.2) can distinguish Tequila from other distilled drinks (Cardeal and Marriott, 2009), and mezcal produced from different species of *Agave* can also be differentiated using SPME-GC/MS (Sections 4.2.4 and 4.3.2) by the presence of unique compounds. Mezcal from *A. salmania* contained limonene and pentyl butanoate, which could be used as markers of authenticity (De Léon-Rodríguez *et al.*, 2006). Similarly, mezcal obtained from *A. angustifolia* was distinguished from Tequila and sotol by the presence of ethyl nonanoate, 2-acetylfuran and 2-methylnaphthalene, respectively (López and Guevara-Yáñez, 2001). Furthermore, mezcal with larvae could be distinguished by the presence of 3-hexen-1-ol and 6,9-pentadecadien-1-ol (De Léon-Rodríguez *et al.*, 2006). Also, using principal component analysis of the fluorescent background of Raman spectra (Section 4.4.2) it has been possible to distinguish Tequila blanco (unaged) from aged Tequila (Frausto-Reyes *et al.*, 2005).

In recent years, mezcal and Tequila have received international recognition and worldwide consumption of tequila has increased enormously; for example, its sales in the USA are about the same as brandy, prepared cocktails and Scotch whisky (Corrigan, 2004). Frequent fraud, particularly aldulteration of Tequila with grain spirits or the labeling of 'mixed' category Tequila as '100% Agave' (the 100% *Agave* category is more expensive) has accompanied this growth and hence it is necessary to exert authenticity control of *Agave* spirits (Lachenmeier *et al.*, 2006). This is particularly, so since much of the lower grade 'mixed' Tequila is shipped in bulk and bottled outside Mexico. In a study of a wide range of Mexican *Agave* spirits, using GC and ion chromatography (Section 4.3.3), Lachenmeier *et al.* (2006) found that the two Tequila categories (100% *Agave* and mixed; made with added sugar) could be differentiated on the basis of methanol, 2- and 3-methylbutanol and 2-phenylethanol. The mixed category samples had lower levels of these constituents. Likewise, all *Agave* spirits had concentrations of oxalate (0.1–9.7 mg/l), derived from the *Agave* plant material, although there was considerable overlap of concentrations in samples of 100% *Agave* and mixed Tequila. Hence oxalate content was not recommended as a discriminator between the two Tequila categories. Additionally, higher total levels of anions were observed for artisanal *Agave* spirits, reflecting the lesser technological sophistication in the production of these spirits; less pure water used for dilution, for example.

Raman spectroscopy, although used primarily to determine the ethanol content of Tequila (using the OH region profile of water), was able to distinguish silver Tequila from aged tequilas, via application of a

chemometric (principal component analysis, PCA) to the fluorescence background of the Raman spectra (Frausto-Reyes *et al.*, 2005).

More recent work has shown that the four categories of Tequila and mezcal could be differentiated on the basis of chemometric analysis of the concentrations of 12 elements (Al, Ba, Ca, Cu, Fe, K, Mg, Mn, Na, Sr, S and Zn), determined by inductively coupled plasma optical emission spectrometry ICOES (Section 4.4.4) (Ceballos-Magaña *et al.*, 2009). Several chemometric treatments were tried, with the probabilistic neural networks method giving 100% success in the differentiation of extra aged, aged, gold and silver Tequila, and mezcal.

3.5.6 Aniseed Flavored Spirits

Aniseed flavored spirits are produced in many countries around the Mediterranean Sea: Egypt, France, Greece, Israel, Italy, Lebanon, Palestine, Spain, Syria and Turkey. They are also made in a number of Balkan countries, such as Bulgaria and Macedonia, as well as in some Middle Eastern countries, such as Iraq and Jordan. Most are based on brandy (distilled wine; Chapter 3.6) or grappa (distilled pomace; Chapter 3.7), although some are based on fruit brandies (Chapter 3.8) and others on cane sugar spirits or grain/vegetable spirits (Chapter 3.4). In the Middle East their generic name is arak. Here, they can be made from distilled date, fig or plum wine, rather than brandy or grappa, and in Israel, spirits are made from sugar cane 'beer' as well as wine. In the European Mediterranean countries, they are usually distilled from wine or pomace and are known by many different names, rather than arak. For example, there are ouzo, raki, tsikoudia and tsipouro in Greece; mastika in several Balkan countries; pastis in France; anesone and sambuca in Italy; ojén in Spain.

Methods of production of aniseed flavored beverages and related spirits vary widely, as does the spirit base and the flavorings, thus giving rise to a family of drinks with an obvious similarity, but at the same time with subtle differences. Middle Eastern arak (e.g. of Lebanon, Palestine and Syria), based on brandy, is usually made in the weeks following the grape harvest – for example in the mountainous areas of Lebanon, in October or November. The grapes are often fermented on the pulp for 2–3 weeks and the resulting vinous mixture is distilled in an alembic (pot still) to give a crude brandy. The alembic is emptied of the residue, washed and the crude brandy is then returned to it and mixed with aniseed, the amount of which depends on the distiller. A second (slow, low temperature) distillation yields arak as the middle distillate, usually of ~65% ethanol (v:v) content. In the Lebanon and some other countries, such as Greece and Macedonia, completion of the first distillation is accompanied by a ceremonial party at the distillery.

The major flavor component of aniseed, and hence of arak, is anethole. In the 1980s, the anethole content of 30 commercial Lebanese Arak samples was found to vary between 1.2 and 3.8 g/l, with an average value of 2.4 g/l. Arak from artisanal distillers had a much wider range of anethole content: 0.5–4.2 g/l, but with a similar average of 2.5 g/l (Geahchan *et al.*, 1991). Acetaldehyde, methanol and 1-propanol were found in all Lebanese arak based on brandy, where the ranges were 6–220 m/l, 9–540 mg/l and 17–760 mg/l, respectively. These components were missing from arak based on high proof alcohol. Other components were ethyl acetate (0–870 mg/l), 2-butanol (0–524 mg/l), 1-butanol (0–400 mg/l) and amyl alcohol/*iso*amyl alcohol (0–1692 mg/l) (Geahchan *et al.*, 1991).

Aniseed flavored spirits are popular in Greece, where again, they are usually based on brandy or grappa. These include tsipouro (τσίπουρο; called tsikoudia or raki on Crete), masticka (μαστίχα; similar to the мастика of Bulgaria and Macedonia) and the most popular and most heavily commercialized spirit ouzo. Tsipouro and tsikoudia are often unflavored pomace brandies, like aguadiente, grappa or marc (Chapter 3.7), but some versions of tsipouro are flavored with aniseed and some tsikoudia is flavored with herbs, such as thyme. Masticka (and sometimes other spirits) is flavored with gum mastic.

One the most famous aniseed flavored spirits is ouzo, whose name is probably derived from uzum, the mediaeval Turkish word for grapes. The drink probably evolved from tsipouro and rose to prominence

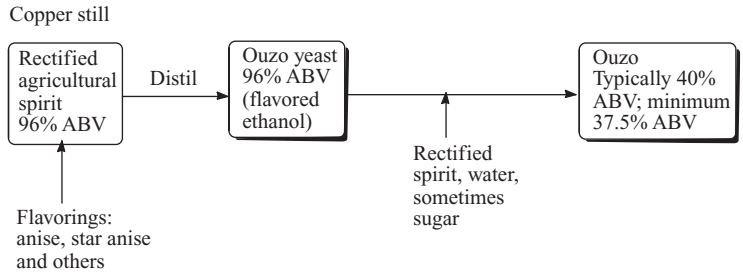

Figure 3.5.6 *Simplified diagram for the production of ouzo*

following Greek independence from the Ottoman Empire (1832). Its popularity increased when absinthe (see later) was banned by the French government in 1915. Nowadays, ouzo is distilled all over Greece, but the island of Lesbos remains a major producer and in fact claims to be the originator of the beverage. Most ouzo is now made like gin (Section 3.4.2) from rectified spirit, which in theory can be of any agricultural origin, in practice is most likely to be of wine or pomace origin.

Flavorings, which include natural anethole, anise (aniseed; *Pimpinella anisum*), cinnamon (*Cinnamomum verum*), coriander (*Coriandrum sativum*), cloves (*Syzygium aromaticum*) and star anise (*Illicium verum*), according to the style of the distiller, are added to the spirit in a copper still and then distilled (Figure 3.5.6). The highly flavored distillate (called μαγιά ούζου or 'ouzo yeast'), containing around 96% ABV is either diluted with distilled or mountain spring water to *ca.* 40% ABV or mixed with neutral spirit and then diluted. Ouzo based only on ouzo yeast is generally considered to be the finest. Greek law stipulates that at least 20% the total final alcohol all ouzo must be derived from ouzo yeast. Ouzo, tsipouro and tsikoudia were all accorded Protected Designation of Origin status by the European Commission (2006), so that according to EU law, these names may only be used for the spirits produced in Greece and certain of its island dependencies.

Further west, pastis (France) and sambuca (Italy) are the most common aniseed flavored spirits. Pastis came into being after 1915, when the French wartime government banned absinthe, a drink that had already received much criticism relating to its perceived unhealthy effects, including claimed hallucinogenic effects. The blame for these undesirable properties fell largely upon α-thujone, a major constituent of wormwood (*Artemesia pontica*), one of the major flavoring ingredients of absinthe. There is now considerable doubt regarding the focus of this blame – see Section 5.11.2. At the time it was banned, absinthe was a very popular beverage, so the two main producers, Pernod Fils and Ricard (now Pernod Ricard) created pastis: absinthe without the wormwood constituent, without the green coloring matter, but with more star anise component and less alcohol.

Aniseed flavored spirits are often consumed with cold spring water (about 1:3), to which ice is sometimes added. A characteristic common to all these beverages is their milky appearance when mixed with water. This occurs because some of the oily components of the aniseed flavoring (e.g. anethole) are soluble in 40–45% ethanol–water mixtures (as in the undiluted spirit), but not in the diluted drink. The micrometer sized oil droplets grow only very slowly, thus preserving the attractive milky appearance of the mixture. Slow growth has been attributed to very low interfacial tension of the droplets. Growth occurs by two processes:

- Ostwald ripening. This involves diffusive transport of dissolved oil through the medium, giving a linear droplet volume increase with time.
- Droplet coalescence (creaming). This involves the merging of two or more droplets, resulting in an exponential increase in droplet volume with time.

A study of the interfacial tensions of the three phase system anethole–ethanol–water (a pastis–water simulation), measurement of both types of growth rates and comparison of the results with predicted by Ostwald ripening and creaming models led to the conclusion that normal Ostwald ripening theory may not be applicable to this system because of the different gradients of concentration, density and pressure that exist in a critical system such as the three phase system studied here (Scholten *et al.*, 2008).

In the eastern Mediterranean and certain Balkan countries, these spirits are often consumed at ceremonies or with meals such as mezedes (small dishes made from fish, meat and vegetables). They are sometimes mixed with fruit juices or liqueurs, like the Bulgarian 'Cloud' (облак) – masticka and menta, a mint liqueur. Otherwise, aniseed flavored spirits, including pastis, are used as apéritifs. There are also many cocktails based upon pastis, like canditini, cornichon, mauresque, parroquet and tomate.

Anisette and sambuca are aniseed flavored liqueurs, that is to say they are rather sweeter than arak, ouzo, pastis and others, so they are dealt with in Chapter 3.9. The former was created to replace absinthe, but the latter dates back to the latter half of the nineteenth century.

3.6
Brandy

3.6.1 Introduction and Brief History

The word 'brandy' originates from the Dutch word *brandewijn*, meaning 'burnt wine.' In South Africa (where brandy is the top selling spirit drink), the Afrikaans term for the beverage is also *brandewyn*. The German term *weinbrand* is similarly derived, but outside the German speaking countries it is usually only used to refer to brandy produced in Austria and Germany. The 'burnt wine' label is appropriate, as most brandies are made through heating wine (without burning it), distilling over the alcohol (ethanol) and volatiles, and ageing the distillate in small oak barrels.

Distillation as a process is so old that the origins are uncertain. It may have been carried out as early as *ca.* 3000 BC in China, and was certainly used in Egypt around 2000 BC to make wood extracts during charcoal processing. There is evidence that the making of rose water in Persia and India in ancient times involved distillation (Amerine and Singleton, 1977), possibly using wool to trap and condense vapors, and the technique spread through Europe in the sixth century AD with the influx of Arab traders and scholars.

According to Léauté (1990), the art of distilling *wine* was first 'perfected' by a returned crusader, Arnaud de Villeneuve in France, in around the middle of the thirteenth century. Villeneuve proclaimed that the distillates prolonged life. In the Cognac region around 1600, the Chevalier of Croix Marron mastered double distillation, which further concentrated the alcohol. Distillates were also mixed or infused with a variety of herbs, and the medicinal (and antiseptic) properties associated with these infusions were probably the reason that they were known as *aqua vitae* (water of life) in Latin, and are still known in France today as *eau de vie*. The tradition of herb infused distillates led to the development of many of the flavored liqueurs (for example, Benedictine, Chartreuse, Jagermeister – see Section 3.9.3) that are available today.

It is probable that wine was initially distilled in order to decrease the volume before transport on ships. Distillate may also have been added to wine to preserve it during transit. The containers in which the fortified wines and distillates were stored and transported were made from wood, and extraction of various aromatics and phenolics would intensify flavors further during lengthy voyages. When water was added back to the distilled liquor before consumption, the resulting product had greater complexity, and was probably a considerable improvement on the original harsh wine. Jackson (2000) noted that although there are records of distillation of alcoholic beverages being carried out in Europe as early as the twelfth century, distillation on a larger scale for beverage production really only took off in the sixteenth century, with the first Cognac being made in the seventeenth century. According to the South African Brandy Foundation, brandy was first

distilled in the Cape on 19 May 1672 by a chef on the Dutch ship *De Pijl* (South African Brandy Foundation, 2010).

Modern brandy is usually made from the fermented juice of *Vitis vinifera* grapes, but distillates can be made from any fermented beverage that originally contained carbohydrates (for example whisky is the distillate of fermented grains). According to modern EU regulations (EEC, 1989) brandy or *weinbrand* '. . .is a spirit drink, produced from wine spirit, matured for at least one year in oak receptacles or for at least six months in oak casks with a capacity of less than 1000 litres, containing a quantity of volatile substances equal to or exceeding 125 grams per hectolitre of 100% vol. alcohol, and derived exclusively from the distillation or redistillation of the raw materials used, having a maximum methanol content of 200 grams per hectolitre of 100% vol. alcohol. The minimum alcoholic strength by volume of brandy or *weinbrand* shall be 36%. No addition of alcohol as defined in Annex I (5), diluted or not, shall take place. Brandy or *weinbrand* shall not be flavored. This shall not exclude traditional production methods. Brandy or *weinbrand* may only contain added caramel as a means to adapt color.'

The EU definition excludes fruit spirits (Chapter 3.8), pomace spirits (Chapter 3.7), and even grape brandy that has not undergone ageing. The same European Union regulation defines the names of these excluded spirits as 'fruit spirit,' 'grape marc spirit,' and 'wine spirit,' i.e. in terms of the legislation, these beverages are not allowed to be known as 'brandy.'

Brandies are usually classified by region of production, even though the soil conditions, climate and grapes used to produce the base wine have less influence on the final product than the distillation process used and ageing practices (Amerine and Singleton, 1977). The best known brandies are Cognac and Armagnac, which are described in more detail in Sections 3.6.2 and 3.6.3. Cognac is produced in the Charente region north of Bordeaux, and is made from the wine of the St. Émillion, Colombard (or Folle Blanche) grapes. The soil of the district contains a high percentage of calcium carbonate and it is generally accepted (although the theory remains to be tested scientifically) that the best brandies come from grapes grown on these calcareous soils.

The Base (Rebate) Wine

It is incorrect to assume that all wine that is not seen as good enough to be bottled as wine for the table is simply carted off to distilleries for brandy production. Certainly, some wineries will try to recoup financial losses through selling off poor quality batches for distilling, but most good brandy production is dependent on a good quality base wine, albeit one that is often rather thin and acidic.

Wine that has oxidative or reductive taints, or is oversulfured, is infected with microorganisms or has produced peculiar characteristics during fermentation as a result of yeast stress, is unlikely to be accepted for distilling, except perhaps to make industrial alcohol. Good quality brandy is generally distilled from wine made for the purpose and should have a moderate alcohol content, crisp acidity and little or no sulfur dioxide added to it. The choice of grape variety, the *terroir*, the time of harvest and the wine making process are specifically defined to produce the best possible raw material to distil. Healthy grapes from white cultivars are usually used that are necessarily neutral in character, for example in South Africa, Chenin Blanc and Colombard account for 90% of production, but Cinsaut and Sultana may also be included. Grapes are harvested early so as to avoid high concentrations of primary aroma compounds, which would not suit the style of the final product. In France, Ugni Blanc (also known as Trebbiano) is often used for base wine production for Cognac, but other grapes such as Colombard and Folle Blanche may also be used. In the cool Charente region, these varieties yield grapes that naturally produce between 8 and 9% alcohol in most years (Amerine and Singleton, 1977).

In California, cultivars without distinctive varietal character such as Colombard and Thompson Seedless (a table grape) are commonly used (Jackson, 2000). Other pale colored varieties such as Tokay, Mission and Emperor may also be used. According to Léauté (1990), Professor James F. Guymon studied several

Table 3.6.1 *Requirements set for quality wine that is to be used as pot still brandy (rebate wine) as stipulated by the Wine and Spirits Control Act (Act 47 of 1979) in South Africa*

	%w/v Total solids ≤ 45	%w/v Total solids > 45:
Total polyphenol content (mg/l GAE)	<250	<1200
Residual sugar content (g/l)	<4	<4
Volatile acidity (g/l)	<0.7	<1.2
Total sulphur dioxide (mg/l)	<20	<70

grape varieties used for brandy production in the United States in the early 1970s and came to the conclusion that early harvested French Colombard wines produce a better brandy than Thompson Seedless. Generally, producers recommend that grapes are pressed at a sugar content of 17 to 18 °Balling and a total acid content of between 7 and 9 g/l. If possible, free run juice that has had little skin contact is used so that the wine will meet the requirements of the legislation in terms of the total polyphenols (see Table 3.6.1 for the South African example). It is generally recognized that the lower the total polyphenol and volatile acidity (VA) content of the base wine, the higher the resultant quality of the brandy. Brandy quality tends to increase as the total acidity increases or the pH of the wine decreases. Skin contact is undesirable, and usually only free run juice is used so that the concentrations of total phenols are kept as low as possible. A high polyphenol content can catalyze oxidation, resulting in a product with an aldehyde character. Such a character may be desirable in the grape spirits used for the production of fortified wines, such as Sherry (Section 2.10.2) and Port (Section 2.10.7), but is unwanted in brandy per se.

After pressing, the must is usually clarified by means of settling or centrifuging to remove any scraps of skin and unwanted microorganisms and enzymes. Centrifuging is often used for clarification as the must needs to be cooled as quickly as possible, and long settling times without the protection of sulfur dioxide are not advisable. As very little SO_2 is allowed, it is also of great importance that the wine is made under very hygienic conditions. If pectins are extracted, and pectolytic enzymes are used, methanol will be formed and will distill over into the brandy. The methanol content of distilled spirits is the subject of strict regulation.

A pure yeast culture will be inoculated into the must, in order to prevent any off odors associated with wild strains. The choice of yeast strain can have a marked effect on the quality of the final product. For example, a strain that produces elevated levels of 2-phenylethanol (a floral scent), and low levels of acetaldehyde ('Sherry odor') is advantageous, as these characteristics will influence the distillate positively. In a study conducted by Stegers and Lamprechts (2000), 107 yeast strains were screened for their ability to produce a brandy base wine of exceptional sensory quality. Volatile acids, esters and higher alcohols (or 'fuselols' containing more than two carbon atoms in their structure) were quantified and significant differences between yeast strains for higher alcohol, fatty acid ester and acetate concentrations were observed. On the basis of their chemical profiles, only 16 of the original 107 were re-evaluated in larger-scale fermentations and subsequent double distillations. Not surprisingly, sensory evaluation showed that representatives of the three largest brandy producers in South Africa preferred yeast strains that suited the style of brandy produced by their company, and strains B7, LL2 and 20-2 were therefore recommended for further evaluation on a semi-commercial scale at each of the respective companies.

The fermentation temperature for producing brandy base is generally between 15 and 18 °C, which is higher than normally employed in a white wine fermentation. The reason for a slightly elevated temperature is to guarantee the fermentation proceeds and does not lag or produce off odors, and because the preservation of primary aroma is not an issue. The level of accessible nitrogen (free amino nitrogen) is usually tested and, if necessary, increased to a level of between 600 and 700 mg/l by adding diammonium phosphate. Apart from

suppressing the formation of hydrogen sulfide by nitrogen deprived yeast, the diammonium phosphate helps to prevent a sluggish fermentation, increases ester formation and suppresses the formation of higher alcohols. Wine is fermented dry in order to maximize yield of alcohol and minimize sugars. The latter requirement is due to the fact that during heating, the pentoses give rise to the formation of furfural (burnt), and the hexoses give rise to the formation of hydroxymethylfurfural (scorched or smoky) character.

du Plessis *et al*. (2002) determined the extent to which lactic acid bacteria occurred in brandy base wines, and their effect on the quality of the base wine and the brandy distillate. Lactic acid bacteria were isolated from grape juice and brandy base wines in which spontaneous malolactic fermentation (MLF) had occurred in approximately half the wines. In samples where MLF occurred there was a loss of fruitiness and intensity of aroma. Volatile compounds like isoamyl acetate, ethyl acetate, ethyl caproate, 2-phenethyl acetate and hexyl acetate decreased in samples having undergone MLF, while ethyl lactate, acetic acid and diethyl succinate increased in the same samples. The authors concluded that malolactic fermentation occurred spontaneously in commercial brandy base wines in their study, and that it had a significant effect on brandy quality.

Wine is frequently distilled immediately after fermentation, after partial racking from heavy fermentation lees (Léauté, 1990). Studies have shown that yeast lees have an important effect on the final concentration of higher alcohols and esters in the distillate (Stegers and Lamprechts, 2000). Usually, only a partial racking from the heavy lees takes place after fermentation as yeast lees contain high concentrations of fatty acids and fatty acid esters, and impart important qualities to the product. Samples of the young rebate wine, including its lees, are submitted to the brandy house as soon as the fermentation has finished. No fining agents may be used in the making of the rebate wine so as not to remove or to reduce substances that occur naturally in it.

In South Africa, if the wine is approved for brandy production, it is delivered to the distiller as soon as possible, otherwise it is cooled to around 10 °C. If it has not been delivered within 14 days, a new submission is done. Rebate wine is delivered with all the lees (including the gross lees). The specific requirements for brandy base wine will vary a little according to production region. In South Africa, the Wine and Spirits Control Act (Act 47 of 1970) determines two categories: wines with a solids content of 45% per volume or less and wines with 45% or more solids. Within these categories, the total polyphenol content, residual sugar content, volatile acidity and sulfur dioxide concentration will be lower, or higher, respectively (See Table 3.6.1). In order to carry out the tests, a sample must be taken at a height that is no lower than 30% from the bottom of the tank.

Compounds That Influence the Quality of the Base Wine and Resulting Brandy

Elevated levels of esters and moderate concentrations of the higher alcohols are known to contribute positively to the overall quality of brandy base product, but highly elevated levels of ethyl acetate and *iso*amyl acetate are undesirable. A slight defect, which is below detection in wine may well be detectable in brandy because of the concentrating effect of distillation on volatiles. In a good quality distillate, as mentioned previously, levels of 2-phenylethanol may be higher and volatile acidity (acetic acid and ethyl acetate) and ethyl lactate will be reduced. Undesirable flavors such as rancidity, wet cardboard and cabbage-like aromas (reduction), and aldehydic character (oxidation) that are present in the brandy base wine will have a negative effect on the resultant brandy quality. The compounds responsible for the off characters such as SO_2, H_2S, mercaptans and aldehydes have high volatility and are therefore usually removed in the 'heads' (or early distillate) in column stills. A large portion of the SO_2 and CO_2 leaves the system through 'breathers,' and will not end up in the distillate at all. During batch distillation in copper pot stills, many volatile sulfur compounds, such as H_2S and SO_2, redissolve in the condensed alcohol and water in the coolers, react with the copper of the still and are removed completely in the form of copper sulfide deposits. The quantity of acetaldehyde present will depend on the sulfur dioxide content as well as the oxidative condition of the wine. Normally the aldehyde section of a wine column is effective in concentrating aldehydes and related products, so that they

can be removed with the heads, but if acetaldehyde undergoes reactions to form α-hydroxy-ethane sulfonic acid and acetal, removal is difficult. If aldehydes occur in large concentrations, the distillation material may be treated with caustic soda. Another aldehyde that can cause problems is acrolein (the compound in tear gas), which causes phenolics to taste bitter at concentrations as low as 10 ppm, and has an acrid smell. It appears that acrolein originates from bacterial spoilage during the storage of wine for distilling (de Bod *et al*., 2008).

The Distillation

The objective in distilling wine for good quality brandy is to capture the alcohol and agreeable aromas of the underlying fruit and fermentation in the distillate, and leave unpleasant odors behind. Despite sounding relatively easy, this is in fact a complicated and challenging task, and there is surprisingly little published research available on the effects of various factors on the quality of distillates, considering its commercial importance.

Two main methods are used to produce brandy: batch or pot still distillation, and column or continuous distillation. It is generally recognized that the latter method often produces a lower quality product – but this is not always the case, see Sections 3.6.3 (Armagnac) and 3.8.2 (apple spirit). Figure 3.6.1 shows a diagram of an alembic used to produce Cognac. Although it is similar to pot stills used to make other spirits, such as Scotch whisky (Section 3.2.4), there are several differences, which are described below. Figure 3.6.2 shows a small-scale double pot still apparatus, which can be used in either batch or continuous mode to produce a more highly rectified spirit (a more pure distillate, but one with fewer flavor compounds) than a single pot still.

The equipment used for distillation is simple in principle: it consists of a container (or series of vessels) where wine can be heated, an enclosed headspace (or series of headspaces) above the pot where vapor can collect, cooling conduits where volatiles condense and reception vessels for condensate. Volatile substances

evaporate and are collected in the reception vessels, nonvolatiles such as acids and sugars remain behind in the heated vessel, and are eventually discarded. Ethanol is soluble in, but less dense than, water and boils at a lower temperature (around 78–79 °C depending on the atmospheric pressure). The initial fractions of the condensate will therefore be enriched in ethanol and other lower boiling volatiles. As the distillation continues, water will also evaporate and condense, gradually diluting the condensate. As a result, a second distillation is frequently carried out to concentrate the alcohol. Methanol will boil off along with the ethanol and also collect in the distillate, but wine from *V. vinifera* does not normally contain a lot of methanol unless pectinases have caused pectin ester hydrolysis with methanol as a by-product.

For a more general account of batch distillation and continuous distillation, see Sections 3.1.2 and 3.1.3, respectively. For discussion of distillation of other beverages, see, for example, Sections 3.2.4 (Scotch whisky), 3.3.4 (Bourbon and Tennessee whiskey), 3.5.3 (rum and cachaca), 3.7.2 (pomace spirits) and 3.8.2 (apple and pear spirits).

Higher alcohols are also present in small amounts, but usually the sum of all the concentrations of these do not amount to more than 1% of the total alcohol concentration in the distillate (Amerine and Singleton, 1977). After one distillation, the distillate, called 'low wine,' will contain roughly 30% alcohol (ethanol) by volume. The low wine is then distilled a second time in a batch distillation, or is redistilled automatically in a continuous system.

Distillation does not simply enhance the alcohol content of wine. The heat under which the product is distilled and the material of the still causes chemical reactions to take place during distillation. This leads to the formation of numerous new volatile aroma components, changes in relative amounts of aroma components in the wine and the hydrolysis of components such as esters.

Traditionally, fine brandies are produced in small batches using copper pot stills, which are large pots, usually made out of copper and brass, with a bulbous top. Modern alembics will have stainless steel fittings (valves and the condenser tank) incorporated into their structures, but little else in the design has changed over the ages. The standard alembic copper boiler (see Figure 3.6.1) has a capacity of 660 gallons or 2500 l

(Léauté, 1990), and when filled has a headspace of around 130 gallons or 500 l. Pot stills can come in a variety of capacities, and may have volumes of anything up to 22 000 l, depending on the producer's requirements.

The *boiler* base is convex in relation to the inside of the still, which not only makes it easier to clean, but also means that the pot still can be emptied completely. The thickness of the copper base is an important function of the volume of the pot, as it has a direct influence on the rate of heating of the product that is being distilled. Copper is still the only metal that is used in the production of pot stills and the parts that are in direct contact with the wine. The malleability and ductility of copper, as well as the fact that it is an excellent heat conductor, contribute to the reasons for its use. In addition, copper is eroded very slowly by acids and it bonds undesirable volatile compounds, e.g. the mercaptans and sulfides. Copper pot stills need to be cleaned regularly in order to remove the fatty deposits on surfaces that are in regular contact with vapors. Parts that are not in direct contact with the vapors and/or solutions may be made of stainless steel. For further discussion of the influence of copper on distillates, see Sections 3.2.4, 3.3.4, 3.5.3 and 3.5.4.

Boilers are robustly built to withstand direct heat for sustained periods of time, and resist corrosion by the hot, acidic wine. They may be heated directly by gas burners, with propane, butane and natural gas used (around 200 kg of liquid propane is required to produce approximately 370 l of pure brandy). Most modern facilities use steam, which is less intense and likely to cause localized hotspots and burning of the wine. According to Léauté (1990), the temperature under the boiler may reach 760–870 °C, which is essential in creating the characteristic aromas in the distillate. The inside surface is smooth and well polished for easy cleaning between batches.

The still head (cap) of the pot is the section of the still that is responsible for the fortification (rectification) of the distillate. The total surface of the still head is important and is determined by the shape thereof. The quaintly named 'hat' or *chapeau* is located directly above the boiler and has a capacity of between 2 and 10% of that of the boiler. The volume and shape of the *chapeau*, according to Léauté (1990), directly influence the concentration, separation and selection of volatile components.

The characteristic 'swan's neck' type spirit pipe is a lengthening of the cap and its length is also a function of the capacity of the still. During the distillation process, volatile components may move through the *chapeau* and down into the swan's neck, or reflux back into the boiler. The height and orientation of the swan's neck are reputed to influence the quality of distillate, but there is not much evidence in the literature at this time to support this. It is sloped downwards in the direction of the preheater in order to prevent counter pressure and also to prevent the fluid from being sucked back. The main function of the wine prewarmer is to save energy, in that the heat of the alcohol vapors are used to partially heat the next load of wine and, in addition, it also condenses the rising alcohol vapors to a certain degree.

The pipe from the swan's neck runs through the preheater, and condensate collects and heats here for the second part of the distillation process. The *condenser* is a cylindrical tank made of copper or stainless steel, which is filled with cold water and which contains the coiled copper *serpentin* through which hot vapors pass and condense during distillation. The condenser capacity is high, usually between 4500 and 5000 l. The cold water enters at the bottom of the condenser, and warm water, heated by the condensing fumes, is drawn off at the top. The *heads tank* is a small stainless steel tank, which is used to collect the first part of the distillate. The *serpentin*, or coil pipe, has a number of functions: to react with sulfides and precipitate them from the distillate, to condense the vapors and to cool the distillate. The *serpentin* is contained within the condenser, which is filled with cold water during distillation. Fresh cold water enters at the bottom of the condenser, and warm water is removed from the top. The hydrometer port is also made of copper and has several functions: to monitor the alcohol concentration of the condensate, to filter the distillate and to monitor the temperature of the liquor. The heads tank near the hydrometer port is used to collect the first part of the distillate, which is generally returned to the boiler or discarded.

The First Distillation (*Brouillis* Production)

During the first batch distillation, the base wine, with an alcohol concentration of 8% to 12% v:v and high acidity, is boiled in the pot still. The first distillation is essentially a concentration process in which water is removed, and wine is distilled to raw brandy ('low wine' or *brouillis*). The first 1% or so of this distillate (from the first 3–5 min after the vapors begin to rectify) has an alcohol concentration of about 83% v:v and usually contains unpleasant and highly volatile compounds like ethyl acetate and acetaldehyde. It is known as brandy 'feints' and is usually discarded. The raw brandy therefore contains all the (desirable) volatile compounds that occurred in the wine, and the wine is concentrated threefold by the process. The initial distillation usually takes between six and nine hours. In his review of alembic distillation, Léauté (1990) stated that three separate distillations take place the production of Cognac (discussed later in this section in detail), the first one giving three separate fractions of which only the heart (*brouillis*) is used for the second distillation. This in turn gives four fractions, heads, heart 1 (Cognac), heart 2 (*secondes*) and tails. The *secondes* are redistilled with the next batch of *brouillis*.

After the first distillation, which takes about 8 h, over 13 000 l of wine will be converted to about 4500 l of concentrated liquid with around one third of the original volume of the wine. The volatile components are separated from the nonvolatile components and most of the water in this process, giving a distillate has an alcohol content of between 26 and 32% v:v. This raw brandy or low wine is hard and harsh, and is not protected against microbiological spoiling if it is not distilled again immediately.

The Second Distillation (*La Bonne Chauffe*)

The second stage entails the distillation of raw brandy to pot still brandy with an alcohol content that does not exceed 75% v:v. This phase is usually divided into 'fractions,' and the distiller will monitor alcohol concentrations and quality during the process. French producers limit the second distillation to batches of 2500 1, which makes it far easier to manage the various fractions, and the distiller plays a very important role in evaluating the quality of the distillates.

In a typical pot still distillation, the 'heads' will be collected within the first hour or two, the 'heart' from the 2 h mark to around 7 h, and the 'tails' thereafter. Of an original 2500 l of brouillis (of around 30% v:v), the 'heads' fraction will have a volume of about 25 l, and be approximately 75% v:v in concentration. The first 'heart' fraction distils until an alcohol concentration of 55% per volume registers on the hydrometer in the test glass, in a process lasting 6–7 h, and yielding a product that is approximately 70% v:v alcohol, on average. This distillate comes across until all the alcohol has been distilled, i.e. an alcohol concentration of 0% per volume registers**,** and the process lasts about 5 h. The portion of low wine that remains after distillation, called the 'tails,' will be mixed into another batch of low wine for future use. In total, the second distillation may last about 10–12 hours, depending on the type of pot and the starting temperature, as well as the duration of stoking.

Most pot still brandy is double distilled, so that the alcohol is concentrated twice. As a rough estimation, takes about 8.75 1 of wine to make three l of low wine, which then is distilled again to around 330 ml of brandy. The product of the second distillation usually has an alcohol content of around 72%. The higher the alcohol content the more neutral (cleaner) the distillate will be, with fewer of the underlying flavors remaining in the brandy. A lower alcohol distillate may be more flavorsome, but there is also a greater chance that off flavors will make their way into the final product.

Cognac is a well known example of brandy produced in batches using pot stills, and is discussed in detail later (Section 3.6.2).

Effects of Distillation

There are four broad groups under which most of the flavor compounds from the grape and fermentation can be classified: aldehydes, higher alcohols, esters and volatile acids.

Many different reactions occur between the compounds of mixtures, which are at high temperature, and in this regard the boiler acts as a large reaction vessel. The reactions may involve volatile components in the wine decreasing or increasing in concentration, and new volatiles can appear in the solution as a result of associations between the components. Reactions can involve copper, and include hydrolysis, esterification, acetalisation and occasionally pyrolysis. Monoterpenes (linalool and alpha terpineol, <1 mg/l), ketones (α-ionone and β-ionone, <0.01 mg/l) and vitispirane and trimethyl dihydronaphthalene <0.1 mg/l) may be generated through break down and rearrangement of various terpenoid components (de Bod *et al*., 2008). Most products are fairly easily detected by gas chromatography (Section 4.3.2). The reactions occurring during the first distillation are very important in determining the future characteristics of the brandy. These reactions will be affected by various factors, which include the chemical composition of the wine (i.e. sugar, pH and acidity), the size and condition of the still, the temperature within the boiler and the duration of the distillation. If lees are included during distillation, the distillate is more likely to contain high levels of fatty acids and their esters (e.g. ethyl caprylate, ethyl caprate, ethyl laurate), and nitrogen compounds (like amino acids). Fatty acid esters enhance fruity aromas in Cognac, and according to Léauté (1990), fatty acids give the brandy body and are like 'fixatives' for many other aromatic components. Amino acids and reducing sugars may be involved in Maillard reactions in the heated vessel, which are one source of a complex range of heterocyclic compounds that include volatile flavor components and brown melanoidins of higher molecular weight. The wood used for maturation of brandy would be another source of Maillard products due to the toasting of barrels.

Continuous Distillation

A continuous column still is in essence a series of integrated consecutive pot stills (see Section 3.1.3). The still is a cylindrical column, typically about 30 ft (9 m) high, which is divided into a series of plates or horizontal, hollow baffles that are interconnected. Columns differ in their engineering and orientation, but in principle, wine to be distilled is fed into the middle portion of the column, which is heated by steam from below. The alcohol and other low boiling point liquids in the wine evaporate. The vapors rise while the less volatile liquids drop down so that there is a liquid layer on each plate (known as the liquid phase). The space remaining above the liquid layer accommodates the vapor phase. When the liquid heats on a specific plate, vapors bubble through the liquid layer on the plate directly above it, and are partially condensed in it. The vapor from an alcohol–water mixture will be enriched in alcohol as it is more volatile, and the concentration of the alcohol in the column therefore increases on the upper plates. When the still is in equilibrium, the alcohol concentration remains constant, as the liquid phase is always replenished from the plate above. Continuous stills for brandy production usually consist of a 'stripping' column and a 'rectification' column. The basic function of the stripping (or 'wine-stripping' or just 'wine') column is to remove the nonvolatile compounds, organic and inorganic suspended material, and produce a partially fortified, impure vapor that can be concentrated and purified further in the rectification section.

Although continuous stills do not generally produce the same quality distillate as pot stills, neutral wine spirit, produced in an integrated five column continuous still, is an important building block in the production of various kinds of distilled beverages, including many liqueurs (Chapter 3.9). The basic design allows for side stream removal of the higher alcohols and high boiling point fatty acid esters, first flow removal of aldehydes, low boiling point fatty acid esters and methanol, hydro selection purification of raw spirit and the extraction of the final product, neutral wine spirit, from the base of the final column (De bod *et al.*, 2008). Wine that is not good enough quality to be used for pot still or continuous column still brandy is distilled in such a column to remove all suspended material and to remove all secondary volatile compounds, and the resulting product is a pure spirit, colorless, odorless and tasteless, with an alcohol content of about 96.5%.

Column still brandies are more likely to be made from table grape varieties like Thompson Seedless rather than from fine wine grapes. Column still brandies are also aged in oak casks and blended, diluted to around

40% alcohol, and bottled, although regulations for quality brandy production will usually stipulate a portion (around 30%) of pot still brandy in the blend.

Coopering and Maturation

The brandy is not ready to drink after the second distillation, as it is a harsh, fairly unpleasant product. It is first allowed to age in oak casks for a specified time period; this is viewed as an essential part of the production process and lends most brandies their warm flavorful characteristics. Grape brandies are among the very few foods and beverages that improve with ageing over many decades. Although most brandy consumed is less than six years old, the ageing process is integral to the quality of the product and as a general rule of thumb, the older a brandy is, the better its perceived quality. Fine brandy can be ready for bottling after two years, some after six years and some not for decades. Some fine French Cognacs are alleged to have been made during the time of Napoleon, but as a great number of Cognac makers continually remove 90% of the Cognac from an old barrel and then refill it with younger brandy, this is unlikely.

According to South African legislation, the pot still distillate must be aged in vats with a maximum size of 340 l for a minimum period of three years under the supervision of Customs and Excise officials. The vats are usually constructed from French Limousin oak, but reused bourbon or other barrels of indeterminate lifetimes may also be used (Singleton, 1995). Initially the aroma of the immature brandy is composed mainly of volatile compounds derived the grapes and those formed during fermentation, and it is therefore fairly fruity. Immature distillates also have varying intensities of herbaceous, smooth associated and other aromas, depending on their quality. Snyman (2004), in a study of young distillates, found that examples that were most intense in the 'fruity' aroma descriptor were perceived as good quality, whereas distillates in which the 'herbaceous' descriptor dominates, were perceived as poor quality.

The alcohol content of the distillate placed into the oak barrel may vary from 55 to 70 % (v:v) depending on the method of distillation employed. Once the distillate is transferred to the oak barrel, the extraction of the wood by the alcohol begins almost immediately. Investigators have found various alcohol strengths ranging between 40 and 60% v:v optimal for maximal lactone extraction, with optimal extraction levels of tannins and lignin in Armagnac at 55% v:v (Peuch, 1984). Above 60% v:v the extraction rate of color, solids, tannins and volatile acids tends to decrease (Nykänen, 1986). During barrel maturation, the brandy changes in flavor and color from colorless immature distillate to the golden brown aged version.

Changes in chemical composition as maturation progresses are brought about by extraction of aroma and flavor compounds from the oak (Table 3.6.2), or through reactions between wood components and/or compounds in the distillate. Nonvolatile, polyphenolic compounds such as tannins and lignins, may impact on brandy flavor by reducing the solubility of volatile compounds. Fatty acids and sterols, which may be derived in part from oak wood, can cause cloudiness or precipitation in distilled beverages. The gradually acquired rancid taste of Cognac is associated with the hydrolysis of fatty acid esters and their oxidation to ketones during maturation (Mosedale and Puech, 1998). This 'rancio taste,' also called '*rancio charentais*' is a highly desirable characteristic of aged Cognac and on of the ways in which the quality of a Cognac is measured (Macrae *et al.*, 1993).

Oxidation and evaporation of some volatile compounds through the cask also play a role in the formation of brandy flavor. Wood not only contains flavor and color compounds which may diffuse into the distillate, but as it is porous, it allows minute amounts of oxygen to slowly diffuse into the distillate where it may participate in maturation reactions between chemical components. As the brandy ages, it is known to become less astringent and aggressive. During the maturation period, volume and alcoholic content decline as the porous nature of the barrel also allows some of the volatile constituents like alcohol and water to diffuse from the ageing brandy, through the oak, into the air of the surrounding barrel storage area. Ethanol has a higher molecular weight than water and therefore diffuses more slowly through the wood, except under high humidity

Table 3.6.2 *Compounds that can be extracted from oak during the maturation of brandy*

Compound	Contribution to brandy flavour
Coumarins	Bitterness
Dimethylpyrazines	Chocolate, biscuit & fresh bread aromas
Ellagitannins	Mouth-feel/ astringency/ colour
Eugenol	Cloves aroma
β- Methyl-γ-lactone	Coconut, sweet, woody aroma
Furfural, 5-methylfurfural	Toasted almond aroma
Maltol, cyclotene	Sweet, caramel aroma
trans-2-Nonenal	Sawdust, raw wood aroma
Terpenes and terpenoids	Floral, fruity, fresh aromas
Vanillin, syringaldehyde	Vanilla, caramel aroma
Volatile phenols: guaiacol, phenol, cresol, dimethoxyphenol	Smoky, spicy, medicinal aromas

conditions. The relative humidity of a barrel storage area is therefore important and is usually kept around the 70% level. The temperature of the maturation process (i.e. the storage area) will influence both the extraction of compounds from oak as well as the formation of flavor congeners in the maturing brandy. However, it is not simple to specify an optimum maturation temperature, since for each compound or compound group this will be different. Generally speaking, barrel rooms are kept cool to discourage evaporation and the activity of molds and other microorganisms.

For discussions on wood maturation of wine and fortified wines, the reader is directed to Section 2.9.5 and Sections 2.10.2, 2.10.6 and 2.10.7, respectively, and for other distilled spirits to Section 3.2.5 (Scotch whisky).

A good quality final brandy product is characterized by a successful balance of the desirable fruit aroma of the original young spirit and the warm, rounded qualities imparted by the oak and maturation process (Table 3.6.2). Unfavorable characteristics such as 'hotness,' 'greenness and 'rawness/sharpness' are often found in young distillates, but are lowered by ageing in oak and the flavor is transformed to more rounded, soft, mellow flavors. The change in sensory character from the unaged distillate, with its prominent 'fruity' and other less desirable aroma descriptors, to that of a mature brandy with the above-mentioned aroma notes is brought about by a change in the chemical composition as maturation progresses. Panyosan *et al.* (2001) used headspace gas chromatography-mass spectrometry (Section 4.3.2) to identify various alcohols and carboxylic acid aldehydes, acetals and ethylates in Cognacs aged for three, 10 and 20 years and found significant differences in their concentrations. The concentration of Cognac flavored compounds, such as diethylacetal and carboxylic acid esters, significantly increased with age, whereas the concentration of alcohols (butanols, allyl alcohol, hexenol and toxic methanol) considerably decreased. The 'nutty,' 'sweet associated' and 'spicy' aroma notes are often associated with brandies aged for longer periods in oak, usually 15 years and older. It is not easy to attribute a specific flavor to a certain compound, since flavor nuances are often due to synergistic effects of several compounds (see Section 4.7.2), and differ depending on their concentrations. Not all compounds are found in brandy at levels above their sensory thresholds, which means they may only add to complexity, rather than contribute unique notes. Fine brandies are also usually blended from many different barrels over a number of vintages, which again increases complexity.

As part of a broader study into techniques for the rapid induction of ageing character in brandy products (van Jaarsveld *et al*., 2009a), the effect of oak type on quality and chemical composition of oak wood extracts,

and matured and unmatured pot still brandy was investigated. Extracts of American and French oak chips at different levels of toasting were added to 70% (v:v) unmatured pot still brandy and stored for eight months in glass containers at room temperature, and then analyzed by HPLC and GC. Although French oak initially yielded better quality products with higher concentrations of wood derived congeners (including eugenol, the furan derivatives and aromatic aldehydes), these effects lost prominence over time. American oak generally contained higher concentrations of oak lactones than their French counterparts, with higher proportions of the more sensorially potent *cis* form of lactone than its *trans* isomer. In an additional study, van Jaarsveld and his coworkers (2009b) found that the treatments that yielded the highest observed quality were those that made use of toasted oak as opposed to untoasted oak, and that the medium toast level yielded higher quality products overall. Higher toasting levels could also lead to charring, the formation of unwanted polycyclic hydrocarbons, and immediate degradation and loss of flavor compounds. The authors stated that there was a definite relationship between wood derived congener concentrations and pot still brandy quality.

Blending

When the distillate (heart fraction) is at least three years old, it is pumped from the barrels into tanks and cold stabilized (cooled to between –10 to –12 °C) in order to precipitate unstable dissolved substances such as calcium and iron containing compounds. After filtration, the taste of the aged product is still fairly harsh, but it is assessed and classified according to fullness, balance, softness of taste and intensity of flavor. Once all the components of a brandy have been combined according to its recipe, the blend is diluted with pure (distilled) water to around 43% v:v. During Cognac production, this process, known as 'reduction' is carried out very slowly during the barrel aging period. If color adjustments need to be made, caramel may be added, but not all brandies have caramel in them. Although brandy should have a maximum sugar content of 15 g/l, the 'degree of sweetness' is expressed as the 'obscuration' of a brandy. There is a direct relationship between obscuration and reducing sugar content or RS. An RS of 15 g/l is known to give an obscuration of 3% v:v. Fruit extracts, in particular prune extract, also provide smoothness and may also be added up to a maximum of 3% of the 430 ml of alcohol. The fruit extracts used are called '*bonificateurs*' and may consist of prune extract, almond etc. A small amount of caramel may be added to obtain consistency of color across the entire production run.

Like many other distilled alcoholic beverages (see, for example, Section 3.2.5), blending is an important part of the brandy production process. The true skill of the brandy master is demonstrated in the choice and proportion of components used in blending the final product. A variety of matured distillates from various grape varieties, wooden barrels of varying ages, oak cask toasting levels and maturation periods will be blended to create varying tastes and styles to create products for a specific market sector or with a particularly unique flavor and mixing qualities. The success and value of the brand is dependent on consistency and quality of the blend, which is often a carefully guarded secret.

Blended brandies are usually bottled at 43% v:v. This means that in every 1000 ml of brandy there must be at least 430 ml of absolute alcohol. Regulations vary according to region of production but in South Africa, at least 30% of this 430 ml of alcohol must come from the matured pot still distillate. A maximum of 70% of this 430 ml of alcohol may be neutral wine spirit.

3.6.2 Cognac

The European Union legally enforces 'Cognac' as the exclusive name for brandy produced and distilled in the Cognac area of France, and 'Armagnac' from the Gascony area of France, using specified traditional techniques. Brandy made, for example, in California in an identical manner to the method used to make

Cognac, and which tastes very similar to Cognac, cannot be so called in Europe as it is not from the Cognac region of France.

The most well known French Cognacs are produced in the Charente district north of Bordeaux. The Cognac district is one of only three officially designated brandy regions in Europe, along with Armagnac, France, and Jerez, Spain. The name comes from the city of Cognac in the central part of the area. Cognac has been made in these areas for centuries, with some of the well known houses like Martell and Remy Martin being established in the early eighteenth century. Today there are only about 200 producers of Cognac, and most of them use the same methods that they have been using for hundreds of years. Popular brands include Hine, Martell, Rémy Martin, Hennessy, Ragnaud-Sabourin, Delamain and Courvoisier.

The Charente area is demarcated by legislation – only brandy produced here and adhering to mandated guidelines may legally be designated Cognac, and all Cognac must be produced from grapes grown and harvested within these regions. Charente is divided into six vineyard districts, which are listed below in order of decreasing quality: the Grande Champagne (not to be confused with the Champagne region that gave its name to champagne), which comprises around 12% of the region, Petite Champagne (also around 12% of the area), Borderies (3.9%), Fins Bois (33%), Bons Bois (28%) and Bois Ordinaires (11%), which is westernmost of the regions. Cognacs from the Fin Bois are said to reach their peak quickly and are used as blending components to soften younger, hard brandies. Those from the Bons Bois are reputed to have the lowest quality, and yield 'coarser' liquors. Brandies from the Bois Ordinaires are said to have a distinct '*gout de terroir*,' or characteristic aroma and are usually drunk by the locals in the area, rather than being blended with other brandies for export.

Cultivars used in the production of base wine for Cognac include St Emillion, Ugni Blanc, Folle Blanche, Colombard, Jurançon Blanc, Montils, Sémillon, Sauvignon Blanc. The Ugni Blanc cultivar accounts for 94% of the total vineyards planted today. Grapes for Cognac base wine are grown in chalky soil (that is rich in lime, and it is recognized that a high percentage of chalk in soil yields the most fragrant and subtle brandies. A decrease in percentage chalk in the soil occurs across the appellations, with the Grand Champagne region having the highest chalk content and Bons Bois having a mixture of sand and chalk. Because of the climate and the latitude of Cognac area, Ugni Blanc (known as Trebbiano in Italy; see Robinson, 1986) has not yet reached maturity when grapes are harvested at the beginning of October, and so are reasonably unripe, containing sugar levels between 14 and 18 °B. If the grapes are left longer than this, rotting often creates problems as the weather grows cool and damp. Acidity is usually very high; pHs are generally low (2.5 to 2.8).

The grapes are directly crushed in hydraulic presses (pressed in bunches) at moderate pressures in order to avoid phenolic extraction. The juice is fermented to dryness with the preferred house strain of *Saccharomyces cerevisiae*, or less often with 'wild' strains (yeast that are present naturally on the grapes, almost always *S. cerevisiae*). Very little (less than 20 mg/l) of sulfur dioxide is added, or none at all, depending on the producer's preference and the condition of the grapes. The wine that is obtained has is neutral in flavor, light in alcohol, highly acidic and produced specifically for distillation (Léauté, 1990).

The yeast lees content of wine used for distillation is highly correlated with the even numbered fatty acid ester content of the brandy distillate, and this in turn plays a role in the concentrations of the corresponding methylketones, which are associated with quality of Cognac (Watts and Butzke, 2003). As lees content is a function of juice nitrogen status, grape composition could also have some impact on the availability of methylketone precursors in the distillate.

The characteristic Charente pot (*Alambique charentais*) gradually developed the specific flask shape it has today, and the distillation therein is a selection and a concentration of volatile compounds, which give the specific character to Cognac. In addition, during distillation in alembic, the wine and the *brouillis* are heated intensely, and reactions occur between the compounds generating the delicate aromas characteristic of the product. The first distillation gives three fractions: the heads (which distill over for around 15 min),

the heart (*brouillis)*, which distill over for around 6 h, and the tails (which distill over for another hour). The heads and tails are redistilled with the successive batches of wine. After the first distillation, the *brouillis* is cooled to form an opalescent liquid (the 'soul' out of the wine) with an alcoholic strength of 27–30 % v:v. This is then redistilled into four fractions: the heads (around 30 minutes of distillation time), the heart 1 (Cognac), which takes around 6 h to distill over, the heart 2 (*secondes*, which takes around $4\frac{1}{2}$ h to distil) followed by the tails – which distil for an hour. The first distillation therefore takes around 9 h, and the second around 14 h, giving a total of nearly a full day's distillation to go from base wine to immature brandy. The very young brandy has an alcohol content which may not, by law, exceed 72% v:v. During the long Cognac distillation process at approximately pH 3.0, volatile esters may form and distil over. Some of these can then hydrolyze in the slightly acidic distillate (pH 4–5), resulting in free fatty acids. Despite their low volatility, some fatty acids may also distil over directly during distillation through azeotrope formation. In some areas of the world, this liquor is marketed and consumed, but in Cognac, a strictly mandated ageing process in 350 l barrels is necessary before the product is considered ready for sale. The French '*appellation d'origine controlée*' (AOC) *eaux-de-vie*, are traditionally matured in barrels made from oak from nearby regions (Limousin, Allier, Troncais and Nevers), with Cognac almost exclusively matured in oak from the Limousin and Troncais regions. Cognac producers are careful to use barrels of exceptionally good quality, as their products are dependent on the wood for flavor and maturity. Many houses employ their own coopers to ensure that their barrels are made to a particular specification in terms of their conditioning, construction and toasting. The brandy is vatted at full strength of around 65 to 70% alc/vol. The barrels are not filled completely or topped up, and oxygen is constantly in contact with the distillate. Chemical reactions take place throughout the process, and depending on the age of the distillate, different aromas become apparent, ranging from exotic fruits, nuts and dried flowers, to port wine, balsamic and tropical fruit characters. The required minimum period of oak ageing is two and a half years, but the vast majority of Cognacs mature for a longer period than this. The maturation stores are cool in temperature, so maturation processes are slow and controlled.

Genuine Cognac should be 100% pot still brandy. However, due to the expense of long maturation periods and the need for rapid turnover, there is a tendency even in France to mix pot still brandy with column distilled spirit, which does have the same complexity or quality. The lack of esters and other components is supplemented with wood extract, lees oils and other *bonificateurs* (essences and aromas).

Cognacs are usually sold as blends made from distillates of different vintages. Some Cognacs can contain brandy from up to a 100 different barrels. The unaged brandies from the different farms/producers may be purchased by the large Cognac houses, and blended according to origin and character with older batches. Regulations specify that all Cognac be aged for at least two and a half years from 1 October of the year the grapes were harvested. Even though the ageing process is paramount to Cognac's quality, Cognac makers rarely use vintage years as identification, preferring instead to use a lettering system. Brandies are classified using a '*compte*' system to designate their age. For example, '*compte* 00' will be a young distillate that was produced between harvest and the following 1st of March. '*Compte* 1' are Cognacs that are more than a year old on the 1 April of a given year. The *compte* system now goes up to *compte* 10 (10 years old on 1 April of that year). This has relevance as Cognacs may not be sold in France until they are at least *compte* 2. Most other major markets insist that Cognacs must be at least *compte* 3. Reserve, VO, VSOP type Cognacs have the youngest component as a minimum *compte* 4 (around four and a half years old). Extra, Napoleon, Vieux and Vielle Reserve types all have their youngest components as *compte* 6, and XO indicates at least *compte* 10.

Although these regulations specify the minimum age of the youngest component in a blend, blends often contain much older distillates, as with Scotch whisky (Section 3.2.5). The blending process is complex and overseen by an experienced cellar master. Cognac is often aged for decades and sometimes over a century, possibly the longest of all consumables. Some finer Cognacs may be the result of blending as

many as 50 different Cognacs in effort to achieve a house's desired flavor and maintain a uniform standard of taste and quality. Since 1988, vintage Cognacs are also possible. Very old Cognacs are known to develop unique complex flavor characteristics collectively called *rancio charentais* or *Cognac rancio*. It is usually recognizable in the aroma and taste of Cognacs aged between 15 and 20 years and is therefore mostly characteristic of expensive Cognac blends. It has been described as an aroma of 'rancid butter and mushrooms, accented by notes of dried fruits and touches of raisins and nuts' (Watts and Butzke, 2003). Similar notes can be found in extensively aged (and oxidized) fortified wines, such as oloroso Sherry (Section 2.10.2), Madeira (Section 2.10.6), tawny Port (Section 2.10.7) and the *rancio* styles of vin doux naturel (Section 2.10.9). Despite the term 'rancid' usually being used in a negative sense, traces of a rancid character are very desirable in aged Cognacs. Methylketone concentrations were correlated with Cognac age classifications, despite a large variation due to the variable nature of the production practices. It has been determined that 2-heptanone and 2-nonanone are the most abundant methylketones in aged Cognac, but 2-undecanone and 2-tridecanone have also been shown to play an important role in the development of the *rancio* character (Watts and Butzke, 2003). Oxidation products of lignin, lignans and lactones in oak wood contribute a balsamic component of the *rancio*. The ketones are likely to form as a result of the β-oxidation and subsequent decarboxylation of even numbered long chain fatty acids (C8, C10, C12 and C14) during barrel ageing. Peroxidases from molds present on the barrel surfaces have also been implicated in the process. Higher fatty acid esters such as propyl octanoate and ethyl octanoate may add a certain dimension to the ketone aroma, modifying it to a more fruity character often associated with *rancio*.

3.6.3 Armagnac

Armagnac was the first distilled spirit in France, is the oldest French brandy and has been distilled since 1411. The area is in the southwest of France in the Gascony province and is divided into three demarcations, namely Bas Armagnac (or Armagnac noir), Haut Armagnac (or Armagnac blanc) and the Ténarèze. It comprises 66 000 ha in southwest of France framed by the Pyrenees, and is generally warmer than the Cognac region, with grapes ripening earlier and more completely. Sandy soils such as those found in the Bas Armagnac region on the west coast of France are reputed to produce Armagnacs with the greatest suppleness and finesse, while clay soils (found in the Ténarèze region further inland) produce lighter brandies, which mature more quickly. Chalk and limestone soils such as those found in Haut Armagnac are reputed to give spirit of a mediocre quality, according to some critics (compare this situation with that of Cognac). Cultivars used in the production of Armagnac include Folle Blanche (around 7% of total plantings), Baco blanc or 'Baco 22' (47% of total plantings), Ugni blanc or Trebbiano (40% of total plantings – mainly in St Emilion), Colombard (4% of total plantings) with Graisse, Jurançon and Clairette de Gascogne making up the balance.

Like Cognac, Armagnac is distilled in copper stills (known as '*alambique Armagnacais*' or the *Verdier systéme*), but in a column still rather than the pot still used in Cognac production. The wine flows into a feed tank situated above the still house containing the still, preheater, cooler and condenser. The Armagnac still is an arrangement of five to six plates situated in a column above the boiler. The wine is preheated by flowing over the condensing coils, and then is fed in to the top of the column, whereupon it flows down over the column plates, and alcohol and other volatiles evaporate as they are heated. The wine collects in the bottom of the column where it boils, generating vapors that bubble through the descending wine and eventually collect in the condenser. The condensate forms the immature brandy, and has an alcohol content of around 53% v:v. It is blended and diluted to 40% ABV.

Periodically, wine will be removed from the lower part of the column, but no heads or tails are collected, as it is a continuous process. The distillate is put into new casks sourced from the Monzelun forest in Gascony

or Limousin until it has enough woody flavor and is then further matured in old casks. The size of the casks varies from 400 to 420 l. Vintages are kept separate, but vintage Armagnac is becoming less popular. Strict control is carried out under AC laws. Until 1999, Armagnac followed roughly the same regulations as Cognac, but recently has adopted a more simple, sensible classification: 'Armagnac' is between two and six years old, 'Vieil Armagnac' is over six years old, and 'Millesimes' must be more than 10 years old. Well known Cognac houses with an interest in Armagnac include Martell in Janneau, Camus, Marquias de Puysegur, Prince de Chabot, Courvoisier and Maillac, and other popular brands of Armagnac include Darroze, Baron de Sigognac, Delord, Laubade, and Gélas.

3.6.4 Other Brandies

Spain and Other Southern European Countries

Brandy de Jerez is a product that originates from Jerez de la Frontera in southwest Spain. It is used to fortify some Sherries and is also available as a separate product. The vast majority of Spanish brandy is produced using wine made from the very widely planted Airen cultivar from various locations around Spain. Nowadays most of the distilling is done using column stills, and a continuous distillation process which has as its end product a distillate known as *hollandas* with an alcohol concentration of 65 to 70% v:v. Brandies are matured within certain areas of production (Jerez de la Frontera, El Puerto de Santa María, and Sanlúcar de Barrameda). They can be aged in American oak casks with a capacity of 500 l, which previously contained sherry, or produced through the use of a traditional ageing system of criaderas and soleras (see Section 2.10.2). A solera is a series of large casks or butts, each holding a sequentially older spirit than the previous one. Some soleras have over 30 stages. When brandy is racked from the last butt, no more than a third of the volume is removed and it is replenished with brandy drawn from the previous butt in the system. This process, which imitates that used in sherry production, is repeated all the way down the solera line to the first butt, where newly distilled brandy is added. This blends together a variety of vintages and results in a speeding up of the maturation process. As far as the quality designation system goes, the basic brandy can be sold after only six months, but 'Reserva' indicates the brandy has had a minimum of a year of maturation in a cask in a solera system, and 'Gran Reserva' indicates three years in solera. Most producers mature for much longer than the minimum requirement, with the best Reservas and Gran Reservas frequently having been aged for more than a decade. Spanish brandy is far sweeter than Cognac or Armagnac, with the sweet and fruity notes coming not only from ageing in Sherry casks, but also from the judicious use of caramel, fruit based flavors and oak essence (*boise*). Pot still brandy is also produced in Spain, an example being Penedès brandy from the Catalonia near Barcelona in northeastern Spain. It is made by two local producers (Torres and Mascaro) from a mix of regional grapes and locally grown Ugni Blanc. The Torres company ages its distillates in solera systems using casks made from French Limousin oak, whereas the Mascaro company matures its brandies in the standard Cognac manner, in Limousin oak vats.

The Balkan countries (especially the states of the former Yugoslavia, and Greece) produce notable examples of brandy, although pomace spirits (Chapter 3.7), plum spirits (Section 3.8.4) and aniseed flavored spirits (Section 3.5.6) are also important here. Good brandies are made by several companies (e.g. ETKO, Keo and Haggipavlu) around Limassol, in the southern half of the island of Cyprus. They are generally produced from the white wine of the Xynisteri vine variety, the island's major white cultivar (Robinson, 1986b), using double distillation in pot stills and maturation in oak casks, often for more than three years.

The United States

American brandy derives in the main from the state of California, also the center of the thriving wine industry, with the San Joaquin Valley producing notable examples. Cultivars used include a table grape

variety, Thompson seedless, as well as smaller quantities of the more traditional brandy cultivars like Ugni Blanc, Colombard and Folle Blanche. Pot stills are rare in the USA (notably, Jepson and RMS use original pot charentaise), with most brandy being distilled continuously in column stills. The process is more efficient than the pot still process and some producers claim that the product is softer and more finished, so shorter periods of maturation are required. A single column is usually most frequently used. The strength of the product varies from 78 to 85% v:v, which will be diluted to between 50 and 55% alcohol v:v before maturation. Rules governing American brandy production are not quite as strict as the French procedures, but there are still criteria in place for quality, for example, the maximum new make spirit strength allowed in production is 85% v:v, and the minimum age before release is two years. If less than this, 'unmatured' should be indicated on the label. It is more usual for producers to release brandies after four years maturation in either used American oak casks or casks that have been used to store Bourbon whiskey (Section 3.3.4). Brandy character can be overpowered by the wood flavor if newer American oak wood barrels are used. Frequently blends will include older brandies. Well known producers include the Christian brothers, Paul Masson, Schenley Distillers and E. & J. Gallo.

South Africa

Brandy is South Africa's top selling spirit drink, with average sales as at 2009, of around 45 million liters per year. Most South African grape brandies are, by law, made in the same way as Cognac, using a double distillation process in copper pot stills. Current European Union legislation demands that any product labelled as 'brandy' must be grape based and aged for at least six months in oak. South African legislation is even more stringent and requires ageing in oak barrels for a minimum of three years. Grapes for brandy production are mostly grown in the warmer wine production areas like Breede River Valley, Orange River region, Robertson, Worcester and Rawsonville. Cultivars include Colombard and Chenin Blanc, which account for around 90% of production, with other cultivars, Cinsaut, Palomino, Ugni Blanc and Sultana, making up the remainder. Distillates are aged in French oak, specifically Limousin and Tronçais for a minimum of three years by law for a 100% 'Pot Still' designation.

'Blended' brandies must contain 43% of three year old distillate and 'Vintage' brandy needs to be at least eight years old. Well known 'Blended' brandies include Klipdrift, Oude Meester, Richelieu, and Viceroy. These brandies are not as strongly flavored as pot still brandy, and are usually used as mixers. 'Vintage' brandies are composed of at least 30% pot still brandy, and should be matured for at least eight years. It is bottled at 38% alcohol by volume, and is generally served neat, or with a little water. 'Pot still' brandies must have at least 90% of their volume from pot still distillate, and be matured for a minimum of three years. These are the most complex of the brandies, and are often drunk neat. 'Pot Still' brands include Flight of the Fish Eagle, and Van Ryn (a distilling company that was established in Cape Town in 1845). The latter company makes 12, 15 and 20 year old brandies that are internationally recognized as excellent examples of their categories. Individual wine estates such as Backsberg, Laborie, Uitkyk and Avontuur also produce their own house brands, and the Solera system of brandy production is employed by some houses.

Pisco

Pisco is the name given to a certain kinds of brandy produced in a number of South American countries, but notably Chile and Peru (Faria *et al.*, 2003). There are two basic versions, depending on whether the production is based on nonaromatic wines of varieties such as Common Black, Mollar, Quebranta (especially) or Uvina, or on aromatic wines of a very wide range of Muscat varieties. The nonaromatic version is important in Peru, whereas the aromatic version is predominant in Chile, and because production procedures and regulations are rather different in these two countries, there is a considerable range of styles and qualities associated with this brandy. Much of the cheaper versions are used to make 'pisco sour,' consisting of brandy, lemon or lime juice, egg white, sugar syrup and bitters.

In Chile, the grapes used to make pisco are mostly of Muscat cultivars (although there are versions made from Pedro Ximénez or Torontel grapes), grown in warmer viticultural regions, so that the wine to be distilled is usually of *ca.* 14% ABV. Double distillation takes place in copper stills, with or without rectifying columns, so that the new make distillate is collected at 55–60% ABV. It is aged in oak casks for a few months, with higher quality versions being given much longer oak contact. After maturation, the spirit is diluted with deionized water (according to brand category), filtered and bottled. The four brand categories are (with % ABV) are Regular (30–35%), Special (35–40%), Reserve (40–43%) and Great (>43%).

In the production of Chilean pisco, the emphasis is not on varietal character, all versions having at least some wood maturation and most being made from the grapes of several vine varieties. The Chilean government has been keen to work with the producers to ensure a consistency of character and quality, especially regarding the basic versions, which receive only minimal wood maturation. To this end, special consideration has been given to the design and operation of stills used to make pisco (Osorio *et al.*, 2005).

In Peru, pisco production is regulated to preserve the character of the spirit, which must be made from a single vine variety, otherwise it is known as *acholado* ('half breed'). Maturation is carried out for a minimum of three months in glass (like many *Eau de Vie de Fruits* – see Section 3.8.3) or stainless steel, neither of which alter the character of the distillate, unlike oak, which allows oxygen ingress and leeching of phenolic substances into the spirit. A particularly fruity and highly perfumed distillate, *Mosto Verde*, is produced from a partially fermented must. Peruvian pisco is not diluted prior to bottling, so is generally of higher average alcoholic strength (~38–48% ABV) than Chilean pisco.

3.6.5 Quality Control in Brandy Production

Other than measures that are embedded in the legislation to ensure brandy producers adhere to consistent quality standards, Léauté (1990) noted that the distiller has three means to check the quality of wines for distillation in an alembic: tasting, analysis and microdistillation. Microdistillation can be conducted in a small-scale laboratory still with copper shavings placed in the boiler. This technique is very useful to detect butyric smells, oxidation characters, high levels of volatile phenols and/or sulfur-containing compounds. Sometimes a wine will seem fine until it distills, whereupon chemical interactions during heating may release components that were bound, and volatilize them. Checking the quality of distillates before maturation is also crucial. Column distillates are usually relatively odorless and tasteless, the only real quality control required is to check their alcohol content. The quality control process for fine brandies involves trained tasters with years of experience sampling brandy. A large Cognac house might have thousands of barrels in its cellars, each containing maturing spirit, which must be assessed for quality and maturation characteristics. A lot of brandy 'tasting' involves only smelling, as problems will very quickly be detected in the odor of the sample and tasting as such very quickly overwhelms the palate and impairs sensory analysis (see Section 3.2.5 and 4.7.4). The barrels may actually only be properly tasted once a year to assess how it is ageing and to evaluate it for its blending qualities. Brandies that contain off flavors will be discarded. Large establishments will have access to well trained panels of tasters who are used to tasting and assessing off odors and problems in raw distillates, barrel samples and finished products, and will also be used for assessing the success of blends and brands for the market. Interestingly, the standard sensory analysis procedures for Scotch whisky involve only 'nosing' (sniffing) the sample (Section 3.2.5).

3.6.6 Evaluating Brandy

Brandy, like whisky and red wine, exhibits more pleasant aromas and flavors at a lower temperature, e.g., 16 °C (61 °F). In most environments, this would imply that brandy should be cooled rather than heated for maximum enjoyment. Furthermore, alcohol (which makes up 40% of a typical brandy) becomes more volatile

as it is heated (and more viscous when cooled). Thus, cool brandy produces a fuller and smoother mouthfeel and less of a 'burning' sensation. Often it is slightly warmed by holding the glass cupped in the palm, but heating may cause the alcohol vapor to become pungent so that the aromas are overpowered. Brandy is best drunk from a tulip shaped glass or a snifter, which gives a large surface area for maximizing the release of volatiles. The wide base of the glass narrows towards the top, allowing the aromas to concentrate, and the tulip shape will act to funnel aromas up to the nose. The color of the liquor should be assessed against a white background and will be indicative of the age and blend of the brandy. Generally, the darker the brandy, the longer it has been matured in the oak casks, hence the stronger the woody aroma. It is also good to note that the color can also indicate the style of the brandy. Darker brandies are usually fuller and richer in taste. Unlike wine, which is often swirled in the glass to release its aromas, brandy should be kept stable in the glass as the liquid is very volatile and flavors can be lost if it is moved vigorously. In addition, the alcohol strength of brandy, neat, is approximately three times that typically found in wine, which means that the alcohol concentration in the volatile layer is far higher, and can be quite overpowering if swirled. The aromas in brandy are also presented in layers, according to brandy connoisseurs, with an initial impression, and then deeper layers of aroma, and the effect will be lost if the product is swirled.

Table 3.6.3 *A short glossary of brandy terminology*

Brandy term	Meaning
A.C.	Brandy that has been aged two years in wood.
Alambic	The copper pot still used in the Cognac area for the production of distillate
Armagnac	Brandy produced in the Gascony region of France using a specialised column still. Usually between 2 to 6 years old when released.
Brandy de Jerez	Brandy from the Jerez region of Spain, produced using the solera method, at least a year old on release.
Brandy de Jerez Reserva	Brandy from the Jerez region of Spain, produced using the solera method, at least three years old on release
Brandy de Jerez Gran Reserva	Brandy from the Jerez region of Spain, produced using the solera method, at least ten years old on release
Cognac	Brandy produced in the Charente region of France using a potstill. At least two and a half years old when released.
Heads	The first fraction of alcohol and other volatile components to distill over- usually rejected or redistilled due to poor quality
Heart	The major proportion of the alcohol (around 70%) recovered in a distillation
Hors d'age:	Brandies are too old to determine the age, although ten years plus is typical, and are usually of great quality.
Millesimes	Armagnac that is more than ten years old.
Tails	The last fraction of alcohol, usually containing high boilers like fuselols, may not be good quality and usually redistilled.
Vieil Armagnac	Armagnac that is over six years old
Vintage	Stored in the cask until the time it is bottled with the label showing the vintage date.
V.S.	"Very Special" or 3-Star, aged at least three years in wood.
V.S.O.P.	"Very Special Old Product" or 5-Star, aged at least five years in wood.
X.O.	"Extra Old", Napoleon or Vieille Reserve, aged at least six years in wood, Napoleon at least four years in wood.

Aromas associated with brandy can range from herbaceous (grass, mint or eucalyptus) to fresh or dried fruits as well as gooseberry, apple, citrus and even flowers. The impact of oak wood will be detected as vanilla, cedar wood, nuttiness, toast, cloves or cigar box aromas, as well as chocolate and mocha. Generally the younger the components, the grassier the flavor of the brandy, while older brandies tend to exhibit sweeter, fuller aromas and flavors. Additionally, brandy that has spent more time in oak casks tends to have a smoother, more harmonious mouthfeel. Some terminology associated with brandy styles and production can be seen in Table 3.6.2.

3.7
Grape and Other Pomace Spirits

3.7.1 Introduction

Pomace is the name for the mass of fruit skins, pips and other debris left behind after pressing the crushed fruit before or after fermentation (Sections 2.9.1, 2.9.2 and 2.8.3). Although many wine, cider and perrymakers return the pomace to the land to act as a fertilizer, it is generally considered a waste and for centuries in some long established wine producing regions some of it has been converted to a value added product known as pomace spirit. Furthermore, pomace, especially that from red wine production, contains high concentrations of polyphenols, which may not be desirable ingredients to add to the land as fertilizer (Amico *et al.*, 2008). Indeed, disposal of large quantities of pomace and other winery residues on land in more recently established wine producing areas, such as Oregon or New York State is viewed as an increasingly serious problem (Rice, 1976; Hang and Woodams, 2008).

To give some idea of the problem, consider a 1 ha vineyard (a very small vineyard in commercial terms) with a yield of 5000 kg of grapes. This will produce around 3500 l of wine, leaving some 1200 kg (1.2 tonnes) of pomace to be disposed of. Putting this into greater perspective, the countries of the European Union produce around 30 million tonnes of wine grapes each year, from which winemaking leaves about 6 million tonnes of grape pomace (Laufenberg *et al.*, 2003).

Despite the extensive use of grape pomace to give pomace spirit in some areas, such as Sicily, there is some interest in finding further ways of obtaining high added value products from red wine pomace. Fractions rich in antioxidant polyphenols have been obtained in Sicily for possible use as drug or cosmetic formulations or as food additives, although further work is required before these fractions can be exploited commercially (Amico *et al.*, 2008). Additionally, even after the production of pomace spirit from the pressed grape pulp, there remains behind a residue known as distilled grape pomace, which is also rich in polyphenols of high antioxidant activity. Traditionally, this is used as fertilizer, animal feed or is burned as fuel in cogeneration plants to produce energy. Recently, polyphenols from the pressed liquor of distilled grape pomace have been adsorbed on activated charcoal or polymeric resins and recovered in high yield, suggesting a possible commercial use, as for red wine pomace (Soto *et al.*, 2008).

3.7.2 Production of Pomace Spirits

The majority of pomace spirit is derived from pressed red wine or grape pulp and is known in France as eau de vie de marc or more simply as marc (e.g. marc de Bourgogne or marc de Champagne, depending on the region of production), grappa in Italy, orujo/aguardente in Spain, tsipouro/tsikoudia/raki in Greece, zivania in Cyprus and bagaceiras/aguardiente in Portugal. Small amounts of pomace spirit are also made from pressed apple or pear pulp during cider and perry production; these are generally known as eau de vie de marc de cidre or eau de vie de marc de poiré, respectively.

Red wines are made by fermentation of grape juice in contact with the skins and pips, and sometimes stalks (Section 2.9.2). After a certain time, the pomace is separated from the wine by pressing. It is normally a compact mass of fibrous cellulose, lignin material and moisture, in which are impregnated original grape constituents and the products of alcoholic fermentation, including ethanol. The volatile components, and in particular ethanol, can be obtained from the pomace by adding a controlled amount of water (which acts as an extractant and helps break up the solid mass) and then distilling. The heart fraction of the second distillate (if using pot alembic stills) is the pomace spirit and usually contains ~48–58% ethanol (v:v). If a pot still with a rectifying column (such as an alquitara), or more especially, if a columnar still is used, then the pomace spirit usually contains ~64-74% ethanol (v:v) (Cortés *et al.*, 2005).

In the case of spirits being made from pressed white grape pomace (which will be unfermented, since the big majority of white wines are made by crushing and pressing the grapes, and then fermenting the juice: Section 2.9.1), water is added to the pomace, often followed by a cultured yeast starter. After the close of fermentation, which lasts only a few days, the weak wine, with about 4% ABV, is distilled.

As an alternative to both of the above procedures, which are essentially traditional methods, larger distilleries, equipped with rectification columns, often distill the dry (or even partially dried) wine pomace using entrainment with steam; essentially a steam distillation process.

Pomace spirits were once mostly made either by the vineyard owner in his own small distillery or more likely by a travelling distiller ('le bouillier de cru' in France), who visited the vineyards at vintage time with a portable still (le distillerie ambulant), usually a simple alembic. Latterly, the traveling distillery has largely disappeared (mainly because of prohibitive legislation) and most pomace spirit is now either made by the vineyard owner/winemaker or by distilleries set up by the local or state authorities or private companies for that purpose. The larger distilleries often use (mainly) stainless steel column stills, as mentioned above, which many believe gives a different spirit to the smaller traditional copper pot stills (but see the next paragraphs).

The sheer mass of wine pomace at harvest time, located at many different vineyards or winery sites, necessitates storage for a period of time (ensilaging) prior to distillation if the winemaker makes use of the local distillery, rather than distil the pomace himself. During this time, depending on the method and length of storage, further alcoholic fermentation and other microbiological reactions take place in the wine pomace. It is not unusual for pomace to be stored at the distillery for three months (e.g. from the time of pressing at the start of October to the end of December) (Da Porto *et al.*, 2004). It is this extensive storage period that is thought to cause the greatest differences between pomace spirits from industrial distilleries and those from small artisanal distilleries at the vineyard or winery (distilled very soon after pressing; with no storage period) (Cortés Diéguez *et al.*, 2001; Cortés *et al.*, 2003; 2005; Corich *et al.*, 2005), rather than because of different distillation methods (column stills versus alembics), although this will have a certain influence.

The 'traditional' way of storing pomace is in wooden or concrete tanks, holding up to 50–100 tons. When the tanks are full, they are covered with plastic sheets weighed down with sand to prevent exposure to air. Alternatively, smaller quantities of pomace (50–200 kg) have been stored in plastic bags or containers (Cortés Diéguez *et al.*, 2001). Larger quantities of pomace (up to 500 tons) can be stored in concrete rooms (about $20 \times 6 \times 5$ m and closed on three sides). More recently, vertical closed stainless steel containers (silos) of

capacity 200–500 tons, and salami-like plastic bags (like a polytunnel) of capacity ~300 tons have been used to store pomace (Da Porto *et al.*, 2004).

The temperature at the center of a large quantity of stored pomace can exceed 30 °C at times, due to the heat released as a result of microbiological activity. This can lead to a 'stuck' fermentation (thereby giving a low alcohol yield) and also to infection by bacteria or fungi that produce organoleptically undesirable volatile compounds in large quantities, particularly 2-butanol, ethyl esters and volatile acids, such as butanoic acid. Although levels of 2-butanol tends to be high in fruit spirits made from pomaceous fruit (Section 3.8.2) and stone fruit (Sections 3.8.3 and 3.8.4), if concentrations of allyl alcohol, ethyl acetate and the propanols are also high and if the 2-butanol:1-butanol ratio is higher than 6, then it is likely that microbial contamination has occurred (Reinhard, 1981).

Moreover, if the container is not well sealed from the air, acetaldehyde and acetic acid can be formed at levels that are organoleptically detrimental. The spirit resulting from the distillation of unrefrigerated pomace of long storage can have high concentrations of 2-butanol (solvent notes), butanoic acid (sweaty, cheesy notes), ethyl acetate (fruity, solvent notes), ethyl lactate (rancid butter notes), 1-propanol and unsaturated aldehydes (grassy/herbal notes) (Cortés Diéguez *et al.*, 2001), whereas spirit produced from oxidized pomace can have high levels of acetaldehyde, acetic acid and methanol (Cortés Diéguez *et al.*, 2001). Various steps can be taken to either reduce fermentation temperature (by refrigeration) or to prevent oxidation/microbial contamination (by compression/lowering pH by adding acid or addition of metabisulfite). Unfortunately, compression, whilst denying the ingress of excess oxygen, makes refrigeration by conventional cooling ineffective.

Refrigeration of wine pomace in stainless steel silos by traditional methods is ineffective, because of poor heat transfer through the mass of fibrous material. Da Porto *et al.* (2004) have described an effective way of cooling fermenting pomace by trickling wine at 0 °C or 4 °C through the pomace twice during the 90 day storage time. The first distillate (low wines) made from the cooled pomace had a higher ethanol content (22.8–23.3% by volume) than that from the unrefrigerated pomace (18.8% by volume). Moreover, levels of acetaldehyde, 2-butanol, ethyl acetate, ethyl lactate, 1-hexanol (grassy notes), higher alcohols, methanol and unsaturated aldehydes were lower in the first distillates from cooled pomace. Da Porto *et al.* (2004) also showed that pomace stored in plastic salami-like containers, unrefrigerated, but well sealed from the air and relatively uncompacted, also gave low wines of good alcohol content (24.5% by volume) and with low levels of congeners that are detrimental in higher concentrations.

Using a multifactor variance analysis method (ANOVA), Cortés *et al.* (2005) were able to show that significant differences between the mean concentrations of volatile components (determined by GC/FID/MS analysis) of seven industrial and seven homemade orujo samples from Galicia existed only for components whose levels were known to be qualitatively related to processing and storage of pomace. These compounds included ethyl acetate, ethyl lactate, 1-hexanol, methanol and 1-propanol. Methanol and various hexanols in particular were predominant in orujo spirits, and it was evident that the use of rectification columns in the industrial distilleries did not effectively eliminate negative sensory compounds (such as ethyl acetate and ethyl lactate) when they are present in the pomace at such high concentrations because of poor storage. Other compounds, such as allyl alcohol and ethyl myristate, were found (at low levels) only in industrial orujo and so were regarded (without statistical evidence) as being indicative of long storage of wine pomace, with concurrent microbial contamination. Cortés *et al.* (2005) also suggested that the large pneumatic presses used by large-scale winemakers gives a dry pomace, with low alcohol potential, and the typically high pressure exerted on the pomace causes rupture of the pectins from the solid pomace material, making hydrolysis to methanol easier during fermentation and distillation.

Thus much qualitative evidence and at least one statistical study suggest that the length of storage time and the mode of storage of wine pomace can have more impact on the organoleptic character of pomace spirits than the mode of distillation or grape variety. However, the method of distillation, particularly with

regard to the mode of heating the still and with regard to separating head and tail fractions from the heart cut, plays a significant role in determining certain sensory characteristics of the spirit. Furfural is formed by thermal decomposition of sugars during distillation, particularly if the still is heated by direct fire, as in the production of some brandies (Ebeler *et al.*, 2000). Artisanal pomace spirits are more likely to be made using directly fired alembic stills and so tend to contain higher levels furfural (Cortés *et al.*, 2005; Kokkinofta and Theocharis, 2005), especially since furfural mostly distils in the tail fraction. Likewise, 2-phenylethanol is concentrated in the tail fraction and tends to be found at higher levels in homemade pomace spirits as a result of improper separation of this fraction from the heart cut. This observation was found to be commensurate with the lower ethanol content of homemade orujo (~47–57% by volume), as opposed to industrial spirits with 53–74% ABV (Cortés *et al.*, 2005).

As with other spirits, the type of distillation system used and the manner in which it is used can have a considerable influence on the organoleptic character of pomace spirits. In a study of grappa production using traditional batch stills with and without a rectifying column, Da Porto and Longo (1997) found that without the rectifying column, the distillation was best carried out at the lowest possible temperatures in order to ensure a partial rectification of the distillate. They suggested that if a column with several plates is used, a higher quality grappa will be more easily produced.

3.7.3 Types of Pomace Spirits and Sensory Characteristics

Pomace spirits are produced all over the world – almost anywhere that vines are grown and wine is made. In most areas it is a minor product compared with wine and brandy and in some it is very rare: marc de Bourgogne and marc de Champagne are difficult to obtain outside their area of production. Even in areas (such as Cyprus, Galicia or Greece) where a significant volume of pomace spirit is still made by artisanal distillers, most of it is either consumed as such locally, or is used to make fruit and coffee liqueurs (Cortés *et al.*, 2005). In some areas, such as northern Portugal (Minho: the vinho verde region) and northwestern Spain (Galicia), Cyprus and parts of Greece, production of pomace spirit is of significant economic importance and was once of considerable traditional value.

The best known pomace spirits are probably those of Italy, which have the special name of grappa, designated by the European Union (or the European Economic Community as it was in 1989) (EEC, 1989) for spirits produced only in Italy. In recognition of the traditional production in specific regions within the EU, designated names are used for other pomace spirits, such as bagaceiras (Portugal), orujo (Galicia, Spain) and tsikoudia and tsipouro (Greece). The general regulations regarding the production of these spirits (EEC, 1989) indicate procedures to be used and give minimum levels for volatile substances (140 g/hl of 100% alcohol by volume) and maximum levels for ethanol (86% by volume) and methanol (1500 g/hl of 100% ethanol by volume).

Governmental bodies within the member countries of the EU that produce these spirits have awarded special denominations that protect them with regard to origin of raw material, distillation techniques and aspects of the composition of the final product. For each denomination, a regulatory body has been set up to ensure that any spirit labeled under its control complies with the requirements for that spirit. Thus in Galicia, the autonomous government, following the EU ruling, awarded the local pomace spirit the specific denomination of 'Orujo de Galicia/Aguadente de Galicia' in 1993. The government stipulated the origin of the raw material and the limits of several substances in the spirit: ethanol, acetal, acetaldehyde, methanol, total higher alcohol content (1-butanol, 2-butanol, isoamyl alcohols, isobutanol and 1-propanol), copper and total acidity. A regulatory committee was set up to ensure that the spirit in any bottle of 'Orujo de Galicia' complies with these regulations. In addition to chemical tests, the official tasting panel of the regulatory committee assesses the sensory characteristics of each representative sample of spirit from Galician distilleries.

Pomace spirits in the past have had a reputation for variable quality, roughness and fiery character. Compared with many other spirits, concentrations of acetaldehyde, methanol, 2-butanol and a number of carbonyl compounds are often high, as sometimes are furfural and 2-phenylethanol levels. In many cases, these characteristics can be explained by variability in the fermentation (including spectrum of fermentative microbes) and distillation techniques of small-scale winemakers/distillers, as described in Section 3.7.2. Likewise, it has been shown (also in Section 3.7.2) that modern distilleries with relatively sophisticated equipment can produce pomace spirits with high levels of certain less desirable components due, in particular, to overpressing the pomace (giving rise to higher methanol levels) and faulty storage of pomace (giving rise to 2-butanol, carboxylic acids and ethyl esters). The major carboxylic acids are acetic, butanoic, isobutanoic and isovaleric acids, which impart notes of vinegar, cheese and rancid butter. It has been found that Galician pomace stored under deficient conditions produced a defective distillate with high levels of all the above-mentioned acids (Diéguez *et al.*, 2002). Storage of the distillate for more than seven months caused a reduction in total concentration of acids (irrespective of temperature of storage; 5 °C or 25 °C), although quality was still poor. In cases like this, it was recommended that the pomace spirit should be redistilled.

Other than the above features, the aroma and flavor compounds of pomace spirits are similar to those found in most other spirits, with higher alcohols and esters playing a particularly important role (Da Porto, 1998). Carbonyl compounds are also thought to make a significant contribution to grappa aroma (Flamini *et al.*, 2005). Acetaldehyde was found in two commercial and two homemade grappa samples at levels (208–700 mg/l of 100% ethanol by volume), that are similar to those in other pomace spirits, such as orujo (48.5–709 mg/l) (Cortés *et al.*, 2005) and zivania (mean value 375 mg/l of 100% ethanol by volume) (Kokkinofta and Theocharis, 2005). Although high acetaldehyde content of spirits may not make much positive contribution toward organoleptic quality, acetaldehyde is nonetheless considered important in the spirits that are used to make Port wine because of its ability to stabilize the wine color (Section 2.10.7). Flamini *at al.* (2005) also found benzaldehyde, 2,3-butanedione, heptanal, hexanal, 3-hydroxybutanone, 2- and 3-methylbutanal and propanal in the grappa samples. The homemade grappa distilled from partially dried pomace of the Raboso variety had especially high levels of carbonyl compounds, probably the result of greater oxidation occurring as a result of partial drying.

The methanol content of pomace spirits (and others, such as fruit spirits – see Section 3.8.3) has always been a matter for concern. It is formed mainly from the enzymic hydrolysis of fruit pectins during fermentation and once present in the wine, it is distributed throughout all the fractions upon distillation (Claus and Berglund, 2005). The EU upper limit for the methanol content of spirits is 1500 g/hl (= 1500 mg/100 ml) of 100% ethanol by volume, but the USA legal limit is much lower, at 280 mg/100 ml 40% (= 700 mg/ml 100%) of 100% ethanol by volume (US Code of Federal Regulations, 2003). Several factors can influence the concentration of methanol in pomace spirit during its manufacture, including grape variety, acidity of pomace, strain of yeast used (Hang and Woodams, 2008) and wine press pressure. A laboratory-scale study of the methanol content of spirits made from the sweet pomace of white grape varieties (Cayuga White, Chardonnay, Gewurztraminer, Niagara and Riesling), grown in a Finger Lakes (New York) vineyard, showed methanol contents of 38, 55, 138, 44 and 112 mg/100 ml of 40% ethanol, respectively – all well below the legal limit (Hang and Woodams, 2008). The sweet pomace samples were fresh, moist (∼64%) (and hence had been lightly pressed) and fairly acidic (∼0.60% as tartaric acid), with sugar contents (7.81–16.17% as glucose) that gave pomace wine of ethanol content of 4.8–7.4% (v:v). The pomace was treated with sulfur dioxide and then fermented with cultured wine yeast. Distillation was carried out using a small-scale simple laboratory still. The results of this study suggest that clean fermentation of fresh sweet, moist pomace is capable of producing pomace spirit with low methanol levels and that the methanol content is dependent on the grape variety.

Higher alcohols are important contributors to the aroma and flavor of distilled spirits. They are present at higher concentrations than other volatile compounds, their levels in pomace spirit depending on grape variety,

fermentation method and distillation technique (Gerogiannaki-Chrisopoulou *et al.*, 2004). The prominent alcohols in many pomace spirits are 3-methyl-1-butanol (isoamyl alcohol) and 2-methyl-1-butanol. The mean concentration (415.9 mg/l) of the former in nine orujo samples (the pomace spirit of Galicia) was found to be lower than that of Portuguese bagaceira (915.5 mg/l), but higher than that of Italian grappa (243.5 mg/l) (Peña *et al.*, 2008). Other alcohols, such as 3-methyl-1-butanol and 1-propanol had high mean values in orujo (169.7 and 161.3 mg/l, respectively), although the mean 2-phenylethanol content was low (3.2 mg/l) compared with bagaceira and grappa, possibly indicating careful distillation techniques for these particular samples of orujo.

The volatile compounds that contribute most to the pomace spirit's sensory quality are (as with other spirits) probably esters of fatty acids. They are produced by fermentation and are found in the resulting distillate, their concentrations in brandy generally varying according to the grape variety (Milicevic *et al.*, 2002), and generally increasing on aging. Ethyl hexanoate and octanoate levels in orujo were found to be similar to those reported in bagaceira and grappa, but ethyl decanoate and ethyl dodecanoate were present at much higher levels in orujo (Peña *et al.*, 2008). These two esters contribute fatty or waxy notes to spirit aroma. Acetate esters, such as hexyl acetate, isomayl acetate and 2-phenylethyl acetate, are responsible for flowery/fruity notes; all have been found in pomace spirits.

Terpenic alcohols citronellol, geraniol, linalool, nerol and α-terpineol were identified in orujo, linalool (citrus notes) having the highest concentration (2.041 mg/l) (Peña *et al.*, 2008).

Zivania is a pomace spirit produced mainly by artisanal distillers in the Greek speaking part of Cyprus from Maratheftikon, Ofthalmon, Xynisteri and other local grapes varieties.

A study of 20 zivania samples and comparison with a large number of other spirits, including samples of Greek tsipouro, revealed that the mean levels of 2-methyl- and 3-methyl-1-butanol were similar to those of tsipouro, but were higher than those of many other spirits, including grappa (Kokkinofta and Theocharis, 2005). Mean methanol content was low (∼127 mg/l of 100% ethanol by volume), but acetaldehyde contents varied wildly and on average were higher than levels in grappa, tsipouro and other spirits. Copper concentrations were higher (mean value 2.87 mg/l), but varied widely from sample to sample, possibly indicating a wide range of still conditions and distillation techniques.

3.8
Fruit Spirits

3.8.1 Introduction

Fruit spirits, often known as fruit brandies, are distilled fruit wines. Their generic French name is eau de vie de fruit and in German their family name is Schnaps, although there are subdivisions of Wasser and Geist, as discussed later. Individually, they tend to be named after the fruit from which they are derived (e.g. Kirsch(wasser) from cherries and Williams Birne from Williams pears). They are more often than not aged in glass or earthenware containers, rather than in oak casks, and hence are usually colorless, giving rise to yet another generic name, alcools blancs. An important exception to both the above general rules is Calvados, apple brandy named after a French département (in the old province of Normandy), rather than after the fruit, and aged in oak casks. Another exception is Obstler, used in German speaking countries to describe a spirit derived from apples and pears.

Like other alcoholic beverages, there is some confusion of nomenclature regarding fruit spirits and some other beverages. For example the English term cherry brandy can mean either a cherry spirit or more likely a liqueur made by infusing cherries in sweetened brandy (Section 3.9.2). A way around this would be to use the name that contains the word brandy for brandy based fruit liqueurs and to use the name that includes the word spirit for distilled fruit wines – or to use the French or German names for the fruit spirits, since the majority are made in French or German speaking countries. Another confusion is the use of the word schnapps, derived from the German Schnaps. In Germany, Schnaps is an unsweetened fruit spirit, whereas in the USA, schnapps refers to sweetened spirits flavored with fruit or fruit extracts. These drinks (sometimes known as cordials) are more akin to fruit liqueurs (Section 3.9.2) (Lichine, 1982). Additionally, one should be aware that sometimes in Germany the word Schnaps is used loosely to describe any kind of German made spirit.

In France, almost any fruit wine is distilled to produce a very wide range of eau de vie de fruit, whereas in Germany, Schnaps is nearly always made from apple, cherry, pear or plum wine. In French and German speaking countries, the most common fruit spirit is that of the cherry, but in eastern European countries, such as the former Jugoslavia, plum spirit (slivovitz) is the most common.

The most important areas of fruit spirit production are firstly the French Provinces of Normandy, Britanny and Maine for eau de vie de cidre (including Calvados) and eau de vie de poiré. Secondly, areas stretching

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass

from Lorraine and Alsace (France), through Baden (Germany) and northern Switzerland (mostly quite close to the upper Rhine) into the Valais canton of Switzerland (close to the upper Rhône), produce a wide range of fruit spirits, with those from cherry and plum tending to predominate. Thirdly, Croatia, Serbia and other countries of the former Jugoslavia, as well as other central and eastern European countries, produce a clear spirit from blue plum wine known generally as slivovitz. Apart from the above, notable fruit spirits are made in a number of other countries, including the UK and the USA.

3.8.2 Apple and Pear Spirits

Apple spirit is distilled cider or apple wine, and pear spirit is distilled perry or pear wine. By far the most important producers of apple spirit are to be found in northwest France, in Brittany, Maine and Normandy, with the last named predominating. Pear spirit is also made in this part of France from perry, but it is also produced from pear wine in many other parts of Europe. The provinces of Brittany and Normandy are the major producers of cider and perry in France, using special sharp, bittersharp, bittersweet and sweet apple or pear varieties (Section 2.8.2), many of which are of ancient lineage and few of which are grown in any quantity anywhere else in the world. Apple and pear spirits made elsewhere in France (and in most other countries) are distilled from wines produced from noncider apples and pears, the Bartlett or Williams (Bon Chretien) pear variety being especially popular.

A substantial quantity of Norman and Breton cider is distilled each year; a number of cider and perry makers are also distillers, but cider spirit is also produced in northern Spain, and a little in England. Calvados is the most important cider spirit of Brittany and Normandy, although poiré and ordinary eau de vie de cidre are also made. Additionally, a small amount of eau de vie de marc de cidre is made from the cider apple pressings (Section 3.7.2).

Although there are records of cider distilling in the sixteenth century on the Cotentin Peninsular, near Cherbourg, today's most important spirit, Calvados, is named after the département of that name, whose major city is Caen (Figure 3.8.1) (Johnson, 1977). However, the best Calvados usually comes from the valley of the Auge in the eastern sector of Calvados: Calvados du Pays d'Auge was given Appellation Contrôlée

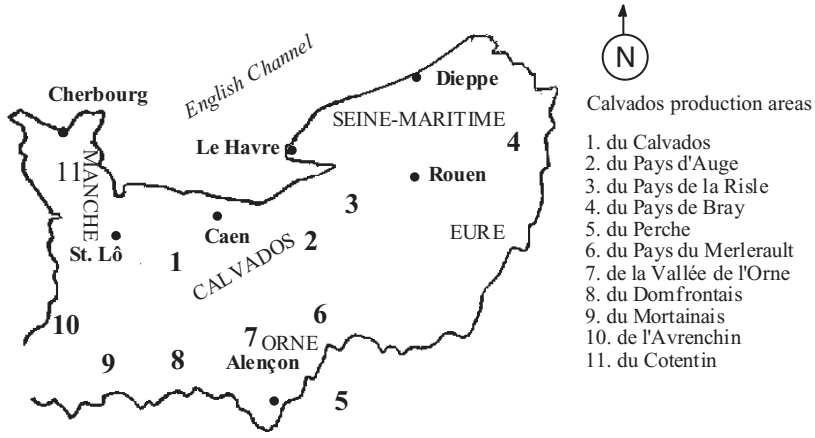

Figure 3.8.1 *Sources of Calvados and eau de vie de cidre*

status in 1942. It therefore must be made in accordance with a strict set of regulations, which are outlined below:

- Calvados du Pays d'Auge must be made in the designated region from cider apples growing in that region
- The cider must be prepared according to traditional practices and fermentation must occur over at least six weeks
- The cider must be double distilled in pot stills to give a spirit of ~72% ABV (in this way the production of Calvados resembles that of Cognac – see Section 3.6.2)
- The spirit must be aged for at least two years and bottled for sale at 40–50% alcohol (v:v).

In general, according to EU regulations, the distillation of fruit spirits must occur at less than 86% ABV, so that the spirit retains some character of the fruit from which it is derived (see for example Council Regulation (EEC) No. 1576/89 of 29 May 1989). In relation to this, there are also minimum and maximum limits on the levels of volatile substances and methanol (respectively) in the spirit; these are discussed more generally in Section 3.8.3.

The volatile components of samples of freshly distilled Calvados have been extensively investigated by a variety of separation techniques followed by analysis using GC-MS (Ledauphin *et al.*, 2004). Liquid–liquid extraction with dichloromethane, preparative GC and silica gel fractionation together allowed characterization of 331 volatile compounds (162 at trace levels) in freshly distilled Calvados and Cognac of which 130 trace aroma compounds were found in Calvados. The nontrace compounds included acetals, alcohols, aldehydes, carboxylic acids, esters, ethers, ketones, norisoprenoids, organosulfur compounds, phenols and terpenoids. Included in the alcohols were the unsaturated prop-2-en-1-ol and 3-methyl-2-en-1-ol, both of which were not found in Cognac. Likewise, hydroxyesters ethyl 2-hydroxybutanoate, ethyl 2-hydroxypentanoate and butyl 2-hydroxypropanoate were unique to Calvados, as were a number of aromatic compounds and phenols (including various guaiacols), 4-terpineol and 3,3-diethoxypropanol. Of the trace compounds, esters ethyl and methyl tiglate; secondary alcohols pentan-3-ol, hexan-2-ol and octan-2-ol; unsaturated alcohols pent-4-en-1-ol, hept-4-en-1-ol and four others; acetals 4-methyl-1,3-dioxane and 2-methyl-1,3-dioxane; unsaturated aldehydes pent-2-enal, oct-2-enal and tridec-2-enal; terpenoids camphor and eucalyptol; and phenolic compounds guaiacol, isoeugenol and various salicylic esters, were unique to Calvados and thus could be used as markers for this spirit. The sensitive preparative GC separation technique allowed identification of many trace compounds such as methional, oct-3-en-one and 4-oxoisophorone, which have low odor threshold values (Section 4.7.3) and which may make significant contributions to the aroma of freshly distilled (cooked potato, mushroom and wood, respectively).

Organosulfur compounds have been found to be much less in evidence in freshly distilled Calvados than in freshly distilled Cognac and terpenoid/norisoprenoid ketones were almost absent from Calvados (Ledauphin *et al.*, 2006). Nevertheless, many saturated and unsaturated carbonyl compounds were found in Calvados, which may provide grassy and mushroom aromas and several sulfur compounds were probably present at high enough levels to provide aroma contribution, particularly dimethyl disulfide (cabbage-vegetal) and methional (potato). The ratio of 3-thiophenecarboxaldehyde to 2-thiophenecarboxaldehyde in Calvados was found to be more than 10 for Calvados, but less than 0.5 for Cognac.

In practice, Calvados du Pays d'Auge is often aged in large oak casks, resembling small vats in size. Because these casks are only rarely replaced (in general like cider casks – see section 2.8.5), relatively few volatile compounds or nonvolatile tannins in the aged spirit are derived from wood contact. Even after several years in cask, many examples of Calvados are almost colorless and are hence given a mild coloration by the addition of a small amount of caramel, the only allowed additive.

Other (specified) regions outside of the Pays d'Auge are able to make cider brandy under the more general AOC Calvados appellation. These areas are in all of the Normandy departéments: Calvados, Eure, Manche,

Orne and Seine-Maritime, plus small areas of Eure-et-Loir, Mayenne and Sarthe départements, which are now outside Normandy (Figure 3.8.1). This AOC is similar to the AOC calvados Pays d'Auge, but is less restrictive and allows single column (batch column) distillation. Cider brandy made outside these areas, using methods outside those required for AOC status is known simply as eau de vie de cidre. Additionally, there is the AOC Calvados Domfrontais for spirit made from apples and pears, using single column distillation the minimum pear content being 30% and minimum required aging in oak being three years. This spirit is made in southern Normandy around the town of Domfrontais in the Orne département on farms which must include 15% of pear trees in the orchards.

Cider brandy or apple spirit is produced in several other European locations, including northern Spain (especially Asturias), northern Italy (especially Alto Adige and Trentino), Germany and England, from a wide range of apple varieties – not solely from classic cider varieties that are grown in the major cider manufacturing areas. Similarly, these apples are grown in different climatic conditions, which for each region vary from year to year. Thus it is expected that the spirit aroma profiles should reflect the apple varieties and the vintage from which the spirit is derived. Versini *et al*. (2009) were able to show apple distillates made from native Sardinian varieties can be distinguished from those produced from locally grown apple varieties in the traditional cider brandy provinces of Trentino, using similar fermentation/distillation equipment/methods. Using GC/FID/MS (Section 4.3.2) to characterize the aroma compounds, univariate statistical analysis (ANOVA) was used to evaluate where significant differences existed between Sardinian distillates of different vintages and between Sardinian and Trentino distillates, depending on variety.

Variables that showed high significance were then used in principal component analysis (PCA). ANOVA and PCA highlighted that ethyl octanoate, hexyl 2-methylbutanoate, 1-hexanol, benzaldehyde and furfural were correlated with apple varieties and were able to differentiate them. Of these, the first named may provide an index of fermentation characteristics, while the last named may be linked to distillation and sugar residues. The remaining three were considered to be linked to apple variety. On the other hand, 3-methyl-1-butanol, total aldehydes, ethyl acetate and 6-methyl-5-hepten-2-ol variables in Sardinian varieties were correlated with vintage.

Recently (Rodríguez Madrera *et al.* (2010) in Asturias have investigated the influence of duration of cider maturation on the aroma quality of the resulting distillate. It was found that the most mature cider gave a distillate of superior aroma (with more sweet and spicy character), with higher levels of ethyl acetate, ethyl lactate and ethyl succinate, and volatiles derived from bacterial metabolism (which is more prevalent in extensively matured cider), such as 2-butanol, 4-ethylguaiacol, eugenol and 2-propen-1-ol. On the other hand, the same group has demonstrated that higher ethyl carbamate (EC) levels were associated with spirits produced from well matured cider (up to 67 μg/l), although use of alquitara (a batch column still) in place of pot stills gave cider spirits with the lowest EC content (Rodríguez Madrera and Suárez Valles, 2009). EC is a carcinogen produced by the reaction between HCN and ethanol during distillation; the HCN in cider spirits is probably derived from urea from alcoholic fermentation (see Section 5.11.5).

Apple juice concentrate (AJC) is widely used in the production of cider, usually large-scale factory cider (Section 2.8.6) in many parts of the world, although its use is strictly regulated in many areas. Analysis by GC/MS of a range of cider spirits from Asturias, Calvados and Herefordshire distilled in either alembic (Charentais) stills or column stills was able to differentiate those derived from fresh apples and those derived from AJC (Rodríguez Madrera and Mangas Alonso, 2005). The analysis was based on the variability of 27 aroma compounds, including nine major volatiles: acetaldehyde, methanol, ethyl acetate, 1-propanol, 2-methyl-1-propanol, 1-butanol, acetal, 2-methyl-1-butanol and 3-methyl-1-butanol. Methods used to prepare AJC (Section 2.8.6) and the way in which it is fermented (normally using *S. cerivisiae* cultures) were considered to account for certain differences in aroma profiles. Thus, spirits derived from AJC tended to be higher in methanol content (due to pectin hydrolysis occurring during the preparation of AJC)) and lower in varietal (prefermentative) aroma compounds, such as 1-butanol and 1-hexanol. Likewise, spirits derived

from fresh apples tended to be higher in acetate esters (except 3-methyl-1-butyl acetate) (due to the action of non-*Saccharomyces* yeasts), whereas ethyl esters from the middle aroma fraction tended to be associated with AJC spirits.

The above paragraphs have discussed how apple distillate aroma profiles differ between vintages of the same apple cultivars, between different cultivars (all aged and with similar fermentation and (alembic) distillation methods), between distillates made from unaged and aged cider and between spirits produced from AJC or fresh apples (with and without aging and using a variety fermentation regimes and stills). However, it seems that the method of distillation and extent of aging, although influencing the overall aroma profiles of apple distillates, do not significantly influence AJC/fresh fruit correlations, provided the aroma compounds chosen for correlation do not vary significantly with distillation methods and aging.

The two major distillation methods for producing apple distillate are pot still distillation (using alembics or 'Charentais' stills – resembling Cognac production: used in Asturias and Normandy/Brittany) (Section 3.1.2) and column still distillation (used in Asturias, England and Normandy/Brittany) (Sections 3.1.3 and 3.8.3). A third method uses the alquitara, a kind of direct heated copper pot still of around 130–350 l capacity that has a pear shaped bulge or reflux condenser at the top coupled to a recipient filled with cold water to condense the vapors. This type of still is used by some Asturian distillers, but is a traditional distillation system more often used in the production marc distillates in Galicia (Section 3.7.2). A study of Asturian cider distillation using alquitaras showed that the resulting spirits compared well with those distilled using alembics, having methanol, ethanol, furfural, lead, copper and zinc below maximum permissible levels, and with the minimum permissible levels of volatile flavor substances (congeners) surpassed (Rodríguez Madrera *et al.*, 2006). However, double distillation (with tails from first distillation) was necessary to give a spirit with adequate ethanol content and so was costly in energy, although double distillation gave reduced furfural and metal levels in the final distillate.

As with all alcoholic beverages, aging in wooden casks alters the organoleptic characteristics of apple spirit: it loses its rough edges, becomes softer in mouthfeel and more rounded and harmonious in aroma and flavor. The processes that cause these changes are discussed in more detail in Sections 2.9.5, 3.2.5, 3.3.4 and 3.5.3. Thus, apple distillates aged in oak generally become richer in certain acetals, ketals, medium and long chain ethyl esters, lactones (e.g. oak or whisky lactones) and phenolic compounds, while losing some aldehydes, ketones, nonethyl esters and fatty acids (except acetic acid) (Mangas *et al.*, 1996). Various attempts have been made to relate the presence of certain components in distilled spirits (both in absolute and relative terms) to maturation history – particularly with regard to aging in oak casks. Low molecular weight phenols and coumarins cannot be used as sole indicators of cask maturation of apple distillates, because of the use of oak extracts and (more commonly) caramel in the production of these spirits (Fernandez Izquierdo *et al.*, 2001). Similarly, furfural, 5-methylfurfural and 5-hydroxymethylfurfural are unreliable markers of oak aging when used alone, because of their presence in caramel and also because their concentrations depend on the distillation method and type of cider or apple wine distilled (Rodríguez Madrera *et al.*, 2003). Chemometric (principle component, linear discriminant and Bayesean) analysis of extracted aroma compounds, furans and phenolic compounds from many samples of cider brandies allowed classification of aged and unaged spirits according to main discriminant variables ethyl caprylate, ethyl isovalerate, 1-propanol and hexyl acetate (Rodríguez Madrera *et al.*, 2003).

Although there are records mentioning cider brandy production in England in the seventeenth century, it seems that the art died out, like many other things, around the time of World War 1. Cider distilling was revived using a small still installed at Bulmer's museum (Hereford) (Section 2.8.6) in 1984, although not on a commercial scale. It wasn't until 1989, that a well established cider producer at Burrow Hill (Somerset) obtained a distiller's license, and using two single column copper stills (Section 3.1.2), began distilling cider at the Somerset Distillery (see Figure 3.8.2). The column stills give a fresher, fruitier spirit, like some AOC calvados examples. The cider is made from around 40 apple varieties by traditional methods and is matured

(without sulfiting) into the year following the vintage before being distilled. As with double pot distilled malt whiskies (Section 3.2.4), the new make spirit is collected at ~70% ABV. It is aged in oak casks of various sizes, typically 500 l, for three to 15 years and is diluted with pure water to ~40% ABV before bottling.

Like apple distillates, pear spirits are made in many locations, but especially in northwestern and eastern France, southwestern Germany and Switzerland. They are made from a wide range of pear varieties, although the Williams or Bartlett cultivar is popular in noncider or nonperry producing regions. Other pear varieties used include Gelbmostler (Austria and Switzerland), Schweizer Wasserbirne (Switzerland) and Theilerbirne (Switzerland). Perry pears (e.g. De Cloche, Plant du Blanc and others) are used to make pear spirit or Calvados Domfrontais in northwestern France.

The components of freshly distilled pear spirit are generally similar to those of other fruit wine distillates – including (apart from ethanol and water), methanol, acetaldehyde, furfural, higher alcohols, 2-phenylethanol, acetate esters and ethyl esters (García-Llobodanin *et al.*, 2007). The first three are toxic at higher levels and hence their concentrations must fall below specified maximum permissible levels, but the remaining components (provided that concentrations are moderate), along with many other low level and trace components, contribute to flavor quality. In particular, 2-phenylethanol contributes a floral, rose character to the spirit, but higher levels of this compound indicate poor separation of heart and tail distillation fractions, since it is a typical tail component.

The most characteristic pear aroma/flavor compounds are ethyl and methyl 2-*trans*-4-*cis*-decadienoate. This compound is found in pear juice, wine and spirit; in the latter distilled from Bartlett pear wine, their typical concentrations were 68 mg/l and 27 mg/l (respectively), which were lower than those of fresh ripe pears, probably because of isomerizations and other reactions occurring during fermentation and distillation (Kralj Cigić and Zupančič-Kralj, 1999). Furthermore, if Bartlett pear spirit is stored in colorless bottles, the 2-*trans*-4-*cis* isomers partially isomerize to the 2-*cis*-4-*trans* and 2-*trans*-4-*trans* isomers, all of which have much less pronounced pear-like odors, so the flavor quality of the spirit decreases. No such isomerization was

noted for pear spirit stored in green bottles. Observation of isomerization of a ethyl 2-*trans*-4-*cis*-decadienoate standard in ethanol:water (40:60 v:v) when exposed to strong UV light suggested that loss of ethyl and methyl 2-*trans*-4-*cis*-decadienoate on storage of spirit in colorless bottles is due to photochemical isomerizations (Kralj Cigić and Zupančič-Kralj, 1999). It is interesting to note that some pear spirits are still sold in colorless bottles.

As with other spirits, it is in the distiller's interest to ensure that his product contains minimal concentrations of acetaldhyde, ethyl acetate, furfural and methanol. This can be done by careful double distilling in pot stills with proper separation of head and tail fractions from the heart fractions (Glatthar *et al.*, 2001). However, apart from this general consideration, there are few reports on the influence of various distillation conditions on the concentration of key components in pear spirit.

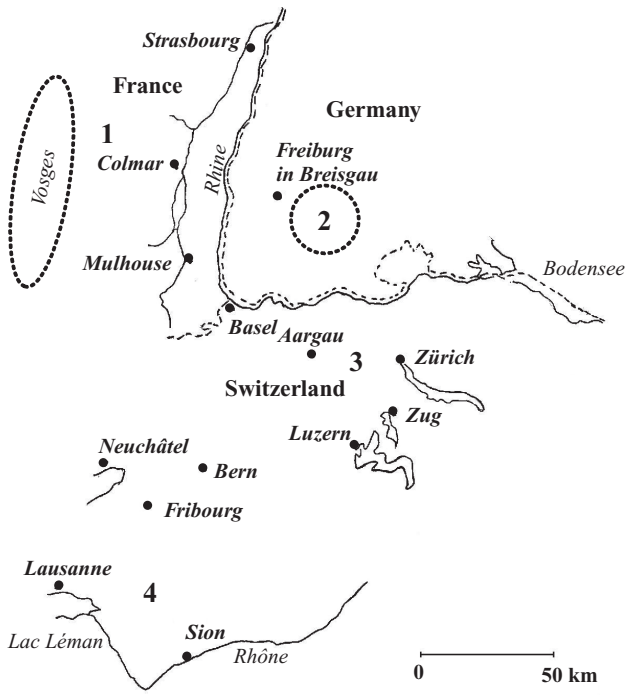
García-Llobodanin *et al.* (2007) investigated the effect the presence of wine lees and the material of the pot still on selected components of the whole first distillate and heart fraction of the first distillate of pear wine produced from Blanquilla pear juice concentrate. It was found that wine distilled from its lees in a copper alembic (as opposed to a glass alembic and a glass alembic containing 5g/l of copper shavings) gave the best results. Under these conditions, concentrations of compounds in the heart fraction considered to have a negative effect on spirit quality (ethyl acetate, furfural and methanol) were minimized, whereas the levels of beneficial components (especially ethyl decanoate and ethyl 2-*trans*-4-*cis*-decadienoate) were maximized.

3.8.3 Fruit Spirits of Central Europe

Fruit spirits, made from a wide range of fruit wines, are produced on a line running parallel to the river Rhine from Lorraine and Alsace in the north through Baden, past the Black Forest area of southern Germany and into Switzerland (Figure 3.8.3). The major, but by no means all of the distilling activity occurs in Lorraine, Alsace, Freiburg in Breisgau and the Black Forest, northern and central Switzerland (as far as Zug and Luzern) and southeastern Switzerland, especially in the canton of Valais, around the wine producing town of Sion (Figure 3.8.3). The different regions specialize in different spirits, depending partly on tradition and partly on the local availability of particular fruits. Thus Lorraine produces in any quantity only one kind of spirit, mirabelle, made from a small yellow plum, Alsace produces the widest range of fruit spirits, whilst the Black Forest region of Germany and Switzerland tend to specialize in cherry, pear and plum spirits. Because of varying production methods, particularly with regard to distillation, the spirit derived from a particular fruit (say Williams pear) can vary markedly from region to region.

Lorraine, just north of Alsace produces mirabelle from yellow plums of that name. The major production areas are those surrounding Nancy and Metz; here the spirit is entitled to the Appellation d'Origine Contrôlée (AOC) Mirabelle de Lorraine, provided it is made according to specified regulations. The best is probably Mirabelle Fine du Val de Metz, made by double distilling (in pot stills) wine made from ripe plums that has fermented/matured for at least two months in wood. The spirit is aged in oak casks (unlike many fruit spirits of the other regions) and, like most others, is diluted to ~45% ABV before bottling. In general, the word Fine in the name of a fruit spirit indicates that it has been aged in wood (vieillie en fûts).

Just like its wines, Alsace is an Aladdin's cave of fruit spirits, with regard to variety and diversity. Distilling activity tends to be centered on the wine producing areas between Obernai in the north, through Ribeauvillé and Colmar to Thann in the south, with many small distilleries situated in the Vosges mountains above the vineyards. Spirits are made from apple, apricot (abricot), bilberry (myrtille), blackberry (mûre sauvage), blackcurrant (cassis), blue plum (quetsch), cherry (Kirsch), elderberry (sureau), holly berry (baie de houx), peach (pêche), pear, quince (coign), raspberry (framboise), redcurrant (groseille), rowanberry (sorbier), serviceberry (alisier), sloe (prunelle), strawberry (fraise), wild plum (prune sauvage) and wild



1. Alsace/Vosges
Noted for a wide range of fruit spirits (alcools blancs and some oak aged): apricot, bilberry, blackberry, cherry, holly berry, peach, pear, plum (various), raspberry, rowanberry, strawberry.
Also noted for fruit liqueurs (Section 3.9.2).

2. Freiburg/Black Forest
Spirits from cherry, peach, pear, plum mainly. Also liqueurs and flavoured fruit spirits, such as *Himbeergeist*.

3. Northern Switzerland
Spirits from mainly cherry, peach and blue plums. Also Enzian, a fruit spirit made from gentian roots.

4. Valais/Southeast Switzerland
Mainly noted for cherry, peach and blue plum (*eau de vie de pruneaux*) spirits.

Figure 3.8.3 *Principal regions of fruit spirit production in central Europe*

strawberry (fraise de bois). Many of these spirits are made by fermenting the fruit pulp and then, after some maturation time, distilling the wine. Fruit spirits of this kind in Germany have the generic name of Wasser. A few fruit types with low natural sugar contents (e.g. holly berries) are sugared before fermentation. Some spirits are made by soaking the fruit (especially soft fruit) in neutral spirit (1 l of spirit to 4 kg of fruit) for several weeks and then distilling. The latter method when used in Germany gives a spirit known as Geist.

There are still many small-scale distillers who sell some of their products to wine producers for sale under the wine producer's name and there are some wine producers who make their own spirits (e.g. Preiss-Henny in Mittelwihr and Trimbach in Ribeauvillé). Many of the producers of fruit spirit in Alsace also make a certain amount of liqueurs (Section 3.9.2). Notable distillers include Jacobert (Colmar), Massenez (Dieffenbach-au-Val), Meyblum (Albé), Miclo (Lapoutroie) Nusbaumer (Steige) and Sainte-Odile (Obernai).

The most famous of the Alsace fruit spirits is Kirsch. Fresh cherries are crushed and fermented on some or all of their stones and then left for a while in contact with the stones before distillation. The stone contact gives rise to the 'almond' flavor common to all Kirsch.

In Germany and Switzerland, Kirsch (sometimes called Kirschwasser) is also the most widely produced and is a most popular fruit spirit. It is made in much the same way as the Alsace spirit, the treatment regarding the cherry stones varying from distiller to distiller. In the Black Forest area, clear spirits of the Wasser type are made from cherries (both wild and cultivated), pears (e.g. Williams-Birne), blue plums (Zwetschenwasser) and yellow plums (Mirabelle) by pulp fermentation, followed by distillation by distillers such as Elztalbrennerei (G. Weis), Kammer, Schladerer and Sutterer. Generally, around 8–10 kg of these fruits are required to produce a single bottle of spirit. Spirits of the Geist type are also made, by steeping soft

fruit, such as raspberries, in neutral agricultural alcohol for a few weeks, and then distilling. Himbeerengeist (from raspberries) is a typical example of this type.

In Switzerland, the majority of fruit spirit distillers are to be found in the central northern part of the country, especially in the area surrounding the towns of Luzern and Zug. The latter is the home of Etter, one of the best known of all producers of fruit spirits, making (apart from the usual range) Apfel Gravenstein (Pomme Gravin) and Birnenquitte, a spirit made from pear-quince wine. Other distillers include Fassbind of Oberarth making Kirsch, Pfümli (plum spirit) and Williams-Birne spirits.

German and Swiss fruit spirits are usually made by distilling the wine or macerate in batch column stills (rather than pure alembics as used in Cognac, Calvados du Pays d'Auge and Lorraine), which are typically copper pot stills with a dephlegmator (a partial condenser) attached at the stillhead (see Section 3.1.2), and with an enrichment section between the still and the condenser. The enrichment section usually consists of three or more bubble plates to control reflux and a dephlegmator that takes water from the top of the main condenser. Some systems also have a catalytic converter or cyan catalyst (a cylinder packed with copper of high surface area) between the enrichment system and the condenser. The purpose of this is to catalyze reaction between ethanol and any cyanide containing components in the vapor to produce ethyl carbamate (EC) (Section 5.11.5), so improving its separation from the heart cuts. Such distillation systems allow the distiller considerable control over the distillation process, which in Germany and Switzerland is used to give a lighter, cleaner spirit, but at the same time one that contains essential congeners to capture the fruit character. Usually two trays are used during distillation (three would give the lightest spirit:highest in ethanol concentration and lowest in congener levels), but if a catalytic converter is also used it acts as a third tray (Claus and Berglund, 2005). This had the effect of reducing *iso*amyl alcohol and 1-propanol congener levels and increasing the levels of ethyl acetate and methanol, whereas there was little effect on acetaldehyde concentrations, in the production of cherry spirit (Claus and Berglund, 2005).

Maturation is generally carried out in glass or earthenware, but sometimes, as in Alsace, in ashwood casks. Like oak casks, the latter allow a certain amount of controlled oxidation (due to slow ingress of oxygen) and the leeching of a certain amount of phenolic compounds into the spirit, but unlike oak casks (especially new, toasted casks), there is virtually no color extracted from the wood, so that spirits matured this way are essentially colorless.

The widespread practice of including stones in the manufacture of cherry and plum spirits, although claiming to give a higher concentration of congeners, some of which provide 'bitter almond' character (which is popular), may also lead to the formation of compounds that present health risks. The compounds of greatest concern are ethyl carbamate (EC – see Section 5.11.5) and hydrogen cyanide. The former may be formed during distillation, when prunasin (in the flesh) and amygdalin (in the stones) (see Figure 5.11.4, in Section 5.11.5) are subjected to heat. They decompose first to mandelonitrile, whence that compound is hydrolyzed to benzaldehyde (responsible for 'bitter almond' character) and HCN. Some of the latter may then react with ethanol to produce EC, although another possible source is urea, which is formed from arginine by some yeast strains during fermentation. Recently Schehl *et al.* (2005) have studied the influence of yeast strain and the inclusion of fruit stones on the organoleptic character, sensory analysis and EC/HCN levels in cherry and plum spirit, using a batch column still. The identity of yeast strain used (a commercial strain CGC62 and a laboratory strain HHD1) made only minor differences to the flavor profiles and little difference in quality (as perceived in the sensory analyses). The levels of EC and HCN in the spirit were similar for each strain, but generally somewhat lower when fruit without stones were fermented. Interestingly, plum stones when fermented alone with Uvaferm yeast gave the highest levels of EC and HCN in the resulting spirit. Also of interest was the observation that, although the panel tasters could detect the differences between spirits from whole mashes (with stones present) and destoned fruit mashes, there was no overall preference, indicating that qualities added by the presence of stones during fermentation are largely a matter of personal taste, rather than a matter of quality difference.

3.8.4 Plum Spirits of Eastern Europe

The Slavic countries of central and eastern Europe have long specialized in the production of colorless plum spirits, usually known as slivovitz. The spirits are generally considered to have originated in the Balkan Peninsular in one of the states of former Yugoslavia, although some authors maintain they were first distilled further northwest in Slovakia. Today, slivovitz is made in all of the former Yugoslavian states, the Czech Republic, Hungary, Poland, Romania and Slovakia, and its equivalent is produced in many other countries in Europe (as discussed in Section 3.8.3) and elsewhere (see below).

Slivovitz is generally made from local cultivated blue plum (*Prunus domestica* L.) varieties, where it is recognized that fresh, good quality fruit of high sugar content produce the best spirit. The plums are crushed with about 15% of the stones being cracked and then fermented on the pulp by natural fermentation (as in some artisanal distilleries) or by inoculation with a yeast culture (as in most industrial distilleries). At the end of fermentation, the mash is usually distilled using a batch column system, (Section 3.1.2) where fractionation (often using a rectifier with four trays or plates) is used to separate heads and tails from the heart fraction and to increase the ethanol content of the latter to 60–75% (v:v). Some artisanal distillers use simple pot stills, with no rectification column, although sometimes with an air dephlegmator above the still. The heart fraction is generally matured in oak casks for 2–5 years and is usually diluted with distilled water to 45–50% ABV before bottling and sale, but 'cask strength' examples exist, with alcohol contents in excess of ∼65–75% (v:v) (Satora and Tuszyński, 2008). As with other spirits, chill filtration may or may not be practiced prior to bottling.

Slivovitz, like any other fruit spirit, varies in aroma profile depending on the mode of fermentation (natural versus inoculation: Satora and Tuszyński, 2005; 2008), distillation process (Tešević *et al.*, 2005) and ageing process (duration, type of oak and size of cask: Tešević *et al.*, 2005). Within the European Union (EU), the levels of methanol and hydrogen cyanide in plum spirits should not exceed 1200 mg/l and 100 mg/l (respectively) for 100% ethanol (EEC, 1989). In the USA, the maximum level of methanol is 700 mg/l for absolute ethanol, meaning that a distilled beverage of 40% ABV should have no more that 280 mg/l of methanol. The maximum allowable level of ethyl carbamate in fruit has not been established by the EU, but most countries use 400 mg/l, the maximum level recommended by Canada and the USA.

An earlier work on the volatile components of industrial and homemade or artisanal Yugoslav slivovitz (Filajdić and Djuković, 1973), using packed column gas chromatography was able to identify and quantify 23 esters and 21 carboxylic acids, as well as a number of higher alcohols. Seventeen carbonyl compounds were also identified. The methanol contents varied enormously, between 300 and 4390 mg/l, being generally higher for the homemade samples. Variation of other components was not so wide, the samples generally having concentrations of 1-propanol, 2-methyl-1-propanol, 1-butanol, 2-methyl-1-butanol and 3-methyl-1-butanol of 400, 190, 50, 100 and 280 mg/l, respectively. The brandies also had ∼500mg/l of ethyl acetate, 30 mg/l of acetaldehyde and 1500 mg/l of carboxylic acids, of which ∼90% was acetic acid. Artisanal samples generally had lower acetic acid contents than commercial samples.

More recent analysis of the volatile components of old slivovitz samples (again homemade and industrial), by continuous dichloromethane extraction followed by GC/MS, allowed the identification of 99 compounds (Tešević *et al.*, 2005). The oldest spirit (an industrial sample) had higher concentrations of some components, such as benzaldehyde, benzyl alcohol, ethyl benzoate, ethyl salicylate, ethyl cinnamate and 2-phenylethanol. Eugenol was found in all the samples, but α-pinene and β-myrcene were found only in the oldest brandy. Sensory analysis by experts showed high scores for all the brandies, but with a significant preference for the oldest one, which had been distilled in a 300 l still fitted with a rectifying column with four trays, whereas the artisanal spirits came from either simple smaller pot stills or a pot still fitted with an air dephlegmator. Also, the oldest spirit was aged in the smallest oak casks (∼500 l) of *Quercus petreae* L. wood (*Q. sessiliflora*), as opposed to *Q. pedunculata* (*Q. robur*).

Śliwowica Łącka is a traditional Polish plum spirit made by artisanal distillers in the area around Łącko, in mountainous country near the Czech border. It is made by natural fermentation of local blue Węgierka Zwykła plums. Comparison of the aroma profiles of Śliwowica Łącka samples and commercial slivovitz samples from Poland, Romania and Slovakia (Satora and Tuszyński, 2008) indicated generally higher levels of methanol (up to 8740 mg/l), 1-propanol (up to 1516 mg/l) and 1-butanol (up to 335 mg/l), and lower levels of 2-butanol (up to 491 mg/l), 1-pentanol (up to 15 mg/l) and 2-phenylethanol (up to 68 mg/l). The figures all relate to 100% ABV. In particular, the amyl alcohols:1-propanol ratio was close to unity for Śliwowica Łącka and closer to 2 for the commercial samples, except the Romanian sample, which had the lowest ratio of all (0.72). This ratio was suggested as a marker to distinguish between plum spirits produced by natural fermentation and those made by cultured yeast fermentation. The acetic acid contents of the samples in this study (14–625 mg/l 100%) were much lower than those reported in an earlier study (Filajdić and Djuković, 1973) on Yugoslavian plum spirits (550–3220 mg/l 100% for artisanal samples and 650–4670 mg.l 100% for industrial samples) and were more in line with other European fruit spirits. Hydrogen cyanide levels (0.67–5.91 mg/l 100%) were well below the EU maximum allowed limit (100 mg/l 100%). Cluster analysis of the chemical composition of the plum brandies clearly differentiated Śliwowica Łącka spirits from the others, suggesting that fermentation methods may play an important role in determining flavor profile, along with plum variety and distillation techniques. Sensory analysis generally favored the commercial foreign samples over the Polish samples and it may be significant that the top scorer (the Slovakian slivovica) and the bottom scorer (the Polish commercial śliwowica) had (respectively) the lowest and highest levels of acetaldehyde and amyl alcohols, with the artisanal spirits having intermediate values.

The yeast microbiota conducting fermentation of Węgierka Zwykła plums in the production of Śliwowica Łącka are diverse, originating from both plant material and distillery equipment (Satora and Tuszyński, 2005). As with wine fermentations (Section 2.2.4), *Kloeckera apiculata* and *Candida pulcherrima* dominate the first 48 h of fermentation, reaching a population of 1.4×10^6 cfu/ml. After this, the ethanol level kills off these species and fermentation is rapidly taken over by 14 *Saccharomyces cerevisiae* strains that changed quantitatively and qualitatively throughout the fermentation period. The ones that dominated the end of the fermentation (~30 days) were those with greatest killer toxin resistance.

3.8.5 Other Fruit Spirits

Fruit spirits are made by both industrial and artisanal distillers in many other European locations, including Austria (e.g. Brennerei Franz Bauer), Hungary (e.g. Pecsetes Distillery) and Saxony (e.g. Augustus Rex Erste Dresdner Spezialitäten Brennerei). Many of these spirits are produced from fruit wine or distilled macerated fruit by methods and from kinds of fruit already discussed in Sections 3.8.2–3.8.4 and are generally available outside the region of production. Others, described next, are either well known local spirits produced by artisanal distillers and are worth considering for standardizing and scaling up for greater distribution, or are novel spirits made from an overproduction of certain fruit in order to cut waste and provide a profitable sideline.

In Greece, a fruit spirit known as 'mouro' or 'mournoraki' (Crete) is made from black mulberry (*Morus nigra* L.) by artisanal distillers (Soufleros *et al.*, 2004). The ripe fruits (with a natural sugar content of (9–22.5% dry weight) are collected and fermented naturally, sometimes with the addition of a little pure water. The pomace is double distilled in copper pot stills, often of 130 l capacity, whence the spirit is usually offered for consumption at 35–45% ABV. Allowing for a wide variation in flavor profiles (typical of artisanal products), concentrations of acetaldehyde, ethyl acetate, ethyl lactate and methanol (which can be detrimental to spirit quality at high levels) were either below official limits or qualitative odor threshold limits (Soufleros

et al., 2004). On the other hand, high levels of aroma/flavor beneficial higher alcohols (total > 1400 mg/l; greater than the authorized minimum for spirits in the EU), esters such as ethyl octanoate (∼13 mg/l) and ethyl decanoate (∼14 mg/l), as well as 2-phenylethanol (trace-127 mg/l) gave the spirits agreeable organoleptic character. If greater attention is paid to the distillation process and maturation, giving more quality control and leading to greater consistency, it was felt that mouro may gain greater overall fame.

There is considerable interest in Spain on producing spirits and liqueurs (Section 3.9.2) from an over-production of melons (especially in the Castilla-La Mancha region), thereby reducing waste and providing an additional valuable outlet. Hernández Gómez *et al.* (2005) investigated the production of melon spirit on a semi-pilot scale using cultured yeast inoculation to ferment either melon juice, paste (without skin) or skins/paste (each pH adjusted or unadjusted) and distilling the wine firstly in an alquitara (reflux still) and then in an alembic still. The paste distillates had higher levels of ethyl butyrate than the others, a component that adversely influences the organoleptic character of spirits. This could explain the rejection of the paste distillates on the basis of sensory analysis. The other melon spirits, derived from juice and skins/paste were not well differentiated by sensory analysis (there was a slight preference for pH unadjusted skins/paste spirit). In a comparison of the volatile components of melon spirits (from juice and skins/paste) with those of commercial fruit spirits (cherry, pear and raspberry) and pomace spirits (grappa and orujo), it was observed that fusel alcohol levels were slightly higher in melon spirits, pear spirit and grappa, methanol content was lowest in melon spirits, 1-propanol levels were higher in melon spirits and pomace spirits and the ethyl acetate contents of melon spirits were the highest. Organoleptically, the juice and skins/paste spirits compared favorably with commercial spirits, although from a commercial viewpoint, the skins/paste substrate was considered preferable, because it gives less waste and does not need to be pressed prior to fermentation/distillation.

3.9

Liqueurs and Their Flavorings

Each and every liqueur, in his opinion, corresponded in taste with the sound of a particular instrument. Dry curaçao, for instance, was like the clarinet with its piercing, velvety note; kümmel like the oboe with its sonorous, nasal timbre; crème de menthe and anisette like the flute, at once sweet and tart, soft and shrill.

—J.K. Huysmans

3.9.1 Introduction and Scope

For the purposes of this book, liqueurs are defined as alcoholic beverages with alcohol contents from as little as 15% to over 40% (v:v) and with sugar contents of at least 10% (w:v). Although this is a good working definition, like many definitions concerning alcoholic beverages, it has a certain amount of arbitrariness attached to it and authors do not always agree where the dividing line is between liqueurs and apéritifs (Sections 3.5.5 and 3.5.6) and bitters, for example. Some authors even describe distilled fruit wines (fruit spirits or *eau de vie de fruits*) (Chapter 3.8) as liqueurs.

In practice, the alcohol in liqueurs is derived entirely from distilled spirits and their sweetness is derived partly or entirely from added sugar (or honey), a fact that sets liqueurs apart from sweet, alcoholic wines, such as the liqueur Muscat and Tokay wines of Australia (Section 2.10.9), where some (if only a little in some cases) of the final alcohol content comes from fermentation of the must, but which never have added sugar. Similarly the French vins de liqueurs (Section 2.10.10): although all their alcohol comes from added spirits, their sugar is all derived from the grapes.

There are two basic ways of making liqueurs:

- By mixing of an infused or macerated flavor base (extract) with sweetened distilled spirit(s) and water. Sometimes these two steps are combined: the flavor base is directly macerated with the sweetened spirit(s)
- By maceration of a flavor base with distilled spirit, followed by distillation and mixing of the distillate with sweetened distilled spirit(s) and water
- In either case, additional flavorings, colorants or other additives can be added at the final compounding stage.

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass

The flavor bases can be fruits, vegetables, flowers, roots, kernels, nuts, beans, herbs, leaves, barks, powdered spices, fruit concentrates, essences, distillates, nature identical flavorings or artificial flavorings, or mixtures of these (Clutton, 2003; Zach, 2007). The spirit can be any single spirit (e.g. grain neutral spirit, brandy, eau de vie de fruit, gin, marc, rum or whisky/whiskey) or a mixture of two or more spirits. The spirit component(s) are sometimes chosen to match the flavoring (e.g. Kirschwasser used to make a cherry liqueur) (Section 3.9.2), although often a grain neutral spirit predominates to allow for maximum expression of the flavorings (Section 3.9.4). Spirit distillates (e.g. minimally aged undiluted or cask strength brandy of *ca.* 60% ABV, or rum of *ca.* 75% ABV) tend to be used to make liqueurs, but some liqueurs are made using more mature spirits for additional flavor. The sweetening agent is usually sugar syrup, but glucose syrup can also be used and some liqueurs are sweetened with honey.

In reality, because liqueurs are essentially flavored, sweetened spirits, there is almost no limit to the number of recipes that can be concocted, and indeed there are a great many commercial liqueurs of a similar type, but whose individual characters vary according the composition of their flavor bases, their sweetness, their spirit(s) components and their methods of production. Thus there are many brands of cherry liqueur (often known confusingly as cherry brandy) – Bols, De Kuyper, Heering etc., but they are all made by carefully guarded recipes. The approximate recipes of many liqueurs are known, but it is the minute details of flavoring ingredients, compositions, spirit types and production methods that are kept secret.

The first liqueurs were probably made in Italy in the thriteenth century, as a result of the researches of Arnáu de Vilanova and Raimundo Lulio on the extraction of herbs by alcohol (Lichine, 1982a). Originally, these sweetened, herb flavored spirits were used as remedies for diseases, just like other kinds of herbal preparations at that time. Arnáu and Lulio were the first to write extensively on the production of ethanol by distillation and their recipes for healing liqueurs became widely known throughout Italy. Later, they introduced fruit pulp and skins, flower petals and even particles of gold into recipes for liqueurs (gold in those days was considered a universal panacea for illnesses). Liqueurs became popular throughout the land and by the fifteenth century; Italy was the world's leading producer of liqueurs. The art was then taken to France by Catherine de' Medici at Montpellier, where there was easy access to grapes (for wine and brandy), fruit and herbs, so this city soon became a major center of liqueur production. By this time, liqueurs were being consumed primarily for enjoyment, although their medicinal properties were still much in mind. Indeed, monks of various orders took up the production of liqueurs for medicinal and restorative purposes at an early stage, especially in France. In the main, these liqueurs were consumed originally only by the monks, along with various people who had connections with the monastery, as well as important visitors. Benedictine D.O.M. (*Deo Optimo Maximo*) liqueur was reportedly first formulated around 1510, the recipe being passed on from generation to generation of Benedictine monks at Frécamp (Normandie) until about the time of the French Revolution. The recipe survived and the liqueur is still made by a secular company of that name; there are no longer any religious connections (Lichine 1982b).

Chartreuse was first formulated about 1605 by Carthusian monks at Voirin (France) purely for consumption by the monks, until it became commercialized in 1848 as the result of the efforts of a group of enthusiastic army officers who had tasted it (Lichine, 1982c). The Chartreuse liqueurs are now made at Tarragona, as well as Voirin, due to two expulsions of the Carthusian order from France and its return in 1932.

Nowadays, some of the best liqueurs still come from Italy and France (there are even some with gold particles), although many other countries produce a very wide range of liqueurs from many different flavor and spirit bases.

The aim of this chapter is to discuss a variety of commercial liqueur types, their approximate recipes, their production methods and their flavor ingredients, while at the same time expanding on what has been written in these introductory paragraphs.

3.9.2 Fruit and Fruit Flavored Liqueurs

These beverages are highly popular and constitute a major category of liqueurs. In fruit liqueurs it is the fruit pulp, juice and/or extract that forms the flavor base and these beverages are often simply named after their fruit ingredient: cherry brandy, strawberry liqueur, sloe gin, liqueur de framboises, crème de pêches, to name but a few. More examples can be seen in Table 3.9.1. Depending on the philosophy or commercial expectations of the manufacturer, fruit liqueurs are made with or without a distillation process that involves the flavor base. Also, depending on the country of manufacture's regulations, additives, such as fruit essences, natural or artificial flavorings, colorants and acidulants, can be found in some fruit liqueurs. A general scheme for the production of fruit liqueurs is shown in Figure 3.9.1. Many manufacturers of fruit liqueurs use only the ripest and healthiest fruit, subjecting them to a period in the freezer (at $\sim -20\ ^{\circ}C$) before macerating them in spirit. The freezing process preserves the essential aromas and also helps soften otherwise rather hard stone fruit such as greengages, damsons and sloes, also making the pulp and skins more easily detached from the kernels. The maceration process (with or without kernels) can take several months, even up to one year. In larger, more modernized companies this process is sometimes carried out in slowly rotating stainless steel drums in the absence of oxygen.

Some of the finest fruit liqueurs are produced in France: in Alsace, Burgundy and the Loire Valley, in particular (Table 3.9.1). Notable amongst these is crème de cassis made originally from blackcurrants growing on the Cote d'Or, near Dijon, but now produced in many locations in France. This liqueur is popular as the minor ingredient of a Burgundian aperitif known as kir, the major ingredient being a light white

Table 3.9.1 *Examples of fruit liqueurs and liqueurs of the Curaçao type*

Liqueur type	Examples of brands or companies producing these liqueurs	Comments
Apricot	Giffard (Loire), Maraska (Croatia)	
Banana	Bols (Grune Bananes) (Holland), Giffard	
Bilberry	Boudier (Liqueur de Myrtilles) (Burgundy)	
Blackberry	Boudier, Chambord[1] (Loire), Combier (Loire), Marchand (Burgundy), Marie Brizard (France), Nusbaumer (Alsace), Tremontis (Italy), Védrenne (Burgundy)	[1] Contains a number of other components
Blackcurrant (Créme de Cassis)	Bols, Boudier, Giffard, Massenez (Alsace), Védrenne	
Cherry	Bols[1], De Kuyper (Holland), Heering (Denmark), Luxardo (Italy)[1], Marnier (France), Maraska	[1] Make both red (infused) and clear (distilled) types
Peach	Boudier, Combier, La Gina (Italy), Marie Brizard, Massenez, Védrenne	
Pear	Boudier	
Raspberry	Boudier, Schladerer (Germany)	
Strawberry	Boudier, Védrenne	
Curacao style and citrus peel	Alize (France), Arancello (Italy)[1], Bols[2], Cointreau (Loire), Grand Marnier, Marie Brizard, Materdomini (Italy)[3], Senior[4]	[1] Orange liqueur [2] This company also makes a blue liqueur [3] Made with lemon peel [4] Made with laraha

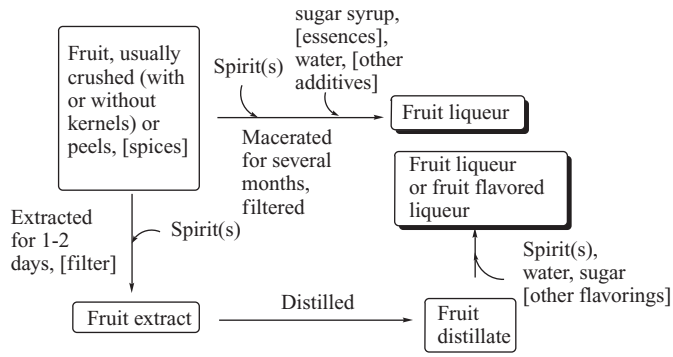

Figure 3.9.1 *General scheme for fruit liqueur and fruit flavored liqueur production. Optional ingredients are in square brackets. Water is distilled or deionized. Based on Zachs (2007).*

Burgundy wine, usually an Aligoté. The apéritif is named after Canon Félix Kir, a leader of the French resistance in Lyon during the Second World War, and a former mayor of Dijon.

Cherry liqueurs, often called cherry brandy if brandy is the spirit base, are amongst the most popular of fruit liqueurs. They are usually made with more flavorful bitter/sour varieties of cherries, such as Morello (as with Cherry Marnier) or Maraschino (as with Luxardo Maraschino and Maraska Maraschino). The liqueurs are usually bright red because of the long maceration time in spirit, but there are also some colorless versions produced by distillation of alcoholic cherry extract, followed by sweetening and dilution to the required alcoholic strength before bottling. Examples of these include the two mentioned above, plus Bols Kirsch liqueur – not to be confused with the eau de vie de fruit, Kirsch, which is unsweetened (Section 3.8.3).

The Asian countries of China, Japan and Korea make many beverages from fruit, particularly blackberry (black raspberry), green or yellow plums and raspberry. Although some of these beverages are fermented and hence fall into the category of fruit wines (Chapter 2.11), the majority of them are made like liqueurs, by macerating fruit in (usually) sweetened rice spirit (soju: see Section 3.4.4) and then filtering before bottling. Their ethanol content is usually around 16% (v:v) (but can be higher), so they are often used to accompany meals, as wines accompany meals in European countries.

Korea has a number of traditional fruit 'wines', produced by combining fruits or berries with alcohol For example, podoju (포도주) is made from soju that is mixed with grapes and sugar. The most popular fruit wines are made from green plums (maeshil), Korean black raspberries (bokbunja, 복분자), Chinese quinces, cherries, pine fruits, mulberries and pomegranates. Bokbunjaju (복분자주, bokbunja wine) is said by many to be especially good for sexual stamina (although many drinks and foods in Korea make this claim!). A particularly popular Korean fruit liqueur known as maeshilju, is made from maeshil, a small greengage-like plum that is gathered hard and unripe in May/June. Maeshilju has a pronounced gage-like flavor overlaid with an almond flavor from the kernels, and some versions of this beverage are sold wide necked bottles containing one or more fruits at the bottom.

Japanese plum wine is essentially a sweetened spirit (shochu – see Section 3.4.4) flavored with partially ripened 'Japanese apricot,' a blue plum containing much acid (citric and malic acids) and minerals. It improves the appetite and aids digestion and is said, like maeshilju of Korea, to be a good restorative with anti-aging properties that help the drinker keep a clear skin.

Sloe gin is a popular liqueur in England and Europe. It is made from the small bitter/sour black fruit of the wild blackthorn tree (*Prunus spinosa*). Traditionally, it was not made until November, after the first frosts of winter, because these have the effect of softening the otherwise hard fruit and hence easing the maceration

process. Nowadays, the fruit is often gathered before the first frosts and kept in the deep freezer until required. The thawed fruit is then bruised and added to sweetened gin at the rate of 450 kg of fruit to 730 l of gin and 200 kg of sugar, to give about 730 l of liqueur. Brandy can be used in place of gin, to give sloe brandy. The mixture is agitated at regular intervals while left to macerate for about three months, after which time it is filtered, adjusted if necessary and bottled. Blanched almonds (30 kg) can also be included in the recipe, and bullaces (yellow wild plums), damsons or greengages can be used in place of sloes.

The production of distilled spirits (or even industrial alcohol) or liqueurs is sometimes used as a cost effective way of using surplus agricultural produce (as in the wine industry, making spirit from excess wine) or commercial process waste (as in the wine and cider industries, making pomace spirits from pressed grape or apple mass). Melon (*Cucumis melo* L.) fruits are produced in large quantities in many warm climate countries, including Mediterranean countries. Consequently, there has been interest in converting excess fruit to a melon distillate and this has been carried out on a pilot scale in Spain (Section 3.8.5) (Hernández Gómez *et al.*, 2005). Further interest has been shown in using melon distillate as a base for a melon liqueur, bearing in mind the general overall popularity of liqueurs. Investigation of maceration of melon pieces, seeds and placenta in melon spirit, showed that, by analysis of color and aroma, as well as sensory analysis, seeds and placenta were more suitable than melon pieces. Apart from the above reasons, liqueur made with seeds and placenta only was more viable because of lower production costs, less waste and easier filtration (Hernández Gómez *et al.*, 2009). The total volatile component content, based on acetaldehyde, ethyl acetate, ethyl butyrate, ethyl lactate, methanol, 2-methyl-1-butanol, 3-methyl-1-butanol, 2-methyl-1-propanol and 1-propanol was highest for melon spirit macerated with seeds and placenta at 0.28 kg/l. The liqueur (with alcohol content 28% (v:v) and sugar content 100 g/l) made from this scored highest in sensory tests.

Fruit flavored liqueurs are made using natural and/or nature identical flavorings, the former usually as distillates or extracts (Section 3.9.6) (Figure 3.9.1). Liqueurs of this type can be made from stone fruits, such as apricots and peaches, but probably the best known and most popular types are the Curaçao liqueurs, involving citrus peel as the major flavor base. These liqueurs were originally made from oranges growing on the Dutch colonial island of Curaçao in the Caribbean Sea. The orange trees, known as lahara (*Aurantium currassuviensis*) and descended from the 'Valencia orange tree,' were introduced by the original Spanish explorers in the fifteenth and sixteenth centuries. Very little Curaçao liqueur is now made from lahara (see Table 3.9.1), other citrus fruit (especially bitter oranges from tropical islands like Haïti or from Spain) or extracts and essences being used instead. Nowadays, there are many brands of Curaçao made by many companies, but the best known are probably Cointreau and Grand Marnier. Further examples can be found in Table 3.9.1. A general scheme for the production of a Curaçao style liqueur can be seen in Figure 3.9.2; detailed recipes can be found in Zachs (2007).

Another well known orange liqueur is the South African Van der Hum, produced using the peel of the nartjie, a local orange, and a number of other ingredients that are closely guarded secrets.

Limoncello is a related Italian liqueur based on lemon. Its manufacture commonly involves maceration of lemon peels in 95% ethanol for a week or so, after which the filtered extract (without distillation) is diluted with sugar syrup to give a final product of ~32% ABV. In the European Union, addition of natural or synthetic flavors or essential oils to limoncello is regulated by Council regulation No. 1576 (EC 1989), as for other spirit beverages.

Limoncellos have been characterized by the presence of selected volatile compounds (mainly alcohols, aldehydes and terpenoids) and nonvolatile compounds (acids, coumarins, phenolic compounds, psoralens and sugars) (Andrea *et al.*, 2003). α-Pinene, myrcene, *trans*-β-bergamottene and β-bisabolene were the most characteristic of terpenoids of limoncellos made using lemon peel maceration. Likewise, the presence of coumarins and psoralens (Figure 3.9.3) gave a likely indication of the use of macerated lemon peels, since these are absent from essential lemon oil produced by steam distillation. Limoncello made using essential oils only can thus be distinguished from the genuine article.

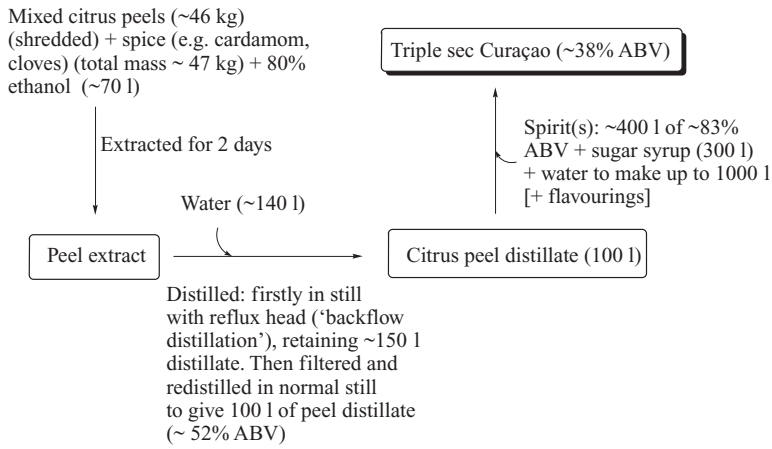

Figure 3.9.2 *General scheme for the production of a Curaçao style liqueur. Distilled or demineralized water is normally used. Optional ingredients are in square brackets. Based on Zachs (2007)*

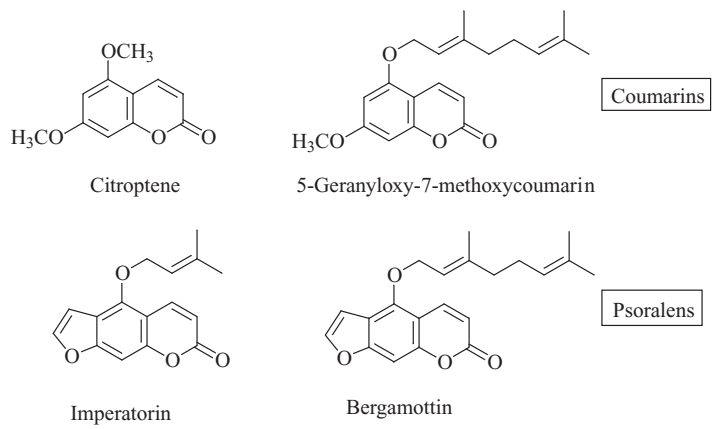

Figure 3.9.3 *Characterstic coumarins and psoralens in authentic limoncello liqueur. Andrea et al. (2003).*

3.9.3 Flower, Herb, Spice and Bitter Liqueurs

This very large and diverse family of liqueurs involves the use of botanicals, natural essential oils and natural essences as the flavor bases. The earliest recorded liqueurs (see Section 3.9.1) were of this type, produced for medicinal purposes in Italy in the thirteenth century. Today, Italy still produces some of the best versions. In time, the manufacture of herbal liqueurs in monasteries spread throughout Europe, the carefully preserved and guarded recipes being handed down from generation to generation of monks over many centuries. In many cases (e.g. Benedictine), the monks' original herbal/spice recipes are still used in the extraction processes used to make modern versions of the liqueurs.

The range of botanicals used in liqueurs is very wide, as in the case of vermouths and other aromatized wines (Sections 2.12.2 and 2.12.3). They can be subdivided into a number of categories that depend on

the flavor, taste or mouthfeel sensation contributed to the liqueur. These are listed next, with a number of examples of each:

- *Herbal botanicals*. Usually leaves, stems, sometimes flowers. Artemesia (e.g. mugwort, wormwood), basil, camomile, hyssop, lemon balm, mint (many varieties), saffron, sage, thyme, woodruff
- *Spice botanicals*. Usually bark, buds, roots or seeds. Ambrette, angelica, cardamom, caraway, celery (seed), cinnamon, cloves, coriander, ginger, mace, turmeric
- *Bitter botanicals*. Usually roots, sometimes stems or flowers. Elecampane, dandelion, gentian, orris, thistle
- *Saponin botanicals*. Usually bark. Cascarilla, Cinchona, quillaja
- *Tannin botanicals*. Bark, oak
- *Flower (glycoside) botanicals*. Elderflower, heather, lime tree flower, orange flower, rose
- *Essential oil botanicals*. Citrus peel
- *Miscellaneous botanicals*. Nuts (e.g. almonds, hazelnut and walnut: they supply oils as well as flavor), beans (e.g. cocoa, coffee, vanilla), mucilaginous botanicals (e.g. fenugreek seeds), silicic acid botanicals (e.g. corn horsetail).

Many of these materials will also contribute to the color of the final liqueur; for example, green if the leaf content is high and an extract rather than a distillate is used to make the liqueur (see next), or yellow if saffron flower extract is added to the mixture of colorless spirit(s), syrup and botanical distillate.

One method for producing herbal type liqueurs involves the preparation of a botanical extract and then mixing this with a mixture of spirit, sugar syrup (or honey) and, in some cases, specific extracts or additives. The botanicals are extracted in ethanol/water for a number of days, after which time the extract is decanted off the debris, stored at low temperatures to effect precipitation of finely suspended matter, after which it is chill filtered before use. A quantity of the herbal extract is mixed with spirit, water and sugar syrup and, since grain neutral spirits are often used in both the extract and the spirit/syrup mixture, the color of the final liqueur will be determined by that of the botanical extract, unless permitted colorants are added.

A more common method involves several days maceration in neutral spirits/water, followed by single pot still distillation to give a herbal distillate of around 65% ABV. This is then mixed with spirit(s)/sugar syrup/water. Additives and colorants (e.g. saffron extract to give a deep yellow color) can also be added at this time if required. Grain neutral spirit is always used for the preparation of the herbal distillate, but brandy, rum or whisky distillates (or mixtures) may be used in place of or as well as neutral spirit in the final compounding of the liqueur.

There are many variations of the above two methods, particularly with regard to the herbal extract or distillate. Some recipes call for both extract and distillate of the same botanical mixture (see Figure 3.9.4), others (e.g. Chartreuse) require the compounding of a number of different botanical distillates, and there are various ways in which the distillation or extraction may be carried out (Section 3.9.6). Additionally, some recipes make use of specific essences or concentrates (e.g. elecampane root extract) at the final compounding stage (Figure 3.9.4). These, like elecampane extract (from *Inula helenium* or horse-heal) (Section 5.11.2), are used to add specific flavors or bitterness, while others such as saffron are added primarily for color. Interestingly, various components of *I. helenium* roots have been found to have antimicrobial activity (Stojakowska *et al.*, 2005) and *in vitro* anticancer activity (Chen *et al.*, 2007). Although there is no direct proof that the presence of these components in liqueurs has any beneficial effects, it should be remembered that liqueurs were originally formulated as medicines and extracts of *I. helenium* and many other herbs used in liqueurs have been used in European and Asian folk medicine for centuries.

Most herb liqueurs are made from a large number of herbs and spices, using secret recipes, although a few of the main components are known or can be guessed in some cases. Probably the best known are Bénédictine, Chartreuse, Galliano, Jägermeister and Strega. The first mentioned claims to be made from only 27 botanicals,

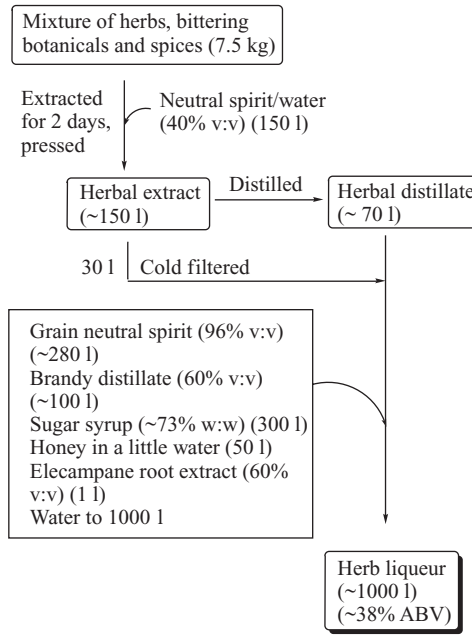

Figure 3.9.4 *Scheme for the production of a monastery type herb liqueur. Based on Zachs (2007).*

as opposed to over 130 for Chartreuse. Nevertheless, neither liqueur has been successfully recreated by competitors or copied by counterfeiters. The standard ethanol content of these liqueurs is around 43% (v:v), but Green Chartreuse has 55% ABV and the Elixir Végétal de la Grande-Charteuse has an exceptional alcohol content of 71% (v:v). Galliano is a bright yellow liqueur made in Italy that contains anise, citrus, ginger, star anise and vanilla, amongst other botanicals; it is the base ingredient of Harvey Wallbanger type cocktails. Its color is provided by tartrazine, in contrast to Strega, another Italian herb liqueur, whose golden color is derived from saffron. Mint and fennel are the major botanical contributors to the flavor of Strega.

Other examples of multiple herb liqueurs include Aiguebelle (France), Angelica (Pays Basques), Bärenfang or Bärenjäger (Germany), Becherovka (Czech Republic), Drambuie (Scotland), Fior D'Alpe (Italy), Glayva (Scotland), Izzara (Pays Basques), Krupnikas (Lithuania), Trappistine (Doubs, France; based on Armagnac), Unicum (Hungary) and Vieille Curé (Cenons, France), to which can be added Amaretto (Italy) and Crème de Noyaux (France and other countries). The last two are sometimes described as almond liqueurs, relating to their dominant flavor of bitter almonds, but this flavor comes from apricot kernel oil or apricot kernel distillate rather than almonds and both contain other botanicals. Honey, rather than (or as well as) sugar syrup is used to sweeten several of these liqueurs: Bärenfang, Drambuie, Glayva and Krupnikas. The first and last named are made using grain neutral spirit or vodka and nectar honey: Bärenfang varies between manufacturers, but is often flavored with few botanicals, including carnation flowers and vanilla pods; Krupnikas is made with clover honey and a greater number of herbal botanicals. Drambuie and Glayva, on the other hand are made with aged Scotch whisky and heather honey, the former having anise, nutmeg and saffron in its botanical make up as well as herbs, the latter having anise, cloves, herbs, citrus peel and almonds. More recent additions to this category of liqueurs include Lochan Ora (Pernod Ricard) made with a base of Scotch whisky and Irish Mist (C&C Group plc) made with Irish whiskey.

Relatively few herb liqueurs are made of just one or a small number of strongly flavored herbs or spices. The foremost example is Crème de Menthe. It is made all over the world, ideally from Corsican mint. The

simplest method involves mixing mint essence with grain neutral spirit (or vodka), sugar syrup, water and a green colorant if a green color is required. Usually, better green versions of this liqueur are produced by macerating mint leaves in neutral spirit/water for several weeks, filtering, and then adding sugar syrup and water to adjust sweetness/alcoholic strength. Alternatively, the mint extract can be distilled and the mint distillate mixed with spirit/sugar syrup/water to produce a clear ('white') Crème de Menthe.

Other examples of single herb or spice dominated liqueurs include the aniseed liqueurs Anisette, Sambuca and Sassolino (both Italian), using star anise as the major flavor ingredient and Kümmel, with caraway as the major flavorings. Kümmel is popular in northern Europe (especially the Baltic countries) and Russia. It is often made by distilling grain spirit over caraway seeds and then diluting to strength (~40% ABV) by adding sugar syrup. In some cases, (Kümmel Crystallize), sugar is allowed to crystallize in the bottle. Sambuca also uses other herbs, including elderflower essence (for the white version) and elderberry extract (for the black version). The Greek liqueurs Tentura and Zamoura, made by distillers such as Chris and Polykala, are dominated by cinnamon/clove flavors, although they may have other botanicals, such as nutmeg and citrus peel, in their recipes. A more recent addition to this group of liqueurs, with a dominant cinnamon flavor, is After Shock from Canada.

Certain herb liqueurs are about the only liqueurs to undergo some aging in cask, the prime example being Chartreuse, especially the version known as VEP – Vieillissement Exceptionnellement Prolongé. Other examples include Bénédictine and Unico.

In Korea, various medicinal alcoholic beverages are made from sweetened spirit and bark, roots or shoots, commercially and at home. For example, ginseng, bamboo shoots, and the root bark of various araliaceous shrubs are soaked in sweetened soju (>35%) (Section 3.4.4) and aged, usually in earthenware pots. The ratio of soju to herbal root is usually 3:1.

Ginseng liqueur is made with ginseng, soju and sugar, after six months aging it becomes suitable to drink. After three years maturation, ginseng liqueur is often a deep golden color and the alcohol aroma becomes subdued, with the unique aroma of ginseng, sweet and slightly earthy/bitter, being dominant. Additionally, jujube (Chinese date) or ginger can be added to the mixture and honey can be used instead of sugar (Jo, 2004).

Korean medicinal liqueurs are known collectively as yagyongju (약용주) (the Korean syllable yak means medicine) and are produced by combining medicinal seeds, herbs, and roots with sweetened soju, although some are made by fermentation and so are more appropriately classed as flavored rice wines (Section 2.7.1). They include Dosoju (도소주 or 屠蘇酒), a popular herbal liqueur, traditionally served only on New Year's Day and Songsunju (송순주 or 松筍酒) made with glutinous rice and soft, immature pine cones or sprouts. Similarly, Ogalpiju (오갈피주) is made from the bark of *Eleutherococcus sessiliflorus* blended with soju and sugar and Jugyeopcheongju (죽엽청주 or 竹葉青酒) is a traditional liquor made with bamboo leaves.

Chuseongju (추성주) is a traditional wine made from glutinous and nonglutinous rice and herbs, including omija (*Schisandra chinensis*) and *Eucommia ulmoides*; it is commercially available in bamboo shaped bottles. Likewise, Daeipsul (대잎술) is another traditional folk wine from South Jeolla Province, made from glutinous rice, brown rice, and bamboo leaves, along with 10 medicinal herbs.

Liqueurs based solely or mainly on flower infusions or macerations are relatively few. The best known is probably Millefiore (Italy), its name implying the use of a thousand (Alpine) flowers and its bottles typically contain a small twig around which sugar has crystallized. Liqueurs made with rose petals include Rosolio (Italy), Rosolis (France) and Roza (Bulgaria).

There are several Korean traditional liqueurs (although they are known as wines in Korea) made from flowers. These include chrysanthemum (gukhwaju, 국화주, marketed by Jinro as Chun Kook), acacia flower, maesil blossom (maehwaju, 梅花酒), peach blossom (dohwaju, 桃花酒), honeysuckle (indongju, 인동주), wild rose and sweet briar petal liqueurs. Dugyeonju (두견주) is a liqueur produced in Chungcheong Province from azalea petals. It is sweet, viscous, and light yellowish brown in color, with a strength of about 21% ABV. Myeoncheon Dugyeonju is protected, being designated by the South Korean government as Important

Intangible Cultural Property No. 86-2. Another variety of flower liqueur, called baekhwaju (백화주 or 白花酒), is made from 100 varieties of flowers, the Korean syllable 'baek' meaning 100.

3.9.4 Cocoa, Coffee and Tea Liqueurs

These liqueurs are made from percolates of the flavor base in neutral spirit:water (30% v:v, typically). The percolate is then filtered and mixed with the spirit(s)/sugar syrup/water mixture, which usually contains vanilla extract or essence, that flavor blending well with cocoa or coffee flavor. Sometimes the coffee percolate will also contain some spice, such as cinnamon or coriander, but this will not be dominant.

Most cocoa liqueurs are simply named Crème de Cacao, although one or two have specific names, such as Liqueur Fogg (Brazil) and Sabra (Israel), a cocoa liqueur flavored with Jaffa orange essence or distillate. Chocolate liqueurs, on the other hand, usually include cream in the recipe and so can be found in Section 3.9.5.

The most famous coffee liqueurs are the Mexican Kahlúa (from Pernod Ricard; and the largest selling liqueur brand in the USA), made from rum, coffee beans, sugar syrup and vanilla, and the Jamaican Tia Maria, made with Blue Mountain coffee beans, vanilla, sugar syrup and cane spirit. There are many other coffee liqueurs (some claiming to be made from freshly brewed coffee), based on a variety of spirit bases, including Kapali Coffee (Mexico), Komora Coffee (Mexico), Oblio Caffe Sambuca (Italy), a liqueur flavored with espresso coffee, anise, fennel and elderflower essence, and Pasha (Turkey).

3.9.5 Nut and Emulsion Liqueurs

Nuts tend to have rather delicate flavors that need careful extraction into ethanol/water. Other flavors, such as vanilla and/or cocoa, are sometimes used in combination and nuts are sometimes used in cream based emulsion liqueurs, again often flavored with cocoa, coffee or mocha. Nut liqueurs include Frangelico, made with hazelnut, cocoa and vanilla, Hazelnut Polykala (Greece), Davis Walnut liqueur (Lurgashall, UK) and Cashew Liqueur (Korea). So called almond liqueurs, such as Amaretto, are actually made from apricot kernels, oil or essence. One potential problem with nut liqueurs is the often large proportion of lipids in the nuts or skins, as with peanuts, whose skins can yield up to 35% of their weight as oil (Sobolev and Cole, 2003). However a palatable liqueur has been made on a laboratory scale from hexane-defatted and dried peanut skins, by adding them ($\sim$ 2% by weight) to a warm alcohol/sugar syrup mixture (of $\sim$40-70% ABV) at 70-90 °C and allowing the mixture to stand overnight (Sobolev and Cole, 2003). The result, after filtration, was a pink peanut flavored liqueur. It was suggested that this may be a way to give some added value to the peanut industry, where 750 000 tons of skins are produced annually, their main use being as a limited ingredient of cattle feed.

The production of dairy cream emulsion liqueurs has rocketed in recent years. These liqueurs depend on the homogenization of dairy cream and sweetened, flavored ethanol/water, using caseinate or other emulsifier, to form a stable liquid with very little or no separation. Flavorings are often chocolate or coffee, but butterscotch, caramel and noisette are also known and more recently, fruit flavorings have been used. Spices (e.g. cinnamon, mint) are also used to flavor many of these liqueurs. Separation of the fatty cream component into a plug of cohesive cream that is difficult to redisperse by mild agitation, is a potential storage hazard associated with these liqueurs. It has been found that cream plug formation during storage can be minimized by ensuring the liqueur has moderate pH and calcium levels, with high levels of sodium caseinate (Dickinson *et al.*, 1989). In experiments with soya oil/aqueous ethanol emulsions stabilized by either sodium caseinate or β-lactoglobulin surfactants, it was found that the kinetics of pH induced aggregation could be explained by

orthokinetic flocculation, whereas ethanol induced aggregation kinetics suggested a mechanism involving Ostwald ripening (Agboola and Dalgleish, 1996).

The best known cream liqueur is Bailey's Irish Cream (Diageo), based on Irish whiskey; it was the first in this field and is one of the most notable market successes in the recent history of distilled spirits. Much more recently, Mussu Crema de Pacharan (Spain) is claimed to be the first cream liqueur made from pacharan, a traditional Spanish liqueur made from sloes soaked in anisette. There is now (2009) a cream based liqueur that contains a variety of flavors, rather than chocolate, coffee or fruit: Voyant Chai Cream (Holland) is composed of aged Virgin Island rum, Dutch spirits, cream, black tea (from India) and herbs (from Asia).

In recent years, milk and yogurt, rather than cream, have been used to make liqueurs. For example, Crème Likier Mleczny (Poland) is made from milk and wodki zoladkowej gorzkiej (bittersweet digestive vodka) and possesses 18% ABV. Chylls Yoghurt Liqueur (Germany) is based on maracuja (passion fruit) liqueur and yogurt.

Advocaat is an egg emulsion liqueur made in the Netherlands from brandy, egg yolk, vanilla, sugar syrup or honey. There are many versions of this liqueur (e.g. those produced by Bols, Cooymans, De Kuyper or Warninks), but they all have around 18% ABV and are frequently used in cocktails such as Bombardier.

One emulsion liqueur based on bananas rather than cream or egg is Licor De Banana Crème (Brazil), made with real bananas (rather than extract or essence) and cane spirit.

3.9.6 Production and Use of Essences and Concentrates

Fruit concentrates, essences, essential oils and extracts are important in the manufacture of liqueurs. Concentrates refer to fruit juices (apricot, cherry, peach, etc.) from which much of the water has been removed by, for example, a ramped low temperature vacuum concentration process (see Section 2.8.6), thus avoiding substantial loss of aroma/flavor compounds. Fruit liqueurs can be made using concentrates as well as fresh fruit (or more likely freshly thawed frozen fruit – see Section 3.9.2), but many liqueur manufacturers, especially smaller companies aiming at a niche market, prefer to use only the latter. Some typical recipes for fruit liqueurs, using both fruit and concentrates, can be found in Zach (2007).

Essences, extracts and essential oils are used to make a wide range of liqueurs. Many liqueur distilleries prefer to use their own formulas, in which case they make an extract of the specific botanicals by infusing them in alcohol/water (Sections 3.9.3 and 3.9.4). This extract can be used as such or can be distilled; in some cases both extract and distillate are used (Figure 3.9.3). However, many liqueur recipes call for the use of essences and essential oils, as well as home produced extracts or distillates. The term essential oil generally refers to a concentrate of aroma compounds from the skins of citrus fruits, whereas essence usually refers to a concentrate of aroma compounds from other botanicals (bark, flowers, leaves, nuts, pods, seeds, etc.), either separate or as mixtures. In practice, however, the two terms are often used interchangeably. Many essential oils and essences are commercially available, including clove essence, essential oil of lemon, essential oil of lime, hop essence (or oil), rose essence (or oil), vanilla essence, violet essence (or oil) and walnut essence.

Essences and essential oils can be made by distillation (including steam distillation for essential oils and vacuum distillation for essences – see Section 3.4.2), soxhlet extraction into ethanol, supercritical fluid extraction, followed by fractionation (as for hop essence – see Section 2.6.3) and the spinning cone column technique. The latter (see Section 2.13.3) is particularly useful in separating volatile compounds from their host materials. It is a (usually heatless) distillation or 'stripping' technique that uses a turbulent counterflow of gas and liquid to give enhanced interphase contact, resulting in efficient extraction. The host materials must be supplied at the top of the column as slurry of finely ground botanicals in ethanol/water.

The soxhlet method (Figure 3.9.5) is a well established continuous extraction technique, in which aroma components of a wide range of solid materials are extracted into ethanol. The solvent is allowed to percolate

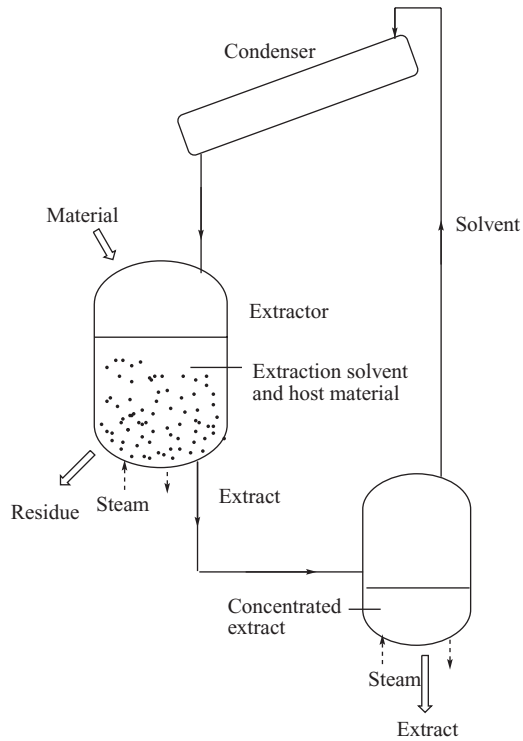

Figure 3.9.5 *Schematic diagram of a Soxhlet extraction device. The extractor vessel will be fitted with a stirrer. Both the extractor and the vapour generator are heated with steam* via *either internal vanes or an external jacket.*

continuously through the ground material, becoming more and more concentrated in flavor components at each pass. Eventually, the concentration of flavor compounds in the solvent vessel will be sufficient and the extraction process is terminated, collecting the concentrated extract solution and discarding the residues.

A more recent technique involved the adsorption of the pear aroma compound ethyl 2,4-decadienoate on granular activated carbon and its consequent solvent desorption, giving a solution 40 times more concentrated than the original (Diban *et al.*, 2008). The authors concluded that this low energy consuming, mild and ecologically friendly method was viable for the concentration of aroma compounds; it is possible that such a method may be used to produce fruit and other concentrates in the food and alcoholic drinks industries.

4.1
Introduction

Analytical science is applied to just about the entire range of aspects associated with the production and consumption of alcoholic beverages. Such methods not only enable producers to maintain a consistent level of quality, but by increasing general knowledge of beverage components and details of biological, chemical and physical processes occurring during manufacture, they can provide the producer with the opportunity to increase the overall quality of his or her products. There is no doubt that the application and development of analytical methods (in research and development, as well as process day to day monitoring) in the alcoholic beverage industry continues to play a crucial role in raising the overall quality of the products.

This chapter reviews the major methods for the analysis of alcoholic beverages and their raw materials, the methods available for the analysis of particular components or physical parameters and the contexts within which such measurements are made. Knowledge of analytical chemistry is assumed at undergraduate level. In particular, it is assumed the reader has a grasp of such concepts as sampling techniques, chemometric methods for the design of experiments, accuracy, recovery, precision, reproducibility, repeatability, robustness, sensitivity, limit of detection, limit of quantification and basic statistical methods for the treatment of results. However, short explanations of some of these terms are given in the Glossary.

Although outline general accounts of important techniques are given in each Chapter (apart from Chapter 4.1) for the sake of background and also to render some perspective to these techniques when applied to the analysis of alcoholic drinks and their raw materials, it is simply not feasible in a book of this kind to give detailed theory. Instead, at relevant points, the reader is referred to a selection of many excellent textbooks in analytical chemistry, chromatography, electrochemistry and spectroscopy.

Chapter 4.1 is meant to serve as a general background to Part 4 and is also a summary of the applications of analytical methods to a variety of aspects relating to alcoholic beverages. Some of the major uses and benefits of the analytical methods applied to alcoholic drinks described later are put into a more general context in Chapter 4.1.

Chapter 4.2 considers the separation and focusing techniques that are necessary for preparing the sample for analysis of very low concentration and trace components. This section also relates how these methods can be linked with specific methods of analysis, particularly chromatographic techniques.

The next chapter discusses the application of chromatographic techniques to the separation, identification and quantification of beverage components. The emphasis is on liquid and gas chromatography and consideration is given to mobile phases, stationary phases, experimental conditions and detector types for particular kinds of analyses. Chapter 4.4 discusses the applications of spectroscopy, where particular

consideration is given to the different methods available for the analysis of particular components or families of components.

Chapter 4.5 relates how electrochemical methods, including miniaturized sensors, can be applied to the analysis of drinks. Electrophoretic methods, techniques using flow injection and physicochemical methods are dealt with in Chapter 4.6, and finally sensory analysis is the subject of Chapter 4.7.

4.1.1 Why Analyze Alcoholic Beverages? An Overview of the Need for Analysis

Understandably, a considerable amount of analysis of alcoholic beverages is commerce driven and is biased toward the elimination of defects and the maximization of quality and therefore of profit. However, there are many more ways in which analysis is being used for the benefit of drinks producers, the general public and the scientific community. The principal areas of contemporary chemical analysis of alcoholic drinks are summarized below, although the reader will realize that there is a certain amount of overlap amongst some of these areas:

- Process monitoring and quality assurance/control. Here, determination of the levels of key components in raw materials, to check whether they are within specification, and regular measurement of specific process parameters are used to maximize quality and consistency of the product.
- Determination of authenticity and identity. Determination of geographical origin (e.g. winegrowing region, etc.), process methods (e.g. pot still versus column still distillation, pasteurization versus filtration or maturation in oak casks versus maturation in concrete vats) and material origin (e.g. beer grain composition, grape variety or origin of CO_2 in sparkling wine) can be reliable indicators of authenticity and can lead to the detection of certain kinds of fraud.
- Detection of fraudulent (illegal) additives. Chemical analysis can be used to detect adulteration (e.g. use of artificial sweeteners in Spanish cider or addition of elderberry juice to grape must to boost color), illegal chemicals (e.g. potassium ferricyanide – in some countries), illegal ingredients (e.g. sweet flag in vermouth) and extraneous sugar; the extent of chapalization of wine is carefully regulated from region to region and from year to year.
- Satisfaction of regulatory requirements. Analytical methods are used here to ensure that the levels of certain components (e.g. ethanol, methanol, residual sugars, sulfur dioxide (a legal preservative), pesticide residues and others) fall within regulatory limits. Regulations differ from country to country, region to region and can differ even between products of a particular region.
- Development of new methods of analysis. Research here is orientated toward the enhancement of one or more of the following aspects of analysis: accuracy/precision, automation, cost, environmental aspects, robustness, safety, speed, selectivity and sensitivity. In many cases, improvements made in methods in the general field of alcoholic beverages are helpful to analytical science as a whole.
- Identification of components or measurement of parameters in relation to quality, character, biochemical history, nutritional or health aspects. Analysis of such components as acids, amino acids, proteins, aroma compounds, carbohydrates, phenols, pigments and others are important here.
- Characterization of new components (e.g. aroma/flavor compounds, phenolic substances or pigments), especially in the context of elucidating process chemistry (e.g. fermentations, maturation or oxidation) or metabolic pathways.
- Investigation of pollutants, natural toxins and their metabolites.

Outline examples of applications of analytical science in some of the above areas will be found in the following sections. More detailed accounts will be found in the other chapters of Part 4, and indeed elsewhere, especially Parts 2 and 3.

4.1.2 Process Monitoring

The pursuit and maintenance of quality are the most important goals for any producer of alcoholic drinks – large or small. At the very least, application of analytical methods at the key stages in the manufacturing procedure (process monitoring) should ensure consistent quality and hence help the market performance of the product. All other things being equal, if it's consistently good, it'll sell consistently well.

This does not mean to say that all breweries, distilleries and wineries need an on site array of sophisticated and expensive analytical and ancillary equipment to carry out routine and special analyses. Although most of the largest producers of alcoholic beverages are part of some giant international company and do indeed have on site or easy access to such equipment, some medium to large- and many small-scale producers make world renowned products using only minimal analytical procedures during the production process. Their secret is to combine the right kinds of analyses at the right times with a time honored production method (i.e. one that is known to give a high quality product), that is *never* altered, unless analytical results early in the process suggest certain modifications must be made to the procedure later on. Their routine analytical methods may be little more than specific gravity, sugar, acid, ethanol or tannin determinations, combined with the all important sensory/organoleptic (including color/clarity) analyses.

At one extreme, Chateau Latour at Pauillac in the Haut Medoc (Bordeaux) manages to make one of the indisputably greatest red wines in the world without the regular use of expensive analytical instruments. Any variation in quality from year to year, is due mainly to differences in climatic conditions, but even so, an overall very high level of quality is achieved. At the other extreme, a particular large brewery company may produce consistently high quality beers, always making routine, but judicious use of a wide range of sophisticated analytical equipment.

There is no hard and fast rule correlating quality with extent or sophistication of process analytical monitoring; consistently high quality beer can be produced by brewers whose regular analytical equipment consists only of balances, thermometers, hydrometers, volumetric equipment and simple microbiological equipment (such as a microscope and an ATP-bioluminescence kit), as well as by brewers who use a much wider and more sophisticated range of equipment.

However, it is generally agreed that, within reason, consistent quality of product is more easily achieved with the use of a rather more than basic range of analytical equipment. A small to medium size brewery, distillery or winery could do well with the equipment mentioned above, plus a simple colorimeter or inexpensive UV-visible spectrophotometer and a basic chromatograph; HPLC and/or GC. To these basic items, one could add a friabilimeter and foam assessment equipment for a brewery, a viscometer for a grain distillery and equipment for measuring total nitrogen content for any laboratory associated with alcoholic beverage production. A Fourier transfer infrared spectrometer (FTIR) could also be included in a malting plant or large brewery/distillery, for the determination of carbohydrates, proteins and moisture in grains. On top of all of this, sensory analysis should be much in evidence, sensory sampling being conducted at key stages during the manufacturing process.

Whether small-scale or large-scale, for consistent production of quality products, irrespective of the range or sophistication of analytical monitoring methods, the common denominator is taking all necessary steps to ensure quality and doing nothing – absolutely nothing – to compromise this.

Quality has been mentioned many times already, but what does it mean? It is necessary to adopt an objective definition of quality, since subjectivity can be unhelpful and even misleading. Consider the situation where a particular brewery has been producing a beer that has sold well over a number of years (i.e. it is one that many people like). Consumers of that beer will come to expect the presence of certain pleasing key characteristics in future purchases of the same brand of beer, in which case quality can be defined as the closeness of match between expectation and reality. Built into this definition is the idea of consistency; an important factor to take care of in the production of 'all the year round' beverages, which includes everything, except vintage wines (and certain fortified wines) and vintage or single cask spirits.

Absolute consistency (from year to year) should not be expected for the latter kinds of drinks, especially vintage wines; instead something approaching this can be found in nonvintage blends. But even here, consumers of a vintage wine would expect consistency from bottle to bottle of the same vintage, provided the wine is not of an ancient vintage, in which case bottle quality variation can be enormous. Additionally, a wine of two different vintages, say Chateau Latour 1960 and 1961, should still be recognizable as products of the same source. In the example above, the wine of the former vintage will be lighter (in all senses) and less well balanced than the 1961 wine; its quality will obviously not be as high, but it should still be a quality product and it should have features recognizable as a product of Chateau Latour.

There are many such ways of defining quality (Bamforth, 2002), but there is no universal way of measuring it and expectations can be quite different for different versions of the same drink. For example, drinkers of Hefeweissen in southern Germany or cask-conditioned ciders in England expect a cloudy drink, whereas drinkers of pale ale, Pilsner beer (and most other beers) or factory cider expect their drinks to be bright.

The commitment to quality pervades throughout a good company from top management to process operators and cleaners. This is sometimes known as total quality management (TQM); simpler for smaller outfits employing a few people and rather more exacting for larger concerns, where coordination and communication are of special importance. It can be achieved by implementing international standards such as ISO 9000 or simply by the adherence to a predetermined and agreed set of protocols and procedures.

The major advantage of ISO 9000 (or similar) accreditation is that it indicates quality consciousness in the company for all to see; companies of like mind will do well to trade with each other. For example, a quality minded winery may buy all its finings from an ISO accredited supplier, and a brewery or distillery may purchase all its malt from an ISO accredited malting company.

There are two basic approaches to quality management in a company, although both require the application of monitoring procedures at various stages during the manufacturing process. Quality assurance (QA) requires the setting up of process specifications all the way along the production stream (from raw materials to finished product) and the implementation of monitoring methods and programs with which to check these. The specifications should be realistic and will have been designed specifically for a particular product or process. The monitoring program will include protocols for recording, disseminating and archiving the information. Quality control (QC) is a regime that is more orientated toward 'reaction to circumstances,' and as such can often be associated with waste and hence expense. A good company will operate a regime that is geared more to the QA side of things, although such regimes are often recorded generally as quality control in the literature.

Monitoring is the process of checking specification parameters at key points in the process, sometimes manually, as in small companies, or sometimes with in line sensors with feedback facilities, as in some larger concerns. Either way, the QA protocol will be clear on what is being monitored, by which method, how frequently and by whom. The QA personnel collect the results, sometimes process them and act upon any indication that part of the process is tending toward an 'out of control' situation; the particular process parameter is heading toward rejection values (Figure 4.1.1). In such a situation, remedies will be put in place to prevent the parameter value from reaching a reject level or the process will be stopped, checked and restarted. It may seem that temporary closure of part of the process is a rather drastic step, but this is infinitely better than allowing an out of specification and possibly defective product to reach the market place.

The kind of tolerance associated with a process parameter depends on how precisely it can be measured, which in turn depends upon the amount of variability associated with measurement of that parameter. A high precision parameter is one whose variation is small compared with the specification value; monitoring of this type of parameter is performed with a narrow tolerance. Typical parameters of this type are acidity (winemaking), clarity or haze value (brewing and winemaking), color (brewing and winemaking; sometimes distilling), density (brewing, distilling and winemaking), diacetyl content (brewing), gas (dissolved CO_2 and O_2) content (brewing and winemaking), temperature (brewing, distilling and winemaking) and viscosity measurement (distilling).

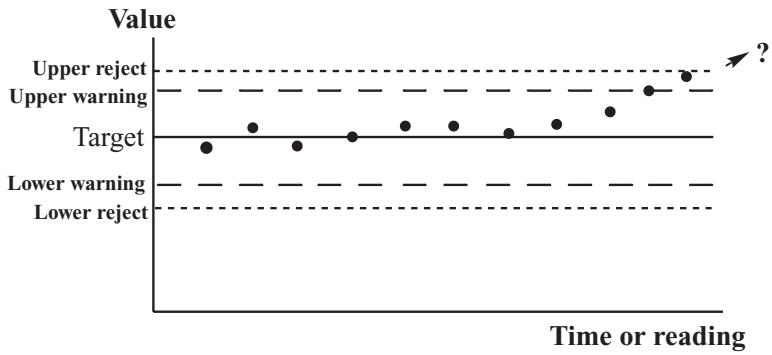

Figure 4.1.1 *Control parameter monitor, showing tendency toward out of specification situation*

Conversely, low precision parameters can usually be monitored with wider tolerances, because of greater natural variability. These parameters include dimethyl sulfide (or its precursor) levels (brewing), phenolic content (winemaking) and the levels of certain congeners (distilling).

Table 4.1.1 displays the parameters that are typically monitored in breweries, distilleries and wineries, but it should be remembered that some producers monitor fewer parameters than these, yet others will include more.

The overall trends in the application of analytical chemistry to this and other areas of alcoholic beverage production include miniaturization of instrumentation, faster method development, simplification and speeding up of sample preparation, increased sample throughput and faster data processing. If more replicate

Table 4.1.1 *Selection of parameters suitable for monitoring during production processes*

Parameter	Examples of typical specifications	Reasonable tolerances (±)
Acidity	<45 μg/l (beer)	1 μg/l
	6 g/l (wine grapes) as tartaric acid	0.1 g/l
Clarity/haze	<50 FTU (0.5 EBC) (beer)	10 FTU (0.1 EBC)
	<2 NTU (red wine)	0.1 NTU
Colour	1.6 ASBC (Pilsner malt)	0.2
Density	Sugar content: 1045 (expressed as OG, beer)	0.5
	12.5% ABV (wine)	0.2
	70% ABV (pot still run off)	0.05 (ultrasound)
Diacetyl	0.1 mg/l (normal beer)	0.01 mg/l
	0.2–0.5 mg/l (wheat beers and some others)	
Dimethyl sulphide (DMS)	40 μg/l (lager)	10
	<20 μg/l (ale)	
Dissolved CO_2	4 g/l (beer)	0.1 g/l
Dissolved O_2	<0.5 mg/l (beer)	0.1 mg/l
SO_2 (free)	<30 mg/l (beer)	1 mg/l
	50 mg/l (white wine with more than 5% (w:v) sugar)	
Temperature	65.5 °C (mashing)	0.1 °C
	12.0 °C (white wine fermentation)	
Viscosity	350 cP (peak viscosity for distillery malt)	10

analyses can be carried out in a fixed time, measurement precision will be increased, thus helping process control. One example involves the use of temperature sensors (linked to a computer with appropriate software; see Section 3.1.2) in stills of large distilleries to monitor the concentration of ethanol in the distillate, as a quality assurance parameter of the spirit. Such sensor systems allow simultaneous monitoring of several distillations, where conventional specific gravity methods would be more difficult, slower and less accurate, especially if there are few process still operators present (Ossorio *et al.*, 2008).

Another example is the use of fast GC to monitor beer flavor compounds (Horák *et al.*, 2009). Short, narrow bore columns (10 m × 0.18 mm, as opposed to conventional columns, such as 25 m × 0.32/0.53 mm) reduced the sample run time by 60%, without compromising resolution.

4.1.3 Identification of Origin, Determination of Authenticity and Detection of Fraud

Fraud is defined as the deliberate production or trading of merchandise that is not true to claimed origin or type. Fraud has existed for as long as alcoholic drinks have been produced, although up to the twentieth century many practices were carried out that were not considered to be fraudulent at that time, since most of the antifraud and protection of origin laws were not formulated until the twentieth century. For example, until well into the nineteenth century, it was common practice to openly 'fill out' the wines of Bordeaux and Burgundy with stronger, fuller and cheaper wines of the Rhône Valley and further south, since there was no law against it. Similarly, wine must was sometimes heavily sugared to boost the alcohol content resulting from fermentation and some wines were mixed with brandy and/or herbs and spices before shipping. Others were blended with elderberry juice to increase the strength of color.

On the other hand, the practice of adding wine spirit to grape must, or fermenting wine, was thought by many in the eighteenth century as fraudulent, yet today, such practice is designated as an essential part of the production process of fortified and liqueur wines (Chapter 2.10). A number of other practices that at one time were considered dubious, if not fraudulent, have become in the fullness of time accepted parts of certain manufacturing processes, sometimes resulting in new or changes in regulations. For example, the use of oak chips in place of oak casks in the production of wine is allowed for many different types of wine, but would be a fraudulent practice in the production of Scotch whisky.

Antifraud laws did exist before the twentieth century, but they were comparatively few and left much room for the manipulators, blenders and counterfeiters. A famous early piece of legislation regarding beer production is the Reinheitsgebot, imposed by Duke Wilhelm of Bavaria in 1516 to ensure that commercial beer in that country was brewed with water, malted barley, hops and yeast only. The law is still in force today for all German domestic beers, excepting wheat beers and rye beers.

Toward the end of the nineteenth century and into the twentieth century, greatly increased legislation in all countries and in all areas of alcoholic drinks production and sales led to much more clearly defined regulations regarding the designation of origin, classification, production processes (including allowed additives or adjuncts) and labeling of alcoholic drinks. At the same time, analytical methods for discovery of fraud improved enormously and policing the regulations became more effective. Thus, much of the open blending, adulteration and general manipulation of wines in the eighteenth and early nineteenth century became illegal and such wines became fraudulent, except in clearly defined cases. Consequently, nowadays there are fewer fraudulent beverages on the market than in previous centuries, but fraud does surface from time to time, much of it merely relatively minor infringements of regulations, although there are still occasional counterfeits of rare and expensive bottles of wine and spirits.

Regulations exist for all commercial alcoholic beverages and in all countries that produce them, although these often differ for a particular drink from country to country. These regulations also naturally vary from drink to drink, but generally include stipulations regarding specific geographic origin (for most wines and

spirits), acceptable cultivars (for many wines, Cognac, Tequila), methods of viticulture, including maximum yields (for many wines), limit of sugar enhancement (for wine – chaptalization – and some cider), minimum alcohol levels (as for most wines and spirits and some beer categories), production practices, including use and levels of additives (for all alcoholic beverages) and maturation (for most spirits), and labeling (for all alcoholic drinks).

Fraud nowadays falls into two main categories; label fraud and adulteration fraud. Adulteration here is defined as the addition of extraneous substances against regulations and does not include the blending of like beverages or additions of sugar or water. In a sense, most drinks frauds are label frauds – the bottle content is not what the label claims – but the most serious kind is counterfeit, because of the large sums of money that are usually involved. Label fraud ranges from the extreme, the completely bogus, to simple infringements of regulations. The first type can involve large-scale counterfeit of a well known, but rather scarce and expensive product, such as the Tuscan red wine Sassicaia (Frank, 2007) or small-scale counterfeit of extremely rare, very old and possibly unique wines that no person alive today has tasted, as alleged in the case of the Jefferson bottles (Keefe, 2007). Here, the authenticities of a number of Bordeaux wines of late eighteenth century vintages that were supposed to have been bottled for Thomas Jefferson and were engraved with his name, were put into serious doubt, the buyer of four such bottles (at *ca.* $100 000 each) claiming they were fakes.

Examples of infringements of regulations (excluding adulterated drinks) include dilution of most types of wine or must with water (and overdilution of spirits), wine with too little of the named grape variety in its composition (e.g. an Oregon Pinot Noir wine with less than the required minimum of 90% wine of that variety), a Chambertin sold as the 1985 vintage, but containing 20% of wine from 1984, wine made from oversugared must (e.g. a Premier Cru Chablis of 12.5% ABV made from grapes with sugars giving potential alcohol of only 10% (v:v) instead of the required 11%), Asturian cider made with local apple juice concentrate and a German Bockbier brewed using wort of only 15 °Plato original gravity, instead of the 16 °P minimum. These are only hypothetical examples of how infringement of regulations might result in fraud, although fraud similar to these is uncovered from time to time, mostly involving wine (see for example Prial, 2001; VinoWire, 2008).

In practice, fraud of this kind may go unnoticed for some time, since organoleptic detection is often quite difficult, although tasting may arouse suspicion in the first instance. Detection usually comes from either the leaking of inside information, from the finding of direct evidence, from the results of analytical investigations or from a combination of these.

Analytical methods fall into two major categories; those that determine a specific beverage component, such as ethanol or water, and those that compare data profiles (or 'fingerprints') of different beverages.

In the first category, analysis of isotope ratios by site specific isotopic fractionation-NMR (SNIF-NMR) (Section 4.4.1) and isotope ratio mass spectrometry (IRMS) (Section 4.4.5) are especially useful tools in the detection of fraud, via determination of the origin of specific components. In particular, these techniques can be used to detect a number of illegal processes: dilution with water, addition of excessive sugars to unfermented must, addition of ethanol from other sources to distilled spirits, presence of exogenous CO_2 in sparkling wine claiming to be 'Méthode Traditionelle' and addition of exogenous glycerol to wine. These methods are based on the fact that certain isotope ratios (e.g. H/D, $^{12}C/^{13}C$, $^{16}O/^{18}O$) of key components (e.g. water, ethanol) depend on whether those components originate from the natural base of the beverage or have been added from some other source.

SNIF-NMR has been used extensively in the detection of fraud and the authentication of wine origin, usually by measurement of $^{2}H/^{1}H$ ratios at the methyl and methylene sites of ethanol, after it has been distilled from the wine (Ogrinc *et al.*, 2003). IRMS has been used in similar ways, often in combination with SNIF-NMR (Ogrinc *et al.*, 2003). It has also been used to analyze the type of sugar (beet, cane or corn) used to produce the bubbles (carbon dioxide, via secondary fermentation – see Section 2.9.3) in sparkling wines (Martinelli *et al.*, 2003).

There are several studies of isotope ratios in the literature using GC-IRMS, in either combustion or pyrolysis modes, including an early one on Tequila authenticity (Aguilar-Cisneros *et al.*, 2002). Here, combustion mode was used to determine $\delta^{13}C_{VPDB}$ values of ethanol and pyrolysis was used to $\delta^{18}O_{VSMOW}$ values of ethanol in authentic and commercial Tequila. The method was able to distinguish between the two gross classes of Tequila, but not between subclasses (see Section 3.5.5) within these. See below for Tequila authenticity determined by another method. See Section 4.4.5 and Glossary for explanations of VPDB and VSMOW.

In the second category, a common procedure is to determine a number of beverage constituents simultaneously and the 'fingerprints' are used to decide authenticity by comparison against authentic samples, via the use of a variety of statistical chemometric methods (see Section 4.1.5), mostly discriminant function analysis. Typical techniques are those that are rapidly and easily applied, such as fast GC/GC-MS (Section 4.3.2), ion chromatography (Section 4.3.3), infrared spectroscopy (Section 4.4.2), Raman spectroscopy (Section 4.4.2), electrochemical methods (Chapter 4.5) and inductively coupled plasma mass spectrometry (ICPMS) (Section 4.4.4).

As an example, the four subclasses of Tequila and mezcal have been differentiated on the basis of chemometric analysis of the concentrations of 12 elements determined by ICPMS (Section 4.4.4) (Ceballos-Magaña *et al.*, 2009), where probabilistic neural networks analysis gave 100% success in the differentiation of extra aged, aged, gold and silver Tequila, and mezcal.

However, some workers have used univariate statistical methods to correlate data with sample origin/authenticity, as in the differentiation between subgroups of Mexican Agave spirits (including Tequila) by application of one way analysis of variance (ANOVA) to GC and ion chromatographic data (Lachenmeier *et al.*, 2006). It may also be possible to differentiate between spirits (e.g. unaged cachaça, aged cachaça and rum) by comparison of aroma 'fingerprints' obtained from a two dimensional GC procedure, such as GC×GC/TOFMS (Cardeal and Marriott, 2009).

Adulteration is defined here as the illegal addition of extraneous substances (those that are not normally present in the beverage or its raw materials). It includes addition of colorants, flavoring substances and sweeteners, but does not include the fruits and 'botanicals' used to flavor beer (Section 2.6.13), vermouth, other aromatized wines (Chapter 2.12), gin (Section 3.4.2), vodka (Section 3.4.3), arak (Section 3.5.6) and liqueurs (Chapter 3.9). Nor does it include the use of caramel as a colorant in the production a wide range of alcoholic beverages, nor the use of artificial sweeteners in the production of some cider (Section 2.8.6) and certain spirits, such as some soju (Section 3.4.4). The many cases where these additions can be made are clearly defined by law, but are otherwise illegal; they are then classed as adulterations. Governments all over the world have constructed regulations and published lists of chemicals and substances that may be legally added to wine and other drinks (Robinson, 2006), and increasing regulatory requirements will mean that, for some of them at least, their presence must be stated on the label.

A common and long standing adulteration of wine is the addition of deep red juice or fruit wine (e.g. those of elderberry), or even an artificial colorant, to pale red grape wines; deepening the color of red wine is a profit enhancer, since the public generally equates deep color with high quality. This kind of adulteration is not so common nowadays, because once suspected, it can be detected easily, especially by HPLC with UV-visible detection (Section 4.3.3). Nowadays, using such a technique it is possible to determine all common artificial colorants in drinks in less than 20 minutes chromatography run time (Yoshioka and Ichihashi, 2008). Likewise, the presence of anthocyanins from the skins of elderberries or blueberries in red grape wine is easily demonstrated by this technique, since anthocyanins tend to be characteristic of their origin (see, for example, Jordheim *et al.*, 2007).

Unfortunately, toxic substances have been used to adulterate wines throughout the years; lead acetate was occasionally used as a wine sweetener in the eighteenth and nineteenth centuries, and even as late as 1986, a particularly unfortunate case of adulteration occurred in Italy, when 23 people died as a result of consuming wine adulterated with methanol to boost its alcohol content.

However, the biggest recent wine adulteration scandal was that concerning diethylene glycol. In 1985, several Austrian wine producers, as well as smaller numbers of German and Italian producers were found to have added diethylene glycol to dry wines in order to give them a smoother mouthfeel and greater sweetness, allowing the producers to sell their wines at higher prices. Fortunately, the diethylene glycol was present in concentrations that were too low to be toxic, but the fraud darkened the reputation of all Austrian wine for many years. Diethylene glycol is readily detected by gas chromatography (Section 4.3.2), but in the 1980s planar chromatographic methods were much in vogue (see, for example, Klaus and Fischer, 1987).

4.1.4 Determination and Characterization of Beverage Components and Processes

Many of the hundreds of compounds known to be present in alcoholic beverages are crucial to the quality of those beverages. Many of these compounds are already present in the raw materials or precursors, but many more are derived from the various production processes, such as fermentation, boiling/distillation, maturation (especially in wood), pasteurization and so on. Moreover, composition inevitably changes during the manufacturing process, with some of the original components rapidly or slowly disappearing to trace level (e.g. being metabolites of fermentation, or as a result of precipitation) and others appearing at various later stages (e.g. fermentation metabolic end products or compounds derived from contact with wood).

The balance of components is very important; too much or too little of certain flavor compounds can profoundly influence beverage quality. For example, the presence of dimethyl sulfide is unwanted in pale ales and other top-fermented beers, but at certain levels, is beneficial to the flavor of pale bottom-fermented beers (Sections 2.6.5 and 2.6.6). Likewise, certain flavor compounds are desirable in one beverage, but not in others – for example β-(*E*)-damascenone is generally desirable in white wine, but not in beer. The balance of many other components can have an effect on the quality of beverages in other ways – for example: proteins and certain carbohydrates (β-glucans) on clarity and foaming characteristics of beer, cider and wine; metal ions on oxidative stability of beer; phenolic compounds on color, taste and mouthfeel of cider and wine; organic acids on the taste of beer, cider and wine. Analytical chemistry, often combined with sensory analysis, can determine key quality factors and can point the way to making changes in the production processes that maximize desirable factors and minimize undesirable ones.

Although it is 'tasting,' or more properly organoleptic or sensory assessment (using sight, smell/flavor, taste and mouthfeel in a scientific way – see Chapter 4.7) that is ultimately used to determine the beverage quality, analytical chemistry plays a crucial role in identifying favorable and unfavorable components, as well as shedding light on the origins of those components and on the huge variety of pathways that produce or degrade them during the course of many different kinds of production processes. Furthermore, analytical chemistry is important in the detection, determination and characterization of components that do not necessarily influence quality, but may have health implications. These include additives such as sulfites (Section 5.9.2), contaminants such as heavy metals (Section 5.10.3) and toxic fungal metabolites (Section 5.11.4).

Table 4.1.2 gives a list of the types of compounds most often determined by analytical methods, along with some examples of the contexts in which these they are analyzed. The list by no means exhaustive; indeed it is fair to say that any component may be the subject of analysis if its presence has (or is suspected of having) some bearing on beverage character or quality.

Analytical investigations include the following broad types. Firstly there is quantitative or semi-quantitative determination of known components. These methods need internal or external standards (for direct determinations) or calibration models (for indirect determinations) and involve the whole spectrum of analytical methods, from chromatography and spectroscopic methods to physicochemical methods. Increased chromatographic resolution can be achieved using one dimensional GC with rapid mass spectrometry and deconvolution or by two dimensional techniques (e.g. GC×GC) (see, for example, Cardeal and Marriott, 2009)

Table 4.1.2 *Some important components of alcoholic beverages and the major analytical methods used for determination or identification*

Component(s)	Raw material/ precursor/beverage	Method of determination/ identification	Contexts
Acids	Mostly must (for wines and spirits) and wine	Physicochemical methods. CZE, HPLC, UV-vis spectroscopy (inc. enzymic methods)	Total acidity. QA/QC, assessment of MLF progress
Alcohols (inc. ethanol and polyols)	All beverages	GC, FTIR, physicochemical methods, IRMS/SNIF NMR (for isotope ratios)	QA/QC, flavor analysis, detection of fraud
Amino acids, peptides and proteins	Cereals, wort (for beer and spirits), must and wine, cider	Kjeldahl, Dumas, etc., FTIR. HPLC, UV-vis spectroscopy, CZE. HPLC, GPC, SDS-PAGE, MS	Total nitrogen content. Nutritional/health value, potential haze formation, foaming ability, production processes
Biogenic amines	All	GC, HPLC, CZE	Health issues, production processes
Carbohydrates	All, except pure distillates	FTIR, physicochemical methods. HPLC, GPC, enzymic methods (UV-vis spectroscopy), NMR, MS	Total carbohydrates. QA/QC, fermentability, health/nutrition, production processes
Esters	All beverages	GC	QA/QC, flavor analysis, production processes
Metal and nonmetal ions (inc. heavy metals and sulfites)	Most, inc. water for brewing and spirits dilution	AAS/AES, HPLC (IC), CZE, electrochemical methods, UV-vis spectroscopy, ICPAES/ICPMS	QA/QC, health issues/regulations, spoilage, bioavailability
Organic contaminants	All	GC, HPLC	Health issues/regulations, production processes
Phenolic compounds (inc. anthocyanins)	All	UV-vis spectroscopy, FTIR, HPLC, NMR, MS	Total phenolic content. QA/QC, sensory analysis, production processes
Sulfur compounds	Most	GC, HPLC	QA/QC, aroma/flavor analysis, spoilage
Terpenoids, carotenoids, norisoprenoids	All	GC, HPLC, NMR, MS	Flavor analysis, production processes
Water	As moisture in cereals In beverages	FTIR IRMS/SNIF	QA/QC. Authentication of origin/detection of fraud

KEY: GC (inc. GC-MS^n) (Section 4.3.2) HPLC (inc. LC-MS^n, IC and GPC) (Section 4.3.3); NMR/SNIF NMR (Section 4.4.1), FTIR (Section 4.4.2), UV-vis (Section 4.4.3) AAS, AES, ICPAES (Section 4.4.4), MS/IRMS (Section 4.4.5); electrochemical methods (Chapter 4.5); CZE, SDS-PAGE (Section 4.6.1), Kjeldahl, Dumas, physicochemical methods (Section 4.6.3). Production processes: examples include malting, mashing, boiling, distillation, fermentation, maturation, pasteurization/heating, fining/filtration.

(Section 4.3.2). Retention time locking is now being used to aid component identification, and quantification is often helped by the use of isotopically labelled internal standards (see, for example, Poisson and Schieberle, 2008; Cooke *et al.*, 2009; Grant-Preece *et al.*, 2010). GC separations are often used in conjunction with sensory analysis in order to correlate organoleptic properties with particular components or combinations of components (see generally Sections 4.3.2 and 4.7.3 for examples of GC-olfactometry and GC-aroma extraction dilution analysis).

Many sophisticated extraction methods are now available for the concentration (focusing) of trace components (Chapter 4.2), allowing their investigation by less sensitive techniques such as NMR spectroscopy. There are many statistical chemometric methods available, as computer software, for the design of experiments and for treatment of results. Multivariate analysis methods, in particular, are being used with rapid analytical methods, such as FTIR spectroscopy (Section 4.4.2) and electrochemical methods (Chapter 4.5) for the routine analysis of large numbers of samples. Electronic noses and tongues are being increasingly used in the classification/identification of origin of samples and miniaturized sensor devices are finding increased use as process monitors.

Secondly, there is the identification of newly discovered components. Sometimes comparison of chromatographic retention times with those of authentics, use of Kovats/other indexes or coinjection of authentic standards may be sufficient, but often structure determination is required. In this case, the two prominent methods are NMR spectroscopy and/or mass spectrometry. Nowadays, a multitude of NMR techniques, involving different pulse regimes, can be applied to solve highly complex structures, including terpenoids, oligomeric polyphenols, their glycosides and carbohydrates (Section 4.4.1). Techniques such as (homonuclear) correlation spectroscopy (COSY), heteronuclear correlation spectroscopy (HETCOR), homonuclear multiple bond coherence spectroscopy (HMBC) and heteronuclear multiple quantum coherence spectroscopy (HMQC), allow H–H and C–H connectivities to be determined and nuclear Overhauser effect spectrocopy (NOESY) gives information on near through space neighbors.

Likewise, mass spectrometry (Section 4.4.5), particularly if using atmospheric pressure chemical ionization (APCI) or electrospray ionization (ESI) modes of ionization and often combined with chromatographic separation (e.g. HPLC; Section 4.3.3) or with capillary zone electrophoresis (CZE) (Section 4.6.1), can be used to determine large or complex molecules. Tandem mass spectrometry (MS^n) is more and more frequently used to give detailed fragmentation information and TOFMS lends itself to the determination of molecular weights of proteins and other large molecules.

Thirdly, there is the investigation of physicochemical processes involved in alcoholic beverage production, including metabolic and nonenzymic pathways. This includes following changes in composition that occur during malting/mashing, fermentation, distillation, heating (including pasteurization and the Maillard reaction), fining, maturation/ageing (including extraction processes from wood, redox reactions and the effects of light and other types of radiation). Investigations of fermentation have often been carried out using isotopically labeled substrates, the fate of the label being determined by either mass spectrometry (often GC-MS or LC-MS) or NMR spectroscopy. In this way, the origins of important components can be elucidated and important precursors can be determined. A recent example of this involved the use [^{13}C6] and [^{12}C6] glucose in a study of the Maillard reaction (see Section 2.6.2) between glucose and various amino acids (Wang *et al.*, 2009). One major pathway was shown to exist for the production of 2,5-dimethyl-4-hydroxy-3[2*H*]-furanone, in which the glucose carbon skeleton remained intact, whereas there were two routes to 2-acetylfuran, one involving glucose only and the other involving both glucose and glycine.

Similarly, analytical science has been directed toward physical and chemical processes that influence sensory perception of drinks. For example, mechanisms of the release of aroma compounds from beverages such as wine during dynamic headspace dilution conditions (similar to normal sniffing conditions) have been investigated by APCI-MS (Tsachaki *et al.*, 2009). Likewise, sensory analysis combined with analytical

chemistry has been used to investigate the release of odorous cysteine-*S*-conjugates from fruits by saliva enzymes (Starkenmann *et al.*, 2008).

4.1.5 Development of New Analytical Methods

There exist many prescribed methods in the literature for the analysis of important parameters and key components of alcoholic beverages and their raw materials (e.g. grapes, fruit, malted barley, water) or precursors (e.g. beer wort). They are known variously as established, official, recommended or reference methods (with quantitative methods predominating) and are published by a number of professional bodies (Table 4.1.3) from time to time, with updates and additions. The aim is to ensure that the determination of a

Table 4.1.3 *Scientific associations providing standard methods of chemical analysis of alcoholic beverages*

Association or Institute	Comments	Association or Institute	Comments
AACC American Association of Cereal Chemists	Provides standard methods for analysis of cereals	IBD Institute of Brewing and Distilling	Publishes recommended methods for cereal, wort, beer and spirit analysis
AOAC Association of Official Analytical Chemists	Publishes recommended methods for assay of many analytes in different matrices, inc. food and drink	ICC International Association for Cereal Science and Technology	Provides standard methods for analysis of cereals
ASBC American Society of Brewing Chemists	Publishes standard research methods for all aspects of beer	ISO International Organization for Standards	Includes many member bodies worldwide – e.g. AFNOR (France), ANSI (USA) and SABS (South Africa). Main interest is in standardization of methods
ASTM American Standards for Testing and Materials		JECFA Joint Expert Committee on Food Additives (FAO/WHO)	Provides scientific expert advice and publishes data and methods for food additive assay
Codex Alimentarus (FAO/WHO)	Main concern is with food and health, especially regarding additives and residues	JMPR Joint Meeting on Pesticide Residues (FAO/WHO)	Publishes toxicological data and references to methods of analysis
EBC European Brewery Convention	Publishes Analytica-EBC series on all aspects of brewing	OIV Office Internationale de la Vigne et du Vin	Publishes codes of enological practices, as well as methods for analysis of wines and spirits
EC European Commission	Joint Research Centre publishes methods for assay of food components, especially additives and residues	RACI Royal Australian Chemical Institute	

particular component is carried out in a particular way, so that results from year to year or between brewery, distillery or winery laboratories can be compared directly (i.e. the results have both high repeatability and high reproducibility), with a high degree of confidence. Some of these associations also publish recommendations regarding evaluation and development of alternative methods against a reference method (e.g. AFNOR, 1999).

Official methods have been carefully and thoroughly constructed for particular kinds of analyses for particular ranges of alcoholic drinks, where development of the methods was usually conducted by well respected experts (sometimes over a period of years), although they are often modified from time to time, as problems or suggested improvements come to light. However, these methods have a considerable range of advantages and disadvantages. Some involve lengthy and labor intensive steps, others lack precision (even though they may be regarded as the best available at the present time for particular analytes) or accuracy (i.e. they may have a bias) and others may lack robustness (i.e. they are susceptible to slight changes in conditions).

As in other areas of analytical science, there is a perpetual search for new methods, not necessarily to replace official methods, but often to provide alternatives that can be used together with existing or official methods. A new method should offer improvements in accuracy, automation, cost, environmental aspects, precision, robustness, safety, speed, selectivity, sensitivity or versatility, without itself having significant disadvantages. All new methods should be rigorously compared with existing and/or official reference methods. In reality, a newly developed and tested method may be used in routine or day to day analysis, whereas for important instances (e.g. providing high confidence data for presentation in a fraud court case or for providing data for an official body such as the Institut National des Appellations d'Origine des vins et Eaux-de-Vie (known as INAO), the official or reference method is used.

Apart from the search for new and improved methods to determine an individual component or parameter *directly*, as discussed above, there is much activity aimed at predicting one or more parameters *indirectly* using other more easily and rapidly measured parameters, the two being correlated by statistical analysis. See Cozzolino *et al*. (2009) for a useful introduction to multivariate statistical methods applied to grape and wine analysis. More generally, the reader is referred to the Statsoft electronic textbook on statistics (http://www.statsoft.com/textbook/) and Cserhàti (2008), Otto (1999), Alfassi *et al.* (2005) and Brereton (2005) for application of statistical methods to analytical chemistry.

Typically, rapid methods such as visible/NIR, MIR, NMR (all Fourier transform) spectroscopic, fast chromatographic or electrochemical methods (especially electronic noses and tongues) are used to predict such parameters as percentage ethanol (v:v), protein content, total N content, glycerol content, Cu^{2+} content, or many others that generally require more time consuming methods to measure directly. The normal methodology is to use multivariate regression analysis to develop a calibration model that correlates the measurement information (e.g. peaks in particular regions of the NIR spectra) contained in the set to the property or parameter of interest (e.g. protein content). Usually, a different data set is then used to test the predictive ability of the regression model, or sometimes the integrity of the model is tested by 'cross-correlation' (see below).

The most commonly used statistical methods are those of the multivariate type, which considers multiple variables (e.g. pH, total nitrogen content, ethanol content, etc.) simultaneously. Of these, principal component analysis (PCA) and partial least squares (PLS) regression analysis (a kind of discriminant function analysis) are probably the two most widely used procedures.

PCA is the main exploratory method, reducing large data sets into linear combinations of variables that can be used to describe and predict some aspect of the data matrix. The results are typically presented as PCA score plots, often centered, with the axes crossing at the origin (Figure 4.1.2). As an example, Nieuwoudt *et al.* (2004) used PCA to correlate ethanol, glucose, glycerol, reducing sugar and volatile acidity contents data (determined by standard methods) with FTIR spectra of South African Chenin Blanc fermenting musts and synthetic musts. Improved PCA score plots were obtained when outliers were removed and certain wavenumber regions (5011–2970; 1716–1543 cm^{-1}) were deselected. Refinements such as this are often

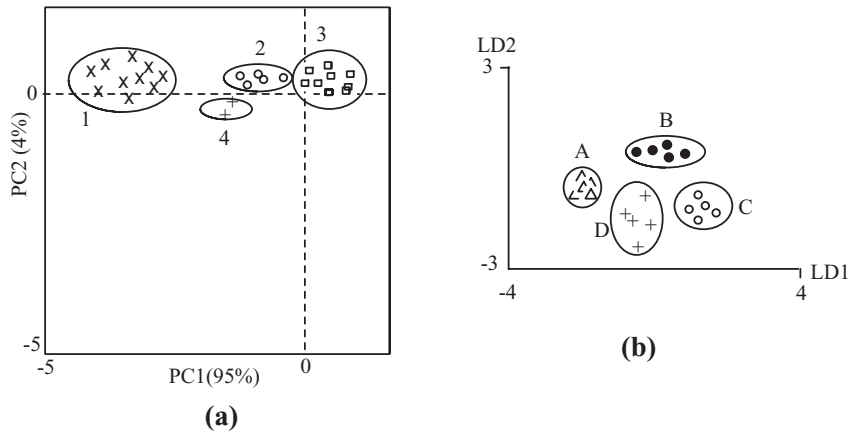

Figure 4.1.2 *Typical PCA (a) and PLS (b) disciminant analysis plots*

used to increase the effectiveness of PCA. See Section 4.4.2 for other examples of FTIR spectroscopy and statistical methods used in this and other ways.

Discriminant analysis gives a set of orthogonal (independent) linear discriminant functions (LD1, LD2, etc.) in order of discriminating aptitude (LD1 first, etc.), but in practice the first two are usually sufficient to describe most of the variation. Ideally, intragroup differences are minimized and intergroup differences are maximized, so that when LD1 is plotted against LD2, the points fall into distinct areas representing characteristic groups (Figure 4.1.2).

These functions are often used to predict group membership of new or unknown samples not used in the development of the original model (see also PLS, below), but if such samples are unavailable cross validation can be used. Here, data for each sample are removed sequentially from the model, whereupon the model is rebuilt without that sample. The categorization of the removed sample is then tested against the rebuilt model.

As an example, an electronic nose based upon 12 metal oxide sensors (Section 4.5.3) was able to discriminate not only between fruit and grape wines from different Ontario wineries, but also between certain different varietal grape wines (McKellar *et al.*, 2005). Here discriminant analysis was used to determine which sensor outputs (relating to the wine aroma profile) could differentiate between samples from several natural groups, which included (from 33 wineries) red and white grape wines from five different varieties and eight different kinds of fruit wines. It was possible to distinguish each wine variety based on different wineries, fruit and grape wines (75.9% correct), and red and white wines (92.2% correct), but overall classification by variety was poor (58.7% correct). The wines could be separated into four distinct groups (79.9% correct). See Section 4.5.3 for other examples of the use of sensor arrays in 'fingerprinting' beverage samples.

PLS regression is a discriminant analysis method that is used as a major qualitative calibration procedure in alcoholic beverage and raw materials analysis. Calibration is carried out using group membership (categories) rather than by use of a continuous variable. Typically, for two groups, A and B, an artificial Y-variable is created that has a zero value for say group A and a unit value for group B. A regression equation between Y and the X variable measurement is set up and is then tested on its ability to predict Y values of new or unknown samples. The magnitude of success is gauged by the standard error of prediction. PLS is a data reduction technique; it reduces the X variables to a set of noncorrelated factors describing the variation of the data.

As an example, Garde-Cerdán *et al.* (2010) used PLS analysis of NIR spectroscopic data to discriminate between Spanish red wines according to the extent of aging in oak casks and according to type of oak cask used: American, French or combination. This type of method could be used for the rapid assessment of

authenticity of new samples and hence in the detection of fraud (see Section 4.1.3). Another example involved the use of an electronic nose (zNose^{TM}; a fast gas chromatograph) to obtain aroma fingerprints of 339 Chilean red wines of known origin, of a number of grape varieties and vintages (Beltrán *et al.*, 2009). Here, the data was analyzed by application of wavelet transform for chromatogram feature extraction, and this was classified by analysis with support vector machines. The mean percentage of correct classification performed on the validation set was obtained by cross validation against the percentage of correct classification found on the test set. This is a good example of how a highly populated, accurate database leads to reliable classification; wines from four valley areas could be discriminated (>94% classification rates) and it was possible to discriminate certain wines from coastal and inland vineyards.

The major limitation of linear regression, PCR and PLS regression is their inability to deal adequately with nonlinear relationships between variables, although locally weighted regression can do this. An artificial neural network (ANN) is a multivariate data processing technique that simulates biological neurons by multiplication of the input signal (X), using the synaptic weight to derive the output signal (Y). This technique can handle nonlinear relationships between variables and hence outperforms standard PLS regression in these circumstances, its superiority arising from the high degree of interconnections.

As an example, capillary zone electrophoresis data on resveratrol levels in wines of eight varieties of three vintages when subjected to ANN allowed the prediction of vine varieties of unknown wines (but within the limits of the database), with a high (<90%) success rate (Pazourek *et al.*, 2005).

4.2

Extraction and Focusing Methods in Sample Preparation

Logic is the last scientific ingredient of Philosophy; its extraction leaves behind only a confusion of non-scientific, pseudo problems.

—Rudolf Carnap

4.2.1 Overview

Apart from a few substances, the components of alcoholic beverages are present at very low levels (μg/l) or even trace levels (ng/l or less) and hence either require highly sensitive methods for their detection and quantification, or need to be concentrated (focused) by some extractive sample preparation technique prior to analysis. Highly sensitive methods are not always suitable and are often subjected to interferences from other components of the highly complex matrices that constitute most alcoholic beverages. This section considers the sample preparation techniques available for the focusing of specific groups of components in alcoholic drinks. The emphasis of the discussion is on volatile compounds responsible for the aroma and flavor of drinks, partly because of their special importance and partly because extractive sample preparation techniques for other analytes, such as non-volatile acids, amino acids, contaminants, mycotoxins, pesticide residues, phenols and others are mentioned elsewhere. Therefore, the analytical technique most widely discussed here in conjunction with the focusing techniques is gas chromatography (GC) (Section 4.3.2).

The quantitative analysis of the volatile compounds present in alcoholic beverages is extremely demanding due to: (i) the complex chemical composition of the volatile fraction and (ii) the fact that individual volatile compounds can be present in a wide range of concentrations. For example, Rapp *et al.* (1978) estimated that the concentrations of volatile flavor compounds in wines range between 1 g/l and 1 ng/l (a factor of 10^9).

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

The concentrations at which volatile compounds influence the flavor of foodstuffs are often extremely low – sometimes at concentrations below the detection limits of even the most sophisticated analytical instruments. It is therefore imperative that the volatile fraction of the alcoholic beverage be isolated from the bulk of the sample and subsequently concentrated (or focused).

The extremely low odor threshold values (OTV – concentrations just barely sufficient to achieve sensory recognition of substances – Section 4.7.2) of some of the more significant flavor compounds, demand that techniques be aimed at isolating these trace level compounds from other less sensory significant components, which may be present at concentrations several orders of magnitude higher. More than 99% of an alcoholic beverage extract is typically composed of fusel alcohols, fatty acids and some fermentation esters (Section 2.2.11), whereas the remaining 1% of the extract (which contributes significantly to the bouquet of a wine for example), is composed of hundreds of compounds which are present at concentrations about 10^6–10^8 times lower than the fusel alcohols (Maarse and Visscher, 1989, Etievant, 1991). The human sensory organs (Section 4.7.1) display somewhat sensitive and variable reactions to these amounts of aroma compounds. Boeckh (1972) and Guadagni *et al.* (1963) reported that threshold values differ considerably and could vary between 10^{-4} and 10^{-12} g/l. For example, Demole *et al.* (1982) quoted the odor threshold value for 1-*p*-menthen-8-thiol as 0.1 ng/l, whereas Guth (1997) gave the value of 0.00001–0.00004 ng/l for wine lactone. Therefore, methods for alcoholic beverage volatile analysis must be able to successfully qualify and quantify compounds over a wide range of concentrations. There are several main sample preparation techniques that have been used to study the aroma compounds of grape juice, wine, beer and spirits. These techniques fall into four general categories which include liquid extraction (or solvent extraction including supercritical fluid extraction or SFE, Section 4.2.2) distillation methods (Section 4.2.3), such as simultaneous steam distillation-extraction (SDE) and solvent assisted flavor evaporation (SAFE), the sorption techniques (Section 4.2.4) solid-phase extraction (SPE), solid-phase micro extraction (SPME), stir bar sorptive extraction (SBSE) and headspace sorptive extraction (HSSE), and headspace methods (including static headspace and purge and trap, Section 4.2.5). It is also very common to combine such sample preparation techniques to obtain alcoholic beverage aroma isolates of which SDE strictly speaking also fits (as it is a combination of both distillation and liquid extraction). Other combinations used in alcoholic beverage analysis also include the chromatographic methods such as a combination of liquid–liquid extraction and high performance liquid chromatography (HPLC) fractionation (Section 4.3.3), a combination of liquid–liquid extraction and countercurrent extraction (Section 4.3.4), a combination of liquid–liquid extraction and solid phase extraction using column/adsorption chromatography (for creation of aroma fractions) and also as a final example, a combination of solid phase extraction and HPLC fractionation.

Research of the available literature over the past five decades indicates that solvent extractions are among the most commonly used sample preparation steps for the analysis of beverage volatiles. However, recent environmental concerns over the use of chlorofluorocarbons such as freon-11 (trichlorofluoromethane, CFC-11, or R-11) have resulted in limitations in the availability of these solvent varieties for research purposes. Other solvent systems are now more commonly employed. However, increasing costs for solvent disposal, as well as safety and environmental concerns, are prompting research and industrial analytical chemists to search for sample preparation methods that minimize or better still eliminate the use of organic solvents. Hence, the sorptive extraction techniques have gained a surge in popularity, mainly because of advantages in sensitivity, speed, robustness, safety and 'greenness' over previously established methods.

4.2.2 Liquid Extraction Techniques

Liquid extraction techniques are based on the distribution of a solute between two immiscible solvents. In most cases, one phase is an aqueous solution of analytes (for example volatile aroma/flavor components) the

other an organic solvent. An analyte which is soluble in both water and solvent phases will distribute itself between these two phases. Equilibrium will be achieved when the free energy of the solute is the same in each phase. The extract is obtained by stirring or mixing and agitating a liquid sample with organic solvent and then separating the subsequent solvent phase. This can be carried out manually (simple extractions with a separating funnel) or automatically and can be either batch extraction or continuous flow extraction (commonly known as continuous liquid–liquid extraction).

The choice of extraction solvent is extremely important, as it must have a low enough boiling point so that it can be easily removed from the extract without a significant loss or change of the original sample aroma volatiles. Ideal extraction solvents must be able to extract polar (such as alcohols and carbonyl compounds) and non-polar (such as terpenoids and esters) components and provide an extract with an aroma/flavor profile reminiscent of the original sample (an important prerequisite of any isolation technique applied to the study of aroma/flavor profiles).

Two terms are employed to describe the distribution of a solute between two immiscible solvents: *distribution (partition) coefficients* and *distribution ratio.* These theoretical concepts have been widely covered from first principles in the literature (Skoog *et al.*, 1996; Holden, 1999; Meloan, 1999).

When the distribution ratio is low, but the separation factor is high, continuous methods of extraction are favored. This technique utilizes a continuous flow of immiscible solvent phase through the aqueous solution to be extracted. As volatile solvents are generally used for aroma analysis, this can be stripped and recycled via distillation and condensation. Although partition/distribution equilibrium may not be achieved during the limited time of contact of the two phases, solute is being removed continuously with the extracting phase and carried back to the solvent flask for subsequent concentration (by using for example a Vigreux column on a steam bath, a Kuderna–Danish evaporative concentrator or rotary evaporator following previous drying of the solvent extract over sodium or magnesium sulfate) and analysis by gas chromatography (Section 4.3.2). Efficiency depends not only upon the value of the partition ratio, but also the viscosity of the phases, the relative phase volumes (phase ratio), the area of contact between the phases and the relative velocity of the phases. As the extraction solvent passes through the solution being extracted, stirrers are used to bring the two phases into closer, more effective and prolonged contact.

Many continuous extraction devices operate on the same general principle (see Figure 4.2.1). This consists of distilling the extracting solvent from a round bottomed flask that serves as a boiler/receiving flask, condensing the solvent, and passing the condensate through the solution to be extracted that is held in an extractor vessel. A rotating distributor in the extractor vessel is driven by a magnetic stirring plate. The extractor solvent fed from the condenser to the distributor is centrifugally forced through the small holes in the distributor ring as fine droplets into the liquid to be extracted, producing optimum exchange of matter. The liquid to be extracted also rotates in the extractor. The rotary distributor on the inlet tube has a magnetic agitating rod, pivot nipple, bearings, antislip lock and separating ring with retaining ring. When the extracting solvent is lighter than the aqueous phase (see Figure 4.2.1, apparatus A) the rotary distributor (or dispersion disk) is placed near the bottom of the extraction vessel. During operation the solvent rises to the surface of the aqueous phase and in doing so allows the extractable analytes to partition between the droplets and the bulk solution. Eventually the extracting liquid flows back into the receiving flask (and boiler), from where it is evaporated and recycled. The extracted analytes remain in the receiving flask. For extraction solvents heavier than water (see Figure 4.2.1, apparatus B) the rotary distributor is placed towards the top of the extraction vessel. Here, the condensed solvent is allowed to drop down through the phase being extracted and then it flows to the outer part of the extractor. Spent solvent rises in the outer cylinder of the extractor and exits into the boiler for stripping and recycling.

Zurbrick (1997) reported a simple example of how analytes partition or distribute themselves between water and an organic extraction solvent. Below is a further example based on this calculation.

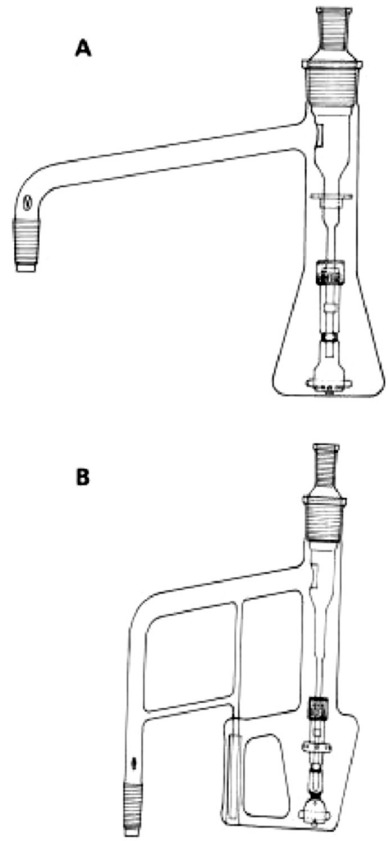

Figure 4.2.1 *Normag® liquid-liquid extractors (A) for extraction with solvents of lower density than water (B) for extraction with solvents of higher density than water. Reproduced with permission from Normag Labor- und Prozesstechnik GmbH, Ilmenau, Germany*

The solubility in water of compound A is 10 g/100 ml. The solubility in diethyl ether of compound A is 5 g/100 ml. From this solubility data, we can calculate firstly the partition (or distribution) coefficient (K_D) for compound A (Equation 4.2.1).

$$K_D = \frac{\text{Solubility of compound A in diethyl ether}}{\text{Solubility of compound A in water}} \tag{4.2.1}$$

This amounts to 5/10 or 0.5.

If we have 50 g of compound A in 1000 ml water and extract with 1000 ml of diethyl ether, compound A will distribute itself between the two immiscible solvents as follows:

$$\text{Weight of compound A in diethyl ether} = (1000\text{ ml})(0.5x\text{ g/ml}) = 500x\text{ g}$$
$$\text{Weight of compound A in water} = (1000\text{ ml})(x\text{ g/ml}) = 1000x\text{ g}$$

Therefore the total weight of compound A is 50 g (now distributed between two layers) and:

$$1500x \text{ g} = 50 \text{ g}$$
$$x = 0.03333$$

Hence:

$$\text{Weight of compound A in diethyl ether} = 500\ (0.03333)\ \text{g} = 16.67\ \text{g}$$
$$\text{Weight of compound A in water} = 1000\ (0.03333)\ \text{g} = 33.33\ \text{g}$$

This example highlights the distribution following a simple, single batch extraction as would be carried out using an ordinary laboratory separating funnel. To demonstrate the benefits of exhaustive extractions (either by multiple batch or continuous liquid–liquid extraction) if we again begin with 50 g of compound A in 1000 ml water and carry out three extractions with 300 ml of diethyl ether, after the first extraction compound A will distribute itself between the two immiscible solvents as follows:

$$\text{Weight of compound A in diethyl ether (300 ml) } (0.5x \text{ g/ml}) = 150x \text{ g}$$
$$\text{Weight of compound A in water} = (1000 \text{ ml})(x \text{ g/ml})\ 1000x \text{ g}$$

Therefore the total weight of compound A is 50 g (now distributed between two layers) and:

$$1150x \text{ g} = 50 \text{ g}$$
$$x = 0.04348$$

Hence:

$$\text{Weight of compound A in diethyl ether} = 150\ (0.04348)\ \text{g} = 6.52\ \text{g}$$
$$\text{Weight of compound A in water} = 1000\ (0.04348) = 43.48\ \text{g}$$

This diethyl ether layer is then removed and replaced with the next 300 ml of diethyl ether and so:

$$\text{Weight of compound A in diethyl ether} = (300 \text{ ml})(0.5x \text{ g/ml}) = 150x \text{ g}$$
$$\text{Weight of compound A in water} = (1000 \text{ ml})(x \text{ g/ml}) = 1000x \text{ g}$$

However, here we began with 43.48 g of compound A (now distributed between two layers) and:

$$1150x \text{ g} = 43.48 \text{ g}$$
$$x = 0.03781$$

Hence:

$$\text{Weight of compound A in diethyl ether} = 150\ (0.03781)\ \text{g} = 5.67\ \text{g}$$
$$\text{Weight of compound A in water} = 1000\ (0.03781)\ \text{g} = 37.81\ \text{g}$$

Finally, this diethyl ether layer is removed and replaced with the last 300 ml and so:

$$\text{Weight of compound A in diethyl ether} = (300\text{ ml})(0.5x\text{ g/ml}) = 150x\text{ g}$$
$$\text{Weight of compound A in water} = (1000\text{ ml})(x\text{ g/ml}) = 1000x\text{ g}$$

Here we began with 37.81 g of compound A (now distributed between two layers) and:

$$1150x\text{ g} = 37.81\text{ g}$$
$$x = 0.03288$$

Hence:

$$\text{Weight of compound A in diethyl ether} = 150\ (0.03288)\text{ g} = 4.93\text{ g}$$
$$\text{Weight of compound A in water} = 1000\ (0.03288)\text{ g} = 32.88\text{ g}$$

Therefore, from the three multiple batch extracts, the total quantity of compound A extracted = 6.52 g + 5.67 g + 4.93 g = 17.12 g.

This is compared against 16.67 g of compound A extracted via the previous single batch extraction into 1000 ml diethyl ether. Although these values are similar (due to the low distribution coefficient of compound A) this example demonstrates that continuous liquid–liquid extraction (using apparatus as previously mentioned) permits the potentially exhaustive extraction of analytes from an aqueous matrix because the extraction solvent is automatically distilled, condensed and forced through the sample before flowing back to its starting point where it is evaporated and recycled. Therefore, the equivalent of several hundred batch extractions with fresh solvent can be achieved with the same starting solvent in a few hours and requires minimal attention once underway.

The choice of solvent is extremely important, as it must have a low boiling point so that it can be easily removed from the extract without a significant loss of sample aroma volatiles and ideal extraction solvents must be able to extract polar and non-polar components.

Hardy and Ramshaw (1970) found they could isolate and quantitatively analyze minor volatile constituents of Riesling white table wine, using the solvent trichlorofluoromethane (freon 11). This solvent does not extract water or ethanol, and was reported to extract other alcohols, carbonyls and esters with recoveries of between 70 and 100% in 17 hours by continuous liquid–liquid extraction.

The bulk of the content of higher alcohols was then removed from the extract by treatment with propylene glycol, allowing the remaining volatile components to be concentrated further. The analysis of the wine extract was carried out by gas chromatography and gas chromatography-mass spectrometry (GC-MS). Forty-five compounds were successfully identified. Freon 11 was also used as extraction solvent for the examination of the volatile flavor fraction of Cabernet Sauvignon wines (Boison and Tomlinson, 1990). New designs of solvent extractor and low temperature, high vacuum, two stage concentrator apparatus were constructed. This enabled the quantitative and qualitative determination of trace level aroma components of *Vitis vinifera* grape musts and wines by capillary gas chromatography. The sensitivity of the technique was demonstrated by the detection and identification of 2-methoxy-3-isobutylpyrazine (in the parts per billion range or μg/l) for the first time in Cabernet Sauvignon wine.

This enrichment technique has also been used recently for the identification of some characteristic aroma compounds in noble rotted grape berries and Aszu wines from Tokaj by GC-MS (Miklosy *et al.*, 2004). Freon 11 has also been used recently as extraction solvent for the comparative study of aromatic compounds

in two young white wines subjected to prefermentative cryomaceration (Peinado *et al.*, 2004) and also recently for the comparison of odor active compounds in Sherry wines (Section 2.10.3) processed from ecologically and conventionally grown Pedro Ximenez grapes (Moyano *et al.*, 2009).

Nelson *et al.* (1979) used a similar liquid–liquid extraction technique to study the volatile composition of three Catawba wines. The volatiles were isolated by stirring equal volumes of sample with the solvent freon 113 (1,1,2-trichloro-1,2,2-trifluoroethane), for 1 h before concentrating 13, 500-fold. The Catawba extracts were then analyzed by gas chromatography and combined gas chromatography-mass spectrometry. The authors concluded that the unidentified trace components, which were less than 5% of the total freon extractable volatiles, were of critical importance to the aroma.

Freon 113 has recently been adopted as extraction solvent, to characterize the aroma of Brazilian Cachaça and Puerto Rican rum (Section 3.5.4) (de Souza *et al.*, 2006). Beverage samples (50 ml) were extracted with 15 ml of solvent and then sonicated at 40 kHz and 20 °C for 10 min. The liquid phases were then separated in a 250 ml separation funnel and the lower freon layer collected. The remaining upper phase was rinsed with an additional 5 ml of solvent and sonicated as previously. This procedure was then repeated for a third and final time with 15 ml of freon. The extracts were then dried with anhydrous magnesium sulfate and concentrated to 1 ml under reduced pressure using a rotary evaporator, prior to being analyzed by gas chromatography-olfactometry (GC-O) and GC-MS.

Ferreira and coworkers (1993) developed a fast and quantitative determination of wine flavor compounds using microextraction. Typically, 10 ml of wine was extracted with only 100 μl of freon 113 as extracting agent. It was concluded that the proposed method allowed quantification of 26 wine flavor compounds with detection limits in the μg/l range. Precision, linearity and accuracy of the method was tested using different wines and synthetic mixtures. Relative precision was shown to be better than 3%.

This sample preparation technique has also been used for the quantitative determination of trace and ultra trace flavor active compounds in red wines (Ferreira *et al.*, 1998a) and for the classification of Slovak varietal wines (Pet'ka *et al.*, 2001).

Many other solvents and solvent mixtures have been utilized to study the volatile composition of grape juices and wines using the liquid–liquid extraction technique. Examples include: dichloromethane (Moio *et al.*, 1995; Baek *et al.*, 1997; Schneider *et al.*, 1998; Tominaga *et al.*, 1998a; Delfini *et al.*, 2001; Ortega *et al.*, 2001; Rocha *et al.*, 2004; Lee *et al.*, 2006; Perestrelo *et al.*, 2006; Selli *et al.*, 2006a; Selli *et al.*, 2006b; Falcão *et al.*, 2008; Hernanz *et al.*, 2009) pentane/dichloromethane mixtures (Gonzalez-Vinas *et al.*, 1996; Lamikanra *et al.*, 1996; Garcia *et al.*, 2003; Garde Cerdán *et al.*, 2004; Guchu *et al.*, 2006; Sánchez Palomo *et al.*, 2007) and hexane/diethyl ether 1:1, v:v (Rogerson *et al.*, 2002). Diethyl ether/pentane (1:1, v:v) has also been utilized to study the volatile composition of Mencia wines (Calleja and Falque, 2005) and for isolation of aroma compounds for differentiation of white wines by their aromatic index (Falqué *et al.*, 2001).

A comparative study of the ability of different solvents and adsorbents to extract aroma compounds from alcoholic beverages has recently been conducted (Ferreira *et al.*, 2000). Seven liquid solvent systems – dichloromethane, dichloromethane/pentane (1:1, v:v), freon 113, diethyl ether/pentane (1:1 and 1:9, v:v), ethyl acetate/pentane (with and without an additional salting-out effect) (1:3 and 1:20, v:v) were comparatively studied along with seven solid phase extraction (SPE) systems. It was concluded that the best liquid extraction solvents were dichloromethane and freon 113 with salt (ammonium sulfate).

Dichloromethane was the extraction solvent of choice for the characterization of Tequila flavor by instrumental and sensory analysis (Benn and Peppard, 1996). The extract obtained was analyzed by gas chromatography with both flame ionization detection (FID) and sulfur chemiluminescence detection (SCD), as well as combined gas chromatography-mass spectrometry. More than 175 components were identified in the extract and the importance of individual chemical constituents was determined by sensory analysis with the use of a GC equipped with an odor port and aroma extract dilution analysis.

Dichloromethane has also been used recently as extraction solvent to compare the odor active compounds in unhopped beer and those hopped with different hop varieties (Kishimoto *et al.*, 2006) and also for the analysis of heavy sulfur compounds in wines (Moreira *et al.*, 2004).

Tominaga and co-workers (1998a; 1998b) reported a method for the specific analysis and identification of volatile thiols from *Vitis vinifera* L. Cv. Sauvignon Blanc wines. Typically, a 500 ml volume of wine containing 4-methoxy-2-methyl-2-mercaptobutane as internal standard was adjusted to pH 7.0 with a sodium hydroxide solution (10 M) and extracted with dichloromethane (2 × 100 ml) in a 2 l flask with magnetic stirring for 5 min each time. The combined organic phases were then centrifuged for 5 min at 3800G to break the emulsion and separated in a separating funnel. The organic phase obtained was subsequently extracted with 2 × 20 ml *p*-hydroxymercuribenzoate solution (1 mM in sodium hydroxide at 0.01 M) for 5 min each time with a pH maintained >7 by the addition of 10 M sodium hydroxide solution. The two aqueous phases from the extraction were then combined and brought to pH 7 by very slow addition of hydrochloric acid solution (5%) to avoid precipitation of *p*-hydroxymercuribenzoate, then loaded into a strongly basic anion exchanger column (1.5 × 3 cm of Dowex 1) which had been previously reactivated using 50 ml of hydrochloric acid solution (0.1 M) and then rinsed with ultrapure water. Percolation of the aqueous phase took 15 min before the column was washed with 10 ml of potassium phosphate buffer (2 mM, pH 7.2) followed by 50 ml of sodium acetate buffer (0.1 M, pH 6). The volatile thiols were then released from the column by percolating for 30 min using a cysteine solution (640 mg/60 ml adjusted to pH 7, previously purified of any volatile contaminants by repeated extractions with 3 × 5 ml of dichloromethane). The eluate containing the volatile thiols was subsequently collected in a 100 ml flask and extracted using 4, 2.5 and 2.5 ml of dichloromethane for 5 min each with stirring before being combined, dried with sodium sulfate and concentrated under a stream of nitrogen to approximately 500 μl. Finally the concentrate was transferred to a 1 ml vial and concentrated further to 25 μl. The authors reported that the method allowed simultaneous analysis of five important volatile thiols and analysis of 10 typical Sauvignon Blanc wines showed that 4-mercapto-4-methylpentan-2-one, 3-mercaptohexyl acetate and 3-mercaptohexan-1-ol were expected to be involved in varietal aroma, as they were most likely present at concentrations greatly in excess of their respective perception thresholds. This specific extraction method has also been recently used to study the presence of polyfunctional thiols in four different fresh light protected lager beers (Section 2.6.6) (Vermeulen *et al.*, 2006), for the identification and characteristics of new volatile thiols from Nelson Sauvin hops (Takoi *et al.*, 2009) and for the identification, quantification and odor impact of new sulfanyl alcohols on the aroma of young botrytized sweet wines (Section 2.9.1) (Sarrazin *et al.*, 2007).

A similar technique was used by Schneider and coworkers (2003) to report the quantitative determination of sulfur containing wine odorants at sub parts per billion (ppb) levels. Wine samples (500 ml) were initially extracted with dichloromethane and concentrated to 1 ml. The extract was then diluted in 2 ml of pentane and passed through a column produced with 500 μl of Affi-Gel 501 loaded into a Pasteur pipette (glass wool at the bottom and conditioned with 5 ml of isopropyl alcohol followed by 5 ml of pentane/dichloromethane mixture, 2:1, v:v). Thiols were then eluted with 5 ml of a 1,4-dithio-DL-threitol solution (5 mM in pentane/dichloromethane mixture, 2:1, v:v) and the resulting extract washed with water, dried over sodium sulfate and concentrated to *ca.* 100 μl, and analyzed by GC-MS or GC-atomic emission detection (AED).

The volatile profiles of commercial Scotch whisky (Chapter 3.2) samples have recently been studied by comparing a conventional liquid-liquid extraction (LLE) method with solid phase microextraction (SPME – Section 4.2.4) and subsequent analysis by gas chromatography (Caldeira *et al.*, 2007). Seven different extraction solvent systems were evaluated including dichloromethane, *n*-hexane, dichloromethane/diethyl ether (3:1 and 1:3, v:v) and dichloromethane/*n*-hexane (3:1 and 1:3, v:v). The high ethanol concentration of the whiskies required dilution to 12%, (v:v) alcohol for both LLE and SPME methods. This dilution was necessary to minimize emulsion formation during liquid–liquid extraction and loss of sensitivity for most

volatiles determined by SPME. The highest extraction efficiency of whisky volatile compounds was obtained when dichloromethane was used as extraction solvent. The researchers concluded that for a complete and quantitative study of volatile composition in food and beverages, two or more sample preparation techniques are recommended. Headspace SPME was demonstrated to offer greater sensitivity when compared to the traditional method of liquid extraction. Similar conclusions have also been reported for the analysis of brandy (Chapter 3.6) aroma by SPME and LLE (Ebeler *et al.*, 2000). Here, headspace solid phase microextraction and continuous liquid–liquid extraction were used to isolate and analyze aroma volatiles in brandy. The authors reported in general, the SPME method using a non-polar poly(dimethylsiloxane) coating was more selective for esters and acids than was LLE which extracted the higher alcohols more efficiently than SPME with freon 11 as extraction solvent.

Andujar-Ortiz and coworkers (2009) evaluated the analytical performance of liquid–liquid extraction using dichloromethane, solid phase extraction (SPE – Section 4.2.4) using a styrene-divinylbenzene copolymer and headspace solid phase microextraction (SPME – Section 4.2.4) using a carboxen-poly(dimethylsiloxane) coated fiber. A comparative analysis of 30 representative wine volatile compounds was carried out and the authors concluded that LLE and SPE showed very good linearity, covering a wide range of concentrations, low limits of detection and high extraction recoveries for most volatiles under investigation. Higher sensitivity was also observed when compared to the headspace SPME procedure and although LLE and SPE required, in general, more tedious sampling treatment and the use of organic solvents, these analytical techniques were reported to be more adequate for the analysis of wine volatiles. The same conclusion was also reported after the comparison of LLE and SPE alongside simultaneous distillation extraction (SDE – Section 4.2.3) for the volatile compounds of Muscat grape juice (Sánchez-Palomo *et al.*, 2009). Results showed that although the three techniques could be recommended for the quantitative analysis of volatile compounds from musts, LLE and SPE were better sample preparation techniques for the determination of polar compounds such as acids or alcohols.

Liquid–liquid extraction continues to be a dominant sample preparation technique for the analysis of alcoholic beverages. Greer *et al.* (2008) utilized this as the core technique to compare a novel distillation method versus a traditional distillation method for preserving volatile aroma chemicals important to the organoleptic attributes of a four botanical model gin (Section 3.4.2). Gin samples (38 ml) were extracted with 2 ml of hexane/dichloromethane (50:50, v:v) and mixed for 30 min before being allowed to rest and separate for subsequent analysis by GC-MS.

Many specific chemical classes of aroma compounds present in alcoholic beverages have also been studied using liquid extraction. Recent examples include the characterization of pyrazines in some Chinese liquors (Fan *et al.*, 2007b), the determination of volatile phenols in red wines (Fariña *et al.*, 2007; Minuti and Pellegrino, 2008) and to study the distribution and organoleptic impact of sotolon (3-hydroxy-4,5-dimethyl-2(5*H*)-furanone) enantiomers in dry white wines (Pons *et al.*, 2008b).

Liquid extraction has also been utilized extensively for the determination of other extremely important alcoholic beverage analytes unrelated to aroma and flavor. A rapid GC method for the determination of residue levels of the insecticide chlorpyrifos and four fungicides (penconazole, fenarimol, vinclozolin and metalaxyl; see Section 5.10.2) in grapes, must and wine was validated by Oliva *et al.* (1999). Samples were extracted with acetone/dichloromethane (1:1, v:v) prior to filtration and concentration before being subjected to analysis by GC with electron capture detection (ECD) for all target analytes other than metalaxyl, which was detected by mass selective detection (MS) in the selected ion monitoring mode (SIM). The proposed method reported analyte recoveries that ranged between 78 and 101% (fortification level 0.1–1 mg/kg) with linear detection rates in the range of 0.02–2 ng/μl, and limits of determination were, in all cases, lower than the maximum residue limits (MRLs) established by different legislations. This method was further adopted for the rapid determination of 17 fungicides widely used by vineyards (Navarro *et al.*, 2000).

Eight commonly used grapevine fungicides (cyprodinil, fludioxonil, metalaxyl, penconazole, pyrimethanil, procymidone, tebuconazole and vinclozolin) have also been extracted from vineyard soil samples by sonication with water followed by extraction (by shaking) with ethyl acetate and subsequent analysis by GC-MS (Rial-Otero *et al.*, 2004). The method was reported to have adequate precision and high sensitivity however, required the use of both internal standard (to control for between sample variation in injection and instrument response) and the standard addition method to control matrix effects.

Other examples of fungicide residues detected in alcoholic beverage samples include spiroxamine extracted from 10 g samples of either grape, must or wine with cyclohexane/dichloromethane (9:1, v:v) and analyzed by GC-MS (Tsiropoulos *et al.*, 2005), famoxadone, trifloxystrobin and fenhexamid residues in tomato, grape and wine samples also extracted with cyclohexane/dichloromethane (9:1, v:v) and analyzed by GC with nitrogen phosphorus (NP) and electron capture (EC) detection with ion trap mass spectrometry (ITMS) for confirmation (Likas *et al.*, 2007), zoxamide residues in grape, must, wine and spirit samples extracted with hexane and analyzed by GC-MS without any sample clean up (Angioni *et al.*, 2005) and hexane extraction of pyrimethanil, metalaxyl, dichlofluanid and penconazol from must, wine and samples undergoing alcoholic fermentation with subsequent analysis by GC with nitrogen-phosphorus detection (Vaquero-Fernández *et al.*, 2009). Famoxadone has also been successfully detected in grapes and wine following extraction with ethyl acetate/hexane (50:50, v:v) and comparison of GC with electron capture and mass spectrometric detectors (de Melo Abreu *et al.*, 2006).

González-Rodríguez *et al.* (2009) recently developed a GC-MS method for the determination of 11 new generation fungicides (benalaxyl, benalaxyl-M, boscalid, cyazofamid, famoxadone, fenamidone, fluquinconazole, iprovalicarb, pyraclostrobin, trifloxystrobin and zoxamide) in grapes and wines. Samples were extracted with ethyl acetate/hexane (1:1, v:v) followed by additional clean up (to remove matrix coextractants) with graphitized carbon black/primary secondary amine (GCB/PSA) solid phase extraction cartridges (SPE – Section 4.2.4). Acetonitrile/toluene (3:1, v:v) was used as elution solvent. The authors concluded that the proposed method demonstrated good linearity, precision and accuracy along with limits of detection (LODs) and limits of quantitation (LOQs) lower than the maximum residue limits (MRLs) established by different European legislations for grapes and wines, and therefore could be a useful tool in routine analysis to ensure product safety.

The determination of multiple pesticides in grapes, musts and wines has been implemented using acetonitrile as extraction solvent and low pressure GC-MS (Cunha *et al.*, 2009). Optimization of the methodology yielded the separation of 27 representative pesticides by applying a quick, easy, cheap, effective, rugged and safe (QuEChERS) approach. Following optimization of several low pressure GC-MS conditions and evaluation of matrix effects, it was concluded that acceptable recoveries for nearly all of the pesticides under investigation were achieved with good repeatability. Limits of quantification were also lower than the maximum residue limits.

Patil *et al.* (2009) described a multiresidue method for the simultaneous estimation of 83 pesticides and 12 dioxin-like polychlorinated biphenyls (PCBs) in red and white wines. Samples (20 ml wine, acidified with HCl) were extracted with 10 ml ethyl acetate (along with 20 g sodium sulfate for drying) and cleaned by dispersive solid phase extraction (DSPE) with anhydrous calcium chloride and Florisil® successively. The final extract (5 ml) was then evaporated to dryness, and the residues remaining reconstituted in 1 ml cyclohexane/ethyl acetate (9:1, v:v) before being further cleaned by DSPE with 25 mg primary secondary amine sorbent, and analyzed by GC-time-of-flight-MS (GC-TOF-MS). The authors concluded that the method described could be adopted to analyze 95 wine compounds within a single GC run of 31 min with high precision, accuracy and low measurement uncertainties.

Liquid extraction has also been utilized in combination with derivatization agents as a means to selectively extract and detect analytes from alcoholic beverages. Examples include GC-MS determination

of diamines (1,3-diaminopropane, putrescine and cadaverine), polyamines (spermidine and spermine) and aromatic amines (β-phenylethylamine and tyramine) found in Port wines (Section 2.10.7) and corresponding grape juices following extraction and derivatization with heptafluorobutyric anhydride (Fernandes and Ferreira, 2000), the GC-MS analysis of biogenic primary alkylamines in wines following conversion to corresponding pentafluorobenzylimines using pentafluorobenzaldehyde (Ngim *et al.*, 2000), the GC-atomic emission detection (AED) analysis of arsenic species present in wine and beer following derivatization with methyl thioglycolate (Campillo *et al.*, 2008b) and the enantiomeric GC analysis of amino acids in beer samples derivatized with ethyl chloroformate (Junge *et al.*, 2007).

A simple and rapid method was described for the extraction of wine volatile compounds based on ultrasonic assisted extraction (UAE) using pentane/diethyl ether (1:2, v:v) as extraction solvents (Vila *et al.*, 1999). Factorial experimental designs were used to optimize the sonication process. Factors such as sample volume, extraction time and solvent volume were considered. A statistical approach was used to find suitable conditions for the ultrasound extraction of aroma compounds of wine. A factorial design at two levels revealed that lower sample volume (100 ml instead of 125 ml) and solvent volume of 50 ml instead of 60 ml contributed to improved extraction efficiency. Performance of the method was evaluated, and the procedure applied to the analysis of aroma compounds in white wines from 'Condado de Huelva' (Spain). It was concluded that the method had advantages over other extraction methods, such as higher reproducibility and the possibility of the simultaneous extraction of several samples. The proposed method allowed the quantification of 24 wine flavor compounds.

A similar UAE, using dichloromethane as extraction solvent, has been optimized for the extraction of volatile compounds from wines (Cabredo-Pinillos *et al.*, 2006).

Recently, two ultrasound assisted liquid–liquid extraction methods were compared to a solid phase extraction (SPE – Section 4.2.4) technique to assess their effectiveness for the analysis of up to 44 volatile components extracted from a synthetic and several commercial wines from Spain (Hernanz *et al.*, 2008). One of the liquid–liquid extraction protocols evaluated gave higher recoveries for a greater number of aroma volatiles that could be attributed to the aroma of the wines, when compared with the SPE methodology however, the SPE method was demonstrated to provide higher repeatability and throughput, and lower solvent consumption. UAE has also been compared with direct immersion SPME for the analysis of monoterpenoids in wine. Both UAE and SPME methodologies were demonstrated to be quantitative, precise, sensitive and linear, however application of both techniques to analysis of red wine samples showed that UAE provided higher extraction of monoterpenic compounds than SPME.

In supercritical fluid extraction (SFE) the extraction phase (usually carbon dioxide, CO_2) is above its critical temperature and is therefore in a supercritical state. Supercritical carbon dioxide is known to have solvent polarity properties similar to diethyl ether and to be particularly selective for esters, aldehydes, ketones and alcohols. If water is present, this will be isolated also (Parliment, 1997).

The primary advantage of optimized SFE is that a highly selective extraction can be conducted if necessary. Exploitation of the selectivity aspects allows the preparation of extracts that can be easily analyzed using chromatographic methods. Other benefits of this methodology are short extraction times and lower reactivity of thermally labile and oxygen sensitive compounds.

The SFE technique is most efficient for the extraction of aroma materials from dry solids or viscous liquids (Da Costa and Eri, 2004), for example high pressure CO_2 extraction is already widely used for the dealcoholization of wine and the processing of hops, and also to extract specific target compounds or active ingredients from foodstuffs, beverages, tobacco, chemicals, pharmaceuticals and cosmetics. Its use has also been reported in the fields of leather, textile and paints (Werkhoff *et al.*, 2002).

Supercritical solvents tend to discriminate against polar components, but this can be overcome by using modifiers such as methanol or ethanol. The reasons for adding a modifier to the CO_2 are threefold:

(i) to increase the solubility of the target compounds, (ii) to destroy analyte–matrix interactions and (iii) to enhance diffusion by swelling of the matrix (Baltussen, 2000). The main disadvantage of SFE is the difficulty in balancing pressure, flow rate and temperature for each type of sample. This often generates time consuming method development. Also, the sample capacity is relatively limited (Da Costa and Eri, 2004).

The applicability of SFE and gas chromatography for analyzing wine aroma was evaluated by Blanch *et al.* (1995). Three different experimental approaches were considered including: (i) off line SFE using an original commercial configuration, (ii) SFE – capillary gas chromatography analysis via programmed temperature vaporization (i.e. using the quartz injection liner of a programmable temperature vaporizer (PTV) for trapping the extracted solutes and then the chromatographic analysis carried out by placing the liner in the injector body of a gas chromatograph), and (iii) on line coupling between SFE and capillary gas chromatography by means of a PTV. It was concluded that on line coupling between SFE and GC using a PTV injector as interface, seemed to be a good option for performing the extraction, collection and analysis of wine aroma in a single step. Relative standard deviations ranging from 0.9% to 19.1% were achieved for a series of test mixture compounds, whereas the recoveries obtained varied from 57.6% to 109.2%, detection limits ranging from 0.08 to 0.34 ng. Off line SFE-GC could be used for the analysis of wine samples and provided satisfactory relative standard deviations (0.1–8.8%) and acceptable recoveries (77–103%), although detection limits were higher (0.2–4.5 μg). Off line SFE-GC via PTV seemed to be a good alternative for the analysis of wine samples, though the quantitation of the most volatile compounds required further optimization.

Kárasek *et al.* (2003) compared direct SFE of wines with CO_2 and conventional indirect extraction by SFE of the sorbent used for solid phase extraction of the same wine samples (SPE-SFE). For direct continuous SFE, wine samples (170 ml) were extracted with supercritical CO_2 in a packed column operated in a continuous, single pass, countercurrent mode. In parallel with the direct method, the wine samples were also analyzed by a more conventional SPE-SFE method as a reference. In the SPE step, 3.5 g of Amberlite® XAD-7 sorbent was mixed with a 40 g sample of wine. The mixture was stirred with a magnetic stirrer at 70 rpm for 2 h and then filtered through common filter paper. The sorbent on the filter paper was allowed to predry for 2 h at 30 °C in order to remove residual wine. The moist Amberlite® resin with sorbed analytes was finally loaded into the extraction cell of a supercritical fluid extractor and extracted dynamically for 45 min at 50 °C. The released analytes were trapped by bubbling the effluent into 4 ml of ethanol at 5 °C. It was concluded that, compared to the two step process of SPE-SFE, the direct continuous SFE of wine resulted in a more specific and representative fingerprint of the sample, as revealed by the GC analysis of the extracts. Direct SFE was preferable because it was more straightforward than SPE-SFE. The additional analyte–sorbent interactions and sorption/desorption steps involved in SPE-SFE resulted in unfavorable alteration of the GC fingerprint, reducing both the peak number and the information obtained. In addition, the study showed the feasibility and expediency of direct SFE for the purpose of wine analysis with the goal to classify the samples according to the respective wine varieties. The superior robustness of direct SFE compared to SPE-SFE of wines was also apparent from multivariate statistical processing of the analytical results.

Supercritical extraction with CO_2 has recently been adopted for isolation of aroma compounds from sugar cane spirits (Gracia *et al.*, 2007). The effects of pressure and temperature on extraction yield and aroma recovery were studied. The researchers concluded SFE appeared to be a viable technology for obtaining concentrates of aroma compounds from intermediate and residual streams from the industrial process of rum production (Sections 3.5.3 and 3.5.4) and that the results could be extended to alcoholic beverage production so as to provide a source for the isolation of aroma substances with commercial interests in food, pharmaceuticals and cosmetics.

4.2.3 Distillation Methods

One of the most important, valuable and often cited sample preparation methods for the isolation and subsequent analysis of volatile aroma compounds from foods and beverages is the simultaneous steam distillation-extraction method (SDE) as invented by Likens and Nickerson (1964; Nickerson and Likens, 1966) for the analysis of hop oil (Section 2.6.3) (see Figure 4.2.2).

Typically with this technique, the sample (an aqueous solution or solid aqueous slurry) is boiled in a 500 ml to 5000 ml round bottomed flask (with stirring to prevent localized heating and subsequent bumping) connected to the left arm. The steam which is then generated during the extraction procedure increases

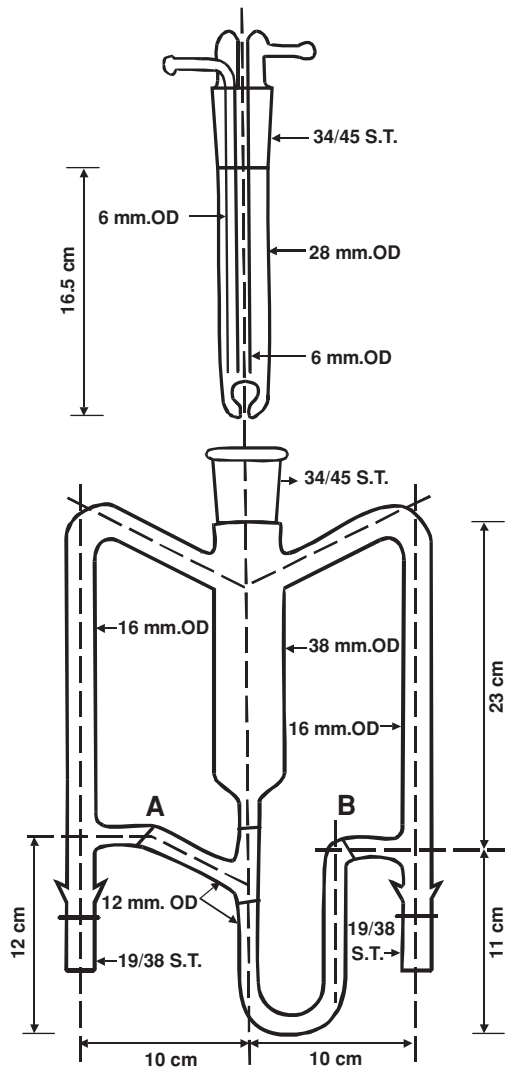

Figure 4.2.2 *Likens' and Nickerson's apparatus for solvent denser than water (Likens and Nickerson, 1964). Reproduced with permission of the American Society of Brewing Chemists, St. Paul, USA*

the vapor pressure of the extraction system. This in turn lowers the boiling point of the water and volatile compounds which are steam distilled through the upper part of the left arm. Simultaneously 10–100 ml of extraction solvent is refluxed and the subsequent solvent vapors distill through the upper part of the right arm of the apparatus. Vapors then condense on the cold finger, and the extraction process begins in the vapor–liquid film that forms. The proposed construction of the apparatus is such that high density extraction solvents (such as dichloromethane) and the low density aqueous layer de-mix and return via the correct return arm back to the appropriate flask to fulfill continuous steam distillation extraction (as shown in Figure 4.2.2). As originally designed by Likens and Nickerson, inverting the apparatus allows the use of low density extraction solvents such as pentane or diethyl ether.

Applied to hop oil components, Likens and Nickerson obtained satisfactory recoveries in the range of 54–99% depending on the compounds used, the extraction time (1–2 h) and the pH. The pentane extract also had to be concentrated prior to GC injection.

Since the original design, various modifications to the SDE apparatus have been made. For example, after increasing the condenser efficiency and insulating the steam distillation arm, yields usually in excess of 80% within 1 h have been reported using dichloromethane as the solvent (Macleod and Cave, 1975). An important and well renowned improvement of atmospheric pressure SDE was reported by Godefroot *et al.* (1981) with a microscale apparatus that allowed the concentration of volatiles into 1 ml of extraction solvent, thus achieving a high concentration factor, reducing problems of artefact build up and allowing direct gas chromatographic injection of the organic extract without the need of a further concentration step (see Figure 4.2.3). Within 1 h, quantitative recoveries were obtained for a wide range of aroma compounds.

Vacuum versions of the SDE technique have also been well discussed in the literature as a way or means of reducing the thermal decomposition of the sample analytes (resulting in artefact formation), i.e. creation of aroma/flavor volatiles in the analytical extract that were not initially present in the original sample. However, it has been reported that operation of SDE under vacuum conditions had a negative effect upon recoveries of analytes when directly compared to atmospheric use (Leahy and Reineccius, 1984). Other researchers have reported that operation under vacuum is complex since the boiling of the two flasks must be balanced, as well as keeping the solvent from evaporating and holding the pressure constant (Parliment, 1997).

An excellent and extensive review of the SDE technique has recently been discussed in the literature (Chaintreau, 2001).

The aroma volatiles of grape juice have been successfully studied with a 1 h distillation time and a further 30 min of solvent extraction with dichloromethane (Blanch *et al.*, 1991; Caven-Quantrill and Buglass, 2006).

Different isolation methods for the volatile components of Muscat grape juice have been compared in terms of the accuracy and precision of the quantitative analysis, and the sensitivity achievable with each analytical procedure (Blanch *et al.*, 1991). The methods included in the study were continuous liquid–liquid extraction, microscale simultaneous distillation-extraction (SDE) with freon-11, dichloromethane and pentane as extracting solvents, as well as a dynamic headspace sampling procedure using both sweeping and an aeration approach. Analysis of the grape juice extracts was carried out by capillary gas chromatography equipped with a programmable temperature vaporizer (PTV) for sample introduction (in the LLE and SDE methods). The injector was also used for trace analysis by enriched trapping in a suitable adsorbent. It was concluded that the use of a PTV injector for the intermediate trapping of Muscat grape juice volatiles, which result from the headspace analysis in the aeration mode, allowed a greater sensitivity than liquid–liquid extraction and steam distillation-extraction procedures, although careful optimization of variables affecting the experimental procedure was required. The headspace method was also less suited for application in quantitative analysis, but could be satisfactorily used for identification purposes. It was recommended that the SDE method with dichloromethane as extraction solvent should be adopted for carrying out an accurate and precise quantitative analysis. Blanch *et al.* (1993) further optimized the SDE method at normal pressure by using the modified sequential simplex method. For this purpose, a new micro steam distillation-extraction

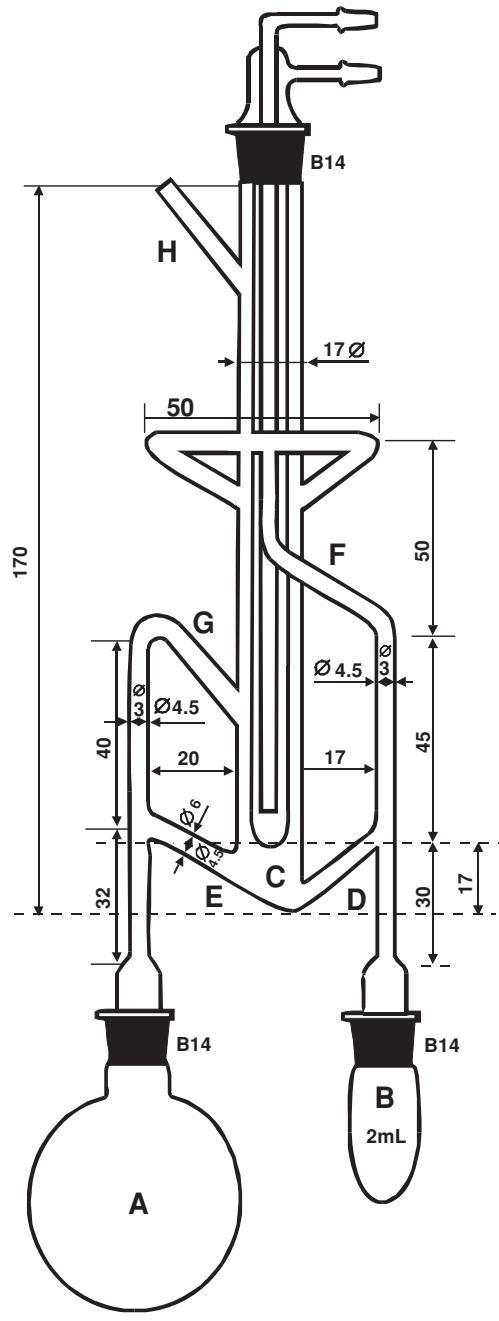

Figure 4.2.3 *Micro-SDE apparatus designed by Godefroot* et al. *(1981). Reproduced with permission of Elsevier Ltd., Oxford, UK*

device was constructed. Determination in the μg/l range of a typical mix of aroma compounds having different polarities and volatilities was tested and accomplished with high recoveries. The optimized method was then used to produce an aroma extract from a Muscat grape juice for determining compounds in the μg/l range and tentative peak identification of several compounds characteristic of the juice was carried out by matching retention times with those of reference compounds. It was concluded that the sequential simplex method allowed the performance of the SDE procedure to be significantly improved. The proposed modified apparatus operated under the optimized conditions rendered, in general, excellent recoveries for the investigated aroma compounds in the mg/l (ppm) or μg/l (ppb) range.

A similar microscale simultaneous distillation-extraction device has very recently been compared with stir bar sorptive extraction (SBSE) for the determination of volatile organic constituents of grape juice (Caven-Quantrill and Buglass, 2005; Caven-Quantrill and Buglass, 2006).

The potential of the micro SDE technique for the rapid enrichment of wine aroma compounds has also been investigated (Blanch *et al.*, 1996). However, the use of dichloromethane as the extracting solvent did not allow performance of the experimental run if a 100 ml volume of wine was placed in the sample flask. This led to ethanol from the sample flask getting into the de-mixing section of the SDE apparatus, thus hindering the equilibrium between the two solvent layers (corresponding to water and dichloromethane) in the separation chamber. This problem was diminished by dilution of the wine sample with water (1:1, v:v). Further dilution of the sample (i.e. 1:3, v:v) made the experimentation more convenient when unattended processing was required, although lower enrichment factors were obtained.

Recently, a compact and versatile distillation unit for the careful isolation of volatiles from complex food matrices has been developed (Engel *et al.*, 1999). The inventors reported that the new technique named solvent assisted flavor evaporation (SAFE) was able to successfully isolate volatiles from either solvent extracts, as well as directly from aqueous foods and beverages (including beer) yielding flavorful aqueous distillates free from co-extracted non-volatile matrix compounds (see Figure 4.2.4). This apparatus (size, 40 × 25 × 7 cm) consists of a dropping funnel (Figure 4.2.4, no.4), a cooling trap (no.6) and a central head (no.2) bearing two 'legs' (nos. 11 and 12), both equipped with ground joints NS 29 (no.17) to fix distillation vessels of various

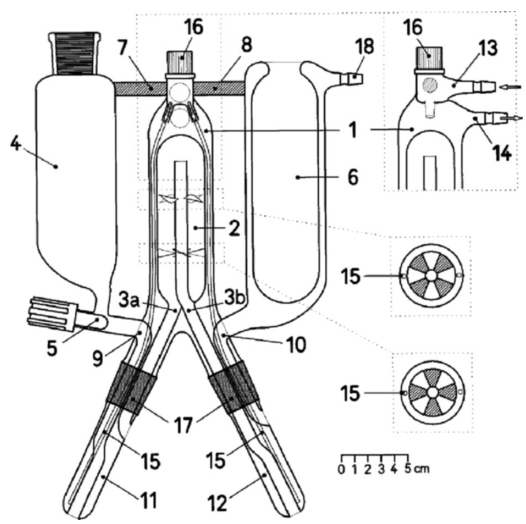

Figure 4.2.4 *Solvent assisted flavor evaporation (SAFE) apparatus designed by Engel* et al. *(1999). Reproduced with permission of Springer-Verlag*

volumes. The outlet of the dropping funnel leads to the bottom of the left 'leg' (no.11). The vapor inlets to the head (no. 3a) and the inlet to the trap are mounted on the sides of each 'leg.' To ensure a constant temperature during distillation and to prevent condensation of the volatiles, the head and the two 'legs' are completely thermostated with water. From the water inlet (no. 13), two flexible polyethylene tubes (no.15) guide the water flow to the bottom of both legs to afford effective temperature regulation by avoiding the formation of air bubbles.

Figure 4.2.5 shows the entire SAFE equipment required for performance as outlined by the inventors. Before commencement of distillation, the head and legs of the apparatus are thermostated at 20 to 30 °C via

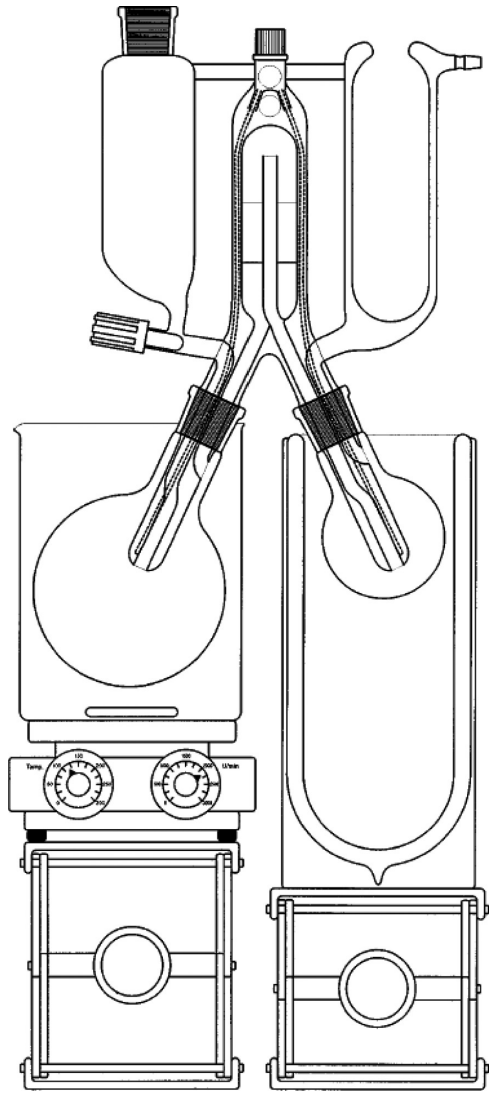

Figure 4.2.5 *Solvent assisted flavor evaporation (SAFE) apparatus assembly. Temperature of water bath, 30 °C; temperature of the trap, −196 °C (Engel* et al.*, 1999). Reproduced with permission of Springer-Verlag*

the outlets 13 and 14 (Figure 4.2.4). The distillation vessel (typically 250 ml to 1000 ml) is heated in a water bath at 20 to 30 °C. A diffusion pump supplying a high vacuum (10^{-3} Pa) is applied to the apparatus via outlet no.18 (Figure 4.2.4) while the high vacuum stopcock of the dropping funnel is carefully closed. Liquid nitrogen is applied to the trap (Figure 4.2.4, no.6) prior to the start of the distillation, which is achieved by dropping aliquots of the sample from the dropping funnel into the left vessel at which point, the volatiles and solvent are transferred via tube 3a (Figure 4.2.4) into the distillation head no.2. Here, two propeller shaped 'barriers' remove non-volatile material from the vapors and the distillate enters a flask, cooled with liquid nitrogen, via tube 3b on the right side of the apparatus. Volatiles, water or other solvents condense along the walls of the vessel.

Since its creation, the SAFE technique has been quickly adopted for the isolation and analysis of aroma compounds from various alcoholic beverages. For example, 500 ml of Bavarian Pilsner type beer (Section 2.6.13) was repeatedly extracted with diethyl ether, before being dried over sodium sulfate and concentrated to 100 ml by distilling off the solvent at 38 °C using a 60 cm × 1 cm i.d. Vigreux column (Fritsch and Schieberle, 2005). Finally, to remove the non-volatile material, the concentrate was distilled using the SAFE method and the resulting distillate treated with aqueous sodium bicarbonate to obtain fractions of the acidic volatiles and of the neutral/basic volatiles. These were subsequently dried with sodium sulfate and concentrated via microdistillation before analysis by high resolution gas chromatography-olfactometry (GC-O) and GC-MS. This approach has also been used to characterize the most odor active compounds in American Bourbon whisky (Section 3.3.4) (Poisson and Schieberle, 2008). Here the researchers extracted the aroma volatiles present in 25 ml of whisky (previously diluted 1:1 with tap water saturated with salt) using diethyl ether (3 × 100 ml). The combined extracts were then dried over sodium sulfate and concentrated to 100 ml using a Vigreux column. SAFE removed the non-volatile compounds and the distillate was finally concentrated to 100 µl and separated into neutral/basic and acidic volatiles as previously.

Similarly, 1000 ml of Oregon Pinot Noir wine was extracted with diethyl ether:pentane (1:1, v:v) three times in a separating funnel (extracts totalled 750 ml) before the aroma volatiles were isolated using SAFE, dried with sodium sulfate and concentrated to 10 ml under a stream of nitrogen. This aroma extract was further separated into acidic/water soluble and neutral/basic fractions by adding 10 ml of distilled water, adjusting the pH of the aqueous phase to pH 11 (with sodium carbonate solution) then separated in a separating funnel and retained. The organic phase was further washed with 10 ml dilute sodium hydroxide solution (pH = 11) three times and the washings combined with the aqueous phase. The organic phase was dried over sodium sulfate, filtered and concentrated to 200 µl for GC-O analysis. The aqueous solution was adjusted to pH 1.7 with sulfuric acid, 10g of salt (NaCl) was added and the solution extracted three times with 50 ml diethyl ether:pentane (1:1, v:v). These extracts were combined, dried with sodium sulfate and concentrated to 500 µl for further GC-O analysis (Fang and Qian, 2005a). An identical approach has also been reported for the characterization of aroma compounds in apple cider (Section 2.8.4) (Xu *et al.*, 2007).

4.2.4 Solid Phase Extraction and Related Methods (Sorption Techniques)

Developed in the late 1970s, solid phase extraction (SPE) quickly became a useful and well cited sample preparation technique and was the forerunner to the present so called 'sorption techniques' solid phase microextraction (SPME) and stir bar sorptive extraction/headspace sorptive extraction (SBSE/HSSE). Solid phase extraction initially evolved from classical liquid solid extraction (LSE) whereby the sorbent was typically placed in a vessel containing the analyte dissolved in a suitable solvent and shaking/mixing for a controlled length of time. The two phases were then separated and the analytes of interest were desorbed using a suitable organic solvent (Handley and McDowall, 1999). This technique was then later modified by packing the sorbent (stationary phase) into glass columns to perform wet column chromatography and then finally the

SPE cartridge was born. An excellent guide to the solid phase technique, including phase types, theory and use is available (Supelco, 1998).

This widely commercially available product contains milligram quantities of sorbent phase which is supported between two fritted disks in a plastic syringe type cartridge. Analytes present in an aqueous/ethanolic matrix can therefore be selectively retained and subsequently eluted by an appropriate solvent.

SPE has several well reported advantages over the previously conventional and dominating liquid–liquid extraction techniques in that it is generally faster, requires less solvent (hence more 'green' and economical), reduces the need for large concentration steps and is easily automated, as well as eliminating the use of expensive speciality glassware.

The 'stationary phases' that are utilized for solid phase extraction are equivalent to those used for high performance liquid chromatography (HPLC) (Section 4.3.3), however, the particle size for conventional HPLC column stationary phases are anywhere between 3 to 10 μm, whereas those for SPE separations are typically in the region of 40–80 μm. There are three main modes of SPE separation. These are reversed phase (non-polar solid stationary phase, polar elution solvent), normal phase (polar solid stationary phase, non-polar elution solvent) and ion exchange (anion or cation) using charged bonded sorbents. In the reverse phase (non-polar extraction), popular commercial sorbent phases include octadecyl (C_{18}), octyl (C_8), phenyl and cyanopropyl. For this type of extraction, the sorbent utilized is generally less polar than the solvent or matrix solution and the non-polar analytes are retained on the SPE bonded phase and eluted with non-polar solvents. In the normal phase (polar extraction), commercial sorbent phases include silica gel (no bonded phase), diol and aminopropyl as examples. Here, polar analytes from the sample matrix are retained and elution is carried out with generally polar solvents. Ion exchange sorbents can contain either a strong or a weak cationic or anionic exchanger and can be silica or resin based. Cationic or anionic analytes in the sample matrix are retained by an oppositely charged group and elution is achieved by altering the pH or increasing the ionic strength of the elution solvent.

The SPE process involves four key steps; conditioning of the column, application of the sample, washing of the column to remove unwanted components and finally elution of the analyte(s) of interest (see Figure 4.2.6).

The SPE cartridge is conditioned by passing through three to four times the sorbent bed volume of a high purity (HPLC grade) organic solvent. Reversed phase sorbents are usually conditioned with a water miscible (polar) solvent such as methanol, followed by water or an aqueous buffer. This conditioning/equilibrium

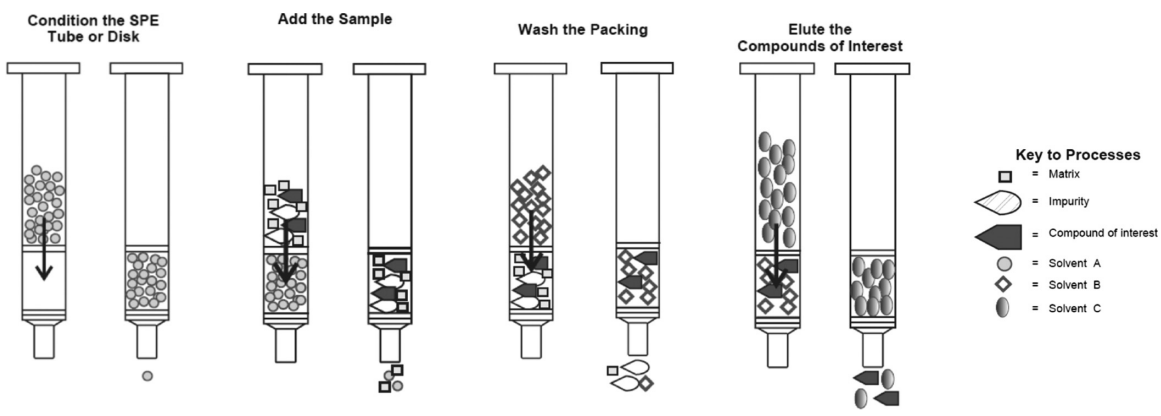

Figure 4.2.6 *Key steps of the SPE process (Supelco, 1998). Reproduced with permission of Sigma Aldrich, St. Louis, USA*

process wets the surface of the sorbent and penetrates the bonded alkyl phases, allowing water to wet the silica surface efficiently and increase the overall surface area available for interaction with subsequent analytes applied to the sorbent phase. This step also aids removal of impurities/residues from the packing material that could interfere with the analysis. Normal phase SPE sorbents are usually conditioned with the organic solvent in which the sample analytes have been dissolved. Ion exchange sorbents that are utilized for analytes in non-polar organic solvents should be conditioned with solvent equivalent to that of the sample, whereas for analytes in polar solvents, a water miscible organic solvent should be adopted, followed by an aqueous solution with a pH, organic solvent content and salt concentration as similar as possible to that of the sample to be extracted.

In the second step of the SPE process (see Figure 4.2.6), the sample is transferred to the column/cartridge and allowed to flow through the sorbent bed. Sample volumes can range from microliters (μl) to liters, however if a large volume aqueous based sample is applied to reversed phase silica packings, the column will gradually lose its 'wetted' effect as the solvent layer added during the conditioning process is lost, and this will result in a reduction in recovery (extraction efficiency) of the analytes of interest. To overcome this problem, for samples above 250 ml, an organic solvent that is water miscible (such as methanol at a concentration of up to 10%) is mixed with the sample prior to transferring to the column. This helps to maintain sufficient wetting of the sorbent phase and hence the equilibrium between the stationary and mobile phases. The sample should be passed slowly through the sorbent phase and many researchers use either vacuum or positive pressure. As the flow rate can affect the retention of the analytes to the stationary sorbent phase, care should be taken to ensure that the sample flow does not exceed 2 ml/min for ion exchange SPE columns/tubes and 5 ml/min for other SPE sorbent phases. Many researchers standardize flow rates to approximately 1 ml/min for most analyzes .

Now that the analytes of interest have been retained on the sorbent phase, unwanted matrix materials or analytes are removed by washing the column with the same solvent in which the sample analytes originated (for example aqueous ethanolic solution for wine). Usually no more than a single column volume of wash solvent is required to remove unwanted matrix or analyte compounds.

The final step of the SPE process is to elute (rinse) the analyte(s) of interest from the sorbent phase and collect the eluent for analysis. This step should only remove the compounds of interest and leave any impurities on the sorbent phase that were not removed previously in the wash step. With SPE cartridges, typically 200 μl of elution solvent is sufficient to remove the analytes of interest. Generally, two 100 μl aliquots are more efficient than a single application of 200 μl and flow rate is critical to ensure high recoveries of analyte(s). Recoveries are highest when each aliquot remains in contact with the sorbent phase for 20 s to 1 min with slow or drop wise flow rates (Supelco, 1998).

Wada and Shibamoto (1997) investigated the recovery efficiencies of the main volatile components of wine from porous polymer Porapak Q, (an ethylvinylbenzene-divinylbenzene copolymer), using dichloromethane, diethyl ether and pentane as solvents. Dichloromethane showed the highest recovery efficiency, followed by diethyl ether and pentane. Volatile components from a commercial wine were trapped on Porapak Q (suspended in a glass column), and subsequently recovered using an organic solvent. This method exhibited satisfactory results on isolation of volatile compounds although relatively low recovery percentages were observed. Overall, this solid-phase extraction method demonstrated the simplicity of the technique with rapid recovery of volatile compounds from aqueous alcohol samples.

In 1985, a method of extraction and determination of free and glycosidically bound grape aroma components was suggested (Gunata *et al.*, 1985). These compounds were adsorbed on the nonionic resin, Amberlite® XAD-2, followed by elution with various selective solvents. Free forms were directly determined by gas chromatography; glycosidically bound forms were first enzymatically hydrolyzed. The method was applied to a number of mature grape varieties and it was found that these could be classified in two groups, those rich in free and bound forms which give aromatic wines (Muscat varieties and Gewürztraminer), and those which contain small amounts of these compounds.

This technique has been used in further studies (Voirin *et al.*, 1992; Wirth *et al.*, 2001; Castro Vazquez *et al.*, 2002; Cabaroglu *et al.*, 2003; Sánchez-Palomo *et al.*, 2006; Botelho *et al.*, 2010) and has also been compared with liquid–liquid extraction for the determination of wine flavor components (Zhou *et al.*, 1996).

Edwards and Beelman (1990) also used a similar SPE method. The relative recoveries of the volatile compounds extracted from a French hybrid wine (Aurore) were found to be quite acceptable, in the range of 90–114%, with the majority being greater than 95%. Diethyl ether was used as the fractionation solvent. This XAD-2 extraction method was shown to be a rapid and simple technique for analysis of volatile compounds in wines. The principle advantage of this method over other commonly used methods (such as liquid–liquid extraction) is the decreased time of extraction. It was concluded that excellent precision and recovery, as well as speed, gave this technique great potential for research and quality control applications.

XAD-2 extraction has also been applied to the recovery of aroma compounds from beer to determine which compounds from hops were most important for beer character (in terms of odor and intensity) via gas chromatography-olfactometry (GC-O) (Lermusieau *et al.*, 2001) and recently it has been used alongside specific liquid–liquid extraction to successfully identify 4-vinylsyringol as a stale beer-like odorant (Callemien *et al.*, 2006).

Other adsorbents have also been adopted to study the volatile aroma compounds of grape juices and wines by solid phase extraction. These include Amberlite® XAD-4 (Ferreira *et al.*, 2002), Merck's Extrelut resin (Gerbi *et al.*, 1992), LiChrolut EN resin (Lopez *et al.*, 2002; Ferreira *et al.*, 2003; Campo *et al.*, 2007, Garde-Cerdán *et al.*, 2008a; Loscos *et al.*, 2010), C-18 (Williams *et al.*, 1982; Mateo *et al.*, 1997; Schneider *et al.*, 2001, Diéguez *et al.*, 2003; Luan *et al.*, 2004; Lukic *et al.*, 2006; Villena *et al.*, 2006), Analytichem's Extube CHEM ELUT (Gelsomini *et al.*, 1990) and IST Isolute ENV+ (Boido *et al.*, 2003). Recently Campo *et al.* (2007) validated an SPE method for the quantification of four powerful aroma compounds (ethyl 2-, 3- and 4-methylpentanoate and ethyl cyclohexanoate) in different samples of wine, whisky and brandy. These compounds were extracted from 100 ml samples on a 200 mg LiChrolut EN bed. Major compounds were eliminated by rinsing with a water:methanol (50:50) solution containing 1% sodium bicarbonate, and the analytes of interest were subsequently eluted with 1.5 ml of dichloromethane. 50 μl of this extract was then analyzed by multidimensional GC-MS. Recoveries were found to be quantitative (99–106%) and the method offered satisfactory repeatability and good linearity.

The notorious off-flavor (cork taint) components 2,4,6-trichloroanisole (TCA) and 2,4,6-tribromoanisole (TBA) have recently been studied using the SPE technique. Insa *et al.* (2006) evaluated the extraction of chlorophenolic compounds from ground cork samples with ethanol/water mixtures combined with SPE or headspace-solid phase microextraction (HS-SPME) and GC-ECD (electron capture detection). Both of the tested sample preparation methodologies were reported to compare well in terms of recovery of the target analytes, and it was demonstrated that chlorophenols could be detected in corks contaminated at the nanogram per gram (ng/g) level, therefore it was suggested that the technique could be successfully applied as a quality control measure in the cork industry.

A miniaturization of the conventional SPE technique has recently been developed as a novel method of sample preparation. This was recently optimized for the quantitative determination of TCA and TBA in wine (Jönsson *et al.*, 2008). Microextraction in packed syringe (commercially known as MEPS) was optimized for the extraction and preconcentration of the analytes using extremely small sample volumes (0.1–1 ml). MEPS was performed using a 100 μl gas-tight syringe filled with 4 mg of C18 phase conditioned with 30 μl of methanol followed by an equivalent volume of water. Extraction was performed by drawing 100 μl or 10×100 μl of the sample through the syringe and the C18 solid phase. The sorbent bed was then subsequently dried and the analytes eluted with 10 μl of toluene into a GC vial for analysis by GC-MS. It was concluded that the optimized and validated technique yielded extremely low limits of detection (LOD) and the target analytes could be detected in wine samples before being sensorially identified as cork tainted.

SPE with a novel porous carbon sorbent CARB GR was reported for the extraction and preconcentration of dicarboxyimide fungicide residues from wines, with subsequent analysis by GC with either flame ionization detection (FID), electron capture detection (ECD) or MS (Matisová *et al.*, 1996). Reliable recovery data was measured at various concentrations of the fungicides vinclozolin and iprodione in standard solutions (0.0005–0.1 mg/ml) and spiked wines (5.90 μg/l–1.96 mg/l) and excellent limits of quantitation (LOQ) were determined.

Recently, Montes *et al.* (2009b) described a novel approach for the determination of seven fungicides (metalaxyl-M, penconazole, folpet, diniconazole, propiconazole, difenoconazole and azoxystrobin) in wine samples. Fungicides were extracted from the samples and then subsequently transferred to a small volume of high density, water insoluble solvent using SPE followed by dispersive liquid–liquid microextraction (DLLME). Following optimization, wine samples (20 ml) were initially concentrated using SPE cartridges packed with 60 mg of Waters Oasis HLB reversed phase sorbent. Target compounds were then eluted with 1 ml of acetone and mixed with 0.1 ml of 1,1,1-trichloroethane before finally being added to 10 ml of ultrapure water. After centrifugation, 1–2 μl of the settled organic phase was analyzed by GC-ECD and GC-MS. The method was reported to provide enrichment factors around 200 times and an improved selectivity in comparison to the use of SPE as a single sample preparation technique. It also offered limits of quantitation low enough for the determination of target analytes in commercial wines.

The existence of pesticide residues in alcoholic beverages offered commercially for public consumption has been extensively studied by SPE and GC. Soleas *et al.* (2000) reported a multiresidue method for the simultaneous quantitation of 17 pesticides in wine: dicloran, dimethoate, diazinon, chlorpyrifos-methyl, vinclozolin, carbaryl, methiocarb, dichlofluanid, parathion-ethyl, triadimefon, procymidone, myclobutanil, iprodione, imidan, dicofol, phosalone and azinphos-methyl. C_{18} bonded porous silica SPE extraction of 0.5 ml of wine sample was initially carried out followed by direct injection of 1 μl and analysis by GC-MS in selective ion monitoring mode (SIM – the operation of the mass spectrometer in which the intensity of one or more specific ion beams are recorded as opposed to the entire mass spectrum). Detection and quantitation limits were around 2 μg/l and 10 μg/l respectively, with linear calibration curves up to 3 mg/l for a majority of the analytes under investigation. Recoveries were reported to be >90% for half of the analytes and >80% for most of the remainder with imprecision (RSD) <10% for most pesticides and <18% in all.

Organochlorine pesticides have recently been determined at low levels in white, red, rosé and sparkling wines by automated SPE and GC-MS-MS detection (Pérez-Serradilla *et al.*, 2010). The efficiency of different commercially available SPE sorbents were initally tested, as well as changes in both the volume flushed through the sorbent and the volume subsequently injected into the GC. This allowed the detection limits of the optimized method to be adapted to the analytes contents in the target wine samples. Preconcentration of 100 ml of wine and injecting 10 μl of extract into the GC, yielded limits of detection obtained for the OCPs in the range of 1.7 and 9.7 ng/l (ppt), depending on the OCP and type of wine. The researchers concluded that the automated method enabled a cheap and fast analysis and provided good sensitivity and precision. The method detection limits (MDLs) were reported to be low enough to determine the target pesticides in wine samples with concentrations far lower than the maximum residue limits (MRLs) of OCPs in grapes (there is not a current legislation regulating the MRLs in wines).

The fate of residues of seven pesticides (chlorfenapyr, quinoxyfen, tebuconazole, fenarimol, pyridaben, and (*E*)- and (*Z*)-dimethomorph) from the treatment of hops to the brewing of beer was studied recently using SPE by Hengel and Shibamoto (2002). Initially a multiresidue analytical method was developed and validated for the determination of pesticide residues in spent hops, trub, wort and finished beer. Recoveries ranged from 73–136% and it was demonstrated that the use of pesticide treated hops resulted in the carryover of certain pesticides into the wort during beer production. Following fermentation, all analytes except (*E*)- and (*Z*)-dimethomorph were found in concentrations lower than 0.0005 ppm in beer. When all seven pesticides were spiked prior to the pinching of yeast into clean wort, most of the non-polar analytes (chlorfenapyr, quinoxyfen

and pyridaben) partioned into the organic material (trub) which settled to the bottom of the fermentation vessel, whereas more polar compounds (fenarimol, tebuconazole, and (*E*)- and (*Z*)-dimethomorph) were generally distributed evenly between the beer and the trub.

Similarly, a multiresidue determination of 142 pesticides (including isomers) in malt beverages was recently reported by Wong and coworkers (2004) using polymeric SPE cartridges and sample cleanup with a magnesium sulfate-topped aminopropyl cartridge, followed by GC-SIM-MS. GC detection limits for most of the analytes studied were 5–10 ng/ml, and linearity was determined from 50–5000 ng/ml. Recoveries were greater than 70% for 85 of the analytes studied and the data demonstrated that different malt beverages matrices had no significant effect on the recoveries. When applied to the screening and analysis of malt beverages for pesticide residues, the method proved effective in detecting the insecticide carbaryl and the fungicide dimethomorph in real samples at concentrations significantly lower than those set by the US Environmental Protection Agency (EPA).

GC determination of *N*-Nitrosamines (Section 5.11.5) in beverages (including beer, wine, liquor, whisky, cognac, rum, vodka, grape juice, cider, tonic water and soft drinks) using automatic SPE and subsequent GC-NPD was recently proposed (Jurado-Sánchez *et al.*, 2007). Following examination of various SPE sorbents, LiChrolut EN was found to provide quantitative elution and the highest preconcentration factors. The authors concluded that the optimized method offered LODs between 7 and 33 ng/kg and precision (RSD) from 4.3–6.0%. The recoveries of *N*-Nitrosamines from real beverage samples spiked with the chosen analytes ranged from 95–102%.

Phthalate esters in wine have been determined using C_{18} SPE and GC-MS (Del Carlo *et al.*, 2008). Following initial optimization, the method was applied to the screening of 62 samples of white and red wines obtained from the market, winemakers and an experimental pilot plant and it was reported that all samples analyzed were phthalate contaminated.

Solid phase microextraction (SPME) was first described for the analysis of environmental chemicals in water by Berlardi and Pawliszyn (1989). Following its commercial introduction by Supelco (Bellefonte, PA), SPME rapidly gained popularity for the extraction of volatile and semi-volatile organic compounds from a wide variety of sample matrices. Since this technique does not require the use of organic solvent, extractions (in either immersion or headspace modes) can generally be performed at ambient temperature without heating the sample, thus reducing, if not completely eliminating, the formation of artefacts. Furthermore, only small sample volumes are required, hence as with SPE, the process is 'green', economical, and is easily automated using specially modified SPME devices now manufactured by a large number of analytical equipment suppliers such as CTC, Gerstel and Thermo Scientific.

The stages of the SPME process are shown in Figure 4.2.7. A small fiber of fused silica (1 cm length and 0.11 mm internal diameter) coated with a polymeric phase is bonded to a spring loaded stainless steel plunger which allows movement of the silica fiber in and out of a hollow needle. For extraction of volatiles by liquid (immersion) sampling, each sample is placed, along with a small magnetic stirring bar, in a glass vial crimp sealed with a septum and cap. The SPME fiber is then drawn into the needle of the syringe, which in turn pierces the septum and the fiber is extended and brought into contact with the liquid sample. Used in the headspace mode, the fiber of the SPME device is extended into the vapor phase above the sample. In either mode, over time with stirring of the sample, aroma/flavor analytes of interest from alcoholic beverages adsorb to the polymeric phase of the fiber. Adsorption equilibrium is usually achieved using sampling times ranging anywhere between 2 and 30 min after which the fiber is drawn back into the needle, which is then removed from the septum and inserted immediately (whether manually or automatically) into the injection port of a gas chromatograph (GC) for 1–2 min for subsequent thermal desorption and analysis. Prior to analysis of samples, the SPME fiber should be cleaned (preconditioned) by inserting the fiber into the heated injection port of a gas chromatogram or in a fiber bakeout station that are now also commonly supplied as an optional extra on automated samplers (CTC, Gerstel and Thermo Scientific).

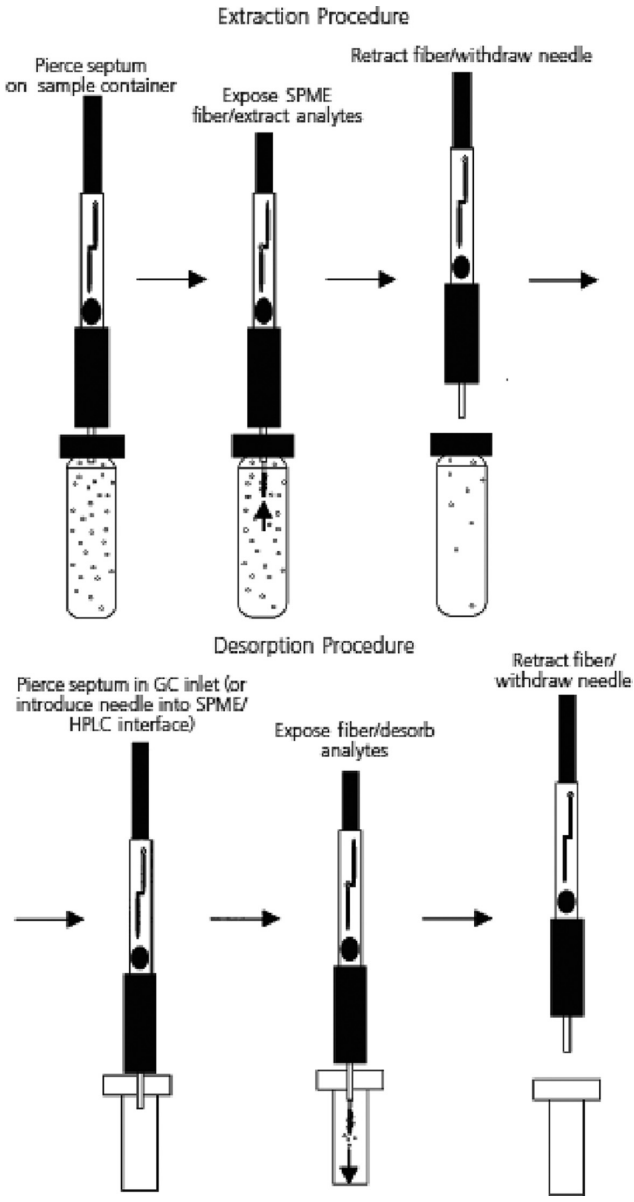

Figure 4.2.7 *Stages of the solid phase microextraction process (Supelco, 2004). Reproduced with permission of Sigma Aldrich, St. Louis, USA*

As with other sample preparation techniques such as liquid–liquid extraction and simultaneous steam distillation-extraction (SDE), extraction efficiency with SPME is also affected by contact time, immersion depth (in liquid sampling), efficiency of mixing, pH, salt concentration, temperature and phase ratio (ratio of sample volume/adsorbent volume). These factors can all affect the partitioning in SPME extractions (Harmon, 1997). Therefore, extraction selectivity can be manipulated by altering the type of polymer coating (adsorbent)

on the fiber, or the coating thickness to match and subsequently extract analytes of interest from aqueous ethanolic matrices (in the case of alcoholic beverages).

For liquid polymeric SPME coatings, the amount of analyte adsorbed by the coating at equilibrium is directly related to the concentration of the analyte in the sample (Zhang and Pawliszyn, 1993; Yang and Peppard; 1994, Supelco, 2004), as expressed in Equation 4.2.2.

$$n = \frac{K_{\mathrm{fs}} V_{\mathrm{f}} C_0 V_{\mathrm{s}}}{K_{\mathrm{fs}} V_{\mathrm{f}} + V_{\mathrm{s}}} \tag{4.2.2}$$

Here, n is the mass of analyte adsorbed by the coating/fiber, C_0 is the initial concentration of the analyte in the sample, K_{fs} is the partition coefficient for the analyte between the coating and sample matrix and V_f and V_s are the respective volumes of the sample and coating (fiber phase). This equation demonstrates a linear relationship between the initial concentration of the analyte in the sample and the amount of analyte adsorbed by the SPME fiber.

Because the adsorbent coatings utilized in SPME are selected to have strong affinities for the analytes they are intended to extract, the partition coefficient for the analyte between the coating and sample matrix is large, hence complete (>90% of the analyte adsorbed by the SPME coating) extractions are rarely required to obtain quantitative results. All extraction conditions should, however, be carefully controlled and repeated for high accuracy and precision from SPME.

As headspace SPME relies on the equilibrium partitioning of an analyte between the fiber coating and the vapor phase above a liquid sample, the sample headspace should be kept as small as possible. The diffusion of analytes to the SPME fiber in the vapor phase has been reported to be in the region of four orders of magnitude greater than diffusion in solution (Zhang and Pawliszyn, 1993; Harmon, 1997).

Desorption of analytes from a SPME fiber depends on a number of factors, such as the boiling points of the analytes adsorbed, the film thickness of the fiber coating and the temperature of the GC injection port. Generally, GC inlet liners with narrow internal diameter of around 0.75 mm aid sharpening of the subsequent chromatographic peaks and often eliminate the need for cryogenic cooling of the inlet (trapping analytes with liquid nitrogen or carbon dioxide at subzero temperatures in a GC inlet as an aid to sharpen early eluting aroma volatiles).

Vas *et al.* (1998) used SPME to study volatile aroma compounds of Blaufrankisch (Gamay Noir) wines. Two different SPME extraction fibers were used in either static headspace mode (by inserting the fiber into the headspace of a 130 ml sampling bottle containing 125 ml of wine), or immersed in the liquid for 1 h at ambient temperature with stirring. The extraction fibers chosen were the non-polar poly(dimethylsiloxane) (PDMS) with 100 μm film thickness and polar poly(acrylate) (PA) with 85 μm film thickness. A 'classical' liquid–liquid extraction method was also used for comparison. Semi-quantitation (peak area measurement) was performed using gas chromatography and mass spectrometry. Thirty-three major volatiles were identified and it was concluded that the SPME sample preparation technique coupled with GC analysis is well suited for qualitative and semi-quantitative analysis of the major components in wine and, because of its speed and reproducibility, had good potential for wine aroma characterization and quality control applications.

An identical technique using a PDMS fiber was later used for the determination of volatiles from red wines made by carbonic maceration (Section 2.9.2) (Vas and Lorincz, 1999).

Recently, SPME has been optimized for analysis of wine aroma compounds (Demyttenaere *et al.*, 2003a; Peña *et al.*, 2005; Tat *et al.*, 2005). Also a PDMS) SPME-GC method for the analysis of volatile compounds in wines has been validated (Pozo-Bayon *et al.*, 2001).

Headspace solid phase microextraction and gas chromatography (HS-SPME-GC) has also been used for the rapid determination of volatile compounds in grapes (Sánchez-Palomo *et al.*, 2005) and for the determination of major aroma compounds in sweet wines (Rodriguez-Bencomo *et al.*, 2003). Here, five different SPME fibers

were tested, including PDMS 100 μm, PDMS 7 μm, PDMS-divinylbenzene (DVB) 65 μm, PA 85 μm and carbowax (CW)-DVB 65 μm. The influence of different factors, such as temperature and time of desorption, extraction time, stirring, sample and vial volume, sugar and ethanol content, were studied and optimized using model solutions. The method was validated using a direct injection method. It was concluded that the CW-DVB fiber offered the greatest sensitivity when applying an ambient temperature 20 min extraction time with stirring and saturation of the 4 ml samples with sodium chloride in a 16 ml vial. The ethanol and sugar content was shown not to influence the extraction, which allowed the technique to be applied to sweet wine samples.

The aroma volatiles of many other wine varieties, from different origins, have been studied using the SPME technique. Examples include: the classification of Nebbiolo-based wines from Italy (Marengo *et al.*, 2001), the analysis of two different palm wine species from Cameroon (Jirovetz *et al.*, 2001), Tokaji Aszu wine from Hungary (Toth-Markus *et al.*, 2002), extraction of the volatile flavor components of mandarin wine (Selli *et al.*, 2004), the rapid analysis of flavor volatiles in apple wines (Wang *et al.*, 2004; Satora *et al.*, 2008) the characterization of an Italian Piedmont wine (Bonino *et al.*, 2003), the analysis of volatile compounds for the analytical classification of Chinese red wines from different varieties (Zhang *et al.*, 2010) and for the profiling of free volatile compounds in Cabernet Sauvignon grapes (during ripening) and wines (Canuti *et al.*, 2009). It has also been used in combination with principal component analysis as a rapid tool for distinction of wines based on the global volatile signature (Rocha *et al.*, 2006). The technique has also been investigated extensively for the analysis of specific aroma components such as sulfur compounds (Mestres *et al.*, 1998; 1999; 2000; 2002; Fang and Qian, 2005b; Lopez *et al.*, 2007), pyrazines (Sala *et al.*, 2000; 2002; Chapman *et al.*, 2004; Ryan *et al.*, 2005), esters (Vianna and Ebeler, 2001; Rodriguez-Bencomo *et al.*, 2002), volatile phenols (Martorell *et al.*, 2002; Mejias *et al.*, 2003; Pizarro *et al.*, 2007) 2-aminoacetophenone (Fan *et al.*, 2007a), 'brett' character (ethylphenols) (Romano *et al.*, 2009), stereoselective formation of rose oxide during fermentation (Koslitz *et al.*, 2008), assessment of C_{13} norisoprenoids (Vinholes *et al.*, 2009) and diacetyl (Hayasaka and Bartowsky, 1999).

A serious and highly costly problem related to the off flavor called 'cork taint' has been studied using SPME-GC-ECD by Alzaga *et al*. (2003). A headspace SPME procedure at 30 °C with a 100 μm PDMS fiber was optimized for the determination of 2,4,6-trichloroanisole (TCA) with 2,4,6-tribromoanisole (TBA) as internal standard. The researchers reported a limit of quantitation for TCA in wine within 2.9–18 ng/l (parts per trillion) with a relative standard deviation of 2.5–13.4%, depending on the TCA concentration level and wine characteristics. It was concluded that the proposed method was comparable to existing HS-SPME methodologies, however analysis cost was reduced. A similar method for the analysis of TCA in wine and cork samples has recently been proposed (Vlachos *et al.*, 2007).

A headspace SPME method for the determination of 12 haloanisoles in wines and spirits using GC-atomic emission detection (GC-AED) was developed and optimized by Campillo *et al.* (2008a). A DVB-carboxen (CAR)-PDMS fiber was reported to be the most suitable for preconcentration of the target analytes from aqueous dilutions of samples. Limits of detection ranged from 1.2–18.5 ng/l with a fiber exposure time of 60 min at 75 °C.

The SPME technique has also been compared to other established techniques for the analysis of wine flavor. This includes liquid–liquid extraction with pentane and diethyl ether as solvents (Castro *et al.*, 2004), solid phase extraction with ENV+® cartridges (highly cross linked styrene-divinylbenzene polyhydroxylated polymer) for the determination of 3-mercaptohexan-1-ol and 3-mercaptohexyl acetate, whereby the application of the two proposed methods to 52 wines of different varieties gave similar results (Fedrizzi *et al.*, 2007), and extraction with Amberlite® XAD-2 (Bohlscheid *et al.*, 2006). In the latter it was concluded that the optimized HS-SPME extraction conditions provided comparable results to XAD-2 extraction for the analysis of higher alcohols, esters and medium chain fatty acids present in wine. The HS-SPME method

provided a less complicated and time consuming analysis of wine volatiles to subsensory threshold levels, whilst retaining high efficiency and reproducibility.

SPME has been very recently adopted to study the influence of saliva on aroma release from both white and red wines in a model mouth system (Genovese *et al.*, 2009). Aroma compounds were analyzed in the dynamic headspace of wines using a DVB-CAR-PDMS fiber and GC with flame ionization detection (FID) and mass spectrometry (MS). It was demonstrated that saliva showed a greater influence on aroma release in white wine than red wine. White wine treated with human saliva yielded a reduction in esters and fusel alcohols (32–80%), whereas in contrast, the concentrations of 2-phenylethanol and furfural (responsible for rose and toasted almond notes) were increased by 27% and 155%, respectively. In red wine treated with human saliva, relatively few esters showed a decrease in concentration due to the protein binding ability of polyphenols that were able to inhibit the activity of the saliva.

The volatile flavor/aroma compounds of both wort (Section 2.6.2) and beer have very recently been studied using headspace SPME. Fibers with different stationary phases and various film thicknesses were evaluated to optimize wort volatile analysis (De Schutter *et al.*, 2008). PDMS 100 μm, PDMS-DVB 65 μm, CW-DVB 70 μm, CW-PDMS 85 μm and DVB-CAR-PDMS 50/30 μm were all compared for extraction performance by placing 10 ml of wort into 20 ml vials containing 3.5 g of sodium chloride prior to capping. Samples were then equilibrated for 10 min at 40 °C with a magnetic stirring speed of 500 rpm. The SPME fiber was introduced automatically through the septum of the vial and exposed to the headspace of the sample for 20 min at 40 °C, under continuous stirring at 250 rpm. Extraction temperatures were also evaluated, along with extraction time and salting out effect, and it was concluded that the HS-SPME method, combined with gas chromatography-mass spectrometry seemed to be an easy and promising technique for the analysis of volatiles in wort. The DVB-CAR-PDMS fiber with an extraction time of 30 min at 40 °C and the addition of 3.5 g salt to 10 ml wort samples was proven to offer the most complete extraction profile of a broad range of volatiles. The method was reported to allow detection limits of volatile compounds in concentrations as low as 12 ng/l (12 parts per trillion). Moreover, the optimized analytical procedure showed good linearity and was applied to the analysis of wort samples taken from a wort boiling process in an industrial brewery.

A similar optimization method development approach has also been completed for the quantification of 32 volatiles which represent the typical chemical reactions that can occur during the ageing of beer (Saison *et al.*, 2008). Detection was achieved using on-fiber derivatization using *ortho*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine (PFBHA) and conventional HS-SPME extraction. The two procedures were optimized for fiber selection, PFBHA loading temperature and time, extraction temperature and time, and effect of salt addition. Matrix interference effects were overcome by calibrating according to the standard addition method and by using internal standards. The method was finally validated and applied to study the flavor stability of different beer samples. It was concluded that aldehydes showed optimal extraction following loading of a PDMS-DVB fiber with PFBHA for 10 min at 45 °C and subsequent extraction of 30 min after saturation of the beer through the addition of 3.5 g of sodium chloride. Extraction of all other compounds was optimal after extraction for 30 min at 40 °C with a DVB-CAR-PDMS fiber, after saturation of the beer with sodium chloride.

Sulfur compounds of beer have also been studied using the SPME technique. Scarlata and Ebeler (1999) proposed a headspace SPME method with a CAR-PDMS fiber for the GC-flame photometric detection (FPD) of dimethyl sulfide (DMS). It was reported that the technique was rapid, low cost, solvent free, and required no sample preparation steps (i.e. decarbonation) or modification to the GC. Furthermore, combination of HS-SPME with sensitive and selective GC detectors such as the FPD provided quantitative results comparable to those of existing methods. HS-SPME with a CAR-PDMS fiber has been further used in combination

with GC-FPD for the determination of volatile and semi-volatile sulfur compounds in beer at trace levels (Hill and Smith, 2000). PDMS-HS-SPME has also been compared with headspace and direct single-drop microextraction (Xiao *et al.*, 2006) and a CAR-PDMS-HS-SPME method for the determination of volatile organic sulfur and selenium compounds in beers, wines and spirits using GC and atomic emission detection (AED) has recently been reported (Campillo *et al.*, 2009).

The application of SPME and GC-MS to the detection of flavor volatiles present in Irish whiskeys (Section 3.3.2) and Scotch whiskies (Section 3.2.6) was investigated by Fitzgerald *et al.* (2000). A method was developed to characterize, identify and quantify 17 congeners which included fusel alcohols, acetates and esters. The optimum fiber was reported to be PA 85 μm, with an extraction time of 35 min, sample size of 3 ml and desorption time of 5 min. The impact of salt on the sorption process was also studied prior to validation of the method with determination of calibration ranges (coefficients of linearity and relative standard deviations) and detection limits. Characteristic profiles were determined for each of the whisky samples studied and the flavor congeners were quantified using 4-methyl-2-pentanol as the internal standard. The researchers concluded that the optimized SPME-GC method could be considered complementary to the previously used method of direct injection GC, and that it provided many advantages over other methods that have previously been adopted, such as purge and trap, solvent extraction and distillation/extraction.

Blended Scotch whisky has also been analyzed by both SPME and stir bar sorptive extraction (SBSE) (Demyttenaere *et al.*, 2003c). PDMS 100 μm, PA 85 μm and DVB-CAR-PDMS 50/30 μm were compared to analyze whisky flavor volatiles. The authors reported that the best fibers for providing the highest enrichment of volatiles and the highest reproducibility of peak areas following subsequent GC-MS analysis were PDMS and DVB-CAR-PDMS. Optimal extraction conditions consisted of a 30 min extraction time with liquid immersion of the fiber in 17 ml of whisky sample (in a 22 ml crimped glass vial) at 25 °C without addition of salt.

A dynamic HS-SPME-GC-MS method was developed and applied to the quantitative determination of volatile compounds present in commercial whiskey samples, previously diluted to give an alcohol concentration of 13 % (v:v) (Câmara *et al.*, 2007). Experimental conditions tested included fiber coating, extraction temperature and time and the best results were reported to be obtained using a 75 μm CAR-PDMS fiber during headspace extraction at 40 °C with stirring at 750 rpm for 60 min, after saturation of the sample with sodium chloride. The optimized technique was applied to study the volatile profiles of three Scotch whisky samples. Approximately 70 volatile compounds were identified and the authors concluded that HS-SPME-GC-MS is a simple sample preparation procedure offering great capacity of concentration and combined extraction and concentration in a single step providing rapid, sensitive and solventless methodology highly applicable to the determination of volatiles and semi-volatile components in whisky samples.

Headspace SPME has recently been compared with conventional liquid–liquid extraction for the evaluation of volatile constituent patterns in commercial whiskeys (Caldeira *et al.*, 2007). Seven extraction solvents covering a wide range of polarities and two SPME fibers were evaluated for their effectiveness in extraction and quantification of volatile compounds. Highest recoveries of volatile compounds were achieved using dichloromethane as solvent for liquid–liquid extraction and using a CAR-PDMS fiber for HS-SPME. Both sample preparation methods were used to determine the responses of 25 analytes from whiskey samples and calibration standards, in order to provide sensitivity comparisons between the two methods. Calibration curves were established using a model whiskey and linear correlation coefficients were greater than 0.9929 for liquid–liquid extraction and 0.9935 from SPME for all target compounds. Recoveries greater than 80% were reported to be achieved with good precision. The authors recommended that for a complete and quantitative study of volatile composition of food beverages, two or more sample preparation techniques should be adopted.

Various parameters affecting the extraction efficiency have been tested to find suitable SPME sampling conditions to enable the characterization of the volatiles of different dry gin samples (Section 3.4.2) (Vichi *et al.*, 2005). Headspace-SPME, using a 50/30 μm, 2 cm long DVB-CAR-PDMS fiber coupled to GC-MS was developed and applied for the qualitative and semiquantitative characterization of distilled gin volatiles. To evaluate the effect of ethanol content on extraction efficiency, a gin sample was diluted with deionized water to yield alcohol concentrations of 5, 10, 20 and 40 % v:v. Various sampling temperatures (30, 40 and 50 °C) and sample volumes (1, 1.5, 2.5, and 5 ml) were tested. To determine optimum extraction time the fiber was held in the sample headspace for periods of 15, 30 and 45 min. After comparison of the relative MS detector responses, the optimized SPME conditions were found to be 2.5 ml of gin sample diluted at 10% ethanol (v:v) placed into a 10 ml vial fitted with a silicone septum. Samples were then placed in a silicon oil bath at 50 °C and maintained under magnetic stirring at 700 rpm. After 5 min of sample conditioning, the fiber was exposed to the sample headspace for 30 min and then immediately desorbed in the GC injector at 260 °C. The authors reported that 70 components (mainly mono- and sesquiterpenic compounds) of the gin sample's volatile fraction were isolated, tentatively identified or identified by reference aroma compounds. The comparative study of London dry gins and gins with geographical indication (Section 3.4.2) permitted clear differentiation between these sample sets, and the authors concluded that the results obtained may be useful for further sensory studies and that the terpenic composition of gin may also be used to distinguish samples from different commercial brands and gins with geographical indication and to indicate the type and proportions of botanical ingredients employed for gin aromatization (Section 3.4.2).

Vichi and coworkers (2008) have also recently carried out the assessment of some diterpenoids in commercial distilled gin using direct immersion SPME (DI-SPME). A multilevel factorial experimental design was adopted to optimize the methodology coupled to GC-MS and used to analyze eight commercial brands of gin. The variables tested included sample dilution, extraction temperature, salt concentration and extraction time. For all experimental design testing, 10 ml of gin was placed into a 10 ml vial fitted with a silicone septum and immersed in a silicon oil bath where the sample was magnetically stirred at 700 rpm. After 10 min of sample conditioning, the fiber was directly immersed in the sample for a range of times and immediately desorbed in the GC injector at 265 °C. The optimum conditions were reported to be with a DVB-CAR-PDMS fiber, sample dilution with bidistilled water to 50% of gin, extraction temperature and extraction time of 60 °C and 60 min, respectively, with no salt addition. It was concluded that for the first time a simple and reliable DI-SPME/GC-MS method with high sensitivity had been developed that enabled the detection and quantification of diterpenoids in juniper flavored spirits. As the diterpenic composition of gin is related to the juniper used for aromatization and to the production process, the authors stated that the method may also be useful for the characterization of distinct types and commercial brands of juniper based spirits, thereby guaranteeing the authenticity and hence quality of the product.

Fatty acid ethyl esters are the main components of rum aroma (Section 3.5.4) and play an important sensorial impact in this type of distilled alcoholic beverage (Pino *et al.*, 2002). Various HS-SPME (with PDMS fiber) variables were studied and optimized including effects of ethanol concentration, sample ionic strength, sample volume and extraction temperature and time. The study demonstrated that the high ethanol content in distilled alcoholic beverages was problematic and interference was minimized by dilution of samples to provide 12%, v:v of ethanol. The addition of salt to samples (3 M concentration) was selected, as this was reported to increase ester extraction and not ethanol extraction. Extraction times of 30 min at 25 °C in 20 ml vials provided increased extraction efficiencies compared to those obtained with 50 ml vials, due to the reduction of the equilibrium time when a smaller headspace was used, hence a sample volume of 10 ml in a 20 ml vial was selected. Finally, extraction times of 10, 35 and 60 min were tested at 10, 30 and 50 °C and the optimum results were obtained in 35 min at 30 °C. Validation of the optimized method was reported to provide recoveries greater than 91% for the analytes of interest with limits of detection between 0.007 and 0.027 mg/l (ppm), all of which were lower than the range found in the real rum samples

under investigation. This method has been further adopted for the characterization of rum, leading to a total of 184 constituents being identified in the SPME analyses, 68 of which were reported for the first time in rum (Pino, 2007). The author concluded that semi-quantitative analysis (based on peak area percentage) showed very good reproducibility and with the use of standard calibration curves, the method could be applied to measure absolute concentrations. The use of only 15 volatile compounds permitted discrimination between rum samples of three and seven years old.

Zhao and coworkers (2009) devised a headspace SPME-GC-MS method to study the volatile profile of brandy. Before analysis, samples were diluted to approximately 14% (v:v) ethanol with deionized water, saturated with sodium chloride and a 10 ml portion placed into a 20 ml glass vial spiked with 5 μl of internal standard solution (3-octanol, 10 mg/l in ethanol) along with magnetic stirring bar for agitation before sealing with a Teflon faced silicone septum for analysis. Samples were then placed into an isothermal bath held at 50 °C for 15 min to reach equilibrium before extraction. Three fibers, coated with 100 μm PDMS, 75 μm CAR-PDMS and 50/30 μm DVB-CAR-PDMS were evaluated for the extraction of the brandy aroma compounds. The authors observed that PDMS exhibited greater extraction affinity for non-polar compounds than the mixed fibers, whereas the DVB-CAR-PDMS fiber extracted more polar and mid polar compounds and showed the best results overall for the extraction of the volatile compounds of interest. Brandy samples were then extracted for 20, 30, 40 and 60 min and it was demonstrated that 30 min was required to reach extraction equilibrium. Various extraction temperatures were also studied (30, 40, 50, 60 and 70 °C) and it was found that volatile compounds extracted increased with temperatures up to 50 °C, but the extraction efficiency for lower molecular weight dropped dramatically when the temperature was increased to 70 °C. Using the optimized method to study the volatile profile of the real samples, the authors achieved identification of 144 compounds, of which 57 were common to all 11 samples. The volatiles identified were mainly represented by esters and alcohols, such as 2-methyl propanol (isobutyl alcohol), 3-methyl butanol (isoamyl alcohol), 1-hexanol, ethyl octanoate and ethyl decanoate, which were quantitatively determined. Principle component analysis (PCA) and cluster analysis (CA) were applied to study the relationships between volatile composition and brandy, and this enabled the samples to be differentiated into three groups consistent with age and quality.

Previously both SPME and liquid–liquid extraction with freon 11 had been adopted for the analysis of brandy obtained from a commercial Californian distillery (Ebeler *et al.*, 2000). It was reported that, in general, SPME using a PDMS fiber was more selective for analysis of esters and acids than liquid–liquid extraction (LLX). In contrast, LLX with freon 11 extracted the higher alcohols more efficiently than SPME and it was recommended that for a complete and quantitative picture of the volatile composition of foods and beverages, two or more sample preparation techniques should be used.

Tequila (Section 3.5.5) volatile characterization and ethyl ester determination has recently been carried out with SPME-GC-MS as the method of choice (Vallejo-Cordoba *et al.*, 2004). Several factors were observed to determine qualitative and quantitative differences in tequila volatile profiles, namely sampling mode (headspace or immersion extraction), fiber coating and fiber exposure time. Along with other researchers of alcoholic beverage aroma components utilizing SPME as the extraction technique, fused silica fibers coated with PDMS (100 μm), PDMS-DVB (65 μm), CW-DVB (65 μm), and PA (85 μm) were compared for extraction qualities. For direct liquid (immersion) sampling, the syringe of the SPME device was introduced through a septum into a 60 ml vial where a 40 ml sample was held at 40 °C in an Orbit shaker bath (75 rpm). For headspace sampling, the fiber was exposed to the headspace above a 40 ml sample saturated with 28% sodium chloride and once again maintained at 40 °C in the identical Orbit shaker bath. Sampling times of 30, 60 and 90 min were studied and thermal desorption was carried out in the gas chromatographic inlet for 5 min at 150 °C for all samples. Optimum conditions were with a PDMS fiber immersed in the liquid sample for 60 min and the ethyl esters (hexanoate, octanoate and decanoate) were successfully quantitatively determined following construction of linear calibration curves with highly significant determination coefficients ($R^2 = 0.99$) and extraction coefficients of variation (reproducibility) less than 10%. Limits of quantitation (LoQ)

for ethyl esters was reported to be 0.05 ppm, which was below the concentration range of the tequila samples studied.

An extensive study by Rodrigues *et al.* (2008) utilized headspace SPME-GC-MS for the determination of volatile and semi-volatile compounds from wine, beer and whisky samples. Key experimental factors such as fiber coating, extraction time and temperature, sample stirring and ionic strength were optimized for each beverage type. The data obtained suggested that use of a DVB-CAR-PDMS fiber provided effective sample enrichment and enabled extraction of a wide variety of compounds from beer samples, whereas PDMS was identified to be the most applicable to wine samples and CAR-PDMS for whisky analyses. The optimal extraction conditions were reported to be 30 ml of sample with an extraction time of 60 min at 30 °C for wine and beer matrices and 40 °C for whisky, by headspace mode of a stirred sample saturated with NaCl (30% w:v). More than 64 compounds in beer, 44 in white wines and 104 in whisky were identified, belonging to a wide range of chemical classes, such as ethyl esters, higher alcohol acetates, isoamyl esters, fattyacids, carbonyl compounds, furanic compounds, terpenoids, C_{13}-norisoprenoids and volatile phenols.

Many other alcoholic beverages have been successfully studied using the SPME technique. Examples include cider – with a DVB-CAR-PDMS mixed phase fiber for the determination of brett character (Pizarro *et al.*, 2009), volatiles of the Brazilian distilled spirit cachaça (Section 3.5.4) using a PA fiber (Nonato *et al.*, 2001; de Souza *et al.*, 2009) and the determination of volatile compounds in *orujo* spirits with a CW-DVB fiber (García-Martín *et al.*, 2010).

A PA fiber SPME method combined with GC-MS, GC-NPD and GC-FID was developed and optimized for the analysis of 22 nitrogen containing herbicides (Section 5.10.2) in water (Boyd-Boland and Pawliszyn, 1995). The proposed method was concluded to be linear over several orders of magnitude, with either of the chosen GC detectors and analysis of the target analytes from more complex matrices, such as wine, was also successfully performed by utilization of the standard addition procedure.

SPME analysis with PA polar fiber phase has also been chosen for the rapid screening of triazole (Section 5.10.2) residues in wine and strawberries (Zambonin *et al.*, 2002) and also organophosphorus pesticide residues (Section 5.10.2) in wine and fruit juices (Zambonin *et al.*, 2004).

A multiresidue SPME-GC-ECD method for pesticide screening in wine was proposed by Correia *et al.* (2000). Following optimization, a 100 μm PDMS fiber, with 30 min immersion extraction in 3 ml wine samples at 45 °C was used to study pesticide extraction yield at different concentrations of aqueous ethanol solutions representative of Portuguese wines. It was concluded that the method enabled detection of 19 of the 23 pesticides studied, however ethanol content of samples affected the extraction yield and calibration curves with extracted standards was recommended. Extraction yields did not exceed 30%, however limits of detection (average 5 μg/l) were reported to be considerably lower than the recommended maximum levels for the chosen pesticides in commercial wine products.

PDMS fibers have also successfully been applied to the SPME-GC-MS determination of oxazole fungicides in malt beverages (Viñas *et al.*, 2008), the determination of the herbicide oxadiazon residues in ground water, soil, must, wine and human urine samples (Navalón *et al.*, 2002) and to study the distribution of fenbutatin oxide in grapes and white wine (Montes *et al.*, 2009a).

Recently, Carillo and coworkers (2007) described the development of a headspace SPME-GC-MS method for the accurate determination of phthalates in wine. The HS-SPME conditions were rigorously studied by firstly evaluating the performance of six fibers at three temperature values and two sample volumes, by means of a multifactor categorical experimental design. The most applicable fibers were shown to be PDMS-DVB and CW-DVB. Repeatability values obtained for both fibers were reported to be similar, however the CW-DVB was more efficient for extracting the lower molecular weight phthalates and the PDMS-DVB for the higher molecular weight analytes of the study. It was concluded that the proposed method enabled the quantification of phthalate esters in wine in the low ng/ml range, however quantitation by the standard addition method was

required in order to avoid systematic errors caused by matrix effects. Later work adopted the successful use of deuterated phthalates as internal standards to eliminate the standard addition requirement and thus reduce analysis time (Carrillo *et al.*, 2008).

Recently a simple, low cost and sensitive method for the determination of phthalate acid esters in beer was developed and optimized using SPME-GC-MS with a novel sol-gel calixarene-contained fiber (Ye *et al.*, 2009). Under optimized conditions, LODs of 0.003–3.429 μg/l were obtained and the relative standard deviation values were ≤13.51% for all of the analytes studied. The method was further validated using standard addition methodology and recovery values were between 86.3 and 109.3%. The analysis of three real bottled beer samples demonstrated that dibutyl-phthalate ester and bis(2-ethylhexyl)-phthalate ester (DEHP) were the main phthalates found in beer and total concentrations were between 6.22 and 7.76 μg/l. Following migration tests, it was revealed that the high content of DEHP incorporated in PVC gaskets in the lids of the bottled samples could have been a potential source of contamination during transportation and subsequent storage.

By the nature of its simplicity and performance, SPME has already secured itself a concrete position in sample preparation/analytical history and has created a huge level of interest as a sorptive extraction technique since its introduction. Many advantages, such as predictable enrichment, inertness and rapid thermal desorption at mild temperatures, are well documented in the literature. One major drawback of SPME, however, is the amount of extraction medium coated on the fiber. For example, a typical PDMS 100 μm fiber has an approximate 0.5 μl volume of extraction phase. Consequently, the extraction efficiency (recovery) for solutes that are partially water soluble can be quite low and for very non-polar (hydrophobic) compounds, competition can occur between the aqueous phase, the SPME fiber, the glass wall of the extraction vessel and the surface of the polytetrafluoroethylene (PTFE) stir bar used to stir samples (David *et al.*, 2003).

Following these observations, a novel extraction method was developed whereby standard laboratory magnetic stir bars were coated with a layer of PDMS and then used to stir aqueous samples, thereby extracting and enriching analytes into the PDMS coating. The technique was named stir bar sorptive extraction or SBSE (Baltussen *et al.*, 1999). With SBSE, the extraction phase is identical to that used on PDMS coated SPME fibers, however the coating typically uses 50–250 times greater amounts of extraction phase.

Sorptive extraction is an equilibrium technique and for water samples, the extraction of solutes/analytes from an aqueous matrix into the PDMS extraction phase is controlled by the distribution coefficient of the solutes partitioned between the PDMS phase and the aqueous phase. This is identical in principle to a standard liquid–liquid extraction of an aqueous or aqueous ethanolic sample with an immiscible organic solvent. Recently this partitioning coefficient theory has been correlated with octanol–water distribution coefficients ($K_{o/w}$). Although this principle is not strictly correct, the coefficient gives, in most cases, a successful, rapid and hence practical indication of potentially how well a given analyte can be extracted with SPME or SBSE. It is, however, very important to realise that the sorptive equilibrium is also dependent upon the phase ratio and thus on the amount of PDMS coated to the stir bar. This relationship is shown in Equations 4.2.3 and 4.2.4 (Baltussen *et al.*, 1999; David *et al.*, 2003).

$$\begin{aligned} K_{o/w} \approx K_{PDMS/w} &= \frac{C_{PDMS}}{C_w} \\ &= \left(\frac{m_{PDMS}}{m_w}\right)\left(\frac{V_w}{V_{PDMS}}\right) \\ &= \beta\left(\frac{m_{PDMS}}{m_w}\right) \end{aligned} \tag{4.2.3}$$

The distribution coefficient between PDMS and water ($K_{PDMS/w}$) is defined as the ratio between the concentration of a solute in the PDMS phase (C_{PDMS}) over the concentration in the water (C_w) at equilibrium. This ratio is equal to the ratio of the mass of the solute in the PDMS phase (m_{PDMS}) over the mass of the solute in the aqueous phase (m_w) times the phase ratio (β, with β = volume of water (μl) divided by the volume of PDMS (μl) = V_w/V_{PDMS}).

The recovery, expressed as the ratio of the extracted mass of solute (m_{PDMS}) over the original mass of solute in the water ($m_0 = m_w + m_{PDMS}$), is thus dependent upon the distribution coefficient $K_{PDMS/w}$ and on β, as described in Equation 4.2.4.

$$\frac{m_{PDMS}}{m_0} = \frac{\left(\frac{K_{PDMS/w}}{\beta}\right)}{1 + \left(\frac{K_{PDMS/w}}{\beta}\right)} \tag{4.2.4}$$

Using this equation, the theoretical recovery can be calculated for a solute/analyte with a known partition coefficient and a given phase ratio. For example, the theoretical recovery for limonene (CAS 5989-27-5) extracted from a 10 ml aqueous sample volume with a 10 mm stir bar with a phase thickness of 0.5 mm (24 μl) is as follows:

$$\text{Log}K_{o/w}\text{value of limonene} = 4.83$$
$$\text{Phase ratio } (\beta) = V_w / V_{PDMS} = 10000/24(\mu\text{l}) = 417$$

If:

$$\log K_{o/w} = 4.83, \text{ then} K_{o/w} = \log 10^{4.83} = 67608$$

Therefore:

$$\text{Theoretical recovery } (R) = \frac{(67608/417)}{1 + (67608/417)} = 0.99$$

Thus:

$$\%\text{ recovery} = 0.99 \times 100 = 99\%$$

It is therefore evident that extraction efficiency for any given analyte is increased with increasing $K_{PDMS/w}$. Because $K_{PDMS/w}$ is similar to the octanol–water distribution coefficient ($K_{o/w}$), extraction efficiencies can be predicted. Besides the $K_{PDMS/w}$ factor, the phase ratio (β = volume sample/volume PDMS) is also important. The higher the PDMS amount, the lower the phase ratio and the higher the extraction efficiency (David *et al.*, 2003).

Figure 4.2.8 shows the influence of $K_{o/w}$ and phase ratio on extraction efficiency. For SPME, the volume of PDMS coated to the fiber is approximately 0.5 μl. This results in poor recoveries for solutes with lower $K_{o/w}$ values (less than 10 000 or with a log $K_{o/w}$ value less than 4). In SBSE, greater quantities of PDMS (typically 25–125 μl) coatings are adopted, hence the sensitivity is increased by a factor of 50 to 250 when directly compared to SPME as a sample preparation method. The theoretical extraction efficiency reaches 100% for solutes with $K_{o/w}$ values larger than 500 (log $K_{o/w}$ greater than 2.7). The theoretical recoveries

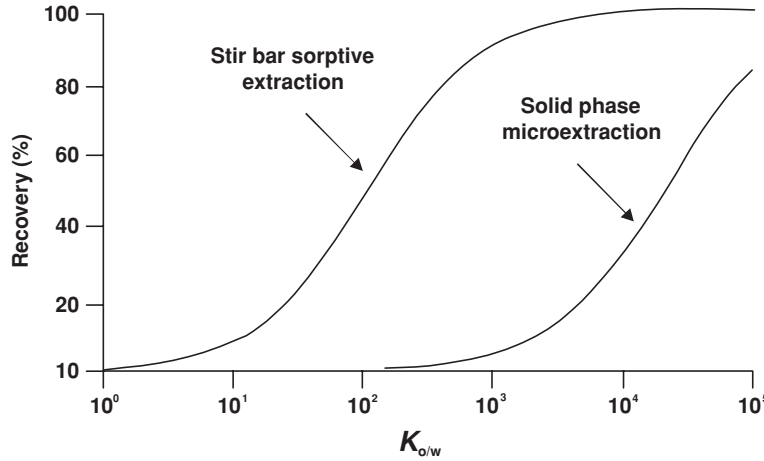

Figure 4.2.8 *Recovery for solutes in function of the octanol-water partitioning coefficient* $K_{o/w}$ *for SPME (10 ml sample, 100 mm PDMS fiber) and for SBSE (10 ml sample, 10 mm x 0.5 mm PDMS-coated stir bar) (David* et al.*, 2003). Reproduced with permission of F. David*

can be calculated for a given sample volume, selected stir bar dimensions and a solute using the $K_{o/w}W$ in a software program (Meylan and Howard, 2000).

Poly(dimethylsiloxane) coated stir bars are manufactured and available from Gerstel GmbH (Mülheim/Ruhr, Germany) under the trade name Twister™. These stir bars have three essential parts (see Figure 4.2.9). The first part at the center of the stir bar is a magnetic stirring rod, which transfers the rotating movement of a stirring plate to the sample liquid. The second part of the stir bar is a thin glass jacket that covers the magnetic stirring rod. The third and outermost part is the sheath or layer of PDMS sorbent into which the analytes are extracted.

To date, only stir bars with PDMS as extraction phase are available commercially (i.e. a non-polar phase), however dual phase bars combining the concentration capabilities of two or more sampling materials operating in different ways (sorption and adsorption) have been described elsewhere and will most likely be available in the future (Bicchi *et al.*, 2005). These new stir bars are reported to consist of a short PDMS tube, the ends of which are closed with two magnetic stoppers, thus creating an inner cavity that can be packed with different types of adsorbents like activated carbons. It was concluded by the authors that the new twister concept was

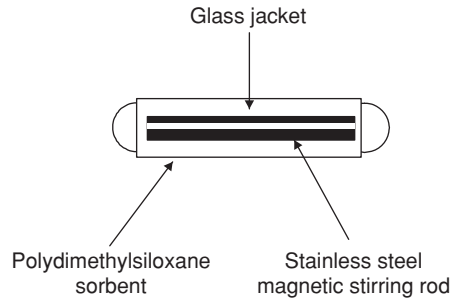

Figure 4.2.9 *Stir bar sorptive extraction device (Twister™) (Lisa Caven-Quantrill)*

shown to improve recovery of volatile and/or polar components when compared to conventional PDMS stir bars.

Interestingly, Gerstel, the commercial manufacturer of the Twister™ device, demonstrated a prototype stir bar with poly(acrylate) (PA) phase at the 2009 Pittsburgh analytical conference (http://www.pittcon.org/) so it is more likely than not that this SBSE option will also soon be available as a standard choice to the practicing analytical chemist.

SBSE of a liquid sample is carried out easily by placing a suitable amount of sample in a headspace vial along with a stir bar. The sample is then typically stirred for 30–240 min. The extraction time is controlled kinetically, determined by sample volume, stirring speed and stir bar dimensions, and must be optimized for a given application (David *et al.*, 2003). This is generally accomplished by measuring the analyte recovery as a function of the extraction time (i.e. optimum conditions are achieved when no additional recovery, or increase in GC-MS peak area counts of analytes of interest, is observed, even if the extraction time is increased further).

On completion of the extraction, the stir bar is removed, rinsed with a small aliquot of analytical grade water (to remove adsorbed co-extracted matrix components) and blotted dry on a clean, lint free tissue to remove water droplets. Finally the stir bar is introduced into a preconditioned empty glass tube for thermal desorption on a GC-MS instrument. Desorption temperatures are application dependent, but typically between 150 °C and 300 °C. Desorption can be accomplished in 5–15 min under a 10–100 ml/min Helium flow (David *et al.*, 2003).

Hoffmann *et al.* (2000) used SBSE and thermal desorption-gas chromatography for the flavor profiling of several alcoholic beverages, including Spumante wine. With this technique, a small magnetic stir bar (10–20 mm length, 1.3 mm outer diameter) coated with PDMS, was placed directly into the sample, which had been previously transferred to a 10 ml headspace vial with minimal headspace, and stirred for either 0.75 to 2 h or overnight (16 h). On completion of the extraction, the stir bar was removed from the sample with forceps, rinsed briefly with distilled water to remove any matrix components such as sugars, blotted dry on a lint free cloth and placed into a clean glass thermal desorption tube for analysis. Analytes were desorbed at 200 °C for 5 min with a 50 ml/min gas flow and cold trapped in a programmable temperature vaporizer with a glass wool liner at –150 °C. Samples were finally transferred to the gas chromatographic column in either split or splitless mode. It was concluded that SBSE was an extremely powerful technique for flavor profiling of different types of beverages since it combined ease of use, ruggedness, precision, speed and sensitivity. In addition, the absence of any organic solvents involved in the sample preparation and analysis made the methodology 'environmentally friendly.' A similar technique has been used recently for the analysis of volatile phenols in wine by GC-MS (Díez *et al.*, 2004). It was concluded that the technique was an easy, fast and reliable analytical method for the quantitative determination of volatile phenols in wines. The procedure was reported to be simple and allowed 15 samples to be extracted simultaneously using a very small sample volume. A low detection limit with good sensitivity was also obtained.

Recently, SBSE coupled with GC-MS was used to analyze wine samples for three applications: flavor and compositional analysis, 2,4,6-trichloroanisole (TCA), a common off-aroma in wine, and agrochemicals (Hayasaka *et al.*, 2003). SBSE was found to be several orders of magnitude more sensitive than modern conventional methodology, allowing for lower detection and quantitation levels and improved confirmation of identity; SBSE often gave better signal to noise in scan mode than other methods in selective ion monitoring (SIM) mode. With the help of their characteristic mass spectra, all agrochemicals could be identified unambiguously at concentrations of 10 μg/l in wine and a further 100 constituents were detected in a Cabernet Sauvignon sample. It was concluded that it was now possible to analyze complex samples such as wine in scan mode, with better confirmation of identity and without sacrificing sensitivity, where previously SIM methodology had to be used.

Caven-Quantrill and Buglass (2006) compared traditional microscale simultaneous steam distillation-extraction (SDE) and SBSE for their effectiveness in the extraction of volatile organic compounds from a

synthetic grape juice and a real grape juice (Huxelrebe) from an English vineyard. The novel immersion mode SBSE method, using stir bars with PDMS sorbent, was optimized using a synthetic grape juice. Although mean percentage relative recoveries and reproducibilities (%CV) of the SBSE method were inferior to SDE (28.4 and 8.5% against 86.9 and 6.3%, respectively), the stir bar method proved to be significantly more sensitive: 126 aroma compounds in Huxelrebe grape juice were identified using SBSE, against 98 using SDE, and five of these were considered as thermal decomposition products of sugars. This allowed the identification of a number of volatile components that had not been reported previously in the juice or wine from the grapes with Muscat ancestry.

The authors concluded that the optimized and validated SBSE method was shown to be a very promising tool for characterizing the aroma compounds of grape juice.

Overall, the microscale SDE method showed excellent recoveries and reproducibility for a majority of the synthetic grape aroma volatiles extracted from a model grape juice, at the concentration studied (400 μg/l of each component).

Although the relative recoveries and reproducibility were generally lower for the SBSE technique, it was emphasized that it was a more sensitive technique than SDE, as the concentrations of aroma compounds in the synthetic grape juice used for SBSE (10 μg/l of each component) were 40 times lower than those used in the SDE study. Moreover, in combination with state of the art analytical instrumentation, the SBSE technique could result in higher sample throughput, as up to 15 samples could be stirred simultaneously. The technique was also solvent free, easy to use, required minimal manpower per sample and the thermal desorption/GC-MSD analysis could be carried out automatically. Furthermore, the whole extract from the stir bar was transferred to the analytical system, which resulted in a higher sensitivity and lower potential analyte loss. Hence, the method could easily be applied to quality control and other related fields. This method was then further adopted for the volatile organic compound analysis of English vineyard Huxelrebe, Ortega, Schönburger and Siegerrebe wine grapes of the 2004 season and Madeleine Angevine 7672 of the 2000 vintage (Caven-Quantrill and Buglass, 2007) and up to four vintages of these varieties to study the seasonal variation of flavor content (Caven-Quantrill and Buglass, 2008).

Similarly, the SBSE technique was used to determine volatile constituents in Monastrell grapes (Salinas *et al.*, 2004). The method proposed involved a maceration step lasting two hours and a sorption time of six hours. The coefficients of variation obtained were below 4% in the case of volatile compounds and below 2% for the internal standard. The behavior of the volatiles during grape ripening was studied, and 34 compounds were determined, some of which were recorded for the first time in this variety. The highest terpene and norisoprenoid contents, together with the lowest values of C6 compounds were observed during the fifth week of ripening, meaning that this would be the optimal time for harvesting in terms of volatile compounds.

SBSE has also been used for the determination of volatile compounds in oak-aged wines (Marín *et al.*, 2005; Garde-Cerdán *et al.*, 2008b), for the enantioselective analysis of monoterpenes in different grape varieties during berry ripening (Luan *et al.*, 2006), for the analysis of wine primary aroma compounds (Zalacain *et al.*, 2007), for off-flavor profiling (Franc *et al.*, 2009), for classification of South African wines according to the volatile composition (Tredoux *et al.*, 2008), to study the impact of deficit irrigation (crop sensitivity to drought stress) during berry development on Merlot wine volatile composition (Qian *et al.*, 2009) and for the characterization of the aroma profile of Madeira wine (Sections 2.10.5 and 2.10.6), where the technique was compared with SPME (Alves *et al.*, 2005). Here the authors concluded that the SBSE methodology allowed better ability for profiling traces and ultra traces of esters, carboxylic acids, alcohols, aldehydes, pyrans, lactones, monoterpenes and C_{13} norisoprenoids.

Recently, SBSE-GC-MS has been used for the analysis of hop derived terpenoids in beer (Kishimoto *et al.*, 2005). Stir bars (20 mm length) coated with 47 μl of PDMS were added to diluted beer samples, and stirred

in a water bath at 40 °C for 2 h prior to removal and subsequent analysis by thermal desorption-GC-MS. The SBSE technique was reported to offer low coefficients of variation, high accuracy and low detection limits.

As an extension of SBSE, headspace sorptive extraction (HSSE) was first developed by Tienpont *et al.* (2000) and Bicchi *et al.* (2002) for the analysis of volatile compounds of solid matrices. In HSSE, the stir bar is suspended in the headspace volume (as with HS-SPME) from where the analytes are sorbed by the PDMS coating. After sampling, the stir bar is placed in a desorption tube and treated identically to SBSE analyses. Applications of this new HSSE technique and its comparison with other extraction methods have been assayed in different matrices (Bicchi *et al.*, 2000; Demyttenaere *et al.*, 2003b; Demyttenaere *et al.*, 2004), however these are not related to the profiling of aroma materials from alcoholic beverages. Only a single research group using HSSE for alcoholic beverage flavor analysis could be identified during the compilation of this chapter (Weldegergis *et al.*, 2007; Weldegergis and Crouch, 2008). The HSSE method was developed for the analysis of alcohols, esters, carbonyls, acids, phenols and lactones in South African wine samples. Extraction conditions were evaluated and it was reported that the optimum conditions consisted of adding 1 ml of wine sample (along with 100 μl of 1.7 mg/l 4-methyl-2-pentanol internal standard solution and 1.5 g of NaCl) and diluting to a total of 6 ml with ultrapure water of 12% ethanol mixture in a 20 ml Gerstel Twister™ headspace vial with glass headspace insert. The pH was adjusted to 3.2 using a formate buffer prior to the addition of a glass coated magnetic stirrer to agitate the sample and a preconditioned 'standard' SBSE stir bar (10 mm length coated with 0.5 mm (25 μl) PDMS layer), which was suspended in the headspace using the glass insert. Following sealing of the vial with a 20 mm aluminum crimp cap and PTFE/silicone molded septa, the spiked sample was stirred for 1 h at 1200 rpm prior to the vial being left standing for 3 h at room temperature (to allow analytes that had migrated into the headspace of the sample to be completely sorbed into the PDMS coating of the stir bar). After sampling, the stir bar was removed, dried with a lint free tissue and placed into a preconditioned thermal desorption (TD) tube ready for analysis by TD GC-MS. The authors concluded that the optimized method was very sensitive, with limits of detection (LODs) and limits of quantitation (LOQs) between 50 pg/l to 299 μg/l and 0.2 ng/l to 0.996 μg/l, respectively, and acceptable repeatability.

A further and most recent spin-off sorptive technique involves SBSE with liquid desorption (Coelho *et al.*, 2008; Coelho *et al.*, 2009; Perestrelo *et al.*, 2009). With this method, SBSE is performed as standard, however on completion the stir bar is removed from the liquid sample extraction vial and back extracted with organic solvent (for example, pentane). The resulting liquid extract is then subjected to large volume injection on the GC instrument. The advantage of this approach is that a dedicated (and often expensive) thermal desorption device is not required, thus lowering the initial financial outlay of this very useful and sensitive sorption technique. Many other examples of this approach are expected to be seen in future flavor research studies.

A method for the determination of stale flavor carbonyl compounds in beer was developed using SBSE with *in situ* derivatization followed by thermal desorption-GC-MS analysis (Ochiai *et al.*, 2003). The derivatization conditions with *O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine and the sampling mode, salt addition, sample volume, phase ratio (sample volume/PDMS volume) and extraction time for the SBSE conditions were studied. The authors concluded that a sample volume of 30 ml, a PDMS volume of 47 μl and extraction time of 60 min were optimum conditions, and this resulted in the successful application of the methodology to determine the stale flavor carbonyl compounds (*E*)-2-octenal, (*E*,*Z*)-2,6-nonadienal, (*E*)-2-nonenal and (*E*,*E*)-2,4-decadienal in real beer samples. The method was reported to show good linearity over the concentration range studied (0.1–10 ng/ml) for all analytes and the correlation coefficients were higher than 0.9993. The limits of detection ranged from 0.021–0.032 ng/ml for all analytes (which was below the reported odor thresholds (Section 4.7.2) of the extremely important and most feared stale flavor compounds (*E*)-2-octenal and (*E*)-2-nonenal), and the recovery of the method was good (98–101%) with acceptable precision (RSD 2.4–7.3%).

Recently Horák *et al.* (2008) developed a method for the determination of free medium chain fatty acids including caproic, caprylic, capric and lauric acids in beer or wort using SBSE and solvent back extraction. Extraction was performed by placing 10 ml of sample into a 20 ml headspace vial along with a 'standard' 10 mm stir bar with a phase thickness of 0.5 mm (24 μl) PDMS. After crimping of the vial with an aluminum coated septum, the sample was stirred at ambient temperature at 1000 rpm for 60 min, then the stir bar was removed, rinsed briefly with distilled water and dried with a lint free tissue. Solvent back extraction was achieved by placing the stir bar into a 350 μl glass vial insert containing 200 μl of organic solvent mixture (dichloromethane:hexane, 50:50) and this was collectively placed into a 2 ml vial and stirred again at 1000 rpm for 40 min. It was concluded that the proposed method was advantageous in many practical aspects, such as small sample volume, simplicity of extraction and only 200 μl of solvent consumption, and offered high repeatability (RSD <6.7%), good linearity (correlation coefficients higher than 0.9963 for quadratic curves over the concentration range of 0.5–8.0 mg/l) and recoveries (57–89%). This method has also recently been compared with SPE and SPME by the same research group (Horák *et al.*, 2009). Results of beer analyses obtained by using these three methods were reported to be highly correlated, however SPME was suggested as overall a more appropriate technique for medium chain fatty acid analysis.

SBSE has also been compared directly with SPME for extraction of flavor volatiles from malt whisky (Demyttenaere *et al.*, 2003c) (Section 3.2.6). Here it was reported that the best fibers for SPME (resulting in the highest reproducibility of the peak areas after GC-MS analysis) were PDMS and DVB-CAR-PDMS, with a 30 min extraction time by liquid immersion of the fiber in a stirred sample at 25 °C without the addition of salt. SBSE was also demonstrated to be an appropriate method for whisky volatile extraction, however it was stressed that the major drawback with this technique was the requirement of a dedicated thermal desorption device. When SBSE was applied in the split desorption–split injection mode, it did not significantly improve the results obtained by SPME. In contrast, when splitless desorption–split injection was utilized, SBSE yielded a higher enrichment of the whisky volatiles with good chromatography (well resolved sharp peaks). For ultratrace analysis, the use of SBSE in splitless desorption–splitless injection was advised to achieve the highest sensitivity of all.

The dicarboximide fungicides vinclozolin, iprodione and procymidone were analyzed in white wines by SBSE in combination with thermal desorption-capillary GC-MS analysis (Sandra *et al.*, 2001). Limits of quantitation (LOQ) in the full scan MS mode (from method optimization using spiked water samples) were reported to be 0.5 μg/l for vinclozolin and procymidone and 5 μg/l for iprodione. With an MS in selective ion monitoring mode, concentrations 100 times lower could be spiked and analyzed successfully. Because of wine matrix effects on the recoveries of the analytes studied, quantification of the target fungicides in wine had to be carried out using the standard addition method. Procymidone and iprodione were detected in wines in concentrations up to 65 μg/l, whereas the highest concentration of vinclozolin was 3 μg/l.

4.2.5 Headspace Methods

In a static headspace method, the sample is placed into a sealed vial, left to equilibrate and the atmosphere above the sample is drawn into a gas-tight syringe (usually 0.1–2.0 ml) and subsequently injected into a gas chromatograph (Da Costa and Eri, 2004). It is easily automated as an analytical technique; indeed many of the commercial analytical instrument manufacturers offer equipment which has the option of heating sample vials and injecting a known volume of the sample headspace directly into a gas chromatograph (GC). Two main types of sample introduction are commonly available. This can either be by the transfer of a measured sample loop of headspace to the GC, often via a heated transfer line (that connects directly to the GC inlet) or by

simple automation of a headspace syringe. In either case, modern sophisticated autosamplers have the ability to carefully control critical method variables such as the temperature of the sample and the equilibration time.

The static headspace sampling technique has limited applicability to the analysis of alcoholic beverages as these samples contain high quantities of water and ethanol. Since the concentration of these matrix components in the headspace (during sampling) is in equilibrium with the concentration in the liquid beverage sample, the headspace is saturated, and subsequently this results in a lack of analytical sensitivity for the aroma/flavor compounds of interest, that are often at concentrations several orders of magnitude lower than the water and ethanol.

The theory of static headspace, including general considerations, advantages and disadvantages, with particular reference to the analysis of food volatiles has been reported by Wampler (2002) and hence this is not discussed further in this section.

Shimoda *et al.* (1993) evaluated the headspace aroma volatiles of twenty 1986 Cabernet Sauvignon wines from six regions of Napa Valley, California, using a direct static headspace sampling technique. 50 ml of each wine sample was placed into a 300 ml Erlenmeyer flask and 500 μl of an aqueous solution of 3-heptanol (100 μg/ml) was added to serve as an internal standard. After the headspace of the sample flask was purged with nitrogen gas for 10 s to remove oxygen, the flask was sealed with a Teflon plug equipped with a stopcock. The wine samples were then heated in a water bath for 20 min at 25 °C, before a sample of headspace gas (4 ml) was drawn into a 20 ml gas-tight syringe equipped with a fused silica capillary column needle and analyzed via GC-MS with on-column injection. Most of the compounds detected were products of yeast fermentation, although two volatile components had not been detected previously in wine. It was concluded that, although the headspace technique was shown to be reproducible and would be useful for analysis of major grape and fermentation volatiles, it could not detect trace compounds, many of which are significant to the overall aroma of wine.

The static headspace technique has also been used for the chromatographic analysis of volatile sulfur compounds in wines with flame photometric detection (FPD) (Mestres *et al.*, 1997). It was concluded that the method developed appeared to be suitable for the determination of a relatively large number of usual volatile sulfur compounds in wines. The interference from other compounds in the complex wine matrix was eliminated by the use of the specific FPD detector, and low concentrations of sulfur compounds could be detected by concentrating the headspace with a cryogenic trap. The method also seemed to be appropriate for enology laboratory work because of the simplicity of the instrumentation used.

Static headspace has also been recently been used for the determination and quantitative analysis of acetoin in beer (Tian *et al.*, 2009) and also to study a decrease of aged beer aroma by the reducing activity of brewing yeast (Saison *et al.*, 2010).

In dynamic headspace, the volatiles above a sample are swept away by an inert carrier gas, usually helium or nitrogen, onto a trap (glass or glass lined stainless steel tube containing porous polymers such as Tenax™ (poly-2,6-diphenyl-*p*-phenylene oxide), graphitized carbon sorbents (such as Carbotrap, Carbopack), silica gel, poly(dimethylsiloxane) and activated charcoal etc).

With liquid samples such as alcoholic beverages, the sample is purged with a flow of carrier gas and the analytes trapped, hence dynamic headspace analysis of liquid samples is usually referred to as purge and trap (the term dynamic headspace is generally used when the sample undergoing analysis is a solid). Figure 4.2.10 details the basic setup for carrying out a manual purge and trap analysis. Commercial instruments are also available for this technique, offering automated drying of moisture from the trap (see Figure 4.2.10 – dry purge gas), preconditioning and reconditioning of the trap in between a sequence of analyses and most include the ability to cryogenically cool the inlet of the gas chromatograph (for example with liquid nitrogen) to focus the aroma volatiles for sharper peaks during analysis. With careful attention to contaminants and system background, it has been reported that this technique is capable of routinely detecting analytes present in a sample in the parts per trillion (ng/l) range (Wampler, 2002).

The headspace volatiles of commercially produced kiwifruit wine and wine produced from Müller-Thurgau grapes have been compared by GC-MS (Craig, 1988). The wine (750 ml) was treated with an internal standard, then held in a water bath at 35 °C and purged with a stream of oxygen free nitrogen, at a flow of 60 ml/min for 22 h. The nitrogen, saturated with wine volatiles, was bubbled through a 10% solution of ethanol in distilled water (50 ml), which was continuously extracted with 50 ml of freon 11. After 22 h, the solvent was evaporated through a vacuum jacketed column, using a water bath at 35 °C, until the volume was reduced to approximately 2 μl. Pentane (20 μl) was then added and the resulting solution used for gas chromatography. Forty-seven compounds were identified and all of the major, and most of the minor, components were present in both wines, along with the presence of fenchone, which had not been previously reported in wine, which was confirmed in the kiwifruit wine sample.

The application of adsorption-thermal desorption-gas chromatography to determine the heavy fraction of wine aroma was studied by Salinas *et al.* (1994, 1997). This technique included the processes of isolation and concentration of volatiles performed in three classic stages of purging, concentration and injection. Initially, the volatiles were separated from the wine (50 ml) by purging dry nitrogen at 67 ml/min through the sample at 30 °C. They were then adsorbed in a metal tube trap containing the adsorbent Tenax™ at 25 °C. In the second stage, the temperature of the initial trap was increased to 300 °C and held for 5 min (first thermal desorption) to release the aroma volatiles that were then concentrated in a second Tenax™ trap, which was subjected to low temperature (–30 °C). In the final stage, the temperature of the second trap was raised to 350 °C to desorb the volatiles, which were immediately transferred into a gas chromatograph equipped with flame ionization detection. The reproducibility of the method was demonstrated using standard aroma solutions and in most cases, the variation coefficients were shown to be in the order of 3%. Calibration graphs were also constructed and it was demonstrated that the correlation coefficients were greater than 0.99 for the entire aroma components studied. It was concluded that the proposed method was fast, required no

sample manipulation and was successful for determining the volatiles of wine aroma. This technique was also used to study the volatiles of *Vitis vinifera* grapes (Rosillo *et al.*, 1999) and also Pinot Noir wines from British Columbia (Girard *et al.*, 2001). Ortega-Heras *et al.* (2002) compared liquid–liquid extraction, static headspace and dynamic headspace, for the analysis of volatile aroma components in wine. The advantages and disadvantages of the three methods regarding sample preparation, component losses and artefact formation were evaluated, along with the sensitivity and reproducibility of each of the techniques. It was concluded that the liquid–liquid extraction and static headspace methods showed good reproducibility, but although the static headspace technique was useful for the analysis of highly volatile compounds, it was not able to detect trace compounds due to its lack of sensitivity. On the other hand, the dynamic headspace method provided an extract free of artefacts and foreign substances that were not in the original wine. However, the technique was shown to have very poor reproducibility.

The purge and trap technique has also been utilized in recent studies for the prediction of the wine sensory properties related to grape variety from dynamic headspace gas chromatography-olfactometry data (Campo *et al.*, 2005), for the evaluation of an aroma similar to that of sparkling wine via sensory and GC analysis of fermented grape musts (Mamede *et al.*, 2005), for the analysis of red and white wines from different Spanish regions (Aznar and Arroyo, 2007), for the identification of a previously unreported odorant (2-methyl-3-(methyldithio)furan) in different monovarietal red wines from the Canary islands (Culleré *et al.*, 2008), for modeling quality of premium Spanish red wines from GC-O data (Ferreira *et al.*, 2009) and for the study of methods for the extraction of volatile compounds from fermented grape must (Mamede and Pastore, 2006) where liquid–liquid extraction was compared with purge and trap. It was concluded by the authors that the liquid–liquid extraction method required more handling of the sample and was time consuming. On the other hand, the purge and trap system was automated and practical, leading to minimal volatile loss, but low extraction of the high and medium boiling point compounds was observed. Overall, it was demonstrated that the purge and trap/dynamic headspace system and liquid–liquid extraction method were complementary in the determination of the aroma profiles of fermented grape musts and characterization of the samples.

The purge and trap technique has been recently validated in order to apply it to the analysis of minor esters in ciders (Roberto *et al.*, 2005). Helium at 50 ml/min was used to purge 5 ml cider samples for 30 min at 20 °C and subsequent trapping onto a Tenax™ trap. It was reported that 49 compounds were identified, obtaining recoveries ranging between 93% for ethyl decanoate and 117% for ethyl-3-methylbutyrate and precision (RSD) ranging between 2.2% for hexyl acetate and ethyl decanoate and 10.9% for isoamyl acetate. The researchers concluded that the validated method allowed the determination of esters and styrene in ciders without prior sample treatment, with a good degree of reproducibility and accuracy. Therefore, the technique could be applied to the analysis of commercial ciders to aid the study of the technical processes that influence manufacture.

The aromatic profile as well as the off-odor of cork stoppers has recently been studied via the purge and trap technique. A method based on initial solvent extraction (with pentane) of either cork or wine samples followed by automated purge and trap GC-AED was reported by Campillo *et al.* (2004) for the determination of 2,4,6-trichloroanisole (TCA). Element specific detection and quantification was carried out by monitoring the chlorine (479 nm) emission line. Detection limits of 25 pg/g and 5 ng/l were obtained for corks and wines alongside reported recoveries from spiked samples ranging from 88.5–102.3%.

The sensory properties and aromatic composition of macerates of five synthetic and three natural corks were recently determined (Culleré *et al.*, 2009). Cork samples were initially submerged in a synthetic aqueous solution containing 15% ethanol and 5g/l of tartaric acid (pH adjustment to 3.2) for 10 days at 40 °C. The volatiles of the macerates were then collected using a purge and trap system containing LiChrolut EN resin as sorbent, and eluted with dichloromethane before freezing for 2 h at –30 °C to remove water. Finally, the extract was concentrated to 200 μl under a stream of pure nitrogen for GC-O

analysis. Natural stoppers were reported to impart sweet, toasted, sweet wood and flowery Muscat aroma to the model wine extracts. Conversely, the synthetic stoppers included a sample with a clear rubber aroma and two samples with a cork/mushroom aromatic note. The results of the GC-O analysis confirmed that the natural cork samples had complex aroma profiles of 10–20 aromatic compounds, all well known natural components of healthy wine, whereas, in contrast, the GC-O analysis of the synthetic stoppers were extremely simple and consisted of only a few odorants (the mushroom odor was successfully attributed to 1-hepten-3-one).

4.2.6 Combinations of Methods (With Particular Application to Enological Products)

A young Grenache red wine from the 1995 harvest was continuously extracted with freon 11 and the extract cleaned with sodium bicarbonate in order to remove the fatty acids (Ferreira *et al.*, 1998b). An aroma extract dilution analysis (AEDA) (Section 4.7.3) was carried out with the extract using a carbowax 20M capillary column and simultaneous GC-MS and olfactometric detection. The AEDA analysis showed that there were 43 odor active regions in the chromatogram. To isolate the odorants, the extract was further washed with propylene glycol, concentrated and then fractionated by normal phase HPLC (Section 4.3.3) with UV detection at 220 nm in order to obtain 29 fractions. All the fractions were concentrated and analyzed in the same GC-MS-olfactometric system in which the AEDA experiment was performed. The strategy allowed isolation of most of the odorants, and 30 of them, among which were the most important, could be clearly identified. It was concluded that amongst the most important odorants there were some well known fermentation esters, but surprisingly the role played by some minor esters, such as the esters of isobutyric, isovaleric and 2-methylbutyric acids, seemed to be very important. Equally important could be the role played by some volatile phenols, terpenols, lactones and norisoprenoids. The suitability of reversed phase HPLC for the semi-preparative fractionation of aroma extracts from wine and other alcoholic beverages was also explored by Ferreira *et al.* (1999). Aroma extracts were separated in a 250 × 10 mm Kromasil-C_{18} column using a water–ethanol gradient system as mobile phase. It was demonstrated that the chromatographic separation did not induce any chemical change in the sample components. It was also shown that the maximum volume that could be injected without altering efficiency was as high as 2 ml if ethanolic extracts were injected, and slightly less in the case of less polar extracts. Aroma extracts were injected directly without the need of any pretreatment. Major compounds eluted first, so it was possible to fractionate all the volatiles contained in a 1–1.5 l sample, without peak distortion or mass overload problems. The usefulness of the method was demonstrated by fractionating an extract from a Chardonnay wine to get 15 fractions that showed different aromas. The GC analysis with olfactometric and MS detection of the fractions allowed the authors to identify more than 70 aroma compounds and to signal some of them as potential key aromas of Chardonnay wine.

This technique has also been used to identify and compare the impact odorants of young red wines made with Merlot, Cabernet Sauvignon and Grenache grape varieties (Section 2.9.2) (Lopez *et al.*, 1999), for isolation and identification of odorants generated in wine during its oxidation (Escudero *et al.*, 2000a) as well as studying the role of 3-(methylthio) propanal (methional) as a character impact odorant of some oxidized wines (Escudero *et al.*, 2000b) and more recently to identify the volatile compounds responsible for prune aroma in prematurely aged red wines (Pons *et al.*, 2008a) and to study specific ‘red’ and ‘blackberry’ aromas in red wines (Pineau *et al.*, 2009).

Countercurrent extraction is a liquid–liquid extraction process in which the solvent and the process stream (sample) in contact with each other, flow in opposite directions (Section 4.3.4).

Nearly 200 volatile compounds were separated from a wine obtained from *Vitis vinifera* cultivar Syrah, originating from the southeast of France (Vernin *et al.*, 1988). The aroma extract was obtained in two steps

by an original process. The first step was a liquid–liquid extraction of a batch of 20 l of Syrah wine, with 5 l of freon 11 as extraction solvent, and a York Scheibel column with countercurrent circulation of the two liquids for 4 h. The second step involved condensation of the volatiles under high vacuum in a trap cooled at –175 °C in liquid nitrogen. It was concluded that the qualitative composition of the aroma extract did not significantly differ from other red wines. Stepwise discriminant analysis applied to Syrah wines of various vintages allowed the authors to obtain a good classification of these wines into three groups using chromatographic data obtained by the use of a dynamic headspace (purge and trap) technique.

Volatile constituents of experimental wines from five white and five red vine cultivars were analyzed by Baumes *et al.* (1986), using continuous liquid–liquid extraction for 8 h with a pentane/dichloromethane mixture (2:1, v:v). The aroma extracts were then fractionated in a jacketed chromatography column refrigerated to 15 °C, packed with silica gel. The volatiles were successively eluted with 300 ml of pentane/diethyl ether (9:1, v:v) and 300 ml of diethyl ether and analyzed by GC-MS. One hundred and twenty two substances were positively identified and 15 tentatively identified. Fourteen of them had not been detected previously in wine. Some sensory evaluation of the various separated compounds was also attempted and a total of 131 volatile constituents were quantified in triplicate.

Herraiz *et al.* (1991) investigated the aroma components of wine resulting from fermentation of grape must from the Verdejo cultivar. The volatiles were isolated by continuous liquid–liquid extraction with freon 11 and further fractionation on a silica gel column. Portions of pentane, pentane/diethyl ether (90:10, v:v), pentane/diethyl ether (70:30, v:v) and diethyl ether (60 ml) were used as eluting solvents. As a result, four different fractions were obtained. These fractions were concentrated to 0.75 ml and 3 μl aliquots were analyzed by GC-MS. The relative quantities of different components in the sample were established by comparison of the peak area measurements resulting from GC analysis with the area of the internal standard peak, without taking into account the extraction and fractionation. One hundred and thirty two substances, including alcohols, esters, carbonyl compounds, terpenes, acids and sulfur compounds were identified; some had not been previously detected in wines.

Ferreira *et al.* (1995) used a similar sample preparation method for the identification of volatile constituents in wines from the *Vitis vinifera* variety Vidadillo. Several wine samples of 500 ml were continuously extracted with 150 ml of freon 11 for 24 h. The aroma extract was then concentrated to 1 ml in a three-ball Snyder column. The extract was then further fractionated in a silica gel column with successive portions of hexane/dichloromethane/diethyl ether mixtures following in elutropic order. Ten fractions showing different odors were isolated and analyzed by GC-MS and GC. More than 200 compounds belonging to different biosynthetic pathways were identified. It was concluded that the silica gel prefractionation was a very promising tool for characterizing the flavor of the wine. The fractionation of the aroma extract in an adsorption chromatographic column leads to class compound separation. Consequently, compounds with similar aroma properties were eluted in the same fractions, allowing the study of their additive effects.

Similarly, the organoleptic volatiles of Chardonnay wine were isolated by continuous liquid–liquid extraction with freon 11 and further fractionation on a silica gel column (Caven-Quantrill, 1999). One hundred substances, including alcohols, esters, carboxylic acids, carbonyl compounds, terpenes, lactones, sulfur compounds, acetals, amides, phenols and furans, were identified and quantified by GC-MS.

The reproducibility of the liquid–liquid extraction system was evaluated and shown to be excellent, with coefficients of variation in the range of 0.39–5.09% for a wide range of wine aroma volatiles isolated from a model wine solution.

The relative recoveries of 28 typical white wine volatiles relative to the chosen internal standards were also studied after isolation and separation by the extraction and fractionation techniques. The recovery trial indicated that the concentrations of identified aroma volatiles reported in the wine sample, after equivalent isolation and fractionation treatment, could be considered as reasonable estimates of the actual concentrations in the wine investigated for most compounds, except the most volatile or the most hydrophilic.

The organoleptic characteristics of a majority of the aroma compounds were discussed, as well as the possible sensory contributions of some volatile compounds to the aroma and flavor of the Chardonnay wine studied.

Recently a new microextraction/solid phase extraction method for the GC analysis of wine volatiles was developed (Ferreira *et al.*, 1996). Repeatability of the method was reported to be better than 5% (as relative standard deviation) for more than 50 wine volatiles. Linearity and recovery of volatiles was also studied and was satisfactory in most cases. It was concluded that this approach had a number of advantages over classical techniques, such as the elimination of long and tedious evaporation steps, which improved the precision of measurements and helped to reduce the amount of solvents used. It was also concluded that separation of the wine aroma extract into fractions helped to prevent major volatile compounds from overlapping minor constituents in the gas chromatogram.

This combined sample preparation technique has also been used for the specific determination of nitrogenous heterocyclic compounds in wine (Keim *et al.*, 2002).

Aznar *et al.* (2001) identified and quantified impact odorants of aged red wines from Rioja using GC-Olfactometry, quantitative GC-MS and odor evaluation of HPLC fractions. The alcoholic degree of the wine was adjusted with pure water to 6%, v:v. 300ml of the diluted wine was passed through a glass column filled with a 10 cm long $\times$ 1 cm diameter bed of XAD-4 resin. The elution of aroma components was achieved with 40 ml of diethyl ether/pentane (1:1, v:v). The extract was finally dried over anhydrous sodium sulfate and concentrated in a micro-Kuderna-Danish concentrator to 1 ml and finally under a stream of pure nitrogen. The extract was analyzed by AEDA and most of the odorants quantified by GC-MS. A second extract was fractionated in a HPLC system with a C-18 semi-preparative column. Fifty fractions were recovered, their alcoholic degree and pH were further adjusted to those of the wine, and those fractions that showed strong odor characteristics were further re-extracted and analyzed by GC-O and GC-MS. Reconstitution experiments were carried out to confirm the role of the odorants detected in the fractions. Fifty-eight odorants were found in the Rioja wine, 52 of which could be identified. Comparison among the three techniques showed good agreement and demonstrated that they were complementary.

4.2.7 Summary

Alcoholic beverage chemists utilize many sample preparation techniques for isolating and analyzing aroma/flavor. However, a major complicating factor is the presence of high concentrations of ethanol, which can dominate flavor extracts and subsequent chromatographic data. Other non-volatile components such as sugars and acids can also be co-extracted yielding complicated analyses and contamination of chromatographic instruments. As a result, selection of an appropriate isolation technique is critical. The resulting extract should be reminiscent of the original sample and should not result in biases of flavor profile. These are important prerequisites for any isolation technique applied to the study of aroma.

4.3

Chromatographic Methods

As in other areas of science, chromatography, particularly gas chromatography (GC) and high performance liquid chromatography (HPLC), has revolutionized the analysis of alcoholic beverages and their precursors (fruit juices, cereal mashes, etc.). With such techniques as two dimensional GC and column switching HPLC along with sophisticated sample preparation techniques (Chapter 4.2) and such materials as monolithic HPLC stationary phases it is now possible to efficiently separate most of these complex samples and to identify many of the components using a variety of detectors and methods.

Detectors include selective types: for HPLC, conductometric (ionic analytes), electrochemical (oxidoreducing analytes) and UV-visible (analytes with electronic chromophores) and for GC, electron capture (for chlorinated analytes) and NP detectors (for analytes containing N or P atoms), amongst others. Nonselective detector types include the all powerful mass spectrometer, flame ionization (for GC), refractive index (for HPLC) and evaporative light scattering (ELS) (for HPLC). Many of these detectors are highly sensitive, and frequently, analytes at the μg/l or ng/l level can be detected and identified by coinjection of known standards and/or by use of Kovacs or other experimental indexes.

Moreover, the combination of any chromatographic method (but most often GC or HPLC) with a mass spectrometer often allows identification of unknown components, from molecular weight or fragmentation data. Modern modes of ionization (particularly ESI and APCI) and tandem mass spectrometry (MS/MS or MS^n) have made it possible to determine the structures of complex oligomeric polyphenols and carbohydrates, and to determine the molecular weights of big peptides and proteins.

The aim of this section is to give an account of the application of chromatographic methods to the analysis of alcoholic beverages in such a way that the reader can grasp an overall picture of the contemporary state of the art. A basic knowledge of the theory of chromatography at undergraduate level is assumed. Although a certain amount of general background theoretical and empirical information is given for each technique, the emphasis is on the types of alcoholic beverage components that can be analyzed by a particular chromatographic method, the experimental conditions required (e.g. stationary phases, mobile phases, detectors etc.) and the kind of information that can be obtained from such analyzes. Thus, it will be seen that the application of chromatographic methods not only leads to quantification and identification of components, but chromatographic profiles can be used as 'fingerprints' in the establishment of beverage authenticity, if suitable chemometric or statistical software is used to analyze the results.

The section begins with planar chromatographic techniques (especially thin layer chromatography), which have long been important methods for the brewer or winemaker, but the emphasis is on GC and HPLC,

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

reflecting the greater role played by these two techniques in alcoholic beverage analysis. The final subsection is dedicated to countercurrent chromatography.

4.3.1 Thin Layer Chromatography and Related Methods

Thin layer chromatography (TLC), together with some of its modifications such as high performance thin layer chromatography (HPTLC) and overpressured layer chromatography (OPLC), and along with paper chromatography and chromatography involving monolithic discs are members of the planar chromatography family. TLC in its simplest form is highly versatile and is the least expensive form of chromatography, whilst at the same time in its more sophisticated forms, it can stand comparison with HPLC. Most TLC is performed in normal phase, with a polar stationary phase (such as alumina, calcium sulfate or silica gel) and nonpolar solvents, such as acetone, ethyl acetate or hexane. Like HPLC, mixed solvent elution and gradient elution are possible, and reversed phase, ion exchange and chiral stationary phases have become more readily available during the past two or three decades. Reversed phase TLC layers, apart from the long established cellulose and alkane impregnated silica gel, now include bonded silica phases, such as C_8, C_{18}, NH_2 and diol bonded phases. The application of TLC to food (including beverages) and agricultural analysis has been reviewed fairly recently (Sherma, 2000).

Unlike HPLC (and GC), planar chromatographic techniques lend themselves very easily to two dimensional chromatography, without any extra equipment or significant extra cost. Colorless analytes can be visualized using any one of a multitude of chromogenic and fluorogenic reagents, which are usually specific to particular analyte types. The big disadvantage, until relatively recently, was the greater difficulty in accurately quantifying spots on TLC plates. This was originally done by visual comparison with standards of varying concentration, but nowadays can be performed using densitometry. Spots on TLC plates can also be examined by mass spectrometry (e.g. TLC-MALDI-TOF) (Zarzycki *et al.*, 2005 and references therein) and Camag has produced an automated TLC-MS interface (connected to an LC-MS system) that uses eluent from the HPLC pump to extract the chosen analyte zone (with its depth profile) on the developed TLC plate, and transfers it to the mass spectrometer.

Many TLC separations are still carried out by gravity flow ascending elution in one dimension with a single mobile phase. On the other hand, HPTLC is an instrumentalized form of TLC in which a special TLC plate is sandwiched between metal plates in a sandwich chamber and subjected to (often gradient) elution (sometimes called development in TLC) by a mobile phase. The stationary phase particles are finer for HPTLC (5 μm, as opposed to 12–20 μm for TLC), are of much narrower size distribution and require application of smaller sample spots (0.5–1 mm, as opposed to 2–6 mm for TLC). Gradient elution can be controlled manually, as in the separation of red wine pigments on reversed phase alkane impregnated silica gel plates, although automated multiple development (AMD) can produce a multistep elution gradient (usually stronger to weaker elution power for normal phase HPTLC) for the separation of complex mixtures with analytes of a wide range of polarities. Overpressured layer chromatography (OPLC) is a forced flow elution technique, which involves pumping under pressure the mobile phase through a layer on a plate sandwiched between a flexible membrane (filled with water) and a rigid stainless steel plate. The analytes are eluted off the plate and are passed through a detector before being collected (Mantovani *et al.*, 1998). In essence, OPLC is a form of planar column chromatography. Both HPTLC and OPLC result in high spot capacities (which aids detection and quantification) and short development times.

Besides being a separation technique in its own right, TLC can be used in a number of ways, as a reaction (e.g. malolactic acid fermentation, MLF) monitor, or as a means of preparing fractions for analysis by other methods, and of course it can be used in conjunction with other sample preparation or chromatographic methods, such as column chromatography, solid phase extraction and/or HPLC. For example, TLC and HPLC

were used to monitor the biogenic amines histamine and tyramine produced by lactic acid bacteria isolated from grape must and wine (Costantini *et al.*, 2006). TLC was used to monitor production of histamine in the broth medium enriched with histidine, whereas the tyramine produced by certain bacteria was quantified by HPLC. TLC has long been useful in checking the qualitative progress of MLF, like paper chromatography (Amerine and Ough, 1980a), but an improved method using a TLC-scanner for quantification has been described as being comparable with HPLC (Boido *et al.*, 1999).

Resolution in TLC can be usually further improved by double development (two elutions in the same direction) or two dimensional development (two elutions at right angles). For example, double development using firstly ethyl acetate:heptane (9:1) and then ethyl acetate:methanol:ammonia (4:3:1) enabled the simultaneous study of resveratrol and biogenic amines in red wine (Sherma, 2000). In an extreme case, multidimensional planar chromatography has been used to fully separate 14 pesticides on a 10 cm × 10 cm TLC plate (Tuzimski, 2007).

Planar chromatography has been applied to analysis of most types of constituents of alcoholic beverages or their raw materials, although probably the greatest focus has been on phenolic compounds, including pigments, and especially in grape musts and wines. Flavan-3-ols, including the dimeric procyanidins have been separated on cellulose TLC plates using water as eluent and dimethylaminocinnamaldehyde (DMACA) as the derivatizing agent, for densitometric determination (Glavnik *et al.*, 2009). Quantification at 655 nm (blue) showed good linearity between 2 and 12 ng of analyte, with a limit of detection of 0.2 ng. DMACA was considered to be superior to vanillin, the established reagent for the visualization of flavanols on TLC plates.

Resveratrols and other stilbene phenolic compounds in wine have been determined by standard TLC with fluorescence scanning (Chen *et al.*, 2005). Good linearity of detector response was found in the range 2.0–27.7 ng, recoveries were 97.1–98.5%, with relative standard deviations of 2.0–3.2%. The mobile phase was benzene:methanol:formic acid (10:5:1). The resveratrol and piceid isomers were separated from other polyphenols by SPE treatment (Section 4.2.4) on a C_{18} phase prior to TLC analysis. OPLC was used to separate stilbene isomers in red wine, with limits of detection 40 ng (for *trans*-resveratrol, *cis*- and *trans*-piceatannol, and 60 ng for *cis*- and *trans*-piceid (Kiraly-Veghely *et al.*, 2004). Resveratrol and biogenic amines in red wine were determined together by silica gel TLC, the resveratrol being determined directly by densitometry, whilst the biogenic amines were determined as their dansyl derivatives (Sherma, 2000). TLC has been much used in the study of red wine pigments, anthocyanins and their derivatives (Amerine and Ough 1980b). More recently, normal phase TLC has been used to produce profiles of Croatian red wines (Rastija *et al.*, 2004) and HPTLC on C_{18} silica gel (i.e. reversed phase) with isocrative elution, using methanol-water-trifluoroacetic acid as the mobile phase has been used to study the anthocyanin composition of red wines (Lambri *et al.*, 2003). The anthocyanins were separated from other components (including polyphenols) C_{18} SPE treatment of the samples.

Previous to these studies, anthocyanins were separated by manual multistep elution reversed phase HPTLC, and by TLC, where characteristic differences in anthocyanin composition allowed differentiation between Pinot Noir red wines and those of other varieties (Holbach and Wilken, 1994).

Other phenolic components of red wine (e.g. catechins, chlorogenic acid, gallic acid and protocatechuic acid) were separated from pigments by cellulose TLC with methanol:water (4:1) eluent, were visualized by 5% aqueous $FeCl_3$ and determined by densitometry at 700 nm (Sherma, 2000). Wine pigments were separated on silica gel TLC plates using 1-butanol:butyl acetate:formic acid:water (13:5:2:3) and quantified by densitometry at 540 nm. Likewise, RPTLC (C_{18}) using water-acetonitrile and water-acetonitrile-trifluoroacetic acid mobile phases has been used to separate anthocyanidins, catechins, flavanones, flavones and flavonols in wines and other sources (Baranowski *et al.*, 2005).

Grape and wine proanthocyanidins were fractionated using C_{18} SPE into monomers, oligomers and polymers by using different SPE eluents (Sun *et al.*, 1998). The fractions were further analyzed by TLC and HPLC, allowing quantification of individual procyanidin dimers and trimers.

More unusual polyphenols, including two new C–C linked biflavonoids in Chardonnay grape pomace were analyzed by a combination of TLC and column chromatography (using Sephadex LH 20 and MCI gel CHP 20P stationary phases) (Yeap Foo *et al.*, 1998). NMR analysis of the isolated biflavonoids showed them to be epicatechin-(6′→8)-epicatechin and epicatechin-(6′→8)-catechin.

Planar chromatography has also been much applied to the analysis of pesticide residues (McLean *et al.*, 1999; Jayarman *et al.*, 2003; Tuzimski, 2007) and mycotoxin residues (Abrunhosa *et al.*, 2001; Dugan, 2003; de Oliveira *et al.*, 2007) in food and beverages. Captan (a contact fungicide) residues in grapes were determined by TLC (Jayarman *et al.*, 2003), and the uptake and metabolism of the systemic fungicide triadimenol by grapevines were investigated using TLC (McLean *et al.*, 1999). Instead of finding degradation product residues of triadimenol in grapes, this group found higher molecular weight conjugates of this molecule with its structure largely intact. Carbon-14 labeled triadimenol was used in this study, with autoradiographic determination.

After solvent extraction from food matrices and sample clean up on a silica SPE cartridge, aflatoxins B1, B2, G1 and G2 (Section 5.11.4) were determined on silica gel G TLC plates using (for confirmation), different mobile phases – toluene:ethyl acetate:acetone (3:2:1), chloroform:acetone:1-propanol (85:10:5) and chloroform:THF (90:10) (Dugan, 2003). Patulin (Section 5.11.4) in grapes extracted into ethyl acetate and ethanol was determined by normal phase TLC, using toluene:ethyl acetate:formic acid (6:3:1) as solvent and 0.5% MBTH (3-methyl-2-benzothiazolinone hydrazone hydrochloride) in 5% aqueous formic acid as visualizing agent (Oliveira *et al.*, 2007). The densitometric quantification limit was 15.87 μg/kg. A TLC method for the simultaneous analysis of several mycotoxins (citrinin, ochratoxin A and patulin) in grapes has been developed, using silica gel 60 plates without indicator, by Abrunhosa *et al.* (2001).

Sugars, polyhydroxy compounds and polyamines have also received considerable attention from TLC analysis. Quantitative monitoring of maltodextroses and monosaccharides in beers on amino bonded HPTLC plates with gradient elution-AMD (Brandolini *et al.*, 1995). The sugars on the developed plates were visualized by thermal *in situ* reaction of the analytes with the amino groups of the HPTLC layer and quantification was performed using a Camag TLC scanner with appropriate computer interface and software. A detailed summary of planar chromatographic methods used to analyze the sugars in beet and cane molasses in the sugar industry has been given by Mantovani *et al.* (1998).

Silica gel 60 HPTLC with isocratic elution was used to separate carbohydrates, glycerol, ethylene glycol and diethylene glycol in alcoholic beverages, such as wines (Klaus and Fischer, 1987). The eluted plates were visualized either by spraying with a vanadium pentoxide reagent or by immersion of the plates in dichlorofluorescine solution. More recently, glycerol in wines has been determined using gradient elution HPTLC (Brandolini *et al.*, 2002). The method was used to compare the glycerol producing ability of different wine yeasts (Chapter 2.2), including *S. cerevisiae*, *S. ludwigii*, *Zygosacharromyces bailii* and *Kloeckera apiculata*.

The most popular stationary phases in planar chromatography are silica gel (for normal phase) and bonded silica phases, such as C_{18}, amino and diol phases. Cellulose layers are also used and sometimes alumina or calcium sulfate layers, these being considered especially effective in the separation of more polar compounds. An example of this can be found in the analysis of polyamines (cadaverine, citrulline, ornithine, putrescine, spermidine and spermine) (Section 5.11.3) (Khan, 2006). Here the polyamines in biological fluids were separated on $CaSO_4$ plates using methanol as the mobile phase. This stationary phase was superior to silica gel in resolution of the polyamines and elution time was one-third shorter compared to silica. The limits of detection and quantification (found by scraping the visualized spots (ninhydrin) off the developed plates and measuring the absorbance at 550 nm) were 0.75 and 1.88 μg, respectively. Although this method has not yet (2009) been applied to the determination of polyamines in alcoholic beverages, it would appear to have potential in this area.

4.3.2 Capillary Gas Chromatography

In 1906, the Russian scientist Mikhail Tswett reported the separation of different natural colored pigments of leaves by passing a percolated extract through a glass column packed with finely divided adsorbents. He was later to use the term chromatography, from the Greek words χρώμα: *chroma* meaning 'color' and γράφει: *graphei* meaning to 'write.'

Today, gas chromatography (GC) is a popular analytical technique that is widely used around the world to achieve the separation, qualification (identification) and quantification (concentration) of the volatile chemical components in complex mixtures (such as alcoholic beverages).

As with other chromatographic techniques, GC uses a *stationary* phase and a *mobile* phase, whereby chemical components of a mixture are carried through the stationary phase (most modern state of the art systems contain a uniform thin film of phase that is affixed to the inner periphery of an open capillary tube) by a stream of gaseous mobile phase (carrier gas). However, in contrast to most other types of chromatography, the mobile phase does not interact with molecules of the analyte; its only function is to transport the analyte through the stationary phase. Separation is based on differences in migration rates among the sample components.

Over 50 years have now passed since GC was first conceived and it remains one of the world's most cited analytical methodologies and a heavyweight analytical tool in many industrial and academic laboratories. The extensive theory of GC has been widely reported by one of its pioneers (Jennings *et al.*, 1997), as well as excellent guidance in the care, maintenance and troubleshooting of instruments (Rood, 1999). Therefore, only the basics are described here for modern instruments using fused silica capillary columns with split/splitless or programmable temperature vaporizer (PTV) injectors, and only recent references of alcoholic beverage analysis using GC are offered – purely as examples. Extensive examples of alcoholic beverage research using GC as the main analytical technique can be found under the extraction and focusing methods in sample preparation section (Chapter 4.2) of this book.

Modern GC systems consist of a carrier gas supply (and associated pressure regulators, gauges, flow controllers and gas filter system to remove impurities such as water, oxygen and hydrocarbons), injector (to introduce the sample into the GC), column, oven, detector and a computer data system.

Carrier Gas

Chemically inert carrier gases used historically for GC include helium, hydrogen and nitrogen. It is generally accepted that helium and hydrogen are the best gases for capillary GC columns, as high linear velocities can be used without sacrificing efficiency when compared to nitrogen, for example. Modern gas chromatographs have the addition of electronic pressure controllers (EPC), which give the analyst a choice of either constant pressure (isobaric) or constant flow (isorheic) for carrier gases with extremely accurate control. Evaluation of column performance in constant pressure and constant flow modes has been carried out by Blumberg *et al.* (1999). The researchers concluded that there was almost no difference in the speed separation performance of a column between constant pressure and constant flow modes of temperature programmed GC and that nearly the same maximum peak capacity at nearly the same analysis time could be achieved in both modes of analysis.

Ultra high purity grade helium and hydrogen are used (99.999+%) which contain less than a few parts per million of oxygen and hydrocarbons as contaminants. Oxygen will rapidly degrade the stationary phase of columns and this will result in a reduction of column life and hence the increased expense of replacement.

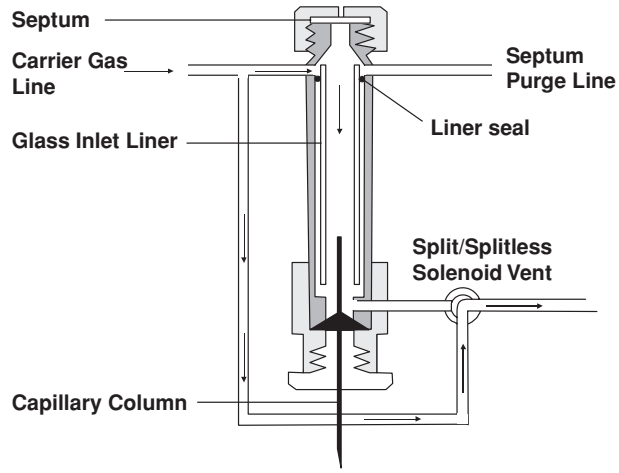

Figure 4.3.1 *A typical GC split/splitless inlet system (splitless mode shown). Reproduced from Gerstel (2002), with permission of Gerstel, GmbH*

Sample Injectors

The most common method of injection involves the use of a microliter syringe to inject a liquid or gaseous sample through a silicone rubber septum into a glass liner that is situated inside a heated metal injector body located at the head of the column. Rapid vaporization of the sample then takes place (the sample port is ideally 50 °C above the boiling point of the least volatile component in the sample or as high as the fused silica stationary phase of the chromatographic column will allow). Figure 4.3.1 is a schematic of a typical split/splitless injection port that is available on modern GC systems from numerous suppliers commercially. Split and splitless injection in capillary GC has also been documented in extensive detail by Grob (2001). Carrier gas enters at the top of the injector and this mixes with the vaporized sample to introduce it to the column for the subsequent separation process to begin. The septum purge is typically 1 to 3 ml/min of carrier gas that flows across the top of the injector immediately below the septum and exits via the septum purge line. This low flow of inert carrier gas is designed to aid the cleanliness of the injection port and to minimize the condensation of nonvolatile and high boiling materials of the sample matrix on the exposed section of the septum.

For samples containing high concentrations of analytes that exceed the capacity of modern columns, the split/splitless injection port is operated in the split mode. In this mode the quantity of sample reaching the column is limited by splitting the sample into two fractions – the size of which can be computer controlled accurately by the analyst. Once split, only a small fraction of the sample enters the chromatographic column and the remainder is discarded down the split line or vent (see split/splitless solenoid vent in Figure 4.3.1). A typical split/splitless injector (Figure 4.3.1) consists of five integral parts, namely the injection port heater, carrier gas line, glass liner, septum purge line and split line/vent. On injection of a sample into the heated injection port, the sample flash vaporizes and is subsequently mixed with the carrier gas and can travel either down the column for separation of volatile components or the split line. The amount of sample entering the column mixed with carrier gas compared to the amount of sample exiting the GC system via the split vent, can be controlled and is measured by what is known as the split ratio. This ratio is generally expressed as the volume of carrier gas entering the column versus the volume leaving via the split line. For example, following injection of a sample with the incoming carrier gas regulated at 100 ml/min, 2 ml/min is lost to the septum

purge vent, then 98 ml/min of carrier gas is sweeping the sample towards the analytical column. If a 1 ml/min column flow is selected for analysis, the remaining 97 ml/min of carrier gas and vaporized sample is sent to the split vent to be discarded. Therefore, the split ratio of this example is 100:1. Because the septum purge flow is low, only a very small volume of sample is lost via the septum purge line and hence is ignored when estimating and calculating split ratios for samples. Many modern split/splitless injectors can deliver 1000 ml/min total gas flow, so high split ratios can be achieved with very high accuracy with computer control.

Many different designs and types of split injection glass liners are available commercially, however the function remains identical, in that it should provide a completely inert environment for the injection and subsequent vaporization of a sample and its volatile constituents. Most modern inlet liners are supplied deactivated (silylated) prior to being vacuum packed ready for use by the analyst. Some also contain a plug of glass wool which is designed to mix the carrier gas and vaporized sample to ensure repeatable split injections. The glass wool also traps nonvolatile materials (such as sugars) and prevents fouling of the column from these contaminants.

Recent examples of research whereby split GC injections have been adopted include analysis of vineyard grape juice for volatile organic compounds with a 20:1 split ratio (Caven-Quantrill and Buglass, 2006), wine volatile profiling with a 60:1 split (Aznar and Arroyo, 2007), analysis of odor active compounds in the spicy fraction of hop essential oil (Section 2.6.3) with a 50:1 split ratio (Eyres *et al.*, 2007), for the direct injection of orujo spirits (Section 3.7.3) (1:1 split) to study the volatile composition (Cortés *et al.*, 2005), for elucidation of the main odor active compounds of whisky (Section 3.2.5) with a 10:1 ratio (Caldeira *et al.*, 2007), amino acid enantiomers in beer with a 30:1 split (Erbe and Brückner, 2000), quantification of major grape polysaccharides with a 20:1 split (Ayestarán *et al.*, 2004) fungicide residues (Section 5.10.2) in wine with a 10:1 split (de Melo Abreu *et al.*, 2006) and free disaccharides and other glycosides in wine with a 40:1 split (Ruiz-Matute *et al.*, 2009).

For trace level analysis, the split/splitless injector can be operated in the splitless mode, whereby a majority of the sample is introduced into the capillary column (see Figure 4.3.1). During a splitless injection, the split/splitless vent remains closed and no carrier gas flows via this line. As the sample is vaporized, it mixes with carrier gas and is introduced to the chromatographic column. As the split vent is closed during this time, the entire vaporized sample is transferred to the column. After a predetermined time, ideally between 40 and 90 s (Rood, 1999), the split/splitless vent is opened and allows carrier gas to flow via the inlet liner to the vent. At this time the inlet purge flow is also switched on to provide an elevated carrier gas flow rate. Any residual sample volatile or nonvolatile material is hence swept away from the injection port and exits via the split vent (identical to a split injection mode). As the vaporized sample to column transfer in the splitless mode occurs over a long period of time, a solvent effect is generally relied upon to focus the sample analytes at the head of the capillary column (by maintaining the start temperature of the column lower than the boiling point of the sample solvent). Other less volatile compounds will be cold trapped at the head of the column regardless of a solvent being present. In contrast to split injection liners, splitless liners rarely contain glass wool as this causes mixing and dilution of the vaporized sample with the carrier gas and this in turn can result in broader and smaller analyte peaks during the resulting analysis.

Recently, splitless injection-GC has been used to analyze the volatile compounds of Muscat grape juice (Section 2.9.1) (Sánchez-Palomo *et al.*, 2009), for the speciation of arsenic in wine and beer (Campillo *et al.*, 2008b), to determine the odorous impact of volatile thiols on the aroma of young botryized sweet wines (Sarrazin *et al.*, 2007), for the determination of volatile phenols in cider (Section 2.8.4) (Pizarro *et al.*, 2009), for the varietal characterization of hop (Shellie *et al.*, 2009) and new thiols derived from hop (Takoi *et al.*, 2009), flavor stability of beer (Section 2.6.12) (Saison *et al.*, 2008), for the aromatic profile of different kinds of wine cork stoppers (Culleré *et al.*, 2009), off flavors and taints in wines (Alzaga *et al.*, 2003, Insa *et al.*, 2007, Pizarro *et al.*, 2007, Campillo *et al.*, 2008a), for the determination of volatile organic sulfur and selenium compounds in beers, wines and spirits (Campillo *et al.*, 2009), for the volatile aroma profiling

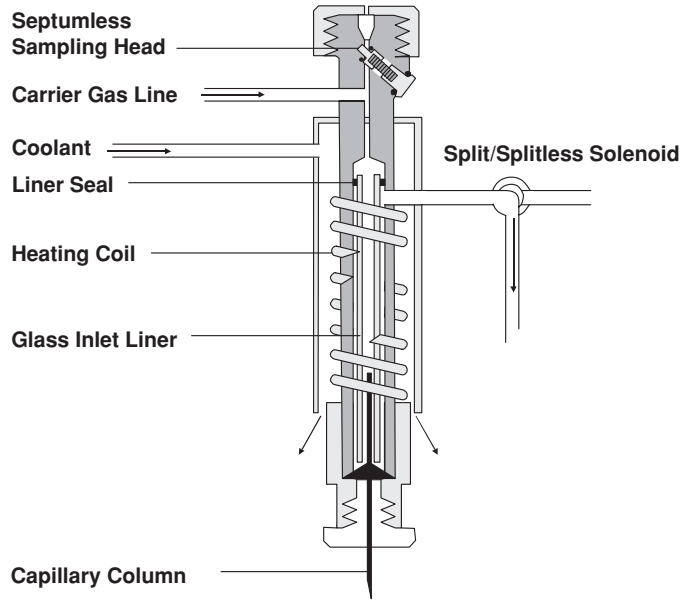

Figure 4.3.2 *A PTV inlet. Reproduced from Gerstel (2002), by permission of Gerstel GmbH*

of whisky (Câmara *et al.*, 2007), brandy (Section 3.6.1) (Zhao *et al.*, 2009), cachaça (Section 3.5.4) (de Souza *et al.*, 2009) and orujo spirits (García-Martín *et al.*, 2010), fungicides in wine (Montes *et al.*, 2009; Vaquero-Fernández *et al.*, 2009), pesticides in grapes, musts and wines (Cunha *et al.*, 2009; Patil *et al.*, 2009) and phthalates in wine (Section 5.10.4) (Carrillo *et al.*, 2008).

Another common design of injection system used for the analysis of volatile alcoholic beverage components is the programmable temperature vaporizer (PTV). This inlet closely resembles a conventional split/splitless inlet (see Figure 4.3.2), however the primary difference is temperature control. The liner of the PTV can be heated or cooled rapidly. Ballistic heating of the inlet body at a rate of 0.5–12 °C/s can easily be achieved, and heating is controlled using a sophisticated electronic controller. Cooling can be performed by using a Peltier element, liquid carbon dioxide or liquid nitrogen (hence the injector can be used as a cold trap). In order to facilitate rapid heating and cooling, the thermal mass of the liner is minimized. For this reason the total internal volume of glass liners for PTV inlets are smaller than those used in conventional split/splitless inlets (150–250 μl versus 1000 μl).

The PTV inlet is a useful sample introduction technique for thermally labile analytes whereby sudden changes in temperature can cause degradation. This can be minimized by injection at a lower temperature and then raised very rapidly to achieve vaporization of the sample. The result is less thermal stress applied to the sample and hence less severe changes in temperature during the analysis.

Rogerson *et al.* (2002) used a PTV injector to analyze liquid extracts (Section 4.2.2) of port wines (Section 2.10.7) and grape berries. Following injection, the PTV was programmed at 70 °C for 0.1 min then heated at 180 °C/min to 250 °C (held 13.9 min) then finally isothermal at 70 °C.

Similarly, Angioni *et al.* (2005) used a PTV to determine residues of the fungicide zoxamide in grapes, grape processing and in the fermentation process. Hexane extracts (8 μl) were injected into the PTV programmed from 60 °C (held 1 min) to 150 °C at 30 °C/min. The injector was operated in the splitless mode (purge valve opened at 2 min). Recently, the residues of 11 new fungicides in grapes and wines were determined via

liquid–liquid extraction (Section 4.2.2) and PTV-GC-MS (González-Rodríguez *et al.*, 2009). Extracts (2 μl) were injected into a PTV operating in solvent split mode which was subsequently programmed from 80 °C (0.1 min), 720 °C/min to 100 °C (0.1 min), 402 °C/min to 275 °C (1.5 min) then finally 402 °C/min to 300 °C (5 min).

Following extraction of wine, whisky and brandy samples by solid phase extraction (SPE, Section 4.2.4) Campo *et al.* (2007) used a programmable injector to perform large volume injections (LVI). Extracts (50 μl) were injected in the solvent split mode and during injection, the PTV was retained at 40 °C and the split valve was opened (split ratio = 30) to promote solvent evaporation. After elimination of solvent (0.25 min), the split valve was closed and the PTV was heated to 250 °C at a rate of 200 °C/min. After 3 min, the split valve was opened again (split ratio = 20) and the PTV was held isothermally at 250 °C. The injection parameters were carefully optimized to ensure a complete transfer of analytes to the GC column with good retention time reproducibility. An identical PTV method has been used recently for the comparative study of the aromatic profile of different kinds of wine cork stoppers (Culleré *et al.*, 2009). Large volume PTV injection has also been reported for the determination of organophosphorus pesticides from spiked samples of red and white wines and apple juice (Schellin *et al.*, 2004), for the low level determination of organochlorine pesticides in wines (Pérez-Serradilla *et al.*, 2010) and for the multiresidue analysis of 50 pesticides in grape and other fruits (Savant *et al.*, 2010).

The PTV injector has also been used successfully with modern techniques such as thermal desorption. In contrast to solid phase microextraction (SPME – Section 4.2.4), in which desorption is performed in a standard GC inlet, stir bar sorptive extraction (SBSE – Section 4.2.4) is used in combination with a thermal desorption system. Because more extraction phase is utilized, the desorption process is slower than that for a SPME fiber, thus desorption combined with cold trapping and reconcentration is required.

The setting of the parameters of thermal desorption will directly affect the desorption efficiency, collection and quantitative analysis of the sample (Grimm *et al.*, 1997). Desorption temperatures must be set high enough to facilitate the stripping of the volatile compounds, yet not alter the sample or analyte. Desorption times should be sufficient to remove the majority of the volatiles. Purge/carrier gas flow rates should be sufficient to purge the analyte from the sample (for example stir bar), but not push the desorbed volatiles through the cold trap.

This whole process has been automated. Two examples of systems that are available commercially are the TDS-2/A, a classic thermal desorption system (see Figure 4.2.3) and a specially designed Twister™ desorption unit (both from Gerstel). These systems can be mounted on Agilent Technologies gas chromatographs equipped with a CIS-4 programmable temperature vaporizing (PTV) inlet (also from Gerstel). The PTV inlet is operated as a cold trap (see Figure 4.3.3) for cryogenic focusing of the thermally desorped analytes. Temperatures as low as –150 °C are achieved using liquid nitrogen cooling (Hoffman *et al.*, 2000; Kreck *et al.*, 2001; Ochiai *et al.*, 2001; Sandra *et al.*, 2001; Wennrich *et al.*, 2001; Kreck *et al.*, 2002; Hayasaka *et al.*, 2003). Both of these systems allow fully automated control of all desorption, trapping and injection conditions, including temperatures, flows and split or splitless modes. Many examples of this technique are discussed in detail under the SBSE section of this book (Section 4.2.4).

A recent addition to the range of GC inlets is a combination of a standard split/splitless with temperature programmable capabilities. This is reported to allow for large volume injection and also support cool injections for improved signal response (Agilent, 2009).

Fused Silica Capillary Columns

Modern GC capillary columns consist of a fused silica tube (a synthetic, quartz like glass) that contains an inner stationary phase and an outer protective polyimide coating. As with glass injection port liners, fused silica tubing is deactivated (silylated) prior to addition of the stationary phase during manufacture. This is

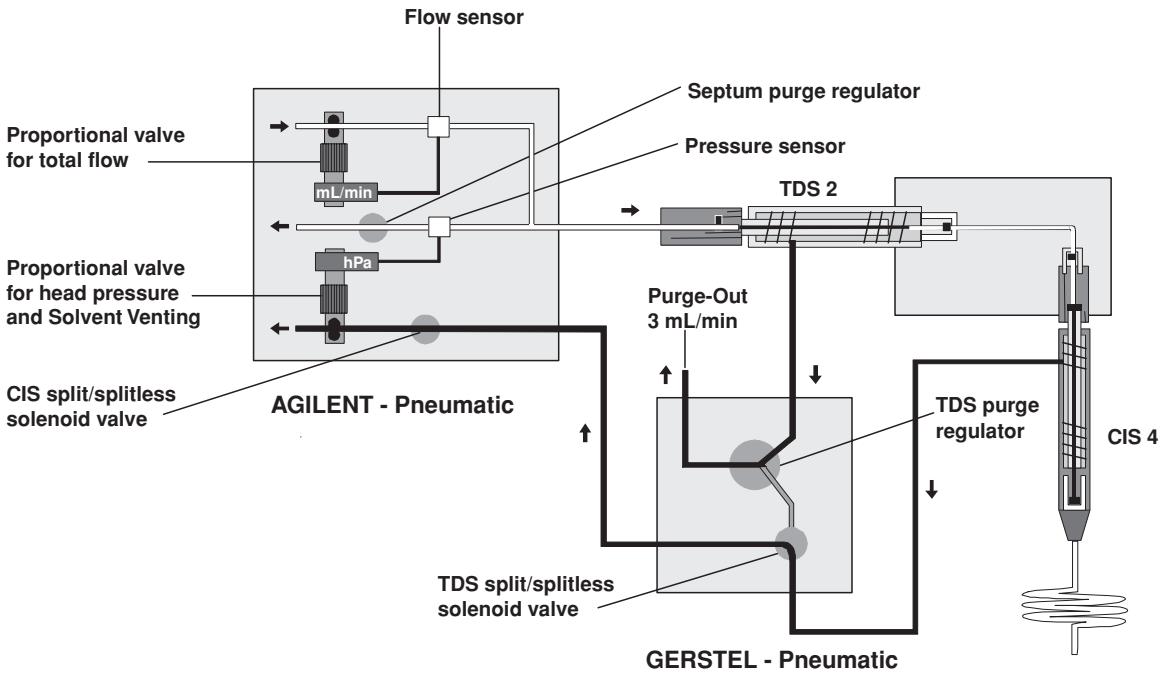

Figure 4.3.3 *TDS-2/CIS-4 flow diagram – TDS splitless desorption. Adapted from Gerstel (1998), with permission of Gerstel GmbH*

designed to limit the surface silanol groups which can hydrogen bond with certain functional groups of volatile compounds during analysis and provide poor chromatographic peak shape. The choice of stationary phase is selected by the analyst to separate the injected volatile organic components of a sample, based on the chemical and physical properties of these analytes. The subsequent retention time of each separated volatile component is a measure of the interaction of the analyte and stationary phase. If one particular stationary phase cannot separate certain target analytes, then it is possible that separation will be achieved with an alternative phase. Stationary phase polarity plays a large role in the ability of a column to separate sample components. Therefore, a nonpolar column is generally chosen for the separation and subsequent analysis of compounds that are composed of only carbon and hydrogen atoms and contain carbon–carbon single bonds (nonpolar compounds) and vice versa, polar columns for target analytes that are composed not only of carbon and hydrogen atoms, but also contain one or more atoms of oxygen, sulfur, nitrogen, chlorine, fluorine, bromine or phosphorus (polar compounds). Compounds that are composed of carbon and hydrogen and also contain double or triple carbon–carbon bonds (for example, aromatic hydrocarbons such as cyclic terpenoids) are classed as polarizable compounds and highly polar stationary phase columns are most commonly employed to separate these compounds of interest. Stationary phase interactions (dispersion, dipole, hydrogen bonding and acid–base) are also important factors of capillary column analysis and have been discussed by Jennings *et al.* (1997) and in some depth by Rood (1999). In basic terms, separations of analytes on a specific stationary phase are determined by differences in the overall effects of these interactions.

Table 4.3.1 lists the most common capillary column stationary phases (in order of increasing polarity) for GC analysis, along with their associated commercial description, stationary phase polarity and examples of typical analytes summarized by many column manufacturers. Low bleed stationary phases (commonly

Table 4.3.1 *Common fused silica capillary column stationary phases (in order of increasing polarity) for GC analysis*

Composition	Commercial Description[a]	Polarity	Typical Analytes
100% Dimethylpolysiloxane	AT-1, BP-1, CP-Sil 5 CB, DB-1, EC-1, HP-1, HP-101, OV-1, PE-1, Rtx-1, SE-30, SPB-1, SPB-Sulfur, SP-2100, Ultra 1, ZB-1, 007-1, AT-1ms, DB-1ms, HP-1ms, Rtx-1ms etc	Nonpolar	Aroma/flavor compounds, sulfur compounds, hydrocarbons, amines, pesticides, polychlorinated biphenyls (PCBs), phenols
5% Phenyl 95% dimethylpolysiloxane or 5% Phenyl 95% dimethyl arylene siloxane	AT-5, BP-5, CP-Sil 8 CB, DB-5, DB-5ht, EC-5, HP-5, OV-5, PAS-5, PE-2, PTE-5, PTE-5QTM, Rtx-5, SAC-5, SE-54, SPB-5, Ultra 2, ZB-5, 007-2, AT-5ms, DB-5ms, HP-5ms etc	Nonpolar	Fatty acid methyl esters (FAMEs), solvents, pesticides, herbicides, aroma/flavor compounds
6% Cyanopropyl-phenyl 94% dimethylpolysiloxane	AT-624, AT-1301, BP-624, CP-624, CP-1301, DB-624, DB-1301, HP-1301, HP-624, Rtx-1301, Rtx-624, SPB-1301, SPB-624, ZB-624, 007-1301, 007-624	Mid polar	Alcohols, pesticides, VOCs, aroclors
35% Phenyl 65% dimethylpolysiloxane or 35% Phenyl 65% dimethyl arylene siloxane	AT-35, BPX-35, DB-35, HP-35, MDN-35, OV-11, PE-35, Rtx-35, SPB-35, SPB-608, SUP-Herb, ZB-35, 007-11, AT-35ms, DB-35ms, HP-35ms etc	Mid polar	Chlorinated pesticides (CLP), aroclors
14% Cyanopropyl-phenyl 86% dimethylpolysiloxane	AT-1701, BP-10, CP-Sil 19 CB, DB-1701, HP-1701, OV-1701, PAS-1701, PE-1701, Rtx-1701, SPB-1701, ZB-1701, 007-1701	Mid polar	Pesticides, herbicides, trimethylsilyl (TMS) sugars, aroclors
50% Phenyl 50% dimethylpolysiloxane or 50% Phenyl 50% dimethyl arylene siloxane	AT-50, BPX-50, CP-Sil 24CB, CP-TAB-CB, DB-17, DB-17ht, HP-17, H5-50+, HP-50+, PE-17, Rtx-50, Rtx-65TG, SP-2250, SPB -17, SPB-50, SP-50, SP-2250, ZB-50, 007-17, DB-17ms etc	Mid polar	Glycols, pesticides
50% Cyanopropyl-phenyl 50% dimethylpolysiloxane	AT-225, BP-225, CP-Sil 43CB, DB-225, HP-225, OV-225, PE-225, Rtx-225, 007-225	Polar	Fatty acid methyl esters (FAMEs)
Polyethylene glycol	AT-Wax, AT-Aquawax, BP-20, Carbowax-20M, CP-Wax 52 CB, DB-Wax, DB-Waxetr, EC-Wax, HP-Wax, HP-20M, HP-INNOWAX, Omegawax, PE-CW, Rtx-Wax, Stabilwax, Supelcowax-10, ZB-Wax, 007-CW, AT-Waxms etc	Polar	Essential oils, aroma/flavor compounds, alcohols, solvents, free organic acids

(*Continued*)

Table 4.3.1 (*Continued*)

Composition	Commercial Description[a]	Polarity	Typical Analytes
Polyethylene glycol – base modified	AT-Cam, Carbowax amine, CP-Wax 51, Stabilwax-DB	Polar	Amines
Polyethylene glycol – acid modified	AT-1000, AT-Aquawax-DA, BP-21, CP-Wax 58CB, DB-FFAP, EC-1000, HP-FFAP, Nukol, OV-351, SP-1000, Stabilwax-DA	Polar	Organic acids, alcohols, aldehydes, ketones, aroma/flavor compounds, essential oils

[a]AT (Grace Davison), BP/BPX (SGE), CP-Sil (Varian now Agilent), DB (Agilent), EC (Grace Davison), HP (Agilent), MDN/Nukol/Omegawax (Supelco), OV (Ohio Valley), PAS (Agilent), PE (Perkin Elmer), PTE (Supelco), Rtx (Restek), SAC (Supelco), SE (Agilent), SPB/SP/Stabilwax/Supelcowax/SUP (Supelco), Ultra (Agilent), ZB (Phenomenex), 007 (Quadrex Corp),

containing an 'arylene') consist of a phenyl group that is added into the backbone of a standard polysiloxane and most are designed as low bleed equivalents to familiar stationary phases (for example, a 5% phenyl 95% dimethylpolysiloxane standard phase has the 5% phenyl 95% dimethyl arylene siloxane low bleed version – see Table 4.3.1). These are particularly useful where analytical sensitivity needs to be considered for certain GC detectors. Column bleed is most commonly observed as a rising baseline during analysis of a sample by GC and is most evident at temperatures around the upper limit of the column stationary phase. This phenomenon is completely normal and continues to increase with the lifetime of the column (and is dependant on the polarity of the stationary phase, the temperature of the column during analysis and the concentration of oxygen in the carrier gas). Therefore, due to the sensitivity of certain GC detectors to the stationary phase degradation products, the analyst may need to take into consideration the possible disappearance of peaks of interest into the column bleed with low level analysis of samples.

It is important to understand that the correct choice of column, to fullfil fit for purpose analysis of alcoholic beverage samples, is not only governed by the chemistry of the stationary phase. The selection of a column to provide the analyst with optimized chromatographic separation also needs to take into account the importance of the internal diameter of the fused silica tubing, the stationary phase film thickness and the overall column length.

The internal diameter (i.d.) of common commercially available capillary columns ranges between 0.10 mm and 0.53 mm. This enables the optimization of two important factors, namely efficiency and capacity. High efficiency is achieved when narrow and well resolved peaks (i.e, baseline separation of closely eluting analytes) are observed and the efficiency of the column (measured in plates (N) or plates per meter (N/m)) increases as the column i.d. decreases. On the other hand, sample capacity, which is the concentration of any one analyte that can be introduced to the column without causing a negative effect on the resulting chromatography (by causing a desired sharp symmetrical peak shape to overload and become a 'shark fin' shape) increases with column i.d. Optimisation of one of these factors is to the detriment to the other opposing factor therefore, 0.25 mm i.d. columns are generally considered standard, as this diameter provides adequate efficiency with acceptable sample capacity. Sharper chromatographic peaks and shorter retention times of separated sample analytes are also achieved generally with thinner film columns. Increasing stationary phase film thickness can reduce the interaction of analytes with the fused silica tubing and increase sample capacity. However this can also lead to an increase in chromatographic peak widths which in turn can lower resolution, increase column bleed (resulting in possible disapearance of peaks of interest into the column bleed with low level analysis of samples – commonly known as having a low signal to noise ratio) and a reduction in the upper temperature limit of the column during use. This can be restrictive to the analyst, as increased film thickness also leads to greater retention of analytes and hence the requirement of higher elution temperatures.

Typical capillary columns are available in lengths of 10 to 60 m. Longer columns will provide increased resolution when directly compared to shorter columns of equivalent stationary phase and film thickness, however the result is an increase in analysis time and head (inlet) pressure required to transport analytes through the column. The most common column length of 30 m for standard GC analysis generally provides the best compromise of resolution, analysis time and column head pressure. For many analyses, the use of a 60 m column to increase resolution should only be considered as a last resort, as a shorter column with a thicker film of stationary phase will most likely achieve an acceptable separation in far less time.

It is a fair statement to make that for a large majority of samples requiring separation of target analytes by GC can be achieved readily by the use of either a highly nonpolar phase (100% dimethyl polysiloxane or 5% phenyl 95% dimethylpolysiloxane and their associated low bleed equivalents) or highly polar phase (polyethylene glycol and modified polyethylene glycol phases). Indeed, a high percentage of the references that use modern capillary column GC analysis discussed under the extraction and focusing methods in sample preparation section (Chapter 4.2) of this book, either used straightforward nonpolar phases (DB-1, HP-1, CP-Sil 5 CB, DB-1ms etc. – see Table 4.3.1) or polar phases (Carbowax, Innowax, DB-Wax, Supelcowax, DB-FFAP etc. – see Table 4.3.1), obviously dependant on the types/chemical classes of volatile compounds that required separation and subsequent analysis.

Examples of alcoholic beverage analytes that have been recently analyzed via GC with a mid polarity phase include sulfur and selenium compounds in beers, wines and spirits using a DB-624 column (6% cyanopropyl-phenyl 94% dimethylpolysiloxane – see Table 4.3.1) (Campillo *et al.*, 2009), aroma compounds from sugar cane spirits, again using a DB-624 (Gracia *et al.*, 2007), odor active compounds from American Bourbon whisky (Section 3.3.4) using a DB-1701 column (14% cyanopropyl-phenyl 86% dimethylpolysiloxane) (Poisson and Schieberle, 2008), hop metabolites with a BPX-35 column (35% phenyl 65% dimethylpolysiloxane) (Shellie *et al.*, 2009), the fungicide famoxadone with a DB-17ms (50% phenyl 50% dimethyl arylene siloxane) (de Melo Abreu *et al.*, 2006) and pesticides with a BPX-50 or low bleed MS equivalent column (50% phenyl 50% dimethylpolysiloxane) (Patil *et al.*, 2009; Ramos *et al.*, 2009).

When a single GC column cannot provide effective resolution of the target analytes of a sample, then multidimensional GC (MDGC) can be applied. With this technique, two columns of different polarity (often housed in separate GC ovens) are connected via a switching mechanism. The sample is introduced onto the first capillary column and as the analyte(s) of interest elute they are switched (also known as heart cut) onto the second column for subsequent separation. For example, Ryan *et al.* (2005) reported an optimized headspace solid phase microextraction (HS-SPME – Section 4.2.4) for the determination of methoxypyrazines in wine. Analysis was performed using comprehensive two dimensional GC with nitrogen phosphorus detection (GC × GC-NPD) and time of flight mass spectrometry (GC × GC-TOFMS). For each system, the first dimension of the GC × GC column set was a BPX-5 (5% phenyl polysilphenylene-siloxane) column with a BP-20 (polyethylene glycol) column in the second dimension. It was concluded that both the multidimensional techniques were highly sensitive, yielding detection limits for 2-methoxy-3-(2-methylpropyl) pyrazine of 0.5 and 1.95 ng/l, respectively.

Following solid phase extraction (SPE – Section 4.2.4) of wine and other alcoholic beverages, Campo *et al.* (2007) used MDGC to determine four novel aroma powerful ethyl esters (ethyl 2-, 3- and 4-methyl pentanoate and ethyl cyclohexanoate). Here, the first dimension of the GC × GC column set was a DB-WAX (polyethylene glycol) and the second a FactorFour-VF5ms (polymethylsiloxane – 5% diphenyl). The authors concluded that the proposed method made it possible to provide (for the first time) an assessment of the levels and potential sensory importance of the novel esters in different beverages.

A further recent example of the use of MDGC for the evaluation of aroma compounds in wines includes the identification of volatile compounds responsible for prune aroma in prematurely aged red wines (Pons *et al.*, 2008), where a SPB-1 (100% dimethylpolysiloxane) and BP-20 (polyethylene glycol) set of columns were used.

Two dimensional GC has also recently been used for the determination of volatile compounds in cachaça (Section 3.5.4) (de Souza *et al.*, 2009). The nonpolar/polar column set consisted of a BPX-5 (5% phenyl 95% dimethyl polysilphenylene-siloxane) in the first dimension and a BP-20 (polyethylene glycol) in the second. The researchers concluded that the GC × GC method proved to be an effective technique to study production processes, due to its high resolution, improved revelation of headspace composition and sensitivity.

MDGC has unsurprisingly also found its use in the field of pesticide analysis. Recently a number of GC × GC–TOFMS methods have been proposed with a nonpolar (5% phenyl 95% dimethyl polysilphenylene-siloxane) and mid polar (50% phenyl 50% dimethylpolysiloxane) set of columns for the determination of pesticide residues in grapes (Banerjee *et al.*, 2008, Ramos *et al.*, 2009).

An extremely useful and analytically important group of GC stationary phases not listed in Table 4.3.1 are the chiral family of capillary columns. These can be used as either the main GC column to separate target analytes into their respective enantiomers or used as one of the dimensions in a GC × GC setup.

Different multidimensional chromatographic approaches applied to the study of wine malolactic fermentation (Chapter 2.3) were reported by Fernandes *et al.* (2003). For enantioselective GC, a 30 m × 0.22 mm i.d. tailor made fused silica capillary column coated with a 0.25 μm film thickness of 15% heptakis (2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin in SE52 (5% phenyl 95% dimethylpolysiloxane – replaced by SE-54) was used. For enantiomultidimensional GC-MS, a dual oven system was used with a SE-52 (30 m × 0.25 mm i.d.) in the first dimension and in the second oven the same DiMe β-CD phase column as used for the enantioselective analysis, but with different i.d. (30 m × 0.25 mm). First and second columns were connected via a live switching T piece. (*R*,*R*), and (*S*,*S*) and meso-butane-2,3-diol and pentane-2,4-diol (reported for the first time in wines) were submitted to untrained sensory panel tests and it was concluded that all stereoisomers revealed different sensory notes; pentane-2,4-diol showed an aromatic impact.

Enantioselective MDGC was used to determine the ratios of various free and glycosidically bound monoterpene polyols in musts of the aromatic grapes *Vitis vinifera* L. cvs. Morio Muscat and Muscat Ottonel (Luan *et al.*, 2004). The dual oven GC system contained a 30 m × 0.25 mm i.d. column coated with 0.25 μm SE52 in the first dimension and in the second oven, a column coated with heptakis (2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin in SE52. It was reported for the first time that the linalool-derived polyol 3,7-dimethylocta-1,7-dien-3,6-diol occurred predominantly as the (3*S*-6*S*)-configured stereoisomer.

The chiral separation of amino acids derivatized with ethyl chloroformate by using comprehensive two dimensional GC has recently been reported (Junge *et al.*, 2007). Analyses were performed on a chiral/polar column set incorporating a 25 m × 0.25 mm i.d. × 0.16 μm film thickness Chiralsil-L-Val (L-valine-*tert*-butylamine linked poly(dimethylsiloxane) ex-Varian – now Agilent) first dimension and a 1 m or 3 m × 0.1 mm i.d. × 0.10 μm BPX50 (50% phenyl 50% dimethylpolysiloxane) in the second dimension. For chiral/low polarity analysis, the first dimension column consisted of either a 1 m or 3 m × 0.10 mm i.d. × 0.10 μm film thickness BP1 (100% dimethylpolysiloxane). It was concluded that the best results were obtained when the enantioselective first dimension column was combined with the nonpolar BP1 phase in the second dimension. A selection of beer samples were analyzed with the optimized method and proline was determined as the major amino acid.

Chiral MDGC has also been utilized for the analysis of many specific volatile alcoholic beverage compounds. Recent examples include wine lactone (Luan *et al.*, 2006) and rose oxide (Koslitz *et al.*, 2008) both using a heptakis (2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin in SE52 chiral stationary phase to separate enantiomers.

The composition of essential oils and their mixtures used to formulate gin is usually too complex to enable separation of all components by standard GC. Minor constituents that possess important organoleptic properties can be masked or hidden by coelution with major sample components. Mac Namara *et al.* (2007) used sequential two dimensional GC-MS (consisting of a 30 m × 0.25 mm × 0.25 μm Supelcowax-10 in the first dimension and a nonpolar HP5-MS column also 30 m × 0.25 mm × 0.25 μm in the

second – see Table 4.3.1) to produce a target compound library, with orthogonal GC × GC providing the separation power required to obtain peak retention times and the corresponding mass spectra needed for the creation of a deconvolution database (once the mass spectrum, retention time window and/or retention index for each component is known, the deconvolution method is constructed). Following this, individual compounds could be identified using standard one dimensional GC and commercially available deconvolution software (Ion Signature Software from Ion Signature Technology, North Smithfield, RI, USA). The authors concluded that 101 unique mass spectra that belonged to compounds from a mixture of essential oils used in the production of gin (Section 3.4.2) (whose resultant ion fingerprints under GC × GC separation produced invariant signals in at least four consecutive scans across the peak) were identified. The identical fingerprints were found in the initial test mixture and a modified mixture where one of the 10 botanical and citrus oils was exchanged with nutmeg oil. In addition to the identification of the constituents of the remaining initial test mix, 17 of the 20 additional components in nutmeg were identified in the model mixture. The peaks for the three common compounds increased in signal count as expected, following fortification of the sample. It was concluded that because the acceptable scan to scan variance in the relative abundance could be set in the deconvolution method, it was easy to visually inspect the peak to determine whether the target compound had been correctly indentified. This made the total product characterization, shelf life studies, routine quality control and consumer flavor/aroma perception studies amenable to low level compound identification in the presence of large concentrations of coeluting matrix components. The deconvolution software allowed the optimization of spectral search matching conditions and hence the method proposed could lead to the identification of low concentration analytes usually difficult to identify without prior sample cleanup procedures.

An ever increasing number of analyses are now moving away from conventional GC analysis with 0.25 mm i.d. columns. This is due to the recent commercialization and hence availability of modern narrow i.d. columns (0.10 to 0.18 mm) which contain thinner films of stationary phase (typically 0.10–0.18 μm) and 10 to 20 m in length. This state of the art GC technique known as fast GC, can provide typically a three- to 10-fold reduction in analysis time, whilst still providing acceptable resolution of target analytes during an analysis. This is achieved by manipulation of the crucial analytical variables, namely column length, column i.d. and film thickness, increased linear velocity of carrier gas, oven temperature and oven ramp rate during analysis. Although historically helium, hydrogen and nitrogen have been used as typical GC carrier gases, hydrogen is considered the optimum choice for fast GC due to its high diffusivity and high optimal linear velocity (Supelco, 2008). One disadvantage of modern narrow i.d. columns is limited sample capacity when compared to conventional 0.25 mm i.d. columns (as less sample can be introduced onto the column for analysis), hence high injection split ratios are adopted to yield narrow, sharp and symetrical peak shapes, which in turn reduces or even eliminates the loss of analytical sensitivity. Many major GC instrument manufacturers now offer instruments and columns that are designed with fast GC in mind, as well as offering free method translation software (or consultancy) that will allow users to translate conventional methods into fast methods very easily, as long as the column phase ratio is maintained (for example, if a conventional method uses a 25 m × 0.25 mm i.d. × 0.25 μm column then a translated fast GC method should adopt the use of a 10 m × 0.10 mm i.d. × 0.10 μm column or 20 m × 0.18 mm i.d. × 0.18 μm to possess the theoretical equivalent resolving power and the order of eluting taget analytes).

Mac Namara *et al.* (2005) reported a fast GC analysis of major volatile compounds in distilled spirits. Initial conditions (split ratio, gas velocity, initial oven temperature and oven ramp rate) were determined from method translation of a similar method using a standard 0.25 mm i.d. column with identical stationary phase. These parameters were then investigated in an experimental design comprising a series of experiments in which the responses were the resolution of two critical peak pairs, the analysis time and the limit of quantitation (LOQ) of eight major compounds. Following chemometric evaluation of the obtained data, a validated model was constructed to allow the prediction of optimum chromatographic conditions. It

was concluded that the use of modern GC hardware made the fast method an ideal candidate for routine analysis.

A recent study focused on the application of 0.18 mm i.d. capillary columns for brewing analysis (Horák *et al.*, 2009). The robustness of the state of the art faster GC, without compromising resolution, was demonstrated with the analysis of beer flavor compounds, and sample run times were reported to be reduced by 60%.

Oven

Column temperature is an important variable that must be controlled very accurately over a wide range of temperatures during a GC analysis. Conventionally, the chromatographic column is housed in an oven which can be either isothermally operated (one in which the oven is maintained at a constant temperature) to elute volatile components of a sample, or by temperature programming (whereby the column temperature is increased either continuously or in steps as the separation proceeds) for complex samples consisting of analytes with a broad boiling range. The optimum column temperature of any method depends upon the boiling point of the sample and the degree of separation required. Roughly, a temperature equal to or slightly above the average boiling point of a sample is generally considered to yield chromatographic results within a reasonable elution time.

With the modern popularity of fast GC and potential decrease of analysis times, the oven temperature ramp rate is also being increased faster than ever previously encountered in conventional analysis. In some cases, a conventional GC oven cannot provide the desired ramp rate for a fast method, therefore new oven inserts have appeared commercially. This type of system enables direct resistive heating of the capillary column using ceramic insulated heating wire with high precision temperature control across the entire length of the chromatographic column, and hence, rapid temperature ramping and cooling rates can be achieved with ease. A recent example of the use of resistive heating gas chromatography (RH-GC) has been reported for the rapid screening of organophosphorus pesticides in fruits (including grape) and vegetables (Patel *et al.*, 2004).

Other devices capitalize on fast oven cooling following completion of an analysis by greatly increasing the mass flow of air through the oven during cool down, resulting in a reduction of the GC cycle time (the time taken to cool the oven from final upper operating temperature to starting temperature for the next analysis to begin – often 15 to 20 min). This is an interesting approach, since it does not interfere with the analysts existing GC methods, only the overall cycle time, hence increasing sample throughput without any change in existing method variables. A commercial version of this approach is available from Anatune (Cambridge, UK), called the GC CoolR+.

Detectors

A number of GC detectors are available commercially; the reason for such a wide and varied choice is because there is currently not one single detector that can satisfy the demands for all GC analyses: Table 4.3.2 details the most common GC detectors. Crucial characteristics and requirements such as dead volume, support gas requirements, detector temperature, linear range, sensitivity and selectivity have been discussed in depth by Rood (1999) and can be found in the literature and websites of the major GC manufacturers. Many extensive examples of alcoholic beverage research using a wide range of GC detectors can be found under the extraction and focusing methods in sample preparation section (Chapter 4.2) of this book.

An ever increasing number of modern GC analyses use only a mass spectrometer as detector for a wide array of analytes. This is because MS detectors can be used as either a universal detector (in scan mode) or a specific detector (in SIM mode). Most modern MS detectors have the ability to be used in dual scan/SIM modes to collect the maximum amount of useful data during each analysis.

Table 4.3.2 *Common detectors for GC analysis*

Detector	Selectivity	Minimal Detectable Level*	Linear Dynamic Range*
Flame Ionization (FID)	Most organic compounds	<1.8 pg C/s (for tridecane)	10^7 (± 10%)
Mass Spectrometer (MS)	Universal (Scan Mode) Specific (SIM Mode)	0.1–1 ng (Full Scan)† 0.1–10 pg (Selective Ion Monitoring)†	10^4–10^5†
Thermal Conductivity (TCD)	Universal	400 pg/mL (for tridecane with He carrier)	10^5 (± 5%)
Flame Photometric (FPD)	Sulfur, Phosphorus	<60 fg P/s, <3.6 pg S/s (with methylparathion)	10^3 (S) 10^4 (P) (with methylparathion)
Pulsed Flame Photometric (PFPD)	Sulfur, Phosphorus	<100 fg P/s, <1 pg S/s‡	Quadratic in response Linear to *ca.* 10^3 Gives 10^5 signal response‡
Sulfur Chemiluminescence (SCD)	Sulfur	<0.5 pg S/s (dimethyl sulfide in toluene)	10^4
Electron Capture (ECD)	Halides, nitrates, nitriles, peroxides, anhydrides, organometallics	<6 fg/ml (for lindane)	5×10^4 (with lindane)
Nitrogen Phosphorus (NPD)	Nitrogen, Phosphorus	<0.4 pg N/s <0.06–0.2 pg P/s	$>10^5$
Nitrogen Chemiluminescence (NCD)	Nitrogen	<3 pg N/s	$>10^4$
Atomic Emission (AED)	Carbon, Sulfur, Nitrogen, Hydrogen, Chlorine, Phosphorus, Oxygen	1 pg C/s (*t*-Butyl disulfide)§ 2 pg S/s (*t*-Butyl disulfide)§ 30 pg N/s (Nitrobenzene)§ 4 pg H/s (*t*-Butyl disulfide)§ 30 pg Cl/s (1,2,4-Trichlorobenzene)§ 2 pg P/s (Triethyl phosphate)§ 150 pg O/s (Nitrobenzene)§	10^4§ 10^4§ 2×10^4§ 5×10^3§ 10^4§ 10^3§ 5×10^3§
Olfactometric (GC-O)	Aroma/flavor compounds	User specific	User specific

Plutowska and Wardencki (2008) recently reported an extensive review of the application of gas chromatography-olfactometry (GC-O) in the analysis and quality assessment of alcoholic beverages. They concluded that despite the fact that odor detectors have been in use for over 40 years, literature indicates that in recent years they have been used more frequently, finding numerous applications in the analysis of food and beverages (including alcoholic beverages). There is, however, still need for improvement of GC-O techniques and the investigations on using them for quantitative analysis of odor compounds. Further studies are also required because past studies on the optimization of working parameters and on the quality and reliability of the obtained results (which is very important considering feasibility of implementing the GC-O technique to industrial practice) have not been well accepted.

4.3.3 Liquid Chromatography

High performance liquid chromatography (HPLC), in its many modes, is probably still the most widely used chromatographic method for the analysis of alcoholic beverages, especially for the determination of less volatile, more polar constituents. A simplified scheme showing a typical HPLC system is shown in Figure 4.3.4.

The mode of HPLC used depends upon the stationary phase in the column (Figure 4.3.4), which in turn depends upon the nature of the analytes (ionic, polar, nonpolar, chiral, polymeric) and influences the mobile phase used. Reversed phase (RP) is the most popular mode, but normal phase (NP), ion exchange (ion chromatography – IC), ion exclusion and size exclusion modes (often known as gel permeation chromatography, GPC or gel filtration chromatography, GFC – for polymers) are also used. Nowadays, many kinds of detectors are available (Figure 4.3.4), but those most widely used in the analysis of alcoholic beverages are mass selective detectors (mass spectrometers) and UV-visible detectors. The former set up (HPLC linked to a mass spectrometer, MS) is usually known as LC-MS. In discussing application of LC-MS to alcoholic beverage analysis, the emphasis in this section will be on the chromatographic aspects; mass spectrometric aspects

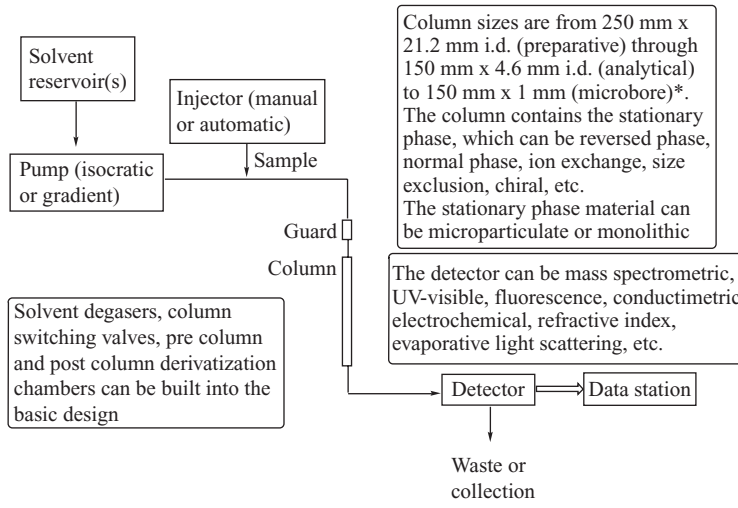

Figure 4.3.4 *Scheme showing arrangement of modules for HPLC analysis. *Nanobore columns are also used, for LC-MS*

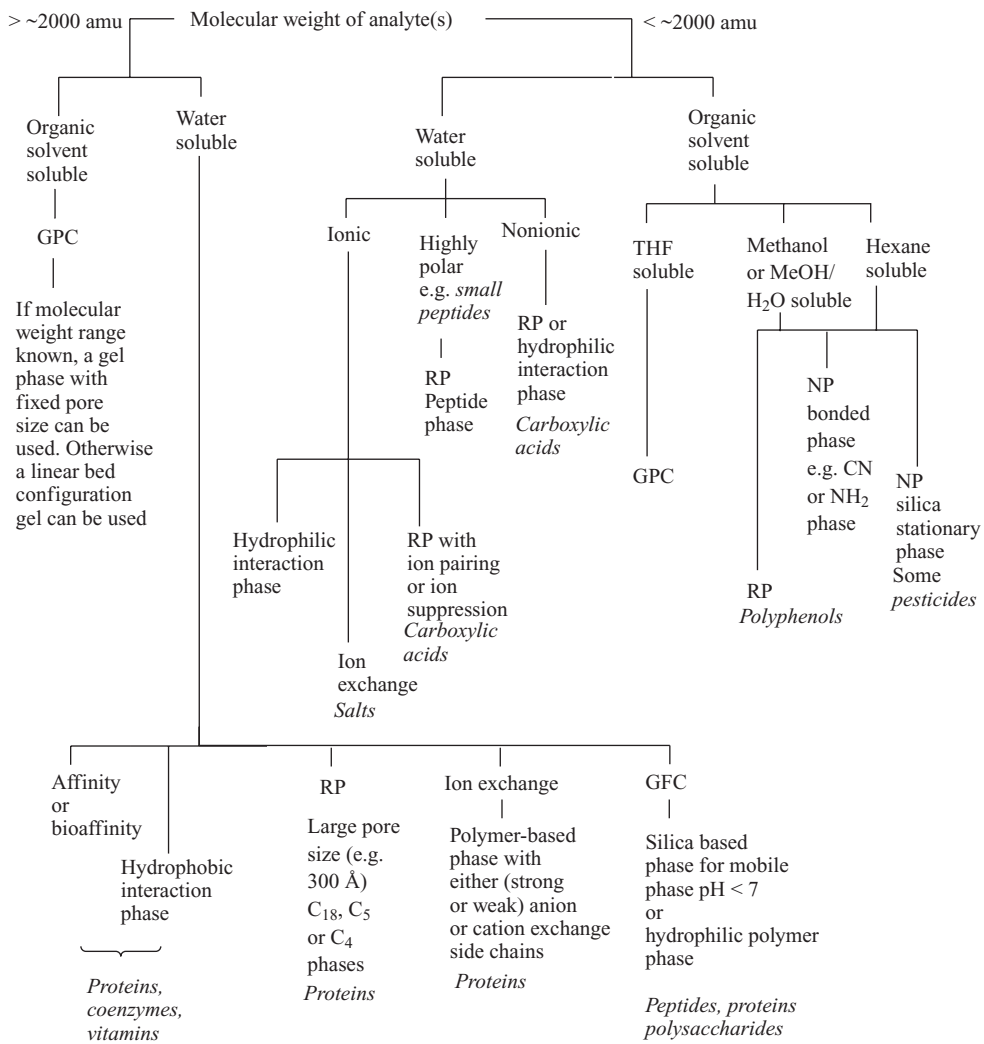

Figure 4.3.5 *Stationary phase selection tree*

(e.g. mode of ionization, fragmentation patterns, etc.) are discussed more fully in Section 4.4.5. In many modern HPLC systems, postcolumn eluent splitting may be used so that analytes can be monitored by two detectors simultaneously, usually a mass spectrometer and a diode array UV-visible detector (LC-MS-DAD).

Deciding on a suitable mode of HPLC for analysis of a particular type of component or range of components in a beverage can be carried out using an HPLC stationary phase tree, as shown in Figure 4.3.5. Once the stationary phase has been decided, initial experimental conditions can be determined by searching the literature and/or by use of software such as ACD Autochrom (a computer assisted method development that combines instrument control and rational method development for Agilent and Waters LC systems). Types of stationary phases that are frequently used to analyze different kinds of compounds in different beverages are summarized in Table 4.3.3. It should be kept in mind that due to the complexity of the

analytical matrix (alcoholic beverages contain large numbers of compounds of many different types) sample pretreatment ('clean up'), such as column chromatography or solid phase extraction (SPE) (Section 4.2.4) or a combination of these, will often need to be carried out.

Reversed Phase HPLC

RP chromatography involves interaction between a nonpolar stationary phase and nonpolar sections of solute molecules in the relatively polar mobile phase. The mechanism of RP chromatography involves a partition effect, which is related to the relative solubilities of the solute molecules in the two phases. In general, the greater the nonpolar character of a solute, the greater is the retention (the higher the values of t_R and k') for

a given mobile phase. Reversed phase is still the most widely used mode of HPLC; it probably accounts for ~70% of all HPLC analyses.

Reversed phases fall into two major categories:

- Alkyl bonded silica gels (including polar bonded phases, which sometimes can be used in normal phase). This includes spherical particulate and monolithic materials.
- Cross linked synthetic polymers. This also includes spherical particulate and monolithic materials.

The particulate materials are usually composed of a very uniform distribution of spheres of diameters from lower than 3 μm to10 μm (Meyer, 1998). Within these particles are many channels or pores (mesopores) of diameters ranging from 80 Å to 300 Å (depending on how the silica is made), giving a large surface area. Typically, alkyl bonded particulate phases have surface areas of 150–500 m^2/g. Loading of bonded phase can be calculated as percentage carbon load or bonded phase coverage ($\mu mol/m^2$). Octadecylsilyl phases, probably the most popular RPHPLC phases, have carbon loads from ~5% (Whatman Partisil) through ~11% (Thermo Fisher Hypersil) to 20% (Nacali Tesque Cosmosil), with bonded phase coverages from 0.63 (Whatman Partisil), through 3.47 (Agilent Zorbax) to 5.50 $\mu mol/m^2$ (Phenomenex Jupiter).

Particulate RP stationary phases are usually spherical (Whatman Partisil is an exception, having irregular particles), with narrow size distribution and are available in 3, 5 and 10 μm sizes. A stationary phase made up of smaller particles (lower than 2 μm) is more efficient than a similar phase made of larger particles, but causes high back pressure due to greater restriction of flow of the mobile phase through the particles. Recently, C_8, C_{18} and similar phases based on type B silica 2.7 μm fused core (superficially porous) particles of extremely narrow size distribution have been shown to be highly efficient, with reduced theoretical plates of 1.5 or lower for small molecules (DeStefano *et al.*, 2008). The fused core and HALO® columns of Advanced Materials Technology also exhibited back pressures of only one half or one third of those of composed of 1.9–1.7 μm particles. The fused core particles consist of 1.7 μm solid silica cores with a spherical coating of 0.5 μm thick shells containing 9 nm pores. Although there are no reports yet (2010) of the use of these columns in alcoholic beverages, a remarkable separation of eight pesticides in less than 0.6 min at a flow rate of 4.0 ml/min (pressure 230 bar) at 60 °C was demonstrated.

Alkyl bonded silica gels, the most widely used of all RP materials, can be subdivided into a number of variants, as shown in Figure 4.3.6. Most of the variants are designed to overcome a number operational problems associated with RPHPLC, as outlined below:

- End capping, to prevent polar interactions between residual silanol groups and analytes
- Smothering of residual silanol groups (by steric hindrance, or cross linking) to prevent polar interactions, as above
- Polar end capping or polar embedded alkyl bonding (Rieger and Riering, 2000), to prevent collapse of alkyl chains in the presence of a largely aqueous phase and to stabilize the phase toward low and high pH
- Polyfunctionization, to prevent decomposition of the phase in mobile phases of low or high pH
- Low loading of C_{18} functionality, with no end capping to give the RP phase extended polarity due to residual silanol groups (Chappell, 2002).

Polar bonded phases usually consist of silanol groups linked to short alkyl chains that have a terminal polar group, such as CN, NH_2 or $CH(OH)CH_2OH$. These phases can be used in either reversed phase mode (with polar solvent) or normal phase mode (with nonpolar solvent).

Other categories of RP stationary phases include graphitized carbon (Shandon Hypercarb) (Ross and Majors, 2000), zirconia based (ZirChrom Separations ZirChrom-EZ), perfluorinated alkyl bonded phases (Przybyciel, 2003) and type C silica (MicroSolv) (Majors, 2003). Porous graphitic carbon phases perform in

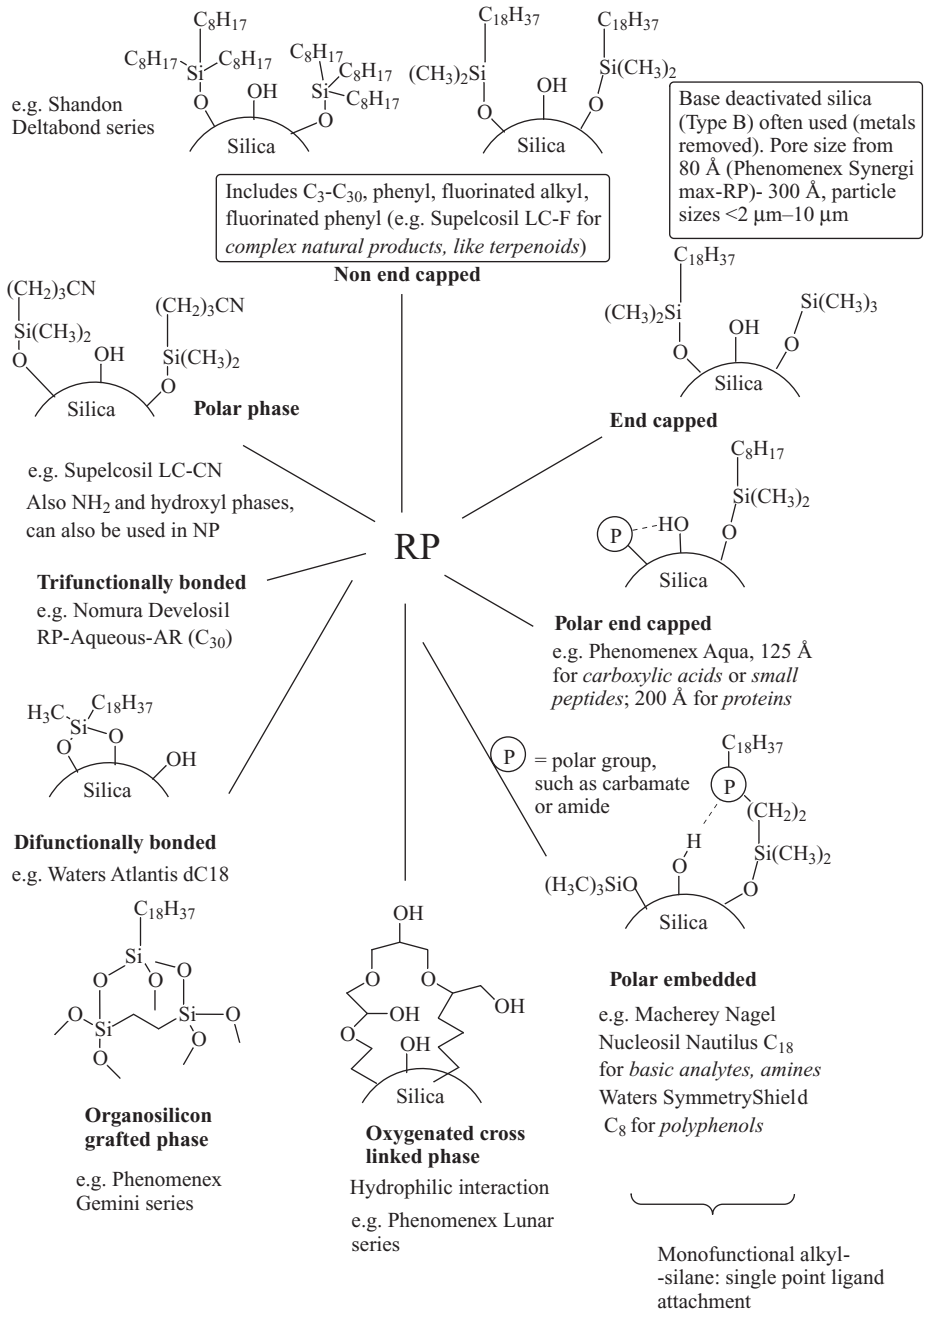

Figure 4.3.6 *Alkyl bonded and related RP stationary phases*

reversed phase mode, but have different selectivities to silica C_{18} phases, in particular they show increased retention of nonpolar analytes and increased selectivity toward structurally related compounds. Zirconia-based RP phases exhibit increased stability at both low and high pH and also at high temperatures.

Many detectors are available for the detection of components separated on an HPLC stationary phase as they emerge from the column (Figure 4.3.5). The most commonly used are UV-visible (including the diode array version, DAD) and mass spectrometric detectors (LC-MS is treated separately, below). Also widely used are fluorometric, refractive index, evaporative light scattering (ELS), electrochemical (amperometric and coulometric), conductometric and chiroptical (polarimetry or circular dichroism) detectors. Less commonly, HPLC systems have also included infrared or nuclear magnetic resonance detectors.

Individual organic acids, important constituents of musts and alcoholic beverages, are often determined by RPHPLC – see Mato *et al.* (2005) for a review of methods for the analysis of grape and wine acids, which includes HPLC. Most methods use UV detection, but photochemically induced luminescence (Peréz-Ruíz *et al.*, 2004) and electrochemical detection (Casella and Gatta, 2002) have also been used. Use of special robust stationary phases, such as radially compressed phases (Billingsley *et al.*, 1996) and acid resistant phases (e.g. Phenomenex Aqua) with largely or wholly aqueous acidic solvents can give good resolution and can be used to monitor malolactic fermentation (Section 2.3.10) (Buglass and Lee, 2003).

The preservative additives benzoic acid and sorbic acid can be determined in alcoholic beverages by RPHPLC with UV-visible detection and often using isocratic mobile phase. Analysis can be simplified by use of a sample pretreatment or clean up procedure, such as reversed phase SPE (Section 4.2.4), as used in the analysis of benzoate and sorbate in Thai rice wines and rice wine distillates (Techakriengkrai and Surakarnkul, 2007). Here, an isocratic method (0.01 M aqueous ammonium acetate buffer:methanol, 60:40) was used with a Waters Spherisorb S100DS2, 250 mm × 4.6 mm (i.d.) stationary phase and detection at 235 nm. Reversed phase SPE (C_{18}) was used for sample pretreatment. Alternatively, acidic preservatives in alcoholic beverages can be determined as their anions (benzoate, sorbate and sulfite) by ion chromatography with conductometric detection (De Borba and Rohrer, 2004).

Sugars in beverages are usually determined by ion exchange or ion exclusion chromatography using cross linked polymer stationary phases (see ion chromatography, below), but the fermentable sugars of beer wort (fructose, glucose, maltose, maltotriose and sucrose) were recently analyzed using a Supelcosil LC-NH_2 phase (an amino bonded silica phase) and acetonitrile:water (70:30) as the mobile phase (Navarro *et al.*, 2007). All five sugars were separated in less than 10 min chromatography run time.

Although terpenoids, norisoprenoids and other flavor compounds in alcoholic beverages are usually determined by GC (often GC-MS) (Section 4.3.2), β-damascenone has been determined in beers, wine and distilled spirits by RPHPLC with UV detection (Carneiro *et al.*, 2006), although a steam distillation/solid phase extraction (Section 4.2.4) preconcentration step was required before HPLC analysis. Carneiro *et al.* (2006) showed that forced ageing of beer, but not wine and spirits, resulted in increased β-damascenone levels (Section 2.6.12). Another flavor compound, rotundone (a sesquiterpene) in Shiraz (Syrah) grapes and wine was determined using normal phase HPLC (Wood *et al.*, 2008). Rotundone is a major contributor to the peppery flavor of certain wine grapes (especially Shiraz) grown in relatively cool regions. Peppery fractions from column chromatography were analyzed on a 5 m silica column (250 mm × 2 mm i.d.) using gradient elution (solvent A was hexane:ethyl acetate (98:2); solvent B was ethyl acetate). Linalool, β-caryophyllene and caryophyllene oxide were used as standard markers and the peppery fractions were combined and studied using GC-MS and GC-MS-O to confirm the presence of (–)-rotundone.

Reversed phase HPLC coupled with liquid–liquid extraction has been suggested as a more specific way than the standard solvent extraction/UV-visible spectrophotometric method (Section 4.4.3) for the determination the *iso*-α-acid bittering agents of hopped beer (Jaskula *et al.*, 2007). The various spectrophotometric methods, although inexpensive and rapid, are rather unspecific, with components other than bittering compounds being measured as well. Although other HPLC methods had been reported before (see references in Jaskula *et al.*,

2007), none were able to resolve all the bittering components. Here, the bittering agents were selectively and quantitatively extracted from beer using *iso*-octane, followed by removal of the solvent and redissolving the residue in ethanol/H_3PO_4 (99.75/0.25 v:v). Analysis was performed on a C_{18} column using isocratic elution at ambient temperature using 48%, eluent A and 52% eleuent B, where eluent A was water adjusted to pH 2.80 with H_3PO_4 and eluent B was acetonitrile. Analysis time was 50 min with a flow rate of 1.8 ml/min. The detector was a diode array detector set at 270 nm (for *iso*-α-acids) and 314 nm (for α-acids). Mean recoveries were very good, ranging from 92.9% to 99.2%, and the bittering agent profile of the extract was identical to profile of the spiked unhopped wort or beer.

The biggest application of RPHPLC to the study of fruit, juices and alcoholic beverages is probably the determination of phenolic compounds, including anthocyanins, flavonoid phenols and their glycosides. Ultraviolet detection is common, with analyte identities generally being obtained by comparison with authentic standards or by combination with LC-MS data. However, the latter technique is the most widely used for the determination of phenols in general, where both quantification from peak areas and identification from mass spectra (often using tandem mass spectrometric techniques) can be achieved, even for more complex polymeric phenols.

Reversed phase HPLC with UV-visible detection has been applied to the study of phenolic compounds in the skins and juice of fruits that can be used to make alcoholic beverages, as well as to cider and wine per se. This technique (aided by NMR and ESI mass spectrometry) was used to identify new anthocyanin glycosides – such as cyanidin 3-*O*-(6″-*O*-arabinosylglucoside) – in the skins of elderberries and other fruits (Jordheim *et al.*, 2007). The changes in phenolic profile of highbush blueberry fruits during ripening were monitored by HPLC-DAD using a Wako Fluofix 120E phase and gradient elution (water:acetonitrile:acetic acid (94.5:5:0.5) (A) and acetonitrile (B)) (Castrejón *et al.*, 2008). Similarly, the anthocyanin content (mainly cyanidin, pelagonidin and peonidin glycosides), flavonol content and nonflavonoid phenol content of blue honeysuckle (*Lonicera Caerulea* L.) fruits (which are similar to bilberries and can be used to make fruit wines and liqueurs) were determined by gradient elution RPHPLC with UV detection (aided by ESI-MS) (Chaovanalikit *et al.*, 2004).

Sixteen flavonoid phenols have been identified by RPHPLC in the skins of the white grape variety Albarín Blanco (Asturias, Spain), where very unusually the most abundant phenols were quercetin dihydroflavonols (Section 5.8.6), thus allowing easy identification of this variety and a useful check of authenticity (Masa and Vilanova, 2008). Also, flavan-3-ols, hydroxycinnamic acids and dihydrochalcones (Section 5.8.6) have been quantified in the juice of crushed Spanish cider apples (Suárez *et al.*, 1998) and the important French cider apple variety Kermerrien using RPHPLC-DAD.

Likewise, the flavonols in Port wine grape varieties (Tinta Amarela, Tinta Barroca, Tinta Cão, Tinta Roriz, Touriga Francesca, Touriga Nacional and Rufete) were determined using a minibore (200 mm × 2.1 mm i.d.) C_{18} RP column and gradient elusion (5% aqueous formic acid (A); methanol (B) (Andrade *et al.*, 2001). Anthocyanins were removed by SPE (C_{18} end capped columns) after the lyophilized grape samples were extracted with methanol. The methanol was then removed after filtration and the residue was redissolved in 0.1 M HCl and applied to the conditioned SPE column. Kaempferol 3-glucoside and isorhamnetin 3-glucoside were significant components of all the varieties, apart from Rufete.

Usually, gradient elution (as in the above examples) is used to analyze fruit skin or fruit extracts, because of the wide range of polarities of the extracted components. However, division of the extraction of *V. vinifera* skins using supercritical CO_2 (with ethanol modifier) (Section 4.2.2) into two fractions allowed the isocratic determination of flavan-3-ols in one fraction and quercetin, rutin and *trans*-resveratrol in the other fraction, using different mobile phases (Chafer *et al.*, 2005).

Reversed phase HPLC with UV detection (often DAD) is also useful in the determination of phenolic and other compounds in wine and other beverages, often the only sample pretreatment being dilution, although solid phase extraction (Section 4.2.4) can be used give analytes in different fractions.

The phenolic profiles of 92 Asturian ciders from two consecutive vintages revealed hydroxycinnamic acids, dihydrochalcones and procyanidins to be the most abundant phenolic compounds, with hydrocaffeic acid, phloridzin, procyanidin B5 and tyrosol being the major of the known components (Rodríguez *et al.*, 2006).

It has long been known that red wines have intrinsically higher phenolic contents than white wines, irrespective of the mode of aging. RPHPLC-DAD analysis of Greek red and white wines from a range of locations and *V. vinifera* varieties supported this generality, with (+)-catechin being the most abundant polyphenol. Retsina white wines (with added pine resin) (Section 2.12.3) had higher levels of phenolic compounds than standard white wines, the extra phenolic content originating from the resin (Proestos *et al.*, 2005). Length of aging in wooden casks, with possible involvement of *Brettanomyces* spp., as well as wine color, can be correlated with concentrations of ethylphenols, which are generally regarded as off flavors if present at levels above their odor threshold values. RPHPLC with fluorescence detection (225/320 nm) showed that 4-ethylphenol and 4-ethylguaiacol were more prevalent in red wines than white wines of the Wurttemberg region, especially if the wine had experienced long storage in wooden casks (Nikfardjam *et al.*, 2009).

The major phenolic compounds in southern Portuguese wines from the *V. vinifera* variety Trincadeira (red) were gallic acid, (+)-catechin, syringic acid, ferulic acid, protocatechuic acid, *trans*-resveratrol and caffeic acid, whereas for the wine of Síria (white), only catechin was abundant (almost as much as in the red wine), with small levels of gallic and protocatechuic acids, and only trace levels of the others (Nave *et al.*, 2007).

The effects of one year's storage on the phenolic contents of wines made from the *V. vinifera* varieties Colombard and Zalema in southwestern Spain have been studied by Hernanz *et al.* (2009). Although the acidity of Colombard wine was higher than that of Zalema wine, the one year's aging had similar effects on the phenolic contents of both types of wine, with concentrations of some (e.g. gallic acid, catechin, caftaric acid and fertaric acid) diminishing, whilst levels of others (e.g. (–)-epicatechin, tyrosol, rutin, *p*-coutaric acid, caffeic acid and ferulic acid) increasing or remaining unchanged.

The free and conjugated flavonol (myricetin and quercetin) content of 65 red wines from many geographical areas were determined by RPHPLC using gradient elution with UV detection (McDonald *et al.*, 1998). The detection limit was *ca.* 0.8 mg/l. Concentrations of total flavonols ranged from 4.6 to 41.6 mg/l, with Chilean wines generally having the highest values. This was attributed to either better exposure of ripening berries to sunlight or to harvesting very ripe grapes, but altitude or other geographic/climatic factors may be important.

Fortified white wines, such as Sherry and Montilla-Moriles are protected from oxidation and browning when undergoing biological aging in the presence of flor (Section 2.10.3). Once removed from the flor, the aging process can be rapid and flor wines, such as fino Sherries are usually best consumed within one year of bottling. In this context, RPHPLC was used to study the effect of various prebottling fining agents on the phenolic content of flor Montilla-Moriles wines (Baron *et al.*, 2000). It was shown that several fining agents; activated charcoal, PVPP and Ridulxhigh, could control browning by removing flavan-3-ols and their dimers from the wine.

On the other hand, some fortified wines, such as Banyuls (Section 2.10.9), Madeira (Section 2.10.5), tawny Ports (Section 2.10.7) are deliberately aged in an oxidative manner. RPHPLC-DAD has been applied to study the phenolic content of a number of these wines (Ho *et al.*, 1999) and it was found that the total phenolic and furan content were greater in the oak aged wines. The chromatograms show clearly that older wines of the same type (e.g. tawny Port) had a higher concentration of total phenols and all the wines studied had significant levels of furans, considered to be the products of nonenzymic browning and the Maillard reaction (Section 2.6.2).

The use of synthetic food colors is often controversial, because different countries have their own regulations regarding permitted food colorants, and falsification of red or white wine or other beverage color by the use of such colorants, although rare, is not unknown. Reversed phase HPLC is very well suited to the identification of such colorants in a complex matrix such as that of wine, vermouth or liqueur. Indeed, Virtanen *et al.* (1999) noted that RPHPLC gave more accurate identification than UV-visible spectroscopy of a number of synthetic

dyes (amaranth, azo ruby, erythrosine, quinoline yellow, ponceau 4R, sunset yellow and tartrazine), as well as natural carmine in wines. In an earlier report, several artificial colorants were separated and quantified by RPHPLC and azorubin, reported to be the main red wine adulterant, could be detected at the 0.8 mg/l level (Flak *et al.*, 1998). More recently, Yoshioka and Ichihashi (2008) have developed an HPLC-DAD method that is able to identify 40 artificial food colorants in beverages in less than 20 min chromatography run time.

Reversed phase HPLC can be used in the analysis of a number of nonphenolic aromatic substances in alcoholic drinks. Coumarin is widely distributed in the plant kingdom and many alcoholic beverages (some liqueurs, Mai Wein, vermouth and some flavored vodkas) are flavored with plant materials that contain coumarin, particularly cinnamon (Section 5.11.2). This substance, once believed to be genotoxic, is presently listed as not being classifiable as a human carcinogen by the International Agency for Research on Cancer (IARC), although there are reports on its hepatotoxicity (Section 5.11.2). With a maximum allowed concentration of 10 mg/kg for some alcoholic beverages in the EU, it is necessary to monitor the coumarin content of beverages that are likely to contain it. Numerous HPLC methods are quoted by Sproll *et al.* (2008), who have developed a fast gradient elution RPHPLC method, with UV detection at 279.8 nm. A Phenomenex Synergi polar-RP column (silica functionalized with $-(CH_2)_3OPh$ and containing polar end capping) was used, as it gives good aromatic selectivity amongst analytes when a methanol containing mobile phase is used.

Folates, such as tetrahydrofolate (THF) and 5-methylene-tetrahydrofolate 5MTHF) are cofactors in the biosynthesis of certain amino acids, but their oxidized form, folates cannot be synthesized by mammals and hence must be obtained from the diet. Cereals are known to be a good source of folic acid. Reversed phase HPLC with fluorescence detection has been applied to the determination of various folates, including folic acid (FA), THF, 5MTHF and others in alcoholic beverages, mostly beers (Owens *et al.*, 2007). The quantity of each folate was calculated in the free acid form using external standard calibration curves. Folates absorbed at 290 nm and emitted at 360 nm. Samples were subjected to a clean up with an SAX (strong acid ion exchange) SPE treatment before analysis. The folate content of beers ranged from 2.2 to 24.2 μg per bottle (355 ml), giving up to 6.1% of the recommended daily allowance.

In HPLC, the universal detectors are mass spectrometric, refractive index and evaporative light scattering; the remaining detectors require the presence of specific groups in the analytes, such as absorption chromophores for UV-visible detection, fluorescent chromophores for fluorescence detection, ionic sites for conductometric detection, chiral groups for polarimetric or circular dichroism detection and oxidizable groups for electrochemical detection. If these groups are not present, then they can be introduced into many specific analyte molecules by the process of derivatization.

Derivatization

Derivatization of analytes is less common nowadays in HPLC than in GC methods. Nevertheless, there are well defined cases where derivatization can help with HPLC analysis. The introduction of detectable groups into analyte molecules can significantly boost detection sensitivity. Groups introduced via derivatization include chromophores (for enhanced UV detection), fluorophores (for fluorescence detection, which is often ultra sensitive) and electrochemically active groups (for electrochemical detection).

The two major types of derivatization processes depend on the timing of the derivatization process, as described below:

- *Precolumn (or exceptionally, on column) derivatization*. Here the previously derivatized analytes are separated as such. Advantages of precolumn derivatization include:
  - Choice: a wide range of derivatization reactions can be used, including slow or high temperature reactions
  - Sample clean up prior to injection can be used to remove by-products or unreacted derivatization reagent, for example
  - Choice of mobile phase is not limited by the derivatization reaction.

- A big disadvantage of the method is that it becomes labor intensive if a large number of samples need to be derivatized; automation is really required here.
- *Postcolumn derivatization*. The analytes are separated normally and then derivatized 'on line' before they reach the detector. Advantages of postcolumn derivatization include:
  - Routine use for the analysis of large numbers of samples; the method lends itself best to automation
  - The separation step is independent of the derivatization reaction; the analytes are separated in their original form.

  Disadvantages of the method include possible long set up times, possible detection interference from unreacted reagent and the necessary compatibility of the derivatization reaction with the mobile phase. Additionally, cost may be an important factor since this method can use large quantities of expensive reagent.

Examples of pre- and postcolumn derivatization schemes and reagents are shown in Tables 4.3.4 and Table 4.3.5, respectively.

Table 4.3.4 *Examples of precolumn derivatization. 3,5-Dinitrobenzoyl chloride can be used to derivatize alcohols; phenacyl halides and 4-Bromomethyl-7-methoxycoumarin can be used to derivatize carboxylic acids*

Analyte	Reagent	Product	Detection enhancement
Amino acids $RNH(CHR')CO_2H$	6-Aminoquinolyl-*N*-hydroxy-succinimidyl carbamate (AQC) 		Fluorescence excitation at 250 nm, emission at 395 nm
Amines, RNH_2, etc.	 1-Fluoro-2,4-dinitrobenzene (Sanger's reagent)		UV
Amines and amino acids	 Dansyl chloride		UV/fluorescence UV at 254 nm; fluorescence excitation at 320 nm, emission at 523 nm
Secondary amines, R_2NH	 'NBD chloride'		Fluorescence

Table 4.3.5 *Examples of postcolumn derivatization*

Analyte	Reagent	Product	Detection enhancement
Amines and amino acids	 Ninhydrin	 'Ruhemann's purple'	UV
Amines and amino acids	 *o*-Phthalaldehyde + $CH_2(SH)CH_2OH$		Fluorescence Excitation at 340 nm; emission at 425-450 nm
Carbohydrates	Ce(IV)	C(III)	Fluorescence

The determination of amino acids and biogenic amines (Section 5.11.3) in alcoholic beverages is often carried out by the use of RPHPLC, with detection of the derivatized analytes by UV spectrophotometry, or more often by the more sensitive fluorometry (Önal, 2007). The most popular derivatization agents are dabsyl chloride, dansyl chloride and *o*-phthalaldehyde, but others, such as naphthaquinone-4-sulfonate and 6-aminoquinolyl-*N*-hydroxy-succinimidyl carbamate (AQC) are sometimes used. In most cases, precolumn derivatization is used, with chromatographic separation of the derivatized analytes being carried out by gradient elution. Interest in the biogenic amine content of alcoholic beverages arises largely from concern over their cause of allergenic reactions in sensitive individuals (Section 5.11.3). Beers have generally higher levels of biogenic amines than wines (Gorinstein *et al.*, 1999; Loukou and Zotou, 2003).

The biogenic amine contents of wines of many grape varieties from several countries and also of Chinese rice wines have been determined by RPHPLC with derivatization (Romero *et al.*, 2000; Loukou and Zotou, 2003; Anli *et al.*, 2004; Landete *et al.*, 2005; Dugo *et al.*, 2006; Yongmei *et al.*, 2007; Hernández-Orte *et al.*, 2008; Huang *et al.*, 2009).

Biogenic amines were analyzed in Spanish wines as dabsyl derivatives (Romero *et al.*, 2000), or as *o*-phthalaldehyde derivatives (Landete *et al.*, 2005) or (along with amino acids) as AQC derivatives (Table 4.3.4) (Hernández-Orte *et al.*, 2008). In the second study, histamine and putrescine were found to vary most between different varietal wines of different regions. In the last study, the biogenic amine contents of Cabernet Sauvignonand Tempranillo wines were found to be greater in post malo-lactic fermentation samples, but MLF performed by bacterial cultures resulted in lower amine levels in the wine compared with native MLF samples.

Biogenic amine contents of a wide range of Greek wines (Loukou and Zotou, 2003) and Turkish wines (Anli *et al.*, 2004) as dansyl derivatives revealed rather higher levels of histamine and tyramine in red wines, with the Greek retsina wines generally having the lowest amine levels. The Greek wines were subjected to treatment with poly(vinylpyrrolidone) (PVP) to remove phenolic interferences before derivatization and then to focusing and clean up with SPE after derivatization. The amines generally associated with poor sanitary conditions, putrescine and cadaverine, were present at low concentrations in nearly all the samples.

The gradient elution regimes for some of the above analyses are rather complex (see Önal, 2007, for many examples), often involving an acidified or buffered aqueous solvent and an aqueous organic solvent. However,

a simple gradient elution program involving only acetonitrile and water components has been used to separate the dansyl derivatives of amines in experimental Sicilian wines from a wide range of *V. vinifera* verieties (Dugo *et al.*, 2006).

Precolumn derivatization with dansyl chloride was used to determine biogenic amines in Chinese rice wines (Section 2.7.1) using RPHLC with acetonitrile-water gradient elution and diode array UV detection (Yongmei *et al.*, 2007). The mean total level of biogenic amines in the samples was 107 mg/l (range: 39.30–241 mg/l. These levels are below the levels that are generally thought to cause direct adverse reactions for most consumers. The detection limits were 0.05 mg/l for cadaverine, histamine and spermidine, 0.1 mg/l for tyramine and 0.25 mg/l for spermine.

More recently, the fluorescence probe 2,6-dimethyl-4-quinolinecarboxylic acid *N*-hydroxysuccinimide ester was applied for the precolumn derivatization of biogenic amines in Chinese rice wines (Huang *et al.*, 2009). The derivatives were extracted from the medium using ultrasound assisted liquid–liquid microextraction and were analyzed by standard RPHPLC using methanol:water (60:40, v:v) as mobile phase and fluorescence detection at 326/412 nm. The calibration data of this method were linear in the range of 5–500 μg/ml (for octopamine and tyramine) and 0.025–2.5 μg/ml (for phenethylamine). The relative standard deviations were 2.4–3.2% (n = 6) and the limits of detection were in the range of 0.02–5 ng/ml, typically much lower than those of the above dansyl chloride UV detection method.

Homocysteine (HCy) is nonprotogenic amino acid, whose plasma levels are often used as a marker of oxidative stress from an imbalance of metabolism; for example, high plasma levels have been correlated with smoking, lack of exercise and excessive alcohol intake (Section 5.6.2). However, it is possible that a certain amount of plasma HCy could be obtained directly from the diet, although there are few reports of the HCy content of foodstuffs. Benkova *et al.* (2009) studied the HCy content of 36 Bulgarian wines, using RPHPLC with precolumn derivatization using *N*-(2-acridonyl)maleimide and fluorescence detection. The method was able to quantify down to 68 fmol of HCy and the levels in white wines (0.09–0.64 mg/l) were found to be generally lower than in red wines (0.10–1.37 mg/l).

Reversed phase HPLC has been performed on the dansyl derivatives of amino acids in Montilla-Moriles wines (or simulated wines) undergoing biological aging (Section 2.10.3) in an attempt to determine, amongst other things, which amino acids are best for yeast cell growth (Mauricio and Ortega, 1997; Valero *et al.*, 2003; Berlanga *et al.*, 2006). The main source of nitrogen for yeast growth was found to be L-proline, with L-leucine being released. Beers are rich in amino acids as demonstrated by a study of 35 beers from six different countries using RPHPLC with precolumn derivatization by AQC (Table 4.3.4) and a three solvent system gradient elution programme (Kabelová *et al.*, 2008).

A more specialized application of a gradient elution RPHPLC method is the determination of the dansyl derivative of hydroxyproline in beer (Chlup *et al.*, 2006). Hydroxyproline is a hydrolysis product of isinglass, which contains collagen proteins and is used to fine many beers, especially cask-conditioned ales (Section 2.6.9). This amino acid is not found in the proteins of brewing raw materials or yeast, so its presence in acid hydrolyzed beer is indicative of the presence of isinglass. This is important because isinglass is still (2008) under investigation regarding supposed allergenic properties. This method can detect amino acids at concentrations as low as $\sim 4 \times 10^{-13}$ mg/l.

The derivatization technique can be used in the analysis of a number of other substances in alcoholic beverages. Derivatization of ethyl carbamate (EC) (urethane) by 9-xanthydrol (Figure 4.3.7), followed by RPHPLC separation of fluorescent xanthylurethane on an amine (polar bonded phase) column allowed the estimation of EC in wines, fortified wines and spirits (Herbert *et al.*, 2002). Since EC is a carcinogen, its concentration in alcoholic beverages is constantly under surveillance (Section 5.11.5). The xanthylurethane derivative was excited at 233 nm and the emission was measured at 600 nm. The detection limit using this method was 4.2 μg/l, well below the maximum allowed limits (30–200 μg/l, depending on the beverage) set by the Canadian government (Section 5.11.5). More recently gradient elution HPLC with fluorescence

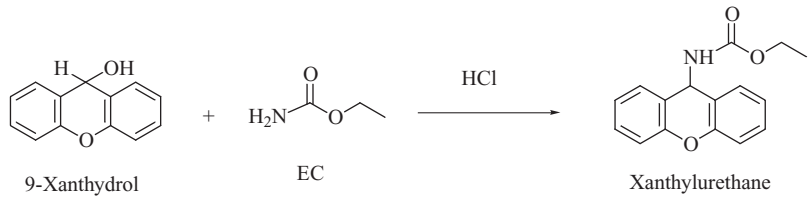

Figure 4.3.7 *Formation of xanthylurethane derivative for HPLC analysis of ethyl carbamate*

detection was used to determine EC, as its 9-xanthhydryl derivative, in cider spirits, with improved detection limit (1.64 μg/l) (Rodríguez Madrera and Suárez Valles, 2009).

Mycotoxin residues (Section 5.11.4) in fungus infected grains used for brewing in the production of beer, whisky and other spirits can be determined by RPHPLC using fluorescence detection and postcolumn derivatization for certain analytes (aflatoxins and fumonisins), whereas others (ochratoxin A and zearalenone) are already fluorescent and DON can be determined by UV (DAD) (Pickering, 2004). Photochemical derivatization was used for aflatoxins, and *o*-phthalaldehyde/thiofluor reagent was used to derivatize fumonisins. The fluorescent analytes could be detected at levels down to 0.01 ppb (for aflatoxin B2) to 9 ppb (μg/l) (for zearelenone).

Ochratoxin A, produced by many species of fungus (e.g. *Penicillium* and *Aspergillus* spp.), is a more serious contaminant of grape must and wines (Section 5.11.4) and needs to be monitored regularly so that levels in wines are below 2 μg/l and weekly intake (from all sources) is less than 100 ng per kilogram of bodyweight, as recommended by JECFA of FAO/WHO (Section 5.11.4). A solid phase microextraction technique (Section 4.2.4) using a PDMS/DVB fiber and interfaced with RPHPLC-fluorescence detection was able to quantify ochratoxin A in wine samples at levels down to a limit of quantification (LOQ) of 0.22 μg/l. The limit of detection was 0.07 μg/l, based on a signal to noise ration of 3:1. Furthermore, the method requires only isocratic conditions and the chromatography run time was under 15 minutes.

The Office International de la Vigne et du Vin (OIV) method for the analysis of ochratoxin A in beverages requires the passage of the pH adjusted, centrifuged and filtered sample (100 ml) through an immunoaffinity column, washing through with water, air drying the column and desorbing the ochratoxin A by passing methanol:acetic acid (98:2 v:v) (1.5 ml) through the column, evaporating to dryness and redissolving in themobile phase (2 ml) (Bellí *et al.*, 2004). Using this method, Bellí *et al.* (2004) were able to determine ochratoxin levels in 240 musts and wines (including Sherry, Malaga and vermouth). The detection limit for this method was 0.05 μg/l, based on a signal to noise ratio of 3:1. Aresta *et al.* (2006) used HPLC with fluorescence detection to determine ochratixin A concentrations in wine samples. Here SPME (Section 4.2.4) was used for sample clean up in place of the usual immunoaffinity column method. The limit of quantification at a signal to noise ratio of 10 was 0.22 ng/ml.

Sugars can be derivatized as their *p*-aminobenzoate esters and analyzed via RPHPLC. Such a method has been used to determine the sugar profiles of ciders, where, with the help of various chemometric techniques, the use of apple juice concentrate (AJC) (Section 2.8.6) can be detected (Blanco Gomis *et al.*, 2004). A C_8 column was chosen for these analyses, with gradient elution and detection at 307 nm. The variables chosen for principal component analysis were arabinose, fucose, D-galactouronic acid, D-glucuronic acid, rhamnose, ribose and xylose, because AJC tends to be richer in these sugars due to the action of hydrolytic enzymes (liquefaction AJC) or due to fast pressing and stabilization (press AJC) that occur in the production of AJC. Using the Bayesean modeling method, it was possible to distinguish between natural ciders, and ciders made from either liquefaction or press concentrate. Moreover natural ciders with more than 10% of

press concentrate added or with more than 5% liquefaction concentrate added could be detected. At the time of writing (2009), the use of AJC in Spanish natural cider is forbidden and so there is a need for analysis methods for the detection of fraud.

In HPLC, an alternative to the process of derivatization, described above, is the use of a universal detector, the most important of which are refractive index (RI) (the original), evaporative light scattering (ELS) and mass spectrometry (MS). The last named is so important (as LC-MS) it is dealt with separately at the end of Section 4.3.3.

Evaporative light scattering detectors measure the scattering of light as components pass through a heated drift tube (70–250 °C) and undergo evaporation. ELSD can be used to quantify and profile the monosaccharide and disaccharide sugars in fruit juices and other media. For example, an Alltech Prevail Carbohydrate ES phase has been used with 75% (v:v) acetonitrile:water mobile phase for the quantification of fructose, glucose and sucrose in orange juice (Alltech Associates, 2002). RPHPLC with ELSD was used to determine the sugar profile (fructose, glucose, lactose, maltose, rhamnose, sucrose and xylose contents) of Marsala wines (Section 2.10.8), the total sugar content of whose categories 'secco,' 'semi-secco' and 'dolce' are fixed by law (La Torre *et al.*, 2008).

Intense sweeteners are used in a wide range of foodstuffs, but are generally not allowed for the sweetening of alcoholic drinks (Section 5.9.4), so it is important to have reliable methods of analysis for the detection of adulteration and fraud. Nine intense sweeteners were simultaneously determined in foodstuffs using RPHPLC and ESLD (Wasik *et al.*, 2007).

Stationary phases used were Agilent Zorbax Extend-C_{18}, Merck Nucleodur C_{18} and Macherey-Nagel C_8 Gravity and C_{18} Pyramid, with gradient elution after SPE clean up of the homogenized sample.

Glycerol is an important constituent of wine (Sections 2.2.4 and 2.2.6), giving an attractive appearance to the wine and contributing to a good mouthfeel, as a result of its high viscosity. When a sample containing glycerol is subjected to HPLC with ELSD the high temperatures experienced in the drift tube result in loss of analyte and glycerol may not be detected. Low temperature (28 °C) evaporative light scattering has been used to successfully separate and quantify glycerol (in the presence of fructose, glucose and sucrose) in Bordeaux white wine, using a bonded amino phase and acetonitrile:0.4 mM aqueous ammonia (80:20), with a Shimadzu ELSD-LT detector (Young, 2002).

Ion Chromatography

This is sometimes the preferred method for the analysis of anions in juices, beverages or potable water, although the analysis of cations is often conducted using atomic spectroscopy (Section 4.4.4), ion selective electrodes (Section 4.5.1) or various voltametric techniques (Section 4.5.2). Nowadays, capillary zone electrophoresis techniques offer a powerful alternative for the analysis of organic anions in juices and alcoholic drinks (Section 4.6.1). Although the stationary phases used in ion methods for the separation of ionic or ionizable solutes are essentially ion exchange materials, the mechanisms of separation are complex. Indeed, some of these stationary phases can be used to separate mixtures of ionizable and polar covalent solutes. The major interactions which contribute toward separation are:

- Ion exchange
- Ion exclusion
- Ligand exchange
- Adsorption
- Partition
- Size exclusion

The mechanisms of some of these processes will be considered later.

The following are the more common types of stationary phases:

(a) *Porous Synthetic Polymers.* These have cationic or anionic exchange functions (e.g. $SO_3^-M^+$, $-CH_2-NR_3^+X^-$). The polymer backbone is typically polystyrene-divinylbenzene copolymer (PSDVB) as in the Bio-Rad Aminex series, Dionex IonPac series, Dionex CarboPac PA1, Supelcogel (H and C-610H) and Phenomenex Rezex series. Alternatively the backbone can be based on poly(methyl methacrylate), as with Waters IC-Pak, or vinyl alcohol copolymers, as with the Asahipak ES series and some Shodex IC columns. The majority of ion chromatography phases are porous synthetic polymers.

(b) *Bonded Silica Phases.* The hydrocarbon chains linked to the silica gel possess ionic (ion exchanger) end groups or with quaternary ammonium groups embedded in C_{18} or similar chains. This gives both RP and IE capabilities.

(c) *Polymer Coated Silica Phases.* Here a polymer, such as butadiene-maleic acid copolymer, is coated onto silica gel and then cross linked.

Advantages and disadvantages of these systems include the following points:

Type (a). Good pH stability (e.g. 0–14), but not so tolerant of high pressure
Type (b). High pressure tolerant, but limited pH stability (e.g. 2–8)
Type (c). High pressure tolerant along with no need for high pH eluents, like type (b), however, pH stability is limited.

The types of separations possible with ion exchange stationary phases are summarized in Table 4.3.6.

Ion chromatography falls into two major categories that depend on the number of ion exchange groups on the stationary phase and hence on the ionic strength of the mobile phase.

- *Low capacity ion exchange columns (unsuppressed ion chromatography).* These are usually rigidly cross linked (typically PS-DVB with 4% to 8% cross linking) polymers with low surface coverage of ion exchanger groups (typically $-NR_3^+X^-$ or $-COO^-H^+$). Relatively weak eluents are used (e.g. 0.005M phosphate buffer or water) and detection is usually by conductometric or spectrophotometric detection.
- *High capacity ion exchange columns (suppressed ion chromatography).* These have a high density of ion exchanger groups at the surface of the spherical polymer beads. They are more widely used than the low capacity type. A typical example of a cation exchanger of this type is the Dionex IonPac CS17

Table 4.3.6 *Summary of analytes determined by ion chromatographic methods*

Solutes	Method	Detection
Inorganic ions	*High capacity ion exchangers	UV, RI/ELSD, (cond)
	*Low capacity ion exchangers	Cond, UV, RI/ELSD
Organic anions	Anion exclusion	UV, RI/ELSD, cond
	Anion exchange	
Organic acids	Cation exchangers (H^+ form)	UV, RI/ELSD
Sugars and polyols	Cation exchangers (Ca^{2+}, Pb^{2+}, Ag^+ forms)	UV, RI/ELSD
Peptides and proteins	PSDVB (15μm)	UV
	PMMA	

Cond = conductometric, RI = refractive index, UV = ultraviolet

phase, consisting of a hydrophobic resin with surface grafted carboxylic groups. It acts as a weak cation exchanger and its main application is in the analysis of biogenic amines, including polyamines. An example of an anion exchanger is the Alltech Novosep A-2 phase, a quaternary ammonium functionalized poly(vinyl alcohol), useful in the determination of anions (including oxyhalide ions) in water that is to used for brewing or dilution of distilled spirits. Another anion exchanger, the Dionex CarboPac PA20 phase, is useful in the separation of mono- and disaccharides. It is an ethylvinylbenzene-divinylbenzene cross linked polymer functionalized with a difunctional latex containing quaternary ammonium groups (Majors, 2003). The carbohydrates are separated in their ionized forms at high pH.

More concentrated ionic eluents must be used with these columns, thus requiring ion suppression methods, if the ideal detection (conductometric) method is to be used. The ion suppression methods involve the conversion of an ionic eluent to a weakly ionized (i.e. weakly conducting) eluent and the removal of counter ions.

Types of ion suppression include packed bed (the original method; see Small *et al.*, 1975, which is really two column ion chromatography), fiber, micromembrane and electrochemical.

The first three methods are chemical methods and work by ion exchange mechanisms as the eluent and solutes leave the column, but before they reach the detector. Nowadays, the chemical methods of ion suppression have given way to self-regeneration suppression (SRS), in which the solution used to suppress ionic background is continually regenerated by electrochemical reactions. The mode of action of a typical SRS system is shown schematically in Figure 4.3.8, for analysis of anions. Some modern ion chromatography systems also have eluent regenerating capabilities, using the regenerator to reconstitute the mobile phase. After passing through the detector, the suppressed eluent is led to a trap column where analyte ions are

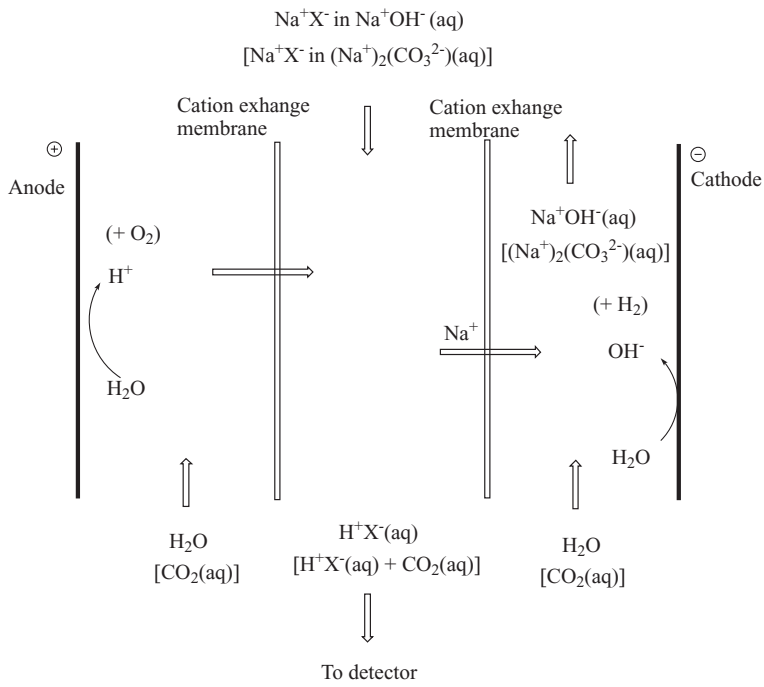

Figure 4.3.8 *Schematic mode of action of an SRS device. X^- is the anion of analytical interest. Schemes for hydroxide and carbonate mobile phases are shown*

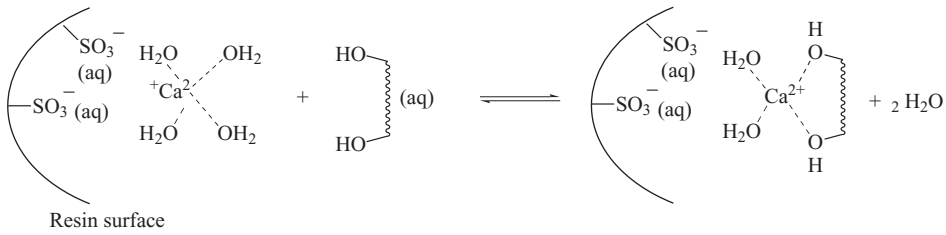

Figure 4.3.9 *Scheme for possible ligand exchange action of some ion exchange stationary phases*

removed. The eluent is then returned to the suppressor to provide the water for electrolytic suppression once more. The suppressor effluent, containing eluent ions, H_2 and O_2, is circulated to a catalytic column (not shown in Figure 4.3.8) where the gases are recombined to give water and is then returned to the eluent reservoir for reuse (Dionex, 2009).

As mentioned earlier, a number of interactions occur in ion chromatography, all of which influence the chromatographic features (retention times, resolution, peak shape etc.) to a greater or lesser extent.

Ligand exchange interaction appears to be dominant in the separation of carbohydrates and polyols, when the metal forms of strongly acidic (sulfonate type) cation exchange resins are used as the stationary phases. Typical metal counter ions include $Ca^{2+,}$ Pb^{2+} and Ag^{+}; examples include the Phenomenex Rezex series and the Bio Rad HPX series, both phases being widely used in the analysis of sugars, polyols and acids in foodstuffs, including alcoholic beverages, particularly the last named.

Separation occurs mainly by selective interaction of solute OH groups with hydrated metal counter ions, via ligand exchange (Figure 4.3.9).

These methods are widely used in the food industry and have the advantages:

- Short retention times
- High resolution
- Use of water as eluent.

Disadvantages are minor, but include:

- Price
- Need for column heating: most experiments need to be carried out at $\sim$50 °C.

Ion exclusion is thought to be the major interaction in the separation of organic acids (e.g. in fruit juice and wines) using strongly acidic cation exchangers in the acid form, as the stationary phase. Examples include Phenomenex Rezex ROA and Bio-Rad HPX-87N. Mobile phases are weakly acidic (e.g. 1% H_3PO_4 or 0.005M-H_2SO_4:MeCN, 90:10).

Presumably, more polar (or more easily ionizable) solutes are excluded from the stationary phase matrix by unfavorable interactions and hence are not retained as well as less easily ionizable solutes.

Size exclusion interaction probably plays some part in all separations involving cross linked polymer stationary phases, especially if there are considerable size differences between solute molecules. The extent of interaction appears to depend on the polymer pore size and the amount of cross linking.

The majority of ion chromatography beverage analysis is used to separate inorganic and low molecular weight organic anions and cations using suppressed conductivity detection and isocratic elution. For anion analysis, common eluents are dilute aqueous sodium or potassium hydroxide (e.g. of a few millimolar

concentration) or dilute aqueous sodium carbonate/sodium bicarbonate are commonly used, and sometimes a small amount of organic component can be included in the eluent (e.g. 13% methanol (v:v)) (Masson, 2000). Many ion chromatography stationary phases are not compatible with organic solvents. Cations are often determined by ion chromatography using aqueous methanesulfonic acid as eluent.

Analysis of inorganic anions in wines by ion chromatography can also be achieved using 8 mM phthalic acid in pH 4 tris buffer in 98:2 (v:v) water:acetonitrile (Dugo *et al.*, 2005), thus allowing determination of sulfate in the presence of tartrate, the ionization of organic acids being suppressed at this low pH.

There are many examples in the literature of analysis of juice or wine organic acids (as anions) (Edelmann *et al.*, 2003; Soyer *et al.*, 2003; Casella and Gatta, 2002; Vonach *et al.*, 1998; Mongay *et al.*, 1996; Hunter *et al.*, 1991) and/or inorganic anions (Dugo *et al.*, 2005; Masson, 2000; Perez-Cerrada *et al.*, 1989) using ion chromatography. Methods for the analysis of organic acids in wines are reviewed by Mato *et al.* (2005). Most chromatographic methods use ion exchange mode with conductometric or spectrophotometric detection, but Fourier transform infrared (FTIR) detection (Edelmann *et al.*, 2003; Vonach *et al.*, 1998) has also been used.

Benzoate (a preservative – see Section 2.5.8) in soft drinks or fruit juices has been determined by reagent free ion chromatography using 35 mM KOH the mobile phase and an IonPac AS18 mobile phase. This allowed the quantification of benzoate in the presence of high concentrations of other anions, such as chloride, phosphate, citrate and others (De Borba and Rohrer, 2004). Although benzoate is little used as a preservative of alcoholic beverages, because of the possibility of its use and because of differing regulatory requirements in different parts of the world, it is important to have a reliable method for its determination.

Carbohydrates and reduced sugars (polyols, such as arabitol, mannitol, sorbitol and xylitol) can be analyzed in the ion exchange mode (i.e. as anions) using special cross linked polymer resin stationary phases and high pH mobile phases. Carbohydrate –OH functions are more acidic than those of reduced sugars, as a result of the absence of the potential carbonyl group in the latter. Hence carbohydrates can be determined on Dionex CarboPac PA type columns (polystyrene/divinylbenzene or ethylvinylbenzene/divinylbenzene substrates agglomerated with a quaternary ammonium functionalized microbead latex) using moderate eluents of moderate pH (e.g. 16 mM aqueous NaOH). Reduced carbohydrates, on the other hand, can be analyzed on a CarboPac MA type of column (macroporous vinylbenzyl chloride/divinylbenzene substrate functionalized with alkyl quaternary ammonium groups – no latex) using a high pH eluent, such as 0.6M aqueous NaOH (Dionex, 2009). In all cases, since carbohydrates and, especially polyols, do not absorb strongly in the UV region, either a universal detection method, such as refractive index or evaporative light scattering, or a highly selective method, such as pulsed amperometry (Dionex, 2009) is preferred.

Similarly, sugars in beer wort (glucose, lactose, maltose, maltotriose and sucrose) have been determined by ion chromatography using a Metrohm Carb-1 phase, gradient elution with 180 mM and 500 mM aqueous NaOH and a pulsed amperometric detector (Benton, 2004). The detection method was considered superior to the traditional refractive index detection, because of poor baseline resolution and because the high temperatures often used with these stationary phases may lead to some decomposition of maltotriose.

Ion exclusion chromatography, usually carried out on cross linked polymer based ion exchange columns at low pH, has been used to determine the organic acids of grape must (Soyer *et al.*, 2003) or wine (Casella and Gatta, 2002), the former using UV spectrophotometric detection, the latter using electrochemical detection.

A similar method can be used to assay carbohydrates (sometimes as well as organic acids) in beverages, using phases such as Alltech Prevail, Bio-Rad Aminex, Phenomenex Rezex, Supelco Supelcogel or Waters Sugar-Pak. Selectivity between carbohydrates and organic acids can be altered for some phases (e.g. Rezex ROA-Organic Acid: an 8% cross linked sulfonated styrene-divinylbenzene copolymer phase in its hydrogen ion form) by change of pH, thus combining ion exchange with ion exclusion. Generally, weakly acidic (e.g. 0.005M H_2SO_4, 1% aqueous phosphoric acid or 0.5% aqueous trifluroacetic acid) mobile phases are used for organic acids or amino sugars, whereas water alone is used for carbohydrates. Refractive index and evaporative light scattering are the preferred methods of detection for carbohydrates.

Size Exclusion Chromatography (SEC): Gel Permeation and Gel Fitration Chromatography (GPC and GFC)

The stationary phases used to effect separation by size exclusion are usually cross linked polymers (either synthetic or natural), which are swellable by certain solvents. Because of their swellability, they are known as gels and contain pores whose sizes lie within a certain, usually quite narrow range. Larger molecules in a mobile phase are unable to enter the pores in the gel as they pass through the stationary phase. They are thus obliged to travel through the stationary phase via the liquid spaces between the particles (the void or interstitial volume). Smaller molecules are able to enter the pores, where they interact with stationary phase in a variety of ways and are hence retained more strongly. The process of size exclusion separation is illustrated in Figure 4.3.10.

Stationary phases for size exclusion chromatography fall into two categories – hydrophobic (organophilic) gels and hydrophilic gels – giving rise to two versions of SEC: gel permeation chromatography (GPC) and gel filtration chromatography (GFC).

Gel permeation chromatography makes use of hydrophobic stationary phases, typically poly(styrene-divinylbenzene) copolymers, cross-linked up to about 8%. They are similar to stationary phases used elsewhere in HPLC, see ion chromatography, for example. They are best used for the separation of synthetic polymer mixtures, the mobile phases being organic solvents, based on acetonitrile or DMF, for example.

Alkyl-bonded silica gels with wide pores (typically 30 nm) are useful hydrophobic phases which are frequently used to separate biopolymers (e.g. proteins), using mainly acetonitrile-water mobile phases. Separation is probably effected by partition (see RPHPLC), as well as size exclusion.

Gel filtration chromatography uses hydrophilic stationary phases, such as Sephadex and related materials, which are essentially cross linked polysaccharides. Also much used are synthetic polymers with hydrophilic side chains, such as poly(acrylamide) and poly(vinyl alcohol), and silica gel based phases. They are of special importance in the separation of larger biomolecules, such as peptides and proteins. Aqueous based mobile phases are used, which minimize loss of biological activity during separation (see hydrophobic example above for contrast). The mode of separation appears to be complex, but size exclusion plays some part.

As with other modes of HPLC, a range of detection methods is possible, but with one method based on molecular size; a reflection of the application to size exclusion chromatography to the separation of polymers and oligomers. The major detection methods used are comparative refractometry, ELSD, UV absorption and molecular size detection.

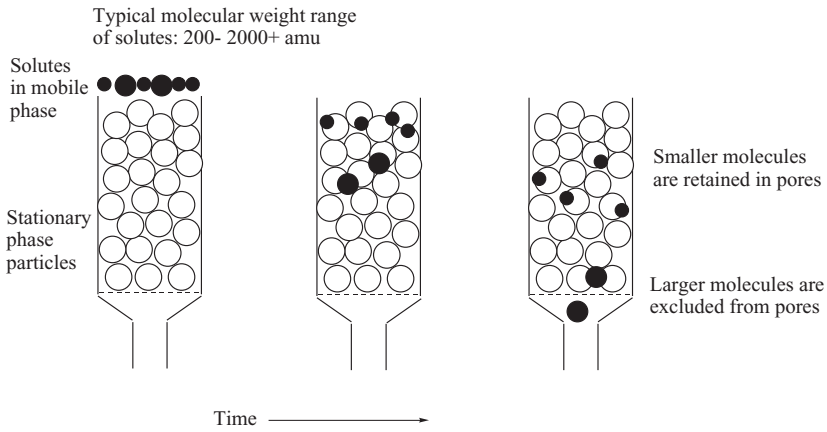

Figure 4.3.10 *Simplified scheme for SEC separation not drawn to scale*

The major application of size exclusion chromatography to alcoholic beverages or materials from which alcoholic drinks are derived, is to protein analysis. Alternative methods of protein analysis include sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) (Section 4.6.1) and RPHPLC-MS (LC/MS) (later in this section). Of particular interest are haze forming proteins, prolamins (Section 5.11.3) and the influence various processing methods (e.g. fining) have on protein/peptide composition.

Thaumatin-like proteins (along with other proteins) are responsible for haze formation in wine and can be costly (in terms of both material costs and loss of quality) to remove by use of bentonite or other fining agents. Grape proteins of Semillon juice have been analyzed on a Phenomenex BioSep SEC S2000 column (a silica gel based phase) using 50 mM aqueous KH_2PO_4 buffer, with UV detection at 210 nm (Marangon *et al.*, 2009). Size exclusion chromatography was carried out on fractions from a hydrophobic interaction chromatography column, one having a protein identified as a VvTL (*Vitis vinifera* thaumatin-like) protein of about 20 000 amu. Chitinases, PR-4 type proteins, vacuolar invertase and lipid transfer protein (LTP) were also found.

The effects of processing (malting, mashing, boiling, fermentation and filtration) on the protein/peptide profile of wort and beer were studied using a Millipore Marex Cellufine GCL-300 Medium phase and 50 mM acetate buffer (pH 5.5) (Osman *et al.*, 2003). The wort and beer samples were centrifuged, concentrated by ultrafiltration and dialyzed prior to gel fitration. The results showed that soluble protein concentrations almost double during malting, especially with regard to proteins of 14,000 amu and lower. The combined GCF and SDS-PAGE results suggested most of the higher molecular weight proteins were formed by the combination of peptides.

Maltodextrins (α-glucans), produced by the hydrolytic degradation of starch during malting and mashing (Section 2.6.2) are important in brewing; many are either slowly fermentable or nonfermentable (depending on the type and extent of branching), but they give texture and viscosity to the beer and may also be flavor carriers. Although the majority of α-glucans in beer are of relatively low molecular weight (typically ∼1000–3600 amu), higher molecular weight species are present in malted barley or can be produced from starch by the action of diastase enzymes. GPC using multiple detectors (e.g. refractive index, low angle light scattering, right angle light scattering differential viscometry and UV) can characterize different maltodextrins according to molecular weight, branching etc. (Clarke, 2004; Viscotek, 2009), particularly with regard to high molecular weight (∼60 000–>800 000) α-glucans. A single Viscotek Viscogel GMPWXL column or two columns in series can be used with 0.1 M or 0.2 M aqueous $NaNO_3$ mobile phase (or similar) to characterize different maltodextrin samples with similar viscosities, in terms of molecular weight, molecular weight distribution, average size and extent of branching.

Chiral HPLC

Although chiral HPLC is of paramount importance in the pharmaceutical industry, it has found relatively few applications in the food and alcoholic beverage industries, although here chiral GC has found greater application, especially in the analysis of aroma compounds (Section 4.3.2). Chiral chromatography involves the separation of enantiomeric analytes. All types of chiral chromatography depend on chiral selectivity, which can be achieved in various ways. These are summarized for HPLC in Figure 4.3.11.

A rare example of method 2 is the determination of amino acid enantiomers in grape must, wines and beers by derivatization of the amino acid analytes using *o*-phthalaldehyde and *N*-isobutyryl-L-cysteine (or its enantiomer) ($(CH_3)_2CHCONHCH(CH_2SH)CO_2H$) and subsequent separation of the diastereoisomeric derivatives on a C_{18} RP phase (Brückner *et al.*, 1995). Fluorescence detection was used, the derivatives absorbing at 230 nm and emitting at 445 nm.

Nowadays, most chiral HPLC is carried out using chiral stationary phases (CSPs), which depend on some chiral moiety in the phase interacting differentially with enantiomers in the mobile phase. For a comprehensive coverage of chiral HPLC, the reader is referred to Aboul-Enein and Ali (2003), although the emphasis here

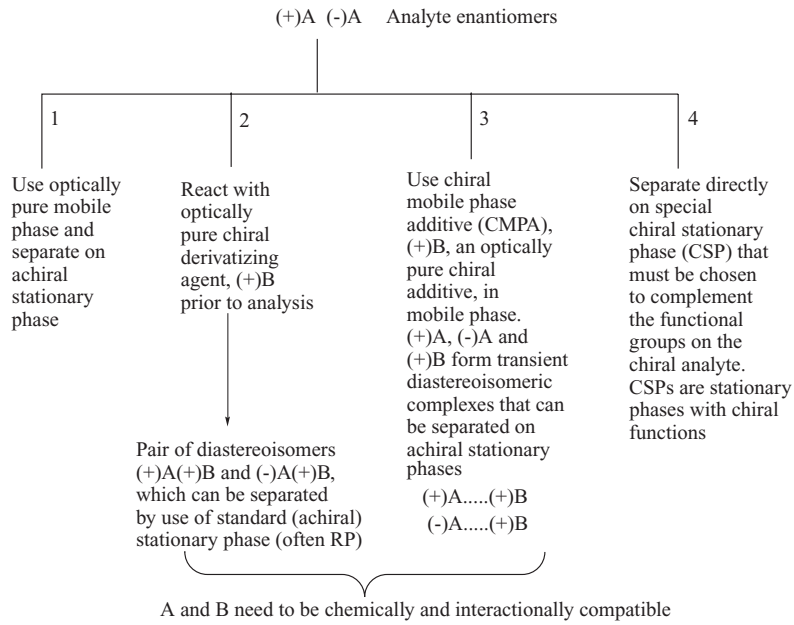

Figure 4.3.11 *Types of chiral chromatography. In recent years, only method 4 has found HPLC application to alcoholic beverages*

is very much on drugs and pharmaceuticals. CSPs are usually composed of silica skeletons bonded or coated with chiral moieties, such as amylose, cellulose, cyclodextrins, macrocyclic glycopeptide antibiotics, aromatic amino acid derivatives (Pirkle phases), proteins, chiral metal complexes, crown ethers and alkaloids.

Most applications of chiral HPLC to alcoholic beverages are based on chiral ligand exchange chromatography (CLEC), where separation involves competition for complexing between the enantiomers (especially amino acids, amino alcohols and hydroxy acids) for the formation complexes with a metal cation (usually Cu^{2+}), which is both in the mobile phase and complexed to a chiral moiety in the stationary phase.

An optically pure chiral ligand such as L-proline or D-penicillamine is bound to silica gel (originally crosslinked polystyrene) and loaded with metal cations, typically Cu^{2+}. The chiral analytes are distributed from an aqueous mobile phase to the immobilized ligand–Cu^{2+} complex, where they form tertiary complexes of different stabilities. Variable interaction between groups on the immobilized ligand and/or the matrix and groups on the analytes give rise to differences in stability and hence to chiral selectivity. A schematic representation of a possible separation mechanism is shown in Figure 4.3.12.

These CSPs are good for the separation of amino acids and various derivatives like amino alcohols and hydroxy acids. Although reversed phase mode is used, ligand exchange CSPs need care in handling; Cu^{2+} needs to be in the mobile phase and the columns require storage in 2 mM $CuSO_4$ solution when not in use. They are also sensitive to low or high pH and to the presence of organic solvents in the mobile phase (15% maximum).

CLEC methods, although useful in the determination of underivatized bifunctional chiral analytes, are in general of low efficiency, giving rather broad peaks.

Lactic acid enantiomers in wines, beers and other foodstuffs have been determined by this method (Buglass and Lee, 2000; 2003), using a D-penicillamine type phase (Phenomenex Chirex 3126 or Daicel Chiralpak MA(+)) and 1 mM aqueous $CuSO_4$. Interferences due to amino acids can be removed by sample treatment with PRS (propanesulfonate ion exchange) SPE (Buglass and Lee, 2000). The detection limit was 3 mg/l.

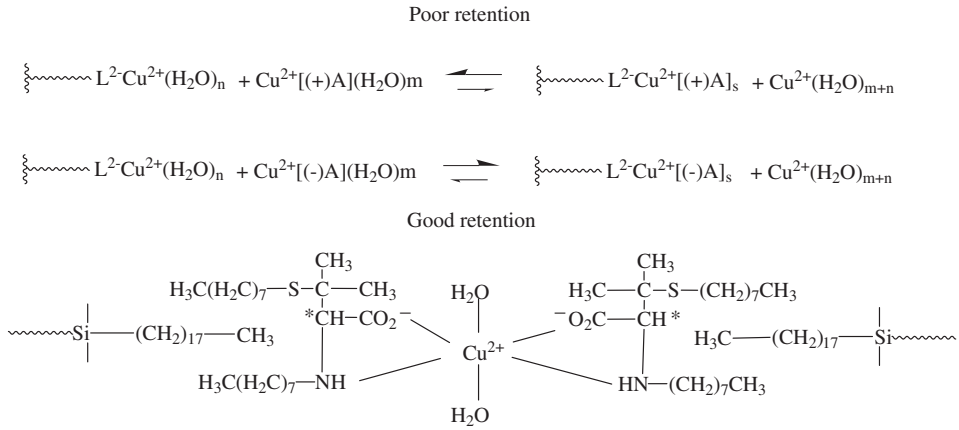

Figure 4.3.12 *Possible mechanism of CLEC and example of D-penicillamine phase. *chiral center*

Changes in concentration of both lactic acid enantiomers during both alcoholic and malolactic fermentation were monitored by this method (Buglass and Lee, 2003).

Zerbinati *et al.* (1994) were able to quantify enantiomers of malic and lactic acids in wines by using an achiral (C_{18}) stationary phase, but with a circular dichroism detector. By comparison of the CD spectra with those of optically pure standards, it was possible to determine the concentrations of major and minor enantiomers of the two acids in wine. The limit of detection for lactic acid was 178 mg/l.

Earlier, Doner and Cavender (1988) used an L-proline phase and 1 mM $CuSO_4$ to separate the enantiomers of malic acid in apple juice. Adulteration of apple juice using inexpensive racemic malic acid could be detected by this method.

More recently, benalaxyl fungicide residues (Section 5.10.2) in grape must were determined using normal phase OD chiral stationary phase, hexane/2-propanol mobile phase and UV detection (Wang *et al.*, 2007). The limit of detection was 0.26 mg/l for both enantiomers.

HPLC Techniques for Difficult Samples and Techniques for the General Improvement of Chromatography

The HPLC analysis of some analytes in some matrices can present certain problems, usually with respect to reasonable retention times or to resolution and accurate quantification, particularly if there are components of widely differing polarities in the sample – which is often the case with alcoholic beverages. Other problems are associated with mobile/stationary phase compatibility with the detector, especially in LC-MS. Yet others are related to high flow rates and back pressure associated with the use of small spherical particulate stationary phases (<3 μm). Other problems are associated with detector sensitivity or with solvent waste. The first of these challenges can be often addressed by the use of some fractionating method or sample preparation method, such as SPE (Section 4.2.4), but the following is a brief account of some techniques applied purely to the chromatographic process itself in order to ease some of these problems.

Column Switching Techniques

Resolution of difficult samples can be improved by using two linked columns, as shown in Figure 4.3.13. The sample is partially resolved on the first column, and at the correct time, the eluent stream containing the

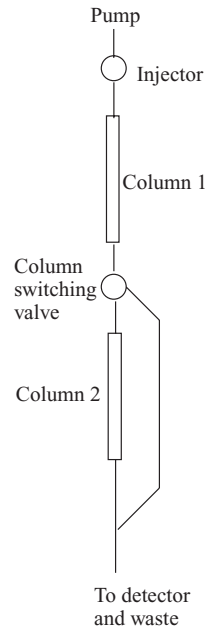

Figure 4.3.13 *Simple 'heart cutting' column switching arrangement*

partially resolved analytes is switched by use of a valve to a second column. Full resolution can then take place on this column without interference from other components. Figure 4.3.13 shows the simplest kind of arrangement – a more complex column switching set up, including a focusing column, is needed if different mobile phases are to be used (Figure 4.3.14).

With the valve in the main switch position (Figure 4.3.14(a)), the sample is pushed by pump A via ports 1 and 2 onto column A, where initial separation takes place. At the same time, pump B is pushing its mobile phase through port 4 and out of port 3 into the ODS retainer column and from here it proceeds back to the valve via port 6, where it emerges from port 5 and goes through column B and detector B.

When the detector indicates that the heart cut part of the mixture coming from column A has almost arrived, pump B is turned off and the valve is switched immediately to position (b) (Figure 4.3.14(b)). Now the components of the heart cut, in a plug of mobile phase A, are diverted to the focusing column via port 6. The mobile phase A, now mixed with some mobile phase B after passing through the focusing column, re-enters the valve at port 3 and leaves via port 2 to the detector.

After a predetermined time (usually 20–30 s), the valve is switched back to the main switch position and pump B is restarted. Now pump B pushes mobile phase B via ports 3 and 4 elutes the components of the heart cut (still unresolved at this point), with their plug of mobile phase A, from the focusing column via valve ports 6 and 5 onto the column B where they are resolved and detected by detector B. In the mean time, pump A pushes mobile phase A via ports 1 and 2 through the detector A, thus washing out the plug of mobile phase B from the previous valve switch position.

An arrangement similar that described above was used to quantify simultaneously malic acid and (*R*)- and (*S*)-lactic acid contents of wines (Buglass and Lee, 2001; 2003). In this case column A contained an RP phase, mobile phase A was aqueous 0.5 mM H_2SO_4 and the heart cut containing the lactic acid enantiomers was resolved on a CLEC stationary phase using 2mM $CuSO_4$ as mobile phase.

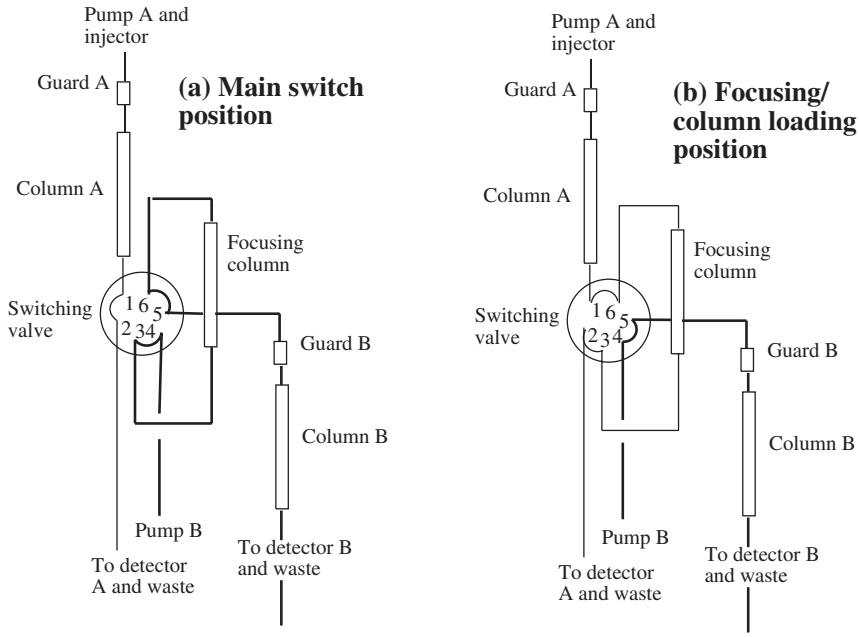

Figure 4.3.14 *Column switching arrangement using different mobile phases and a focusing column. Buglass and Lee (2001). Figure reproduced from the* Journal of Chromatographic Science *by permission of Preston Publications, a division of Preston Industries, Inc*

Narrow Bore Columns

Typical analytical HPLC columns have internal diameters (i.d.) of 4.6–8.0 mm. Smaller bore columns ('midbore,' 3.2 mm i.d.; 'minibore,' 2.1 mm i.d. and 'microbore,' 1.0 mm i.d.) have been shown to both increase detection sensitivity and to reduce solvent consumption (and hence waste).

Special HPLC systems have been devised for the use of microbore columns and such systems have been used to rechromatogram fractions of partially resolved conventionally chromatogrammed complex samples. Also, LC-MS frequently makes use of microbore and even narrower nanobore or capillary columns (e.g. 0.15 mm i.d.) (Marangon *et al*., 2009).

Radial Compression Technology

As the particle diameter of the stationary phase is reduced, particle–particle interactions become more pronounced during the packing process. Thus it becomes increasingly difficult to form a highly efficient packed bed that is stable over a significant period of time. One very useful way round this problem has been patented by Waters as *Radial Compression Technology.* Here the stationary phase is packed into a flexible walled plastic cartridge which is then subjected to a radially compressive force in a compression module prior to HPLC analysis. Radial compression reforms the packed bed and, in particular, removes voids and channels that inevitably form during and after the packing process. Near the rigid wall of a conventional steel column, there is lower resistance to flow as a result of the lower density of the packed bed in these regions. This effect (the 'wall effect') is believed to make a major contribution to band broadening. Radial compression greatly improves flow characteristics near the column wall. The relatively flexible wall of the cartridge molds itself

around the silica particles and significantly reduces voids near the channel wall. Largely because of this, the efficiency of a Radial-Pak radial compression cartridge has been shown to be regularly 25% higher than that of a conventional packed steel column. Furthermore there is good evidence to suggest that the stationary phase life is longer and overall performance better under radial compression: tests at Waters have shown that Radial-Pak cartridges can provide good performance even after 10 500 injections. Billingsley *et al.* (1996) were able to determine the malic and tartaric acid contents of a large number of grape juice samples and the same technique was used to determine the lactic, malic and tartaric acid contents of wine (Buglass and Lee, 2001).

Spherically Ordered Mesoporous Silicas and Monolithic Phases

Many HPLC analyses require stationary phases composed of small spherical particles (say <3 μm) to enable sufficient efficiency and resolution due to more effective mass transfer. However, smaller particles give higher flow resistance, and so to avoid a high column back pressure modest flow rates must be used, thus sometimes resulting in long chromatographic run times. Ordered mesoporous silicas, like those that have been micelle templated (micelle templated silicas; MTS), possess beneficial morphologies, besides having very high surface areas ($\sim$1000 m^2/g) for effective mass transfer. Special morphologies can be acquired by pseudomorphic transformation; amorphous silica particles (like those used in HPLC) are dissolved in alkaline solution and reprecipitated around surfactant micelles into ordered MTS structures. Spherical particles of MTS ($\sim$5 μm) with hexagonal and cubic symmetries, and containing uniform pores with diameters greater than 6 nm have been synthesized and used in fast HPLC separations with low back pressure (Galarneau *et al.*, 2006).

A monolithic phase is a single entity of stationary phase material, without interparticle voids. The more usual particulate stationary phases can be regarded as a large collection of spherical micromonoliths. The first monolithic phases were discs of modified poly(styrene) or poly(methacrylate) copolymers that used ion exchange, hydrophobic interactions or reversed phase in the separation of proteins and other macromolecules (Svec, 2003). In the early 1990s, rigid macroporous polymer columns were developed by reacting the monomers (one of which must be a cross linker), a radical initiator and a porogenic solvent in a sealed tube, which would later act as the chromatography column. After washing out unreacted compounds and porogens from the pores of the columnar monolith, the phase was ready for chromatographic use. Later, tubular and capillary organic polymer monoliths were developed and after those, the first silica based monolithic columns – see Tanaka *et al.* (2002) for a review of monolithic silica columns. Monolithic silica based columns are prepared by hydrolytically initiated polycondensation of tetraalkoxysilane in the presence of poly(ethylene glycol) porogen and are now commercially available (e.g. Merck Chromolith; Phenomenex Onyx) as silica, C_8 and C_{18} phases.

Since monolithic silica based phases are relatively new, there are few applications, but those that exist serve to demonstrate the notable advantages of such phases. A very early application was the analysis of ochratoxin A in red and white wines by LC-MS-MS using a 50 mm Merck Chromolith SpeedRod RP-18e column (Zöllner *et al.*, 2000). The monolithic column and a conventional column gave comparable results (with a limit of detection of 0.5 ng/l), but the former allowed much higher flow rates, reducing analysis time by a factor of three.

Using a second generation 100 mm Chromolith column (C_{18}, end capped), Castellari *et al.* (2002) were able to separate 17 monomeric wine phenolic substances, including hydroxybenzoic acids, hydroxycinnamic acids, hydroxycinnamyltartaric acids, flavanols, flavonols and stilbenes in 36 minutes, including washing and equilibration time. Similarly *cis*- and *trans*-resveratrol and piceid isomers in the must and wine of the *V. vinifera* variety Grenache were separated and quantified by using coupled monolith columns in a single very short run, without any sample preparation (Abert Vian *et al.*, 2005).

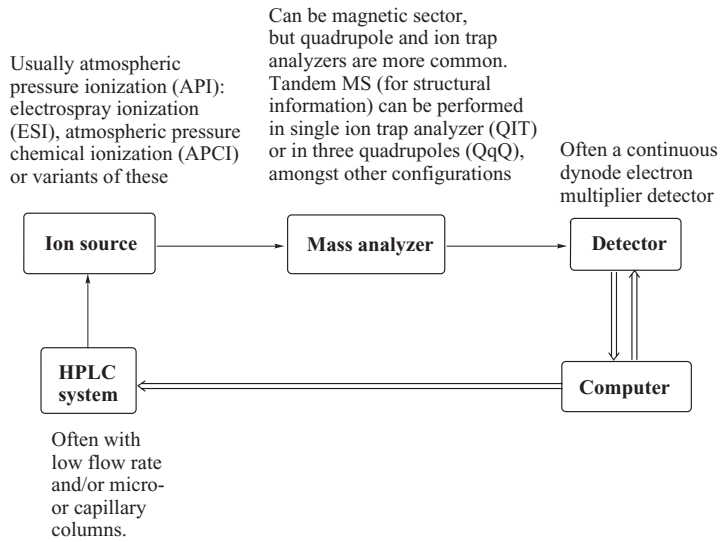

Figure 4.3.15 *Schematic diagram of a basic LC-MS system. Reproduced with permission from the Journal of Chromatographic Science by permission of Preston Publications, A Division of Preston Industries, Inc.*

LC-MS

Nowadays, LC-MS is one of the most powerful of all analytical techniques and is widely used in the analysis of alcoholic beverages, their raw materials and other foodstuffs. In the following paragraphs, the chromatographic aspects of LC-MS will be emphasized, the mass spectrometric aspects being considered largely in Section 4.4.5.

Most modern LC-MS instruments possess interfaces in which the HPLC eluent enters the MS ion source at atmospheric pressure (Figure 4.3.15). Here, ionization occurs, as excess mobile phase is pumped away and the ionized analytes (as cations or anions), now in the gas phase, are passed at very low pressure into the analyzer, where they are sorted or separated (usually according to m/z values) before reaching the detector.

The mode of ionization preferred nowadays is atmospheric pressure ionization (API), of which there are several variants (see Figures 4.4.27 and 4.4.29 in 4.4.5 for details). Electrospray ionization (ESI) (Section 4.4.5) is probably the most widely used API method because, if one includes a variant known as ionspray, it is applicable to the widest range of analyte molecular weights and polarities (Figure 4.3.16). In electrospray ionization, ionized droplets of mobile phase (containing the analyte) are formed as the eluent leaves (at up to 200 μl/min) a heated capillary column (the nebulizer), the end of which is subjected to a high voltage (up to ~5 kV). Regarding the HPLC conditions, typically, minibore (2.1 mm i.d.), microbore 1.0 mm i.d.) or capillary (0.1 mm i.d.) columns are preferred, but larger diameter columns may also be used provided the eluent flow is split before entering the ion source. Eluent flow rates vary from ~1 ml/min down to a few μl/min, depending on the column dimensions and the type of capillary inlet in the ion source.

Alternatively, a high gas flow rate (~ speed of sound), can be used to cause the formation of charged droplets via shear stress as the eluent leaves the capillary tip. Neither heating nor high voltage is required and this ionization technique (sonic spray ionization) may be useful in the study of heat sensitive analytes such as terpenoids, steroids and polyphenols (Volmer, 2000).

Nanospray is a recent development of electrospray, with flow rates of eluent (from a capillary HPLC column or chip based LC system into the ion source) of nl/min (rather than μl/min) via a narrower capillary outlet than in standard ESI. Smaller droplets are produced, leading to more efficient ionization and hence

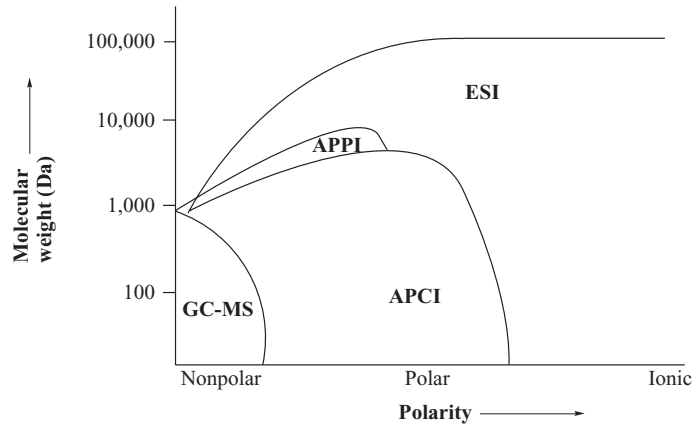

Figure 4.3.16 *LC-MS ionization techniques, analyte polarity and molecular weight*

higher sensitivity. ESI is a 'soft' ionization technique, producing abundant molecular ions, but very little (if any) fragmentation, thus revealing virtually no structural information. However, limited fragmentation can be encouraged by using an increased cone voltage and additionally, collision induced decomposition (CID) and tandem MS (LC-MS-MS) can be used to give the required structural information, if needed (see later and Section 4.4.5).

In APCI (Section 4.4.5), the HPLC eluent is nebulized at high temperature and ionization is caused by the application of a corona discharge in the spray. Solvent molecules are ionized and these ions react with analyte molecules in the gas phase (chemical ionization). A recent variant known as atmospheric pressure photochemical ionization (APPI) uses a photochemically ionized (by UV radiation) 'dopant' substance to initiate a series of ion–molecule reactions to form the ionized analyte. APCI, like conventional chemical ionization, is a 'soft' ionization technique generally producing abundant molecular ions, but usually with more fragmentation than ESI. Once again, tandem MS can be used to gain more structural information via enhanced fragmentation.

Quadrupole and ion trap analyzers are able to scan the m/z range (typically 35–350 units) very rapidly and hence are ideal for LC-MS, despite their other limitations (Section 4.4.5). In practice, the mass spectrometer is programmed to scan continuously (say every 0.5 s) during the course of an HPLC run, over a preselected range of m/z values (e.g. 35–350 units). This means that a typical chromatographic peak of width say 5 or 10 s will be scanned many times during the chromatographic run. In this way, the optimum scanning (close to the peak maximum) can be obtained for each (fully resolved) peak (Figure 4.3.17(a)). For unresolved peaks (coeluting components), continuous rapid scanning can still result in optimum mass spectra for each component (Figure 4.3.17(b)).

The description above is that of a total ion chromatogram (TIC) mode. For the whole of the chromatographic run, the preselected mass range (say, 40–400 m/z) is scanned every (say) 0.5 s. TIC is the most common scanning mode, especially when it is needed to identify unknown components of a mixture. If, however, there is some prior knowledge of the components or if we are searching for specific substances in a mixture, then the selected ion monitoring (SIM) (Section 4.3.2) mode can be used. Here, ions of specific m/z values (often 2–5 characteristic and abundant ions), and no other ions, are monitored during the HPLC separation. Hence, only components whose mass spectra contain ions of the preselected m/z values will be recorded as chromatographic peaks; all other data is not saved. Choice of SIM mode has the effect of greatly simplifying the chromatogram and greatly enhances the sensitivity of the LC-MS experiment (detection limits are often improved from ng/l levels to pg/l levels).

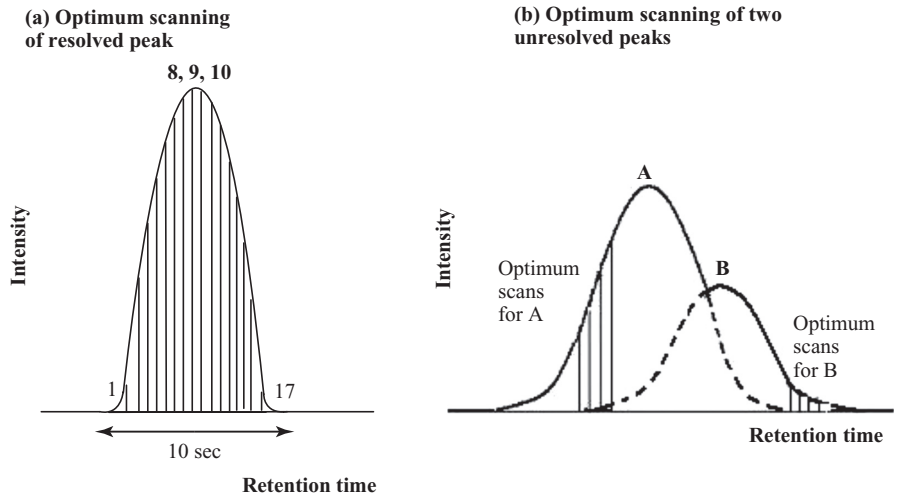

Figure 4.3.17 *Mass spectral scanning of chromatographic peaks*

LC-MS has been used extensively in the quantification and identification of phenolic compounds in both alcoholic drinks and the raw materials from which they are made. Much of the interest focused upon phenolic compounds arises because of their possible *in vivo* antioxidant properties and claimed health benefits (Chapter 5.8). They are present in all raw materials used in the making of fermented beverages, and many survive (but some are modified, transformed or removed, and some are added), during the alcoholic beverage production processes. Thus many alcoholic drinks possess significant concentrations of phenolic compounds. Probably the greater bulk of reports in the literature deal with raw materials, particularly fruit skins and juice. There are many such reports, so only representative examples are discussed here.

LC-MS has been used to study the phenolic content of apple skins and pulp (Kahle *et al.*, 2005), apple extracts (Schieber *et al.*, 2002), pear skins (Lin and Harnly (2008) and of colored fruit skins and must (Dugo *et al.*, 2003; González-Paramas *et al.*, 2006; Pomar *et al.*, 2005; Seeram *et al.*, 2006a; Tian *et al.*, 2005; Vidal *et al.*, 2004). Many of the above references involve a report on some aspect of *in vitro* antioxidant power. Additionally, LC-MS has been used to probe more specific features of fruit juices, such as oxidation of phenols in apple juice (Bernillon *et al.*, 2004), thermal degradation of anthocyanins (Sadilova *et al.*, 2006) and *in vitro* anticancer activity of fruit extracts (Seeram *et al.*, 2006b). Furthermore, more generally, LC-MS methods have been developed for screening and identification of phenols in all plant materials (Lin and Harnly, 2007; Wolfender *et al.*, 1998).

For the analysis of flavonols, flavan-3-ols, hydroxycinnamic acids and other phenols in extracts of apples and pears, either reversed phase C_{18} standard columns with flow rates of 1 ml/min (Schieber *et al.*, 2002; Lin and Harnly, 2007) or a minibore column (100 mm × 2.0 mm i.d.) with a flow rate of 0.2 ml/min (Kahle *et al.*, 2005) were used with gradient elusion, which involved an acidic (formic acid) aqueous solvent as one solvent and either acetonitrile or acidified acetonitrile as the other. The method of ionization was electrospray in both positive and negative mode (Lin and Harnly, 2007), negative mode ESI (Bernillon *et al.*, 2004; Kahle *et al.*, 2005) and negative mode APCI (Schieber *et al.*, 2002).

Analysis of anthocyanins and other polyphenols in colored samples, such as blackberry juice or black grape skins usually involves solvent extraction (González-Paramás *et al.*, 2006; Seeram *et al.*, 2006a; 2006b), freeze drying or other drying and solvent extraction (Lin and Harnly, 2007; Tian *et al.*, 2005; Wolfender *et al.*, 1998), whereas paler fruits, such as oranges, may be simply crushed and filtered (Dugo *et al.*, 2003).

Depending on which groups of polyphenols are under investigation, SPE (González-Paramás *et al.*, 2006) or column chromatographic procedures, such as silica gel (Tian *et al.*, 2005) or XAD-16 and Sephadex (Sadilova *et al.*, 2006) are sometimes used for sample preparation.

Most of the above LC-MS analyses involved normal size analytical reversed phase (C_{18}) columns, although Dugo *et al.* (2003) used a microbore (1 mm i.d.) column. ESI was the most popular LC-MS interface, with positive ionization for anthocyanins (González-Paramás *et al.*, 2006; Seeram *et al.*, 2006a, 2006b; Tian *et al.*, 2004; Sadilova *et al.*, 2006; Dugo *et al.*, 2003, Lin and Harnly, 2007) and negative mode for other phenols (Seeram *et al.*, 2006a, 2006b). FAB and thermospray interfaces, as well as ESI, were used by Wolfender *et al.* (1998).

LC-MS has also been much used in the study of the phenolic components of alcoholic beverages themselves. Reports on the LC-MS analysis of wine and beer phenolic compounds (Callemien and Collin, 2008; Dugo *et al.*, 2004; Morata *et al.*, 2007; Burns *et al.,* 2003; Romero and Bakker, 2000; Salas *et al.*, 2004; Urpí-Sardà *et al.*, 2005; Vivas de Gaulejac *et al.*, 2001) include studies of formation of vitisins from anthocyanins and carbonyl compounds (Morata *et al.*, 2007; Romero and Bakker, 2000), discovery of flavanol-anthocyanin adducts (Salas *et al.*, 2004), identification of resveratrol in LDL and resveratrol metabolites in blood (Urpí-Sardà *et al.*, 2005), identification of monomeric and dimeric phenols in oxidized red wine (Vivas de Gaulejac *et al.*, 2001) and identification of procyanidin dimer and trimer isomers in lager beer (Callemien and Collin, 2008). Examination of the whole anthocyanin profile by HPLC has been shown to be a better indicator of wine authenticity than measurement of certain anthocyanin derivative ratios (Burns *et al.,* 2003).

HPLC conditions were predominantly reversed phase, using either normal size analytical C_{18} columns (Burns *et al.*, 2003; Morata *et al.*, 2007; Vivas de Gaulejac *et al.*, 2001) or minibore columns (Salas *et al.*, 2004; Urpí-Sardà *et al.*, 2005). Gradient elution was again the preferred elution mode and ESI the preferred interface, in the positive ionization mode for anthocyanin analysis (Burns *et al.*, 2003; Morata *et al.*, 2007; Salas *et al.*, 2004) and negative mode for polyphenols, including procyanidins (Callemien and Collin, 2008; Urpí-Sardà *et al.*, 2005; Vivas de Gaulejac *et al.*, 2001).

LC-MS has been applied to the analysis of many other natural components (such as carotenoids, chlorophyll derivatives and terpenoids) of alcoholic drinks and fruits from which they are derived, as well as those obtained from oak maturation. Pentacyclic triterpenoids (Section 5.11.2) and their glycosides are extracted from oakwood during the maturation of wines and spirits. At low concentrations, they often provide a pleasant astringency to the organoleptic properties of the beverage and many of them have been shown to have health benefits (Section 5.11.2); indeed, many are known to be constituents of folk medicines. LC-MS with ESI in the negative ion mode was used to identify and quantify both free and glycosidically bound triterpenoids in wines (red and white) and Armagnac (Arramon *et al.*, 2003). The triterpenoids and their glycosides were isolated from dealcoholized Armagnac samples by extraction with diethyl ether and ethyl acetate, respectively. The detection limits were 1.5–6.0 mg/l and the limits of quantification were 2.5–8.0 mg/l for 2α, 3β, 19α-trihydroxyolean-12-ene-24,28-dioic acid and 2α, 3β, 19α, 23-tetrahydroxyolean-12-ene-24,28-dioic acid and their 28-β-D-glucopyranoside derivatives. The HPLC conditions were reversed phase with gradient elution, the two eluents (95:5 (v:v) water:acetic acid and 95:5 (v:v) methanol:acetic acid, being chosen to facilitate both separation and good electropspray negative ionization. The brandies had much higher levels of triterpenoids than wines, reflecting the superior ability of ~60% ethanol (v;v) over ~12% ethanol (v;v) to extract these somewhat hydrophobic compounds from wood.

Carotenoids, chlorophyll and chlorophyll derived components in grapes and Port wines (Mendes-Pinto *et al.*, 2005), as well as pear skins (Müller *et al.*, 2007) have been investigated using LC-MS. The positive electrospray mode was used to ionize carotenoids, chlorophyllins and pheophytins in grape skins and wine from the Douro region of Portugal, using analytical C_{18} and C_{30} reversed phase columns and gradient elution in the LC part of the instrumentation (Mendes-Pinto *et al.*, 2005). Carotenoids were extracted from homogenized fruit and wine using diethyl ether:hexane (1:1); chlorophyllins a and b and pheophytins a and b were prepared from standard chlorophylls a and b by base and acid hydrolysis, respectively, and

were used with purchased standards to aid identification. Colorless tetrapyrrolic chlorophyll catabolites were extracted from homogenized pears (with skins) after separation of the extracts using preparative HPLC (Müller *et al.*, 2007).

Recently, detailed analysis of proteins in grapes and wine has been achieved by LC-MS/MS, using a variety of analyzers (e.g. ion trap or Q-TOF) (Marangon *et al.*, 2009; Wigand *et al.*, 2009). Proteins from a number of varietal German red and white wines were isolated by lyophilizing (freeze drying) the dialyzed wine (from cellulose membranes with 3.5 kDa molecular weight cutoff (Wigand *et al.*, 2009). Riesling wine (white) and Portugieser wine (red) (both 200 ml) gave 120 mg and 220 mg (respectively) of lyophilized powder. The lyophilized samples were treated with PVP to remove polyphenols and then subjected to SDS-PAGE separation. The relevant protein bands were excised and after various treatments digested with trypsin. The trypsin digests were then analyzed by LC-MS. The HPLC conditions were reversed phase with gradient elution (0.1% formic acid in water; 0.1% formic acid in acetonitrile) using a capillary C_{18} (75 μm × 150 mm) column. The Q-TOF API system was operated in V-mode with 10 000 resolving power and with positive mode ESI using nanospray. Tandem MS for observation of fragmentation sequences was performed using argon atoms for decomposition of molecular ions and peptides/proteins were identified by use of a *V. vinifera* protein and other sequence databases. Twelve grape proteins (pathogenic related, lipid transfer, thaumatin-like, endochitinase and vacuolar invertase proteins) and six yeast proteins, but no fining agent proteins, were found in Portugieser wine.

Using two procedures, proteins from Australian Semillon must and wine were identified by nano LC-MS/MS (Marangon *et al.*, 2009). This time, grape proteins were precipitated by addition of ammonium sulfate, then the protein pellet was redissolved in a Tris-HCl buffer containing 15% glycerol and 1.5% SDS, and subjected to SDS-PAGE separation, excised and, as above, the tryptic digests were subjected to capillary RPHPLC-MS/MS, using nanoelectrospray ionization and a TOF analyzer. Additionally, the protein pellet was subjected to hydrophobic interaction chromatography and five fractions from this were further fractionated by preparative HPLC and all but one of these fractions were subjected to SDS-PAGE in nonreducing conditions and then treated as above, but this time reversed phase capillary gradient elution LC-MS/MS analysis was carried out using a 1.8 kV electrospray voltage and an ion trap analyzer.

LC-MS/MS lends itself well to the analysis of pesticide residues (Section 5.10.2) and mycotoxins (Section 5.11.4) in alcoholic beverages or their raw materials, although in many cases, GC-MS is the preferred method (Section 4.3.2). Generally an extraction/focusing step is required, so that the more concentrated residues can be analyzed in a simplified matrix. Liquid–liquid extraction (Section 4.2.2) and/or sorbent extraction (e.g. SPE, SPME or SBSE) (Section 4.2.4) techniques are the most widely used. Good sample preparation, good chromatography and optimized MS(-MS) operating conditions will minimize matrix effects and maximize sensitivity and selectivity (Bester *et al.*, 2001). The application of LC-tandem mass spectrometry to the analysis of pesticide residues in environmental and food samples has been extensively reviewed (Picó *et al.*, 2004; Budde, 2004). Reversed phase HPLC using minibore columns, with gradient elution, quadrupole (including QqQ) and ion trap (QIT) LC-MS instruments are the most popular, but the more recent hybrid quadrupole-time of flight (Q-TOF) instruments are gaining ground.

LC-MS methods are often developed to analyze a single pesticide residue or residues of specific chemical types in a variety of crops (e.g. cereal, fruit and vegetable matrices), such as the determination of imidazoles and phenylureas in fruit (Bester *et al.*, 2001), fuazipof and imidazolines in cereals, fruit and vegetables (Bolygo and Boseley, 2000), but methods have been developed for the analysis of a wide range of residues, such as amides, benzylimidazoles, carbamates, organophosphates, phenoxy acids, strobilurins and triazoles, often with due consideration of matrix effects (Blasco *et al.*, 2003; Zrotlikova *et al.*, 2003).

Residues of six fungicides (bitertanol, carboxin, flutriafol, pyrimethanil, tebuconazole and triadimefon) in Spanish wine grapes were determined using LC-MS with both APCI and electrospray ionization in positive or negative ion mode, where APCI in positive mode showed the greatest sensitivity (Juan-García *et al.*, 2004). Two extraction/focusing techniques were also compared: SPE and SBSE; the in the latter case, the analytes

being desorbed from the stir bar by sonication in methanol for 15 min. The HPLC conditions were C_{18} reversed phase (150 mm × 4 mm) with methanol-water gradient elution at 0.8 ml/min. The operating conditions for APCI (positive mode) were capillary voltage 4 kV, corona current 10 μA, vaporizer temperature 325 °C and drying gas temperature 250 °C. The limits of quantification were 0.003–0.01 mg/kg (SPE) and 0.01 mg/kg (SBSE).

Cereal crops used for the production of foodstuffs, including alcoholic beverages, are more or less susceptible to a number of fungal infections that give rise to residual mycotoxins in the foodstuff or beverage (Section 5.11.4). These substances usually pose a potential health hazard even at low concentrations and hence require reliable, sensitive and accurate methods for their analysis. LC-MS can provide such methods: 12 mycotoxins (aflatoxins G1, G2, B1 and B2, deoxynivalenol, diacetoxyscripenol, fumonisin B1 and B2, nivalenol, ochratoxin A, T2-toxin and zearalenon) were determined simultaneously in various food products after acetonitrile:water (80:20 v:v) extraction, but with no sample clean up (Huls *et al.*, 2004). The HPLC conditions were reversed phase on a midbore (100 mm × 2.1 mm i.d.) column using gradient elution (0.1% aqueous formic acid; 0.1% formic acid in acetonitrile) and a flow rate of 0.3 ml/min. A heated electrospray was used for ionization and the MS (QqQ) scan mode was highly sensitive reaction monitoring, giving greater sensitivity than standard ESI and single quadrupole instruments. For example, fumonisin B1 and B2 could be quantified at levels well below 0.5 μg/l (0.5 ppb).

A similar reversed phase (C_{18}) minibore LC-MS method, using an MSD with ESI and quadrupole analyzer was able to separate and quantify deoxynivalenol (DON) (vomitoxin) and T-2 toxin in cereal grains (Moncur, 2004). Gradient elution (water; methanol) was used, with a flow rate of 0.2 ml/min at 40 °C column temperature.

Although wine aroma components are volatile and are generally studied by GC-MS (Section 4.3.2), many exist in grape must and wine as glycosides and as such are nonvolatile and hence do not contribute to aroma until hydrolyzed. Terpene glycosides were tentatively determined in must by LC-MS (Prosen *et al.*, 2007). HPLC conditions were reversed phase using gradient elution (acetonitrile:0.5% aqueous acetic acid). The ESI ion source voltage was 5.5 kV and the temperature was 400 °C.

The Maillard reaction (Section 2.6.2) is important in the formation of special aromas and flavors in dark beers and also in certain wines, such as Madeira (Section 2.10.6), that have undergone heat treatments. In reality there are many reactions that constitute the Maillard reaction, involving a large number of intermediates. Maillard intermediates, such as dicarbonyl compounds (e.g. glyoxal, methylglyoxal, diacetyl and pentane-2, 4-dione) and keto acids such as α-keto-γ-(methylthio)butyric acid and β-phenylpyruvic acid were determined by LC-MS (and also as their quinoxaline/quinoxalinol derivatives by HPLC-UV or HPLC-fluorescence) (Silva Ferreira *et al.*, 2007). ESI mass spectra of pure standards were analyzed by LC-MS in both positive and negative ion mode by flow injection.

4.3.4 Counter Current Chromatographic Methods

Counter current chromatography (CCC) can be regarded as a kind of automated liquid–liquid separation procedure or as a kind of partition chromatography in which the liquid stationary phase is not supported in any way. In either view, the analytes, originally in the mobile phase, are partitioned between that phase and an immiscible stationary phase. There are many versions of CCC, summarized in Figure 4.3.18, but probably that which is most popular today is high speed counter current chromatography (HSCCC). This technique uses a rapidly rotating (centrifugal) helical coil to promote mixing and settling cycles, along with their partition chromatographic steps, at a great rate (up to 70 000 cycles per hour). In this way, highly efficient separations can be achieved, from analytical (milligram) levels to full preparative (gram) levels. Many versions of this technique make use of two rotation axes, thus inducing a planetary motion of the coil. In many cases the two

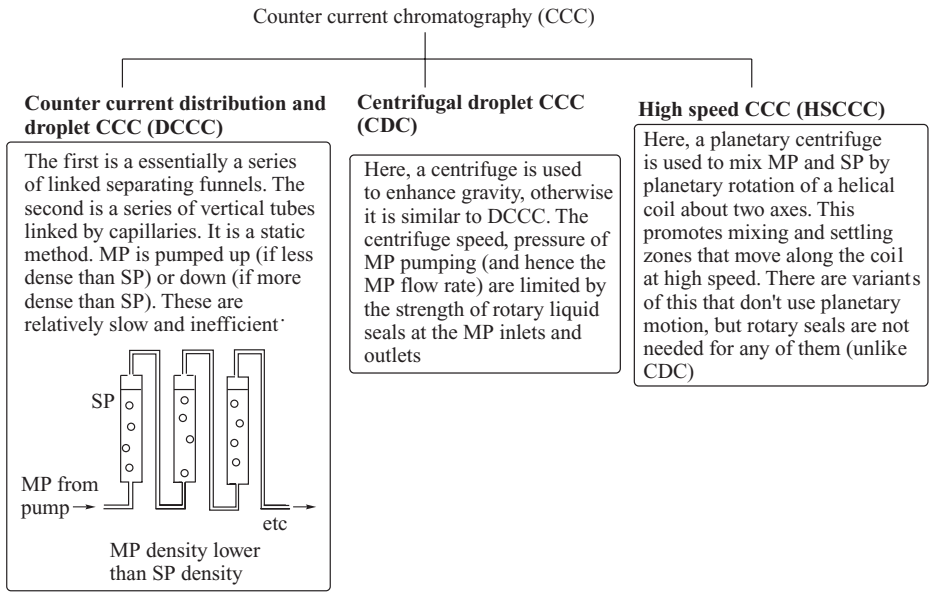

Figure 4.3.18 *Versions of counter current chromatography*

immiscible phases (known as the mobile and stationary phases or head and tail phases, according to how the coil is wound around the holder and the direction of the rotating axis) have an auxiliary solvent that is miscible in both phases to aid partitioning.

Counter current chromatography can be used to both fractionate complex mixtures and to isolate individual components, although the latter is usually performed along with other techniques, such as column chromatography or HPLC. In this way, CCC (usually HSCCC) has helped in the identification of many new constituents of alcoholic beverages (especially wines), mainly by NMR and mass spectrometry.

Application of CCC to alcoholic beverages appears to be in two main areas; fractionation and isolation of flavor precursors (often as glycosides) and fractionation, characterization and isolation of phenolic compounds, especially anthocyanins and their derivatives. Baderschneider and Winterhalter (1997), Roscher and Winterhalter (1993) and Winterhalter *et al.* (1997) used CCC, along with other techniques to fractionate and identify a number of glycosidic components of Riesling grapes or leaves. The aglycones of many of these compounds are flavor compounds or possible flavor compound precursors. In some cases, (e.g. Roscher and Winterhalter, 1993), vine leaves were used as a source of natural products, when it was known that compounds common to vine leaves and grape juice are found at much higher levels in the leaves. In the above study, multilayer coil counter current chromatography (MLCCC) was used to separate leave glucosidic compounds into eight fractions, each of which was tested on its ability to generate 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN), an important flavor component of mature Rheinreisling wines, giving rise to 'petroleum' notes. 3,4-dihydroxy-7,8-dihydro-β-ionone-β-D-glucopyranose was indicated as a major TDN precursor. MLCCC is a variant of HSCCC. More recently, Baderschneider and Winterhalter (1997) used similar methods to isolate a new aroma precursor, 2-ethyl-3-methylmaleimide-*N*-β-D-glucopyranose, from Riesling wine. MLCCC was used to isolate the fraction containing this compound, which was subsequently acetylated, purified by HPLC and characterized by spectroscopic methods. Similarly, the glucose ester of (*E*)-2,6-dimethyl-6-hydroxyocta-2,7-dienoic acid was isolated from Riesling wine by CCC and subsequent acetylation and purification by

flash chromatography and HPLC. It is possible that the compound is a precursor of wine lactone, a powerful flavor compound found in many wines (Winterhalter *et al.*, 1997).

However, the majority of applications of CCC to alcoholic beverages is in the analysis of phenolic compounds in red and white wines. Firstly, some less well studied phenolic compounds of Riesling wine (benzoic acid derivatives, cinnamic acid derivatives, flavonoids and lignans) were isolated in various fractions using MLCCC (Baderschneider and Winterhalter, 2001). Many compounds were characterized by NMR, MS and UV spectroscopy, including 12 benzoic acid and cinnamic acid derivatives, two other phenyl propanoids, seven stilbenes, dihydroflavonols, four dihydroflavonol glycoconjugates, six lignans and three neolignans, with many compounds being reported for the first time in Riesling wine. Using similar methods, seven novel stilbenes, including dimeric species, had previously been isolated from Riesling wine (Baderschneider and Winterhalter, 2000).

Secondly, HSCCC, with the aid of semi-preparative HPLC, has been used to isolate novel anthocyanin derivatives (pigments) in red wines, such as pinotin A in the wines of Pinotage, an important South African variety (Schwarz *et al.*, 2003). The new compound, a malvidin-3-*O*-β-D-glucopyranoside, 4-vinylcatechol adduct, was fully characterized by LC-ESI-MS^n and one and two dimensional NMR (Section 4.4.1).

Still in the realm of grape and wine pigments, centrifugal precipitation chromatography (CPC) was adapted from protein fractionation by ammonium sulfate precipitation to fractionate polymeric pigments from red wine and black tea (Degenhardt *et al.*, 2001). In CPC, the separation column is made up of two high density polythene disks equipped with mutually mirror imaged spiral grooves. A dialysis membrane is sandwiched between the disks, which form two identical channels separated by the membrane. The disk and membrane assembly is mounted on a seal-less continuous flow through centrifuge set to 2000 rpm. The column was entirely filled with hexane or MTBE. The sample was introduced through a 1 ml sample loop. Rotation was applied and then the upper channel was eluted with a linear hexane (or MTBE)/ethanol gradient at 0.5 ml/min using an HPLC pump. The lower channel was eluted with ethanol at 0.06 ml/min with a syringe pump. The sample entered the system from the outer terminal of the lower spiral channel, whereas the MTBE/ethanol gradient was eluted through the upper channel in the opposite direction. Elution was monitored by UV absorption. Solvent gradients are generated in the separation channel by the action of circular motion, where polymeric pigments are precipitated in hexane or MTBE rich solvent and experience increasing ethanol concentration. Thus, repetitive precipitation and dissolution of the analytes occurs along the channel. HPLC analysis of early fractions clearly showed the presence of lower molecular weight phenolic compounds, as well as higher molecular weight species, whereas the lower molecular weight species were missing from the late fractions. The main limitation of CPC was its low sample capacity; scaling up from analytical scale to semi-preparative would enable determination of the degree of polymerization and identification of the monomeric units could be determined by NMR, MS and other analyses.

A good example of a scaled up MLCCC procedure is the fractionation of anthocyanin classes from grape pomace and skins (Vidal *et al.*, 2004). Here, a *tert*-butyl methyl ether:*n*-butanol:acetonitrile:water acidified with trifluoroacetic acid (2:2:*x*:5) solvent system was chosen, with step gradient elution. The amount of material loaded on the system varied between 100 mg and 2000 mg, the coil volumes varying between 100 ml and 700 ml accordingly. Monomeric anthocyanins were separated into their glucosides and corresponding acetylated, coumaroylated and caffeoylated derivatives and identified by UV spectrometry, mass spectrometry and RPHPLC retention times. Isolation of comparatively large quantities of pure anthocyanins is useful in that the compounds can be used as references for analytical methods, as subjects for model studies (e.g. for oxidation or polymerization reactions) and for sensory analysis.

Another good example of the application of HSCCC to wine analysis is the rapid isolation of malvidin 3-glucoside (a major pigment in grape skins and new red wine), following sample clean up on an Amberlite XAD-7 column, in quantities and purities that are sufficiently high for use as an analytical standard (Degenhardt *et al.*, 2000). At the time of writing (2009), a 1 mg/ml solution of malvidin 3-glucoside in ethanol costs around $200 per ml.

4.4

Spectroscopic Methods

Exchange of atomic and molecular energy (i.e. absorption and emission) is quantized – it can only occur in discrete packets or quanta. All types of spectroscopy (except some forms of mass spectrometry) involve the absorption of a quantum of electromagnetic radiation (Figure 4.4.1) by the molecule, thus promoting an energy transition in the molecule from the ground state or a lower energy state to an excited state. The energy of a quantum of radiation, and hence the energy difference between lower and upper atomic or molecular energy levels is given by Equation 4.4.1.

$$E = h\nu = \frac{hc}{\lambda} \tag{4.4.1}$$

where ν is the frequency, λ is the wavelength of radiation, c is the velocity of light and h is Planck's constant.

The type of transition depends on the energy (and hence frequency and wavelength) of the quantum absorbed; relatively high energy ultraviolet and visible radiation (Section 4.4.3) promotes electronic transitions, whereas less energetic infrared radiation (Section 4.4.2) promotes vibrational and rotational transitions (Figure 4.4.1). Even less energetic microwaves and radio waves promote electron spin and nuclear spin transitions (respectively), in the presence of an applied strong magnetic field (Section 4.4.1).

Many spectroscopic techniques (e.g. atomic absorption, infrared and UV-visible spectroscopy) involve measurements of the absorption of electromagnetic radiation by atoms or molecules. This is known as absorption spectroscopy. Emission spectroscopy (e.g. atomic emission and fluorescence spectroscopy) involves the measurement of emitted radiation. For a great many substances, under a reasonable range of conditions (e.g. in solution over a range of concentrations), Beer's law is obeyed, which gives a linear relationship between the extent of absorption or emission and the concentration of the absorbing or emitting species.

Relaxation of excited molecules back to a lower energy state can occur in a number of ways, which include radiationless transitions as well as emission transitions, as shown in Figure 4.4.2. Here, the radiationless relaxation transitions are shown occuring between vibrational levels after absorption of visible radiation by the molecule. Although these transitions are rapid, they are slow compared with emission transitions, which then occur at lower energy (longer wavelength) than the absorption. This phenomenon is known as fluorescence; it can be seen from Figure 4.4.2 that the fluorescence emission spectrum will be more or less a mirror image of the absorption spectrum, but occurring at longer wavelength. Theoretically, all organic molecules are capable of fluorescence, but in practice generally those molecules with extended conjugated

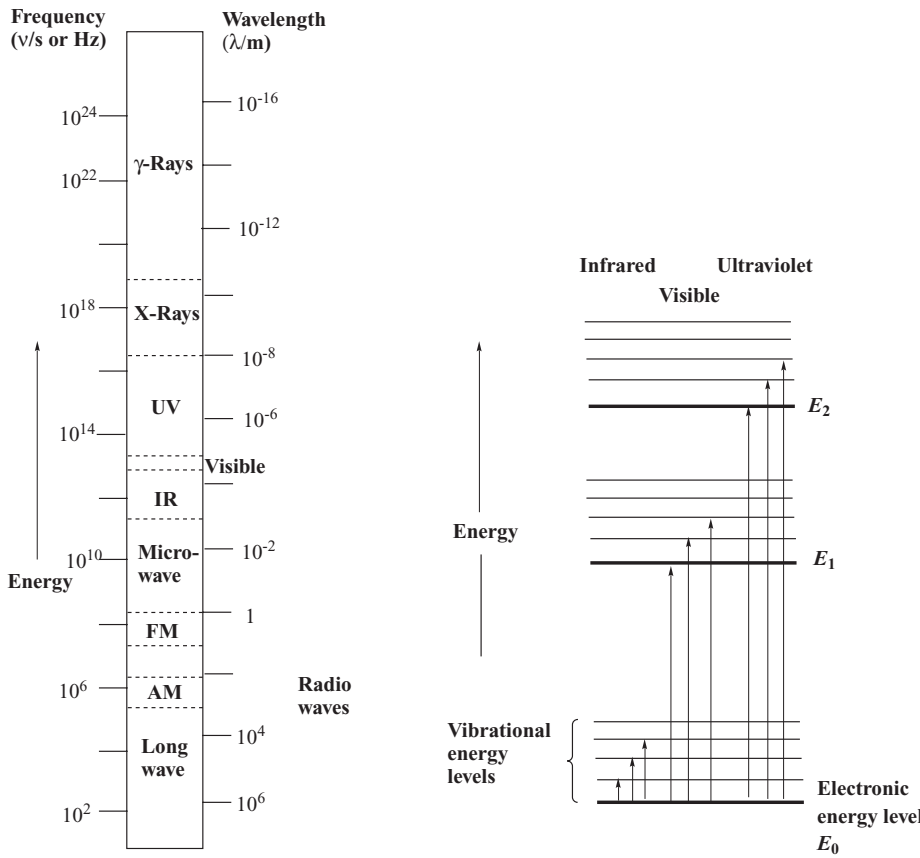

Figure 4.4.1 *The electromagnetic spectrum and energy levels involved in infrared and UV-visible spectroscopy, showing some transitions following absorption of radiation. Rotational levels (not shown) occur between each vibrational level*

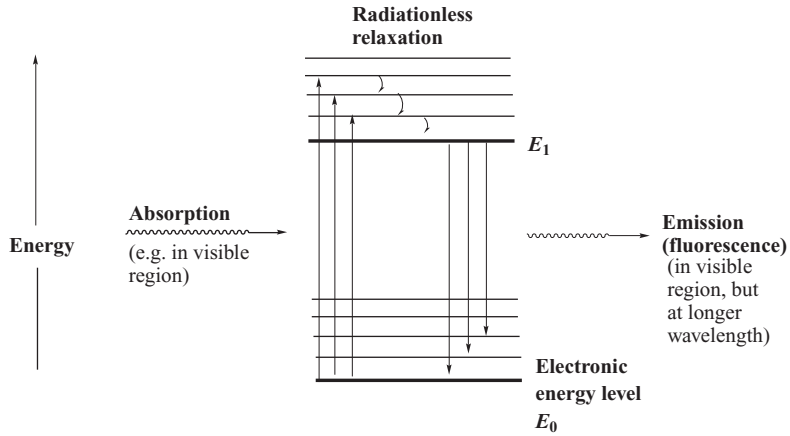

Figure 4.4.2 *Energy changes that occur during fluorescence. See also Figure 4.4.1*

or aromatic groups give the most readily observed fluorescence spectra. The intensities (absorbance) of fluorescence spectra are usually high compared with the corresponding absorption spectra, thus giving an advantage in sensitivity, which can be useful in the analyses of trace components (Section 4.4.3).

Spectroscopic methods are of prime importance in the analysis of alcoholic beverages, as in other areas of science; they enable the identification, quantification and often the determination of the structures of components. These, in turn, enable a better understanding of some of the molecular processes that occur during the production and consumption of alcoholic beverages, such as fermentation, maturation (including the influence of oak), fining, filtration, foam production and interactions between molecules that contribute to organoleptic qualities.

A basic knowledge of spectroscopy at the undergraduate level is assumed for this section, so there is no detailed account of any spectroscopic method given here. Instead there are introductory paragraphs that are designed to give an outline account and set the scene for each technique as applied to the analysis of alcoholic beverages. Within these paragraphs certain features that are considered especially important are dealt with in a bit more detail.

4.4.1 Nuclear Magnetic Resonance

Like electrons, certain atomic nuclei possess spin, and this circulation of charge generates a magnetic moment along the axis of spin. These nuclei are called 'magnetic nuclei' and are characterized by an overall 'spin' (more correctly, spin quantum number, symbol I) that is nonzero in value. By far the most important nuclei in alcoholic beverages are ^{1}H and ^{13}C (both with $I = {}^{1}/_{2}$), although ^{2}H (D) ($I = 1$) is important in certain applications (see below). For detailed discussions on NMR spectroscopy, the reader is referred to Lambert *et al.* (1998), Silverstein *et al.* (2005) and Nelson (2003).

The NMR phenomenon arises from transitions between energy levels, just as in other types of spectroscopy. In NMR, transition occurs when nuclei in a strong magnetic field B_0 are subjected to a radiofrequency field B_1 (frequency ν), normally applied in the x direction, with B_o in the z direction.

Because the energy levels are so close together (even in the strongest magnetic fields available, separation is in millijoules, mJ), thermal motions tend to equalize the energy level populations. For example, for ^{1}H in a field of 7 Tesla at room temperature, the excess fraction in the lower energy level is only 5×10^{-5}. The near equality of population of the two levels is ultimately responsible for the insensitivity of NMR, compared with other spectroscopic techniques. Compounding this are relatively low sensitivities and natural abundances of key nuclei such as ^{13}C (1.1%) – ^{12}C is nonmagnetic – coupled with the low concentrations of many important components of alcoholic beverages. However, advances in electronic engineering and computer technology have largely minimized these problems and NMR spectroscopy takes its rightful place in the armory of analytical methods for the study of alcoholic drinks and other foodstuffs.

Nowadays, it is much more common to have the RF field (B_1) applied as a short pulse, rather than continuously. This is the basis of Fourier transform (FT) NMR, as opposed to continuous wave (CW) NMR spectroscopy. Rather than considering individual nuclei and their magnetic moments, it is more convenient to consider the bulk substance under investigation, where it is assumed that all the nuclei are of one type, with $I = {}^{1}/_{2}$. In the presence of a strong magnetic field, the nuclei distribute themselves between the two energy levels, so that there is a slight excess of nuclei in the lower level, with spins aligned with the applied field. This results in a bulk magnetization M, where M is a vector with a fixed z component and no x or y components. If the population levels are disturbed (by an RF pulse B_1 in the x direction), then M becomes a vector with a fixed z component, but with x and y components that vary sinusoidally, 90° out of phase – that is, executing a circular motion or precession (Figure 4.4.3). In actuality, perturbation causes a more complex double precession (known as nutation) of magnetization vectors and the whole subject benefits by referring to

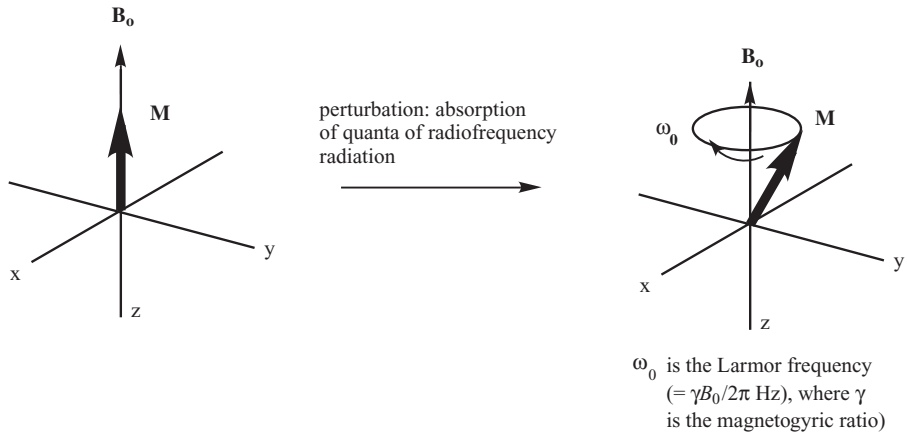

Figure 4.4.3 *Precession of bulk magnetization vector (M) about the z axis upon application of an RF pulse along the x axis*

a rotating frame of reference (x', y' axes), rather than the 'fixed' laboratory frame of reference. If the Larmor frequency and RF pulse frequency are identical, then after the pulse, the magnetization will remain fixed in the $x'y'$ plane of the rotating frame: it will rotate at a frequency of $\gamma B_0/2\pi$ (Hz) with respect to the fixed laboratory xy plane.

The coil that supplies the RF field is wrapped around the (laboratory) x axis (perpendicular the applied field B_0) containing the sample, along with the receiver coil. Hence, the precessing magnetization about the (laboratory z axis) will induce an oscillating current in the receiver coil that can be detected; this is the NMR signal. However, this signal has a limited lifetime (though long compared with pulse duration), since it dies as the nuclei reassume their equilibrium distribution between the two energy levels. This process of signal loss after pulsed excitation (perturbation) is called free induction decay (FID). The signal resulting from just one pulse is likely to be very weak and will be hard to differentiate from the general electronic background ('noise'). Consequently, the pulse, followed by decay time sequence is repeated many times (until the 'signal to noise ratio' is acceptable). The data is accumulated in the computer memory, where noise, being random, gradually diminishes, whereas signals become more intense. Fourier transform can then be carried out on the final FID data to produce the familiar frequency spectrum.

Because a normal organic sample will have nuclei of the same type (e.g. ^{1}H or ^{13}C) in different magnetic environments (corresponding to different locations in different components in the sample), these will have slightly different Larmor frequencies. Hence a pulse of RF field at the nominal precession frequency (say that of ^{1}H or ^{13}C in TMS $(CH_3)_4Si$), will be slightly offset from the actual resonant frequencies of the nuclei in the sample molecules. Consequently, the FID patterns for each environmentally identical set of nuclei will be different, depending on this offset or frequency difference. This gives rise to a complex combined FID pattern for the sample that is unraveled by the application of Fourier transform into a series of peaks at different frequencies, with respect to TMS (chemical shift), corresponding to the various magnetic environments that exist for the nuclei in the sample molecules.

The final position of the magnetization will depend on the time duration of the RF pulse (t_p), which is usually a few microseconds. The flip (or tip) angle (θ) through which the magnetization is flipped from the z axis is given by Equation 4.4.2.

$$\theta = \gamma B_1 t_p \tag{4.4.2}$$

Since in practice, the pulse duration that is needed to produce a particular flip angle varies somewhat from day to day, it is standard practice to refer to this duration by the effective flip angle rather in time units. Thus a pulse width is often described as 90° (in degrees) or $\pi/2$ (in radians), rather than in microseconds.

In practice, the relationship between the pulse width and the flip angle is observed by varying the pulse duration and examining the resultant NMR signal intensity. Since the magnetization is measured in the *xy* plane there will be a sinusoidal variation in the intensity with pulse width, as shown below.

Pulse width	$\pi/2$	π	$3\pi/2$	2π
Intensity	Maximum +	0	Maximum –	0

The most common representation of an NMR experiment, in terms of pulse and acquisition times (etc.), is shown in the Figure 4.4.4, illustrated for one of the simplest kinds of NMR experiments, where the pulse width tips the magnetization on to the y' axis (90°). Repeated acquisition of the FID data and Fourier transform of the accumulated data in the time domain at the end of the experiment gives the familiar 1D NMR spectrum in the frequency domain, showing separate peaks at different chemical shifts for each magnetically different nucleus. Such spectra, with spin–spin coupling normally included for ^{1}H, but removed or subdued for ^{13}C, using broadband decoupling (or nowadays using a form of WALTZ proton decoupling) or *J*-scaling (respectively), are often sufficient for the characterization of smaller, less complex molecules. More complex molecules, with more C–H connectivities, usually need more sophisticated 1D techniques for full characterization, such as Distortionless Enhancement by Polarization Transfer (DEPT), Incredible Natural Abundance Double Quantum Transfer Experiment (INADEQUATE), Insensitive Nuclei Enhanced by Polarization Transfer (INEPT) or Nuclear Overhauser Effect Difference spectroscopy (NOED) – or 2D techniques such as (homonuclear) correlation spectroscopy (COSY), heteronuclear correlation spectroscopy (HETCOR), homonuclear multiple bond coherence spectroscopy (HMBC), heteronuclear multiple quantum coherence spectroscopy (HMQC), nuclear Overhauser effect spectrocopy (NOESY) or total correlation

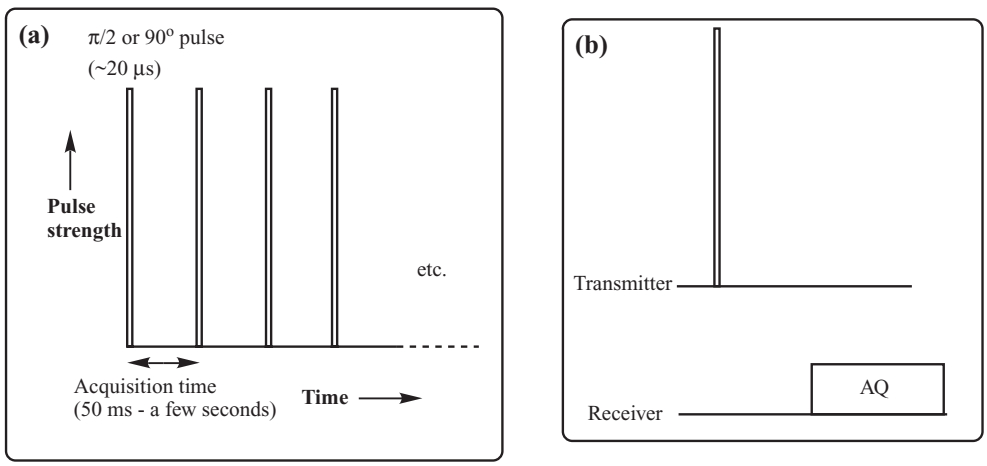

Figure 4.4.4 *Representation of the most basic NMR experiment. Not drawn to scale. (a) shows detail of pulse and acquisition times, (b) is a shorthand presentation. Other shorthand versions exist - e.g. with transmitter and receiver representations on same line and with a FID picture for AQ*

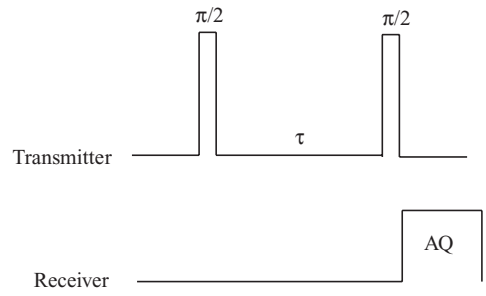

Figure 4.4.5 *Pulse sequence for COSY-90 experiment*

spectroscopy (TOCSY). These techniques, although involving much more complex pulse sequences than that shown in Figure 4.4.4, are now routine.

Multidimensional NMR techniques have been developed to cope with such complex examples: in particular, H–H Correlation Spectroscopy, better known as COSY and H–non-H Correlation Spectroscopy, known as HETCOR. A COSY spectrum is usually a plot of ^{1}H chemical shift on both the *x* and *y* axes, whereas a HETCOR spectrum is usually a plot of ^{1}H chemical shift on one axis against the chemical shift of some other nucleus (usually ^{13}C) on the other axis. The peaks in the whole COSY spectrum (plotted as contour lines derived from a 'stack plot') lie along a diagonal line with cross peaks, representing coupled nuclei. To analyze a COSY spectrum, firstly a diagonal is drawn through the contour lines. The contour lines that are not on the diagonal (called 'cross peaks' or 'off-diagonal peaks') contain the coupling information.

The basic COSY (strictly COSY-90 or COSY-$\pi/2$, since other versions are used) pulse sequence is shown in Figure 4.4.5. Here, τ is an incremental delay. Considering a single line in a complex multiplet, a pulse of $\pi/2$ causes the magnetization vector to precess in the *xy* plane at a frequency ν_1 that depends on the its chemical shift and on each of the couplings with which the multiplet is involved (Figure 4.4.6).

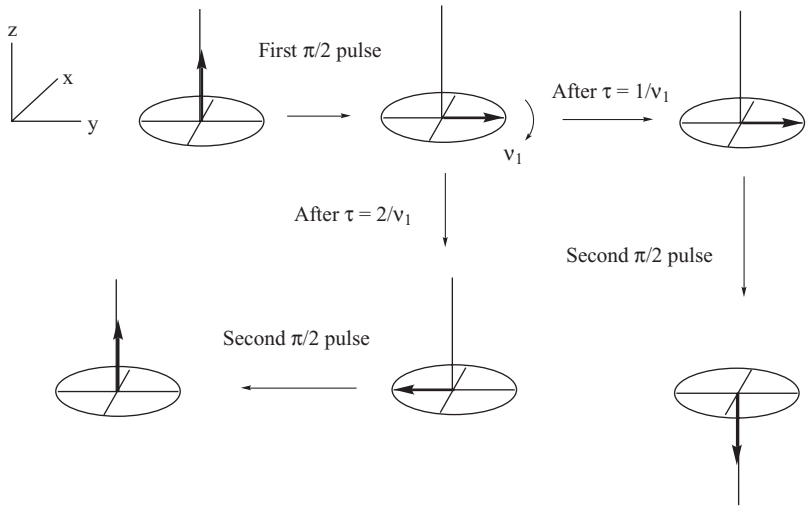

Figure 4.4.6 *Signal intensities and time delay (τ) between COSY-90 pulses*

If the evolution time, $\tau = 1/\nu_1$, then at the end of that time, the vector will be aligned along y and so the second $\pi/2$ pulse will rotate the vector down along the $-z$ axis (see below). This results in inversion of the population distribution for that pair of energy levels and for all the connected transitions in the other resonances to which the proton is coupled (Figure 4.4.6). On the other hand, if $\tau = 1/2\nu_1$, then after that time, the vector will be aligned along $-y$ and the second $\pi/2$ pulse will return the vector to the z axis, resulting in normal population distribution (Figure 4.4.6).

Intermediate values of τ give intermediate results and repeating many experiments with incremented τ results in a set of spectra that have normal chemical shift values and normal coupling, but each peak contains coded information about the frequencies of all other peaks to which it is coupled. The second Fourier transformation then gives a spectrum with ^{1}H chemical shifts in each dimension. The normal spectrum is now found along the diagonal because the intensity of each transition oscillates at ν_1 during t_1 and because its detected frequency in t_2 is also ν_1. The off diagonal 'cross peaks' determine which chemical shifts are connected to which, because the intensity of the ν_1 transition is modulated during t_1 by all the transitions to which it is connected.

HMBC is a particular 2D HETCOR technique used to correlate (determine the connectivity between) ^{1}H and ^{13}C peaks for nuclei separated by (usually) two or three multiple bonds, whereas HMQC indicates direct C–H coupling. HMBC is often used to assign quaternary carbon atoms.

Additionally, the stereochemistry of complex beverage molecules, such as dimeric and oligomeric sugars, can be deduced from NOESY, a technique that makes use of through space interaction between magnetic nuclei (in the same molecule), known as the nuclear Overhauser effect (NOE). Signal enhancement or diminution depends on the magnetogyric ratios of the interacting nuclei and on their proximity; NOE is more pronounced for nuclei that are spatially close.

Signal enhancement due to NOE is an example of cross polarization, a through-space effect in which polarization of spin states of one type of nucleus (say ^{1}H) caused by irradiation (B_1) induces polarization of spin states of another nucleus (say, ^{13}C or ^{1}H). In general, the maximum NOE enhancement is given by Equation 4.4.3.

$$\mathrm{NOE}_{\max} = \frac{1}{2}\left(\frac{\gamma_{\mathrm{irr}}}{\gamma_{\mathrm{obs}}}\right) \tag{4.4.3}$$

Here, γ_{irr} is the magnetogyric ratio of the nucleus being irradiated and γ_{obs} is that for the nucleus under observation. The total (maximum) line intensity is given by $1 + \mathrm{NOE}_{\max}$. Hence, in the case of proton decoupled ^{13}C NMR spectra, the ^{13}C signal can be enhanced up to 200% by the irradiation of protons. This value is a theoretical maximum; most actual ^{13}C lines exhibit less (sometimes much less) than maximum enhancement. Two dimensional NOESY spectra contain cross peaks that represent resonances from nuclear spins that are spatially close. The one dimensional nuclear Overhauser effect difference spectroscopy (NOED) technique is carried out by selecting particular resonances in a molecule for irradiation with an RF pulse, observing the effect on other resonances in the NOE spectrum, and then subtracting the normal NMR spectrum from this. Only those peaks that have significant NOEs with the resonance of interest (the irradiated one) are revealed in the NOED spectrum.

High resolution NMR (mainly ^{1}H and ^{13}C) has been applied extensively to the study of alcoholic beverages and some of the processes involved in their production since the 1970s. The major applications are:

- Identification or structure elucidation of specific components (often with the aid of other spectroscopic techniques, such as mass spectrometry)
- Quantitative determination of specific known components
- Time course studies (e.g. of fermentations, oxidations, etc.)
- Determination of D/H ratios by site specific isotopic fractionation-NMR (SNIF-NMR).

The reader is referred to the reviews of Martin (1988), Rapp *et al.* (1988), Rapp and Markowetz (1990a) and Košir and Kidrič (2002) for general accounts of the application of NMR spectroscopy to alcoholic beverages.

Many of the NMR reports on alcoholic beverage analysis involve the use of statistical or chemometric analysis for interpretation of results (e.g. Petrakis *et al.*, 2005; Conte, 2008; Son *et al.*, 2009).

Identification or structure determination of specific components (often after extraction from the wine sample) includes acetic acid (Weekley *et al.*, 2003) and other acids (Avenoza *et al.*, 2006), amino acids (Košir and Kidrič, 2001; 2002), red wine pigments (Tamura *et al.*, 1994; Bakker and Timberlake, 1997; Fulcrand *et al.*, 1998; Cabrita *et al.*, 2000; Degenhardt *et al.*, 2000; Es-Safi *et al.*, 2000; Atanasova *et al.*, 2002; Schwarz *et al.*, 2003; Mateus *et al.*, 2006), terpenoids (and their glycosides) (Baltenweck-Guyot *et al.*, 1996; 2000; Collado *et al.*, 1996; Bonnländer *et al.*, 1998) phenolic substances (Escribano-Bailón *et al.*, 1996; Guyot *et al.*, 1996a; Yeap Foo *et al.*, 1998; Saucier *et al.*, 1997; Dufour and Bayanove, 1999; Lu and Foo, 1999; Baderschneider and Winterhalter (2000); Remy-Tanneau *et al.*, 2003) and a variety of aroma compounds (many of which are terpenoids or norisoprenoids) (Guth, 1996; Versini *et al.*, 1996; Guth, 1997; Dufour and Bayanove, 1999; Marchand *et al.*, 2002). Also, additives and residues have received some attention from NMR spectroscopists (Rapp *et al.*, 1986; Mojsiewicz-Pienkowska *et al.*, 2003).

NMR spectroscopy (especially ^{13}C NMR) is a powerful tool for the simultaneous qualitative and quantitative determination of beverage components in whole samples. Identification and quantitation by this method are possible for components with known chemical shifts, but structure elucidation of unknown components is not; instead, these generally need to be isolated from the sample as pure compounds and analyzed separately. Typically, the sample is prepared by mixing beverage (1.0 ml) and D_2O (0.2 ml) or D_2O (0.2 ml) with 1,3-propanediol as internal standard for quantitative work. For abundant constituents (>1 g/l), the sample can be analyzed whole, but for minor analytes (<1 g/l), some method of focusing (e.g. by vacuum distillation) is required. For example, a standard 1D ^{13}C NMR spectrum of a wine sample after less than an hour of data accumulation will readily show ethanol, glycerol, carboxylic acids and the major sugars, fructose and glucose (Rapp and Markowetz, 1990b), although the spectra of the latter are complex due to the presence of various anomeric forms. Thus, glucose exhibits 12 signals arising from the α- and β-glucopyranose anomers, whereas fructose gives 30 signals arising from α- and β-fructofuranose, α- and β-fructopyranose and keto anomers. On the other hand, minor sugars such as arabinose, galactose, mannose, rhamnose and trehalose are detected more easily in the wine concentrate. Likewise, amino acids, anthocyanins, esters, minor acids, lactones and polyols and can be identified in wine concentrates (Košir and Kidrič, 2001) or even intact wines (Košir and Kidrič, 2002; Brescia *et al.*, 2003). One and two dimensional NMR (Gradient-selected COSY, TOCSY, HMQC and HSQC) were used to identify 17 amino acids and γ-aminobutyric acid in freeze-dried Slovenian wine samples (Košir and Kidrič, 2001). A WET pulse sequence was used to suppress strong proton signals arising from water (4.80 ppm), ethanol (3.64 ppm), glycerol (3.62 ppm) and other relatively abundant components. Later, Košir and Kidrič (2002) used 1D NMR spectra of amino acids in white wines and chemometric analysis to determine the grape varieties responsible for the wines. The use of signals from seven amino acids allowed good statistical separation of wines according to vine variety, whereas if the signals from butylene glycol, glycerol and succinic acid were included in the chemometric analysis, separation of wines between coastal and continental regions of Slovenia was achieved.

Alcoholic beverages are of such compositional and molecular complexity that even using the most modern high field NMR instruments to investigate the complete beverage, signal overlap, poor signal intensity or lack of coupling information can lead to incomplete or ambiguous assignments. In order to improve this situation, diffusion ordered spectroscopy (DOSY) has been applied to the analysis of differences in constitution of Port wines of varying ages (Nilsson *et al.*, 2004a; 2004b). DOSY is used to separate signals on the basis of their diffusion coefficients, which are related to the hydrodynamic radii (apparent molecular size) of the molecules giving rise to the signals. The DOSY technique offers a means of integrating diffusion encoding into multidimensional pulse sequences. A series of pulsed field gradient stimulated echo NMR spectra is

obtained with increasing gradient pulse strength. These signals then decay at rates that are determined by their diffusion properties. The version of DOSY (2DJ-IDOSY) pioneered by Nilsson *et al.* (2004b), using a simpler, more sensitive pulse sequence, improved the signal to noise ratio by a factor of 2 and reduced experimental time by a factor of 4. Using this technique, Port wines of different ages were found to differ largely by the relative concentrations of amino acid, organic acids, an unidentified (possible) disaccharide and large aromatic species, probably polymeric polyphenols (Nilsson *et al.*, 2004a). In particular, the older wines had lesser amounts of these compounds, probably as a result of significant precipitation during the course of maturation.

Quantitative ^{1}H NMR has also been used in the analysis of organic acids and amino acids in beer (Nord *et al.*, 2004), polyphenols in cider apple juice (Berregi *et al.*, 2003a; 2003b) and methanol and other components in zivania, a traditional Cypriot pomace spirit (Section 3.7.3) (Petrakis *et al.*, 2005). In the last mentioned study, the NMR data in the region 5.5–1.1 ppm, for many versions of zivania and many other European spirits, were used for processing by canonical discriminant analysis (CDA). The method, validated against a comparable GC method, gave a satisfactory degree of prediction and classification between zivania brands and other European (including Greek) spirits.

Contaminants, such as methanol, and illegal additives, such as diethylene glycol (Rapp *et al.*, 1986), are easily detected in a standard ^{13}C NMR spectrum of the whole sample.

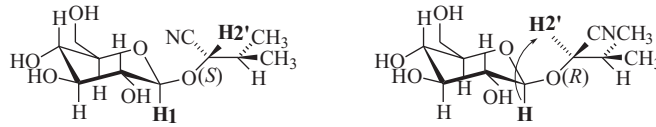
The methods described above, although carried out on whole samples, may require the breaching of a larger sample (e.g. in a bottle, can or cask) and transfer of the small quantity of liquid to an NMR tube, and consequently are invasive and not strictly nondestructive. At the extreme, an NMR probe and spectrometer were developed to study the contents (particularly of ethanol and acetic acid) of intact bottles of wine (Weekley *et al.*, 2003). Careful adjustment of both cryogenic and room temperature magnetic field shims on a 2.01 Tesla 310 mm room temperature superconducting solenoid imaging magnet resulted in an extremely homogeneous magnetic field over the entire bottle of wine giving reasonable resolution (4 Hz line width). Moreover, careful adjustment of the room temperature shims compensated for different bottle shapes, volumes and cork types.

Using a special pulse sequence, ^{1}H signals were found at 4.8 ppm (singlet; water), 3.6 ppm (quartet; $CH_3C\mathbf{H_2}OH$), 2.0 ppm (singlet; $C\mathbf{H_3}CO_2H$) and 1.0 ppm (triplet; $C\mathbf{H_3}CH_2OH$). In this way, using appropriate standards in full bottles, the ethanol and acetic acid contents of wines of different vintages were estimated. Thus, it is possible to determine the quality of an old vintage wine without opening the bottle; the higher the level of acetic acid, the more likely the wine has undergone spoilage, possibly by ingress of oxygen and bacteria through a poor quality, perished or poor fitting cork.

There are numerous examples of the application of NMR spectroscopy to the characterization of new compounds isolated from alcoholic beverages or their precursors, usually by chromatographic methods; only examples of literature where structure determination plays a major role are considered here. Usually, a combination of NMR techniques, involving both ^{1}H and ^{13}C nuclei, is used, such as COSY, DEPT, HETCOR, HMBC, HSQC, NOED, NOESY, SEFT and TOCSY, and often in conjunction with other spectroscopic methods.

Within the realm of carbohydrates, an early example involves the use of NOE combined with molecular mechanics, used to differentiate between heterodendrin and *epi*-heterodendrin, two diastereoisomeric cyanogenic glycosides present in barley (*Hordeum vulgare*) seeds (Lankhorst *et al.*, 1995). *Epi*-heterodendrin in barley is of considerable interest because it is thought to be an important source of the carcinogenic ethyl carbamate in whisky (Section 3.2.2). The NOE between the anomeric proton H1 and the side chain proton H2′ is larger for *epi*-heterodendrin than for heterodendrin, thus indicating a shorter distance between these protons in the former diastereoisomer (Figure 4.4.7). This assertion was supported by molecular mechanics calculations.

Pigments and phenolic compounds in general, especially from colored fruits and their alcoholic beverages, have received considerable attention from NMR spectroscopists. Here, NMR spectroscopy has been



Heterodendrin *Epi*-heterodendrin

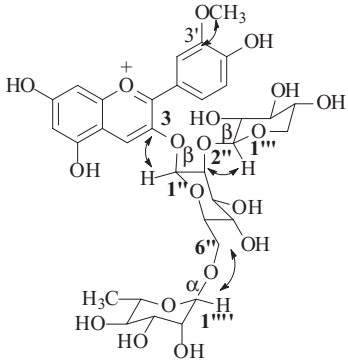
Figure 4.4.7 *Use of NOE to differentiate between heterodendrin diastereoisomers. Lankhorst* et al. *(1995)*

particularly useful in assigning the sugar moieties of anthocyanin and polyphenol glycosides and in determining the structures of oligomers and other condensation products. Novel anthocyanin triglycerides, such as the 3-(6″-α-rhamnosyl)-2″-β-xylosyl-β-glucosides of cyanidin, peonidin and petunidin, were found in the berries of *Vaccinium padifolium*, a member of the blueberry family (Cabrita *et al.*, 2000). The observation of cross peaks from HMBC spectra was used to establish the linkages in the glycoside moieties, as shown in Figure 4.4.8(a) for peonidin 3-(6″-α-rhamnosyl)-2″-β-xylosyl-β-glucoside, although a combination of many techniques, including COSY and TOCSY, were used to assign all the ^{1}H and ^{13}C resonances for these anthocyanins and others in *V. padifolium*. Similarly, Lu and Yeap Foo (1999) identified gallic acid 3-β-glucopyranoside, gallic acid 4-β-glucuronide and 2-hydroxy-5-(2-hydroxyethyl)phenyl-β-glucopyranosides as novel polyphenolic compounds in Chardonnay pomace.

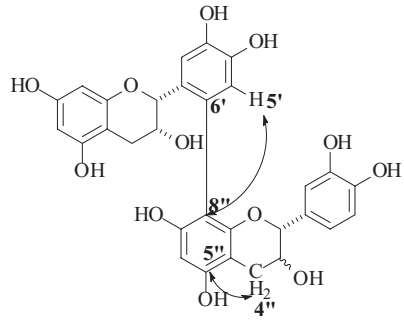
^{13}C and ^{1}H NMR spectroscopies have been used to establish the structures of biphenyl linked flavan-3-ol dimers isolated from Chardonnay pomace (Yeap Foo *et al.*, 1998). In particular, the structures epicatechin [6′→8′]-epicatechin and epicatechin [6′→8′]-catechin (Figure 4.4.8(b)) were established by TOCSY and observation of long range C, H couplings via HMBC (e.g. between H-5′ and C8′; H-4′ and C-5′). Similarly, NMR (along with ESI-MS and molecular mechanics) showed the existence of acetaldehyde mediated flavan-3-ol dimerization in a model wine solution (Saucier *et al.*, 1997). Four isomers were observed for the dimerization of catechin, corresponding to acetaldehyde-bridging at 6-6, 8-8, 6-8 and 8-6 on the A ring of the two catechin monomers, with the 6-8 bridged dimer appearing to be the most abundant isomer, according to HPLC analysis.

NMR spectroscopy has been especially valuable in the determination of the structures of condensation products of anthocyanins, flavan-3-ols and other compounds (including aldehydes, ketones and simple phenols) in grapes (including pomace), wine and model wine solutions. Particularly in the case of ageing red wine, NMR has played a key role in demonstrating that anthocyanins undergo numerous reactions at different rates with wine constituents to produce new pigments, which are more stable than the original anthocyanins. Prior to the discovery of pyranoanthocyanins and similar compounds (including vitisin type derivatives), it was thought that the color changes accompanying red wine aging were due to condensation reactions between original anthocyanins (flavylium ions) and flavan-3-ols (catechins), as well as between flavan-3-ol monomers. Although it is now believed that pyranoanthocyanins are the main pigments in young (say, 1–2 year old) red wines, and therefore the molecules that under condensation during subsequent aging, it is still likely that significant contributions to color changes during the earlier stages of maturation are provided by the reactions mentioned in the previous sentence.

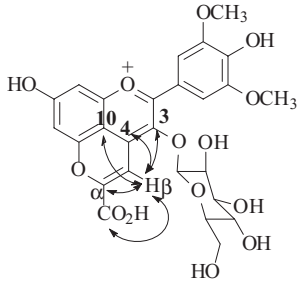
Anthocyanins and catechins, in the presence of acetaldehyde in a model red wine solution were shown to produce dimers and higher oligomers, which were isolated by preparative HPLC or column chromatography and partially characterized by 1D and 2D NMR spectroscopy and FAB-MS (Escribano-Bailón *et al.*, 1996). Although flavan-3-ol dimerizations (and higher oligomerizations) may contribute something to the orange hue of aged red wine, it is more certain that they contribute to the yellow hue of aged white wine (Es-Safi *et al.*, 2000). Simulated aging of a model white wine solution containing (+)-catechin and glyoxylic acid



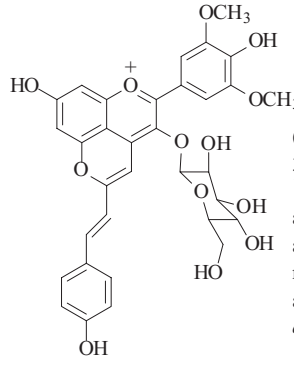
(a) Peonidin 3-(6"-α-rhamnosyl)-2"-β-xylosyl-β-glucoside, showing some HMBC cross-related nuclei. (Cabrita *et al.*, 2000).



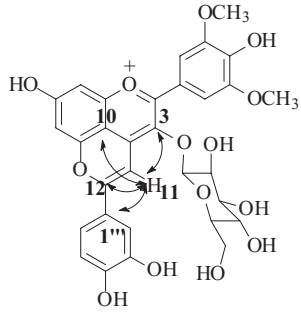
(b) Biphenyl linked flavan-3-ol dimers, showing some HMBC correlations (Yeap Foo *et al.*, 1998).



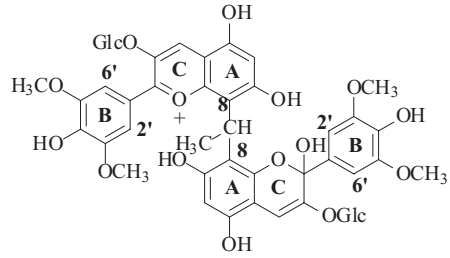
(c) Pyranomalvidin 3-glucoside, showing HMBC correlations for the new pyran ring β proton (Fulcrand *et al.*, 1998).



(d) Vinylpyranomalvidin 3-glucoside-phenol. ^{1}H resonances were assigned using 1-D NMR and *g*COSY; ^{13}C resonances by *g*HMBC and *g*HSQC (Mateus *et al.*, 2006).



(e) Malvidin 3-glucoside 4-vinylcatechol adduct from Pinotage wine, showing selected HMBC correlations. (Schwarz *et al.*, 2003)



(f) Ethyl-linked malvidin 3-glucoside dimer shown in flavylium-hydrated flavylium form. NOESY showed through-space couplings between the central ethyl moeity and H2', H6', OCH_3 of rings B. (Atanasova *et al.*, 2002).

Figure 4.4.8 *Some pigment and polyphenol structures determined largely by NMR. Original notation used*

(a hydrolysis product of tartaric acid) led to the formation of two types of colorless dimers consisting of two flavanol units linked by carboxymethine bridges. After isolation of these dimers and further incubation in alcohol free solution, these were converted to yellow xanthylium salts ($\lambda_{max} \sim 440$ nm and 460 nm) by dehydration, followed by oxidation. NMR spectroscopy showed the colorless dimers to be 6-6, 6-8 (two forms) and 8-8 linked catechins via glyoxylic acid; for example, HMBC for the 6-8 dimers (Figure 4.4.9) indicated correlations between C8a and H2 (for both catechin units), C8a and H4 (for both catechin units),

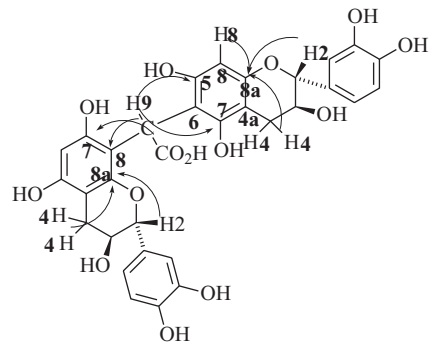


Figure 4.4.9 *HMBC correlations in 6-8 glyoxylic acid-linked dimer of (+)-catechin. Es-Safi* et al. *(2000)*

C8a and H9 (bridge methine proton) (first left hand unit), C8a and H8 (second unit), C5, C7 and H9 (second unit), and C7, C8a and H9 (first unit).

Similarly, Remy-Tanneau *et al.* (2003) demonstrated that an ethanolic (1:1) solution of malvidin 3-glucoside and (–)-epicatechin (or (+)-catechin) kept at 35 °C for 16–19 days formed significant quantities of colorless anthocyanin-flavan-3-ol dimers. The major dimer formed from the anthocyanin and (–)-epicatechin was shown by HMBC to be malvidin 3-glucoside[C2-O-C7,C4-C8]epicatechin (i.e. a dimer with two linkages between the monomers). Figure 4.4.10 depicts this dimer with the major HMBC correlations that imply the linkage positions.

Anthocyanin pyruvates or pyranoanthocyanins (see Figure 4.4.8(c) for one example), whose characteristic colors lie to the blue side of true anthocyanin colors (i.e. $\lambda_{max} < 528$ nm), were shown to be the major pigments in red wines during the first two years of maturation, from reactions of anthocyanins with pyruvate in model solutions and by comparison with real wine components (Bakker and Timberlake, 1997; Fulcrand *et al.*, 1998). Similar reactions were observed between anthocyanins and acetaldehyde, and these derivatives with pyran rings are sometimes known as vitisins. For pyranomalvidin 3-glucoside (Figure 4.4.8(c)), a negative NOE was observed between H8 and H2′ (H6′) and also between Hβ and H2′ (H6′), in agreement with the positions of the hydrogen atom and carboxyl group on the new pyran ring (Fulcrand *et al.*, 1998). Long

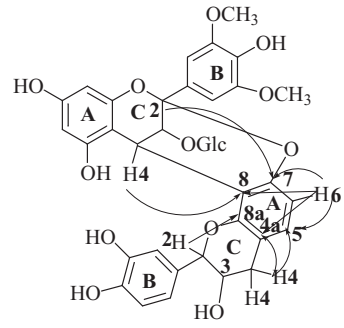

Figure 4.4.10 *Major HMBC correlations for the malvidin 3-glucoside [C2-O-C7, C4-C8] (−)-epicatechin dimer. Remy Tanneau* et al.*, 2003*

range heteronuclear correlation experiments (HMBC) indicated a variety of correlations consistent with the proposed structure (Figure 4.4.8(c)).

More recently, bluish pigments ($\lambda_{max} > 528$ nm), discovered in Port wines were shown to be vinylpyranoanthocyanin-flavanols (Mateus *et al.*, 2003) and vinylpyranomalvidin 3-glucoside-phenol, the latter supported by comparison with a fully NMR characterized sample from a model solution reaction (Mateus *et al.*, 2006) (Figure 4.4.8(d)). A similar pigment was isolated from anthocyanin rich extracts of Pinotage wine by high speed countercurrent chromatography (HSCCC – see Section 4.3.4) and characterized by LC-ESI-MS and NMR (Schwarz *et al.*, 2003). One dimensional ^{1}H and ^{13}C NMR, as well as DEPT, were used to assign resonances, whereas HMBC and HSQC were used to assign all ^{1}H-^{13}C connectivities in the molecule (Figure 4.4.8(e)).

Anthocyanins in red wine can also undergo acetaldehyde mediated self-condensation (dimerization). A new pigment ($\lambda_{max} = 518$ nm) found in a model wine solution containing malvidin 3-glucoside and acetaldehyde was shown by NOESY, COSY, HMBC and HSQC to be the structure shown in Figure 4.4.8(f) – this is the major form at wine pH (Atanasova *et al.*, 2002). Each of the main forms (diflavylium, flavylium-hydrated flavylium and flavylium-quinoid) was detected by LC-ESI-MS. The occurrence of this pigment in red wine was demonstrated by HPLC.

Proanthocyanidins in grape skins and wine are important contributors to astringency, a certain amount of which is necessary for the correct 'mouthfeel' of red wine and other drinks such as cider and perry. Many of these are high molecular weight polymers and it is known that they have a wide diversity of structures, particularly with regard to linkage type and positions between the monomeric subunits. Partly because of this and partly because of the difficulty in obtaining pure samples of the higher polymers, structure determination is difficult, hence acid catalyzed hydrolysis of proanthocyanidins and analysis of the cleavage products by NMR and other techniques can provide some insight into their monomer composition and linkages. A standard procedure is to hydrolyze the polymer in the presence of benzyl mercaptan or phloroglucinol to trap electrophilic flavonoid species (formed from the cleavage of extension subunits–nonterminal units) and so to reveal cleavage positions and consequently linkage positions in the original polymer. Kennedy and Jones (2001) used HPLC to separate the hydrolysis products of skin and seed proanthocyanidins from Chardonnay grapes. A major phloroglucinol trapped hydrolysis subunit (isolated using preparative HPLC) is shown in Figure 4.4.11, along with the NOE correlations that were used to characterize it (HMBC was also used in the structure elucidation).

Like polyphenols, aroma compounds and their glycosidic precursors (nonvolatile themselves, but important potential sources of aroma) are important components of alcoholic beverages and consequently have received some attention from NMR spectroscopists.

Figure 4.4.11 *Acid hydrolysis product of grape proanthocyanidin. Kennedy and Jones (2001)*

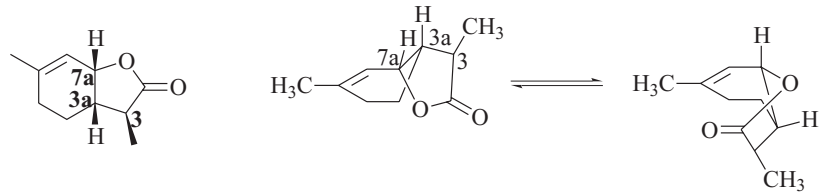

Figure 4.4.12 *Configuration and conformations of wine lactone. Guth (1996)*

Wine lactone (3*S*,3a*S*,7a*R*)-3a,4,5,7a-tetrahydro-3,6-dimethylbenzofuran-2(3*H*)-one (Figure 4.4.12) is powerful odorant (coconut notes) found in white wines, particularly those of 'aromatic' varieties, such as Scheurebe (Riesling type) and Gewürztraminer (Traminer type) (Guth, 1996). Comparison of spectroscopic (NMR, IR, MS and circular dichroism) and chromatographic data (chiral GC) of wine lactone isolated from different white wines and with those of the eight stereoselectively synthesized diastereoisomers showed that wine lactone had the structure given in Figure 4.4.12. In the NMR spectroscopic evaluation, the spin systems of the diastereoisomeric lactones were identified from TOCSY spectra and individual protons were assigned by quantum filtered COSY spectroscopy. In particular, the coupling constant $^{3}J_{7a,3a}$ (6.8 Hz) was consistent with equatorial–axial, rather than equatorial–equatorial or axial–axial configuration of the protons at the ring junction.

Analysis of HPLC and TLC fractions of glycosidic extracts of Alsace Gewürztraminer wines by NMR and MS has revealed a number of isoprenoid and other glycosides and a phenylpropenoid glycerol (Baltenweck-Guyot *et al.*, 1996; 2000). The products were acetylated prior to their analysis by GC-MS and NMR. NOESY and HMBC spectra gave through space and through bond connectivities (respectively) thus enabling the determination of the nature and assemblage of the sugar moieties, as well as confirming the structures of the aglycones, as outlined in Figure 4.4.13 for a glycoside of *cis*-furan linalool oxide. Other glycosides characterized included those of (*E*)-6,9-dihydroxymegastigma-4,7-dienone (a precursor of β-damascenone), benzyl alcohol and phenylethanol.

^{13}C resonances were assigned *via* inverse detection or inverse long range correlations.

Figure 4.4.14 *Selected NMR data for megastigm-4-en-9-one aglycone, a TDN precursor in Riesling grapes. Versini* et al. *(1996)*

1,1,6-Trimethyl-1,2-dihydronaphthalene (TDN), like many other C_{13} norisoprenoids, is a major contributor to the aroma of wine made from 'aromatic' grape varieties, such as Riesling, where it contributes to what is commonly known as kerosene or petroleum odor (especially noticeable in aged wines). Like other odorous norisoprenoids, it is likely that TDN is synthesized during fermentation and aging from norisoprenoid (ultimately carotenoid) precursors. Several such precursors have been suggested for TDN, their common feature being the production of some TDN upon treatment with acid. A megastigm-4-en-9-one glycoside has been suggested as an important precursor in Riesling grape juice (Versini *et al.*, 1996). The structure of the aglycone (Figure 4.4.14) was determined by NMR spectroscopy, especially HMBC (inverse long range ^{1}H–^{13}C correlation), ROESY (the rotating framework version of NOESY) and TOCSY.

The Maillard reaction (Section 2.6.2) is a complex series of reactions that occur between amino acids and carbonyl compounds (including sugars) in foodstuffs, including alcoholic beverages. The reactions can occur to a certain degree at temperature below 37 °C, but are more pronounced at higher temperatures. Many of the products are colored or possess characteristic aromas and hence make particularly important contributions to the organoleptic properties of alcoholic beverages that have had heat treatment, or some of whose ingredients have undergone some kind of heat treatment. Included here are Madeira (Section 2.10.6), certain Sherries (Section 2.10.2), dark beers (Section 2.6.2) and pasteurized drinks, particularly overpasteurized beers. Many important Maillard products are nitrogen, oxygen or sulfur-containing hetetocycles and include 2-acetylthiazole (cooked cereal notes, found in some wines) and 2-acetyl-2-thiazoline (roast meat notes, found in some highly pasteurized beers). Using a wine-like model solution containing cysteine and methylglyoxal, Marchand *et al.* (2002) were able to identify *N*-(2-sulfanylethyl)-2-oxopropanamide (Figure 4.4.15) as a precursor of 2-acetylthiazole from MS, ^{1}H and ^{13}C NMR data. HMBC was used for long range ^{13}C–^{1}H correlations.

Although most polyphenols, especially polymeric species, are considered to be too involatile to contribute much directly to wine aroma, they may make an indirect contribution to flavor by influencing the 'free' concentration of certain types of flavor compounds. They also make an important contribute to taste (mouth-feel) by forming complexes with saliva proteins, thus giving the sensation of astringency. Using a dynamic headspace technique on a water-alcohol model solution, Dufour and Bayanove (1999) were able to show that the flavan-3-ols, (+)-catechin and (–)-epicatechin, reduced the volatility of isoamyl acetate, ethyl hexanoate and benzaldehyde more than that of more hydrophobic limonene, whereas a wine tannin fraction decreased the volatility of benzaldehyde somewhat, had no effect on the ester aroma compounds and actually increased the volatility of limonene. Measurement of ^{1}H chemical shift changes on addition of ligand (aroma compound) to a substrate (a flavan-3-ol or tannin fraction) enabled the estimation of dissociation constants in 1:1 binding models.

In recent years, NMR spectroscopy has been used in kinetic or time course studies of a number of aspects relating to alcoholic beverages, including metabolic processes such as fermentation (Avenoza *et al.*, 2006; Son *et al.*, 2009), oxygenation (Conte, 2008) and reactions between (+)-catechin and aldehydes (Nonier *et al.*, 2007). Son *et al.* (2009) were able to use ^{1}H NMR to investigate metabolic changes occurring during alcoholic fermentation of grape juice and to evaluate the impact of three yeast (*Saccharomyces cerevisiae*) strains (RC-212, KIV-1116 and KUBY-501) on the wine metabolite profile. Using pattern recognition chemometric techniques, differences were observed for each fermentation, the differentiation being based upon the concentrations of 2,3-butanediol, citrate, glucose, glycerol, malate, *N*-methylnicotinic acid, polyphenols, proline, pyruvate, succinate and tartrate. TOCSY, HMBC and HSQC were used to acquire the NMR data. Lyophilized wine samples (1 ml) were dissolved in D_2O (0.4 ml), 400 nM oxalate buffer (pH 4.0) (0.14 ml) and 5 mM sodium 2,2-dimethyl-2-silapentane-5-sulfonate (0.06 ml). The latter provided a chemical shift reference. The supernatant after centrifugation was subjected to NMR experiments using a NOESYPREAST pulse sequence to suppress the residual water signal. This study demonstrated the ability of NMR, coupled with multivariate statistical analysis, to differentiate between the same must fermented by different yeast strains and so NMR could be used as both a fermentation monitor and a check on yeast authenticity.

Avenoza *et al.* (2006) used ^{1}H NMR to monitor the change in malic and lactic acid concentrations in fermenting grape must, with and without added *Oenococcus oeni* for malolactic fermentation. Samples were dissolved directly in D_2O, without prior freeze drying, because of the high sugar contents of the fermenting musts compared with finished wine. Hence the NMR spectra were recorded with a standard pulse sequence (zgpr with p19 at 6 dB and flip angle 90°) for presaturation of the water signal at 1875 Hz. The results compared favorably with those using enzymic/colorimetric methods, with NMR having the advantages of being more robust and requiring minimal sample preparation or manipulation.

A preliminary ^{1}H NMR spectroscopic method has been used to observe molecular changes occurring during microoxygenation of red wine (Conte, 2008). Wine from the same vintage was kept in two identical stainless steel tanks, one of which was micro-oxygenated at the rate of 4 ml of oxygen per ml of wine per month. Samples were taken every week for five weeks. After adjustment of pH to 2.0, the wine samples were extracted with diethyl ether and the residues, after evaporation of solvent, were dissolved in $CDCl_3$ and subjected to 1D ^{1}H NMR spectroscopy. The data was analyzed using multivariate statistical analysis, where it was found that signals corresponding to acetaldehyde, diethyl oxalate, acetoin, L-alanine, diethyl malonate, diethyl oxalate, diethyl succinate and ethyl acetate (all 1.8–1.1 ppm) differentiated between micro-oxygenated and control samples.

Nonier *et al.* (2007) used 1D ^{1}H NMR spectroscopy (and other methods) to study the differences in rates of reaction over a period of 54 days at 20 °C (in the dark) between (+)-catechin and a variety of aldehydes that were known to be derived from toasted oak. Thus the model wine solution containing these substrates was meant to simulate the production of pigments in white wine aging in oak casks. NMR experiments in DCl/D_2O clearly showed that the catechin reactive sites were at C6 and C8. Likewise, disappearance

of the aldehyde proton signal of furfuraldehyde and the C6, C8 protons of (+)-catechin during reaction between these two species, indicated that adducts were formed via catechin C6, C8 and aldehyde, possibly as bridged dimers like those formed between catechin and acetaldehyde. (+)-Catechin was found to react with furfuraldehyde, 5-hydroxymethylfurfuraldehyde and 5-methylfurfuraldehyde much more readily than with the phenolic aldehydes, syringaldehyde and vanillin. UV-visible spectroscopy and HPLC showed that the increase in solution absorbance at 440 nm was closely linked to the formation of products formed via reaction between catechin and aldehydes.

Solid state ^{13}C NMR (with cross polarization and magic angle spinning, CP/MAS) has been used to study the natural lacquer-like pigmented deposits that adhere to the inner surface of around 5–10% of bottles of aged red wines (Waters *et al.*, 1994). The deposit often covers the entire inner surface, and although it does not appear to influence the wine quality, is usually quite firm and is easy to pour out the wine from (with due care), it is nonetheless usually regarded as a negative commercial attribute. Waters *et al.* (1994) found the ^{13}C CP/MAS NMR spectra of deposits to include peaks at 174 ppm (C=O of peptides), 155–116 ppm (O-aryl and aryl region of aromatic amino acids such as tyrosine and histidine, as well as polyphenol carbon atoms), 76–56 ppm (sugar carbon atoms) and 40–20 ppm (aliphatic amino acid side chain carbon atoms). These results suggested that the deposit is composed largely of a protein–polyphenol complex, which also contains sugar molecules, probably as glycoside moieties of the polyphenol polymers. Amino acid analysis of the deposits following acid hydrolysis indicated that ~22% of the mass of the deposit could be accounted for by proteinaceous material, the remainder probably being all polyphenols (with glycoside moieties). The major amino acids in the deposit were (in order of importance) glycine, aspartic acid/asparagines, serine and threonine.

Polyphenols are important components of foodstuffs and alcoholic beverages that are generally thought to give health benefits (Chapters 5.5 and 5.8). Apart from possible direct antioxidant properties, it is believed that they act by forming complexes with proteins, thereby influencing cell signaling pathways. Solid state ^{2}H and ^{31}P NMR spectroscopies have been used to study the *in vitro* interaction between 4-deuteroepigallocatechin gallate and phospholipid bilayers (dimyristoylphosphatidylcholine liposomes) (Kajiya *et al.*, 2008), where it was shown that not only is this polyphenol incorporated into the bilayer, but it is able to move freely on the membrane surface. Hence in an *in vivo* situation, the polyphenol would be able to find its specific binding protein, known to exist in membranes. Epigallocatechin gallate is a tea polyphenol, and although it has been shown that the extent and type of *in vitro* interaction between flavan-3-ols and lipid bilayers is dependent on structure, amongst other factors, it is not unreasonable to suppose that similar interactions occur between cider or wine polyphenols and membranes.

Site specific isotopic fractionation-NMR (SNIF-NMR) is a version of deuterium (^{2}H) NMR developed by G.J. Martin and coworkers in the 1980s that has found particular application in the determination of origin of alcoholic beverages (and other foodstuffs) and in the detection of fraud. Natural deuterium is not distributed uniformly throughout the world and natural hydrogen isotopic distributions in compounds (say, water and plant sugars) are the result of a number of biochemical, chemical and physical processes. For example, the ^{2}H content of water ranges from ~90 ppm in Antarctica to ~160 ppm at the equator, because water vapor from warmer climates is richer in H_2O than HDO, the resulting precipitation in cooler regions is also depleted of HDO. Since plants synthesize sugars from water and carbon dioxide, both geographical and meteorological factors influence the D/H ratio in the sugars. Furthermore, given fixed geographical and meteorological factors, the D/H ratio in plant sugars depends on the biosynthetic pathway from water and carbon dioxide utilized by the plant: the Calvin (C3) or Hatch–Slack (C4) cycle (Section 4.4.5). Hence the D/H ratio in plant sugars is a function of the plant biochemistry, geographical and meteorological factors, and so could be used to identify botanical and geographical origin. This of course can be determined by isotope ratio mass spectrometry (IRMS) (Section 4.4.5), but this technique is not site specific and only gives a global value of D/H for a particular compound.

Deuterium NMR is capable of giving site specific values of D/H, but the procedure is rather complex for molecules such as plant sugars, which contain relatively large numbers of magnetically different hydrogen atoms. Fortunately, the microbiological conversion of sugars to ethanol (alcoholic fermentation) and subsequent processes such as distillation do not significantly influence the individual D/H ratios, and it has been shown that measurements on ethanol deuterium sites CH_3CHDOH (methylene) and CH_2DCH_2OH (methyl) can be directly related to those in the original sugars that produced the ethanol (Martin *et al.*, 1983). The deuteroxy (CH_3CH_2OD) signal overlaps with that of HOD and hence is usually ignored.

SNIF ^{2}H NMR (e.g. NMR frequency 61.4 MHz at 9.4 Tesla) experiments on alcoholic drinks are usually carried out with WALTZ proton decoupling, a fluorine locking device and sometimes with an accurately known mixture of C_6D_6 and C_6H_6 as reference in a concentric capillary NMR tube. Alternatively, a standard of known isotope ratio (e.g. tetramethylurea; D/H = 136 ppm) can be used in place of hexadeuterobenzene and hexafluorobenzene can be used as the locking material. Because of the inherent magnetic insensitivity of the ^{2}H nucleus, and resulting poor signal to noise ratio, SNIF-NMR should normally be used on neat distilled beverages; wines and beers need careful distillation in a spinning band column (Martin *et al.*, 1988).

The parameter R is often used to express the relative ^{2}H distribution in the ethyl fragment of ethanol, as given by Equation 4.4.4.

$$R = \frac{3h(\mathrm{II})}{h(\mathrm{I})} \tag{4.4.4}$$

Here h(II) is the height of the methylene ^{2}H signal and h(I) is the height of the methyl signal, with respect to the height of the reference signal. Water involved in the fermentation has a significant effect on the ^{2}H content of the methylene site, whereas the sugar is the main influence on the deuterium content of the methyl site of ethanol. If the deuterium in ethanol were distributed statistically (if there was no isotope fractionation), h(II)/h(I) would be 2/3, giving R a value of 2.0. In practice, R varies between ~2.20 and ~2.80 and can be used to differentiate some, but not all, sources of sugar in alcoholic drinks, because of data overlap. A new parameter C describing relative deuterium concentration is defined by Equation 4.4.5 (where h(std) is the peak height of the standard and f is a correction factor for ethanol concentration).

$$C = \frac{h(\mathrm{I}) + h(\mathrm{II})}{h(\mathrm{std})\, f} \tag{4.4.5}$$

A combination of R and C values can be used to distinguish between ethanol in spirits derived from different sugar sources, as shown in Table 4.4.1.

Alternatively, the D/H ratios can be calculated via Equation 4.4.6 and are expressed as ppm (Zhang *et al.*, 1998).

$$\left(\frac{D}{H}\right)_i = \frac{N_{\mathrm{D},i}}{P_i N_{\mathrm{H}}} \tag{4.4.6}$$

Here, D_i and H_i are the numbers of deuterium and protium atoms at site i, $N_{D,i}$ is the number of monodeuterated isotopomers of type i, N_H is the number of fully protonated molecules and P_i is the number of equivalent hydrogen positions at site i. A curve fitting algorithm based on a complex least squares treatment of the ^{2}H signal was used for the quantitative evaluation of monodeuterated isotopomers.

SNIF-NMR has been successful in the detection of fraud and the authentication of origin (Ogrinc *et al.*, 2003). SNIF-NMR is usually based on the measurement of ^{2}H/^{1}H ratios at the methyl and methylene sites of ethanol, after it has been distilled from the wine, but methylene sites of glycerol after distillation, solvent

Table 4.4.1 *Relative deuterium data for ethanol derived from different sugar sources*

Sample	Sugar source of ethanol	Mean R (with typical standard deviation)	Mean C (with typical standard deviation)
Synthetic alcohol	Fossil fuel	2.262 (0.007)	1.464 (0.003)
Cognac	Grape	2.528 (0.007)	1.173 (0.004)
Applejack	Apple	2.552 (0.007)	1.140 (0.004)
Cachaca and rum	Sugar cane	2.312 (0.006)	1.232 (0.004)
Tequila	Agave	2.235 (0.001)	1.203 (0.001)
Vodka*	Potato	2.697 (0.011)	1.083 (0.004)

*Most vodka is produced from cereals, especially wheat
R and C are defined by Equations 4.4.4 and 4.4.5

extraction and triacetylation can also be used (Zhang *et al.*, 1998). Combined with IRMS, SNIF-NMR can be used to detect chaptalization that used sugar from either C_3 plants (e.g. cane sugar) or C_4 plants (e.g. beet sugar). By combining $\delta^{13}C$ values (from IRMS – see Section 4.4.5) with the normalized hydrogen isotope ratio – $(D/H)_I$ – of wine ethanol, an 'adulteration triangle' can be constructed (Figure 4.4.16).

Similarly, by analyzing the data from SNIF-NMR and IRMS experiments, using a variety of statistical methods, it has been possible to check the authenticity of large numbers of samples from a number of wine growing regions (Košir *et al.*, 2001; Ogrinc *et al.*, 2003).

Electron spin resonance (ESR) is a sister technique to NMR, involving transitions of unpaired electron spins in an applied magnetic field when subjected to microwave (rather than radio wave) radiation. It has been used for some time to predict the flavor stability of beers by observing the production of free radicals (species with an unpaired electron) in the presence of a spin trapping agent, such as *N-tert*-butyl-α-phenylnitrone (Nyborg *et al.*, 1999). High concentrations of free radicals in beer are associated with staling, part of which is caused by oxidation and which is characterized by a deleterious change in flavor profile (Section 2.6.12). Beer contains a number of compounds (e.g. melanoidins, phenols and proteins) that are able to remove highly

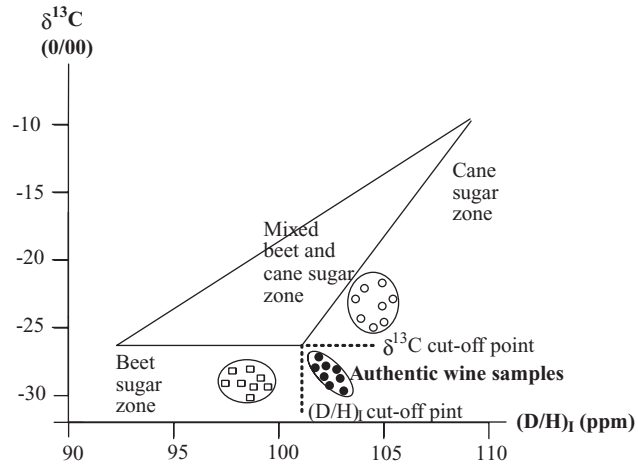

Figure 4.4.16 *Adulteration triangle in a plot of $\delta^{13}C$ versus $(D/H)_I$ for wine ethanol. □ wine samples made with added beet sugar; ○ wine samples made with added cane sugar. Ogrinc* et al. *(2003)*

reactive oxygen and carbon radicals by forming relatively stable free radicals (Section 5.8.7), thus acting as radical scavengers or antioxidants. Spin trapping agents, such as nitrones and *N*-oxides, when added to beer react with free radicals that are in excess of the radical scavenging ability of the beer, to give a stable nitrodioxide or nitroxide radical whose increase in signal strength can be monitored in the ESR spectrometer. This occurs after a certain time lag period; the shorter this period, the more likely (and the quicker) the beer will undergo staling and the lower the flavor stability. If this happens, the brewery must find and put right the cause of increased radical formation; perhaps by adjusting the process to give lower levels of dissolved oxygen and lower levels of metal cations (especially Fe and Mn).

4.4.2 Infrared Spectroscopy

The infrared region of the electromagnetic spectrum is divided for convenience into three subregions according to arbitrary (and therefore approximate) wavelength ranges. These are near, mid and far infrared regions – named by their relationship to the visible region. At the low energy end, the far infrared region ($\sim$400–10 cm^{-1} or 1000–30 μm) lies adjacent to the microwave region and is useful for rotational spectroscopy. The mid infrared region ($\sim$4000–400 cm^{-1} or 30–2.5 μm) is used to study the fundamental vibrations and associated rotational-vibrational structure; this is the region most widely used to study organic functional groups, such as those in the component molecules of alcoholic beverages. The high energy near infrared region ($\sim$14000–4000 cm^{-1}, 2.5–0.8 μm or 2500–800 nm) lies next to the visible region and can be used to study overtone or harmonic vibrations. For detailed discussions on IR spectroscopy, the reader is referred to Lambert *et al.* (1998) and Silverstein *et al.* (2005).

The bonds in molecules are constantly vibrating, that is to say, stretching or bending (deforming), so that when a bond in a molecule absorbs a quantum of infrared radiation (whose frequency corresponds to the vibrational frequency of the bond) that bond vibrates with greater amplitude. This causes a vibrational transition (from lower to higher vibrational energy level), but only occurs if the vibrational motion is accompanied by a change in the permanent dipole moment of the bond (as in nonsymmetric bonds) because the changing electric dipole needs to interact with the sinusoidally changing electromagnetic field of the incident infrared photon in order for a vibrational transition to occur. The energy of the vibrational transition of a bond in a molecule (and hence the wavelength of the IR radiation absorbed) depends upon the following:

- Atomic identity (C–H, O–H, etc.)
- The types of bonds between (single, double, triple) between atoms
- Intramolecular interactions (the molecular neighborhood of the vibrating bond)
- Intermolecular interactions (state of matter of the sample).

This is the basis of infrared spectroscopy. Nowadays, the big majority of IR analyses are carried out using Fourier transform (FT) instruments rather than dispersive instruments (the IR equivalent of continuous wave NMR instruments).

The FT instrument is rather more complex in that it uses a Michaelson interferometer rather than a monochromator and it also requires a computer to convert the interference patterns, by Fourier transform, into conventional frequency (or wavelength) spectra. The interferometer consists of a beam splitter and two mirrors, one fixed and the other moveable (Figure 4.4.17(i)). The beam splitter transmits half the radiation and reflects the other half when incident radiation strikes it at a 45° angle (Figure 4.4.17(ii)). The transmitted and reflected beams from the beam splitter strike the two mirrors that are oriented perpendicular to each beam, and are reflected back to the beam splitter. When only one mirror is in place (Figure 4.4.17(iii)), the beam reflected from the mirror returns to the beam splitter, which sends half the radiation to the detector and

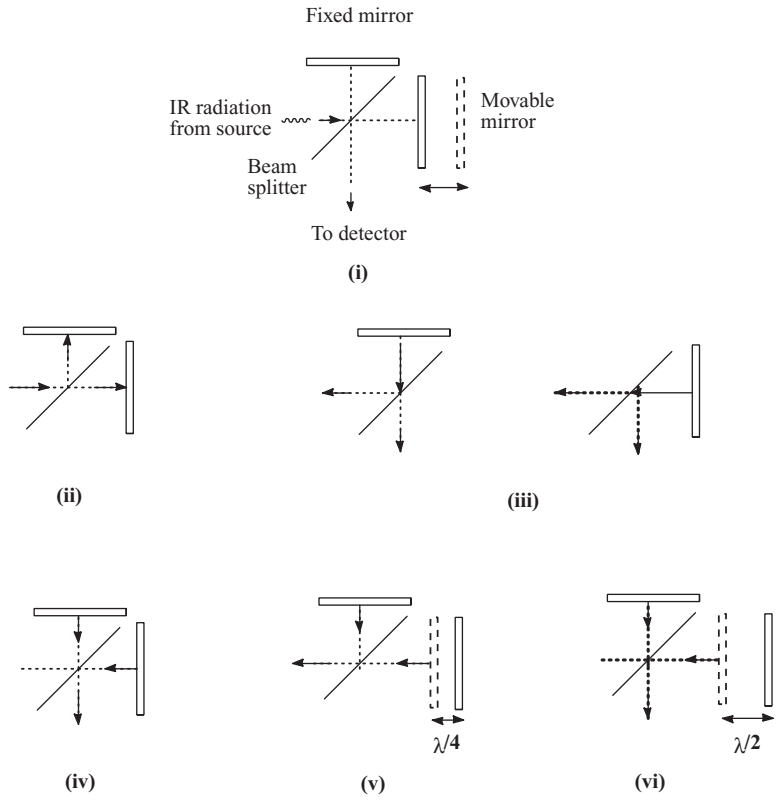

Figure 4.4.17 *FTIR spectroscopy: the interferometer section of an FTIR spectrometer*

the other half back to the source. If both mirrors are in place (see Figure 4.4.17(iv)–(vi)), interference occurs at the beam splitter where there is overlap of the radiation from the two mirrors. When the two mirrors are equidistant from the beam splitter (the 'retardation' is zero), for all wavelengths, constructive interference occurs for the beam passing to the detector, whereas destructive interference occurs to the beam going back to the detector (Figure 4.4.17(iv)). When the retardation is λ/2 (Figure 4.4.17(v)), when the moving mirror has moved λ/4 away from the equidistant position, destructive interference occurs to the beam going to the detector. Conversely, when the retardation is λ (corresponding to the position of the moving mirror at λ/2 – see Figure 4.4.17(vi)), constructive interference occurs to the beam passing to the detector. The detector thus senses a cosine variation of intensity that depends on the retardation and a plot of such a response versus retardation is known as an interferogram.

In practice, the interferogram of the polychromatic source can be considered as the sum of all the cosine waves from each wavelength and they are each detected simultaneously. This interferogram, saved in the computer memory, is converted to a conventional spectrum by Fourier transform. Because several 'scans' can be performed, the signal to noise ratio is superior to that of a dispersive instrument.

Several sampling techniques are available for FTIR spectroscopic analysis, depending on the physical state of the sample. Liquid samples can be sandwiched between two plates of a highly pure salt (commonly sodium chloride, potassium bromide or calcium fluoride). The plates are transparent to the infrared light and hence will contribute nothing to the spectrum, but most salt plates are highly soluble in water, so the sample and

washing reagents must not contain water. Solid samples can be finely ground with pure anhydrous KBr, or made into a slurry (or mull) with a liquid hydrocarbon such as nujol, or alternatively dissolved in a suitable solvent and run in a solution cell made of NaCl, KBr or other material. In the latter two cases (and others) the spectrum of the mulling agent or solvent is subtracted by computer from the spectrum of the sample.

Both solid and liquid samples can be measured in close contact to a crystal of high refractive index, such as diamond, germanium or zinc selenide. This technique is called attenuated total reflectance (ATR) and uses a property of total internal reflection called the evanescent wave. A beam of infrared light passes through the ATR crystal so that it is reflected at least once off the internal surface in contact with the sample. This reflection forms the evanescent wave which extends into the sample by a few micrometers. The beam is then collected by a detector as it exits the crystal.

Standard bench top FTIR instruments have been used or adapted successfully for use in alcoholic beverage analysis, although a dedicated spectrometer made by Foss Electrics (Denmark) meant for routine screening of samples is used in many analytical laboratories. The WineScan FT 120 instrument is usually equipped with an autosampler that pumps the sample through a cuvette of optical pathlength 37 μm. Zeroing and cleaning are built into the automation program, where it is possible to achieve an analysis time of 30 s per sample. However, in the above instrument, the number of scans generated for each sample, the selection of spectral regions (5012–926 cm^{-1}) and the data processing are fixed by the manufacturer.

The application of FTIR spectroscopy to alcoholic beverage analysis is extensive, especially during the past decade, with the advent of increasingly sophisticated spectrometric, data treatment and chemometric software. Because of its speed and simplicity, FTIR has been used for quality control or authentication of grape must (Swanepoel *et al.*, 2007), wine (Palma and Barroso, 2002; Cocciardi *et al.*, 2005; Urbano Cuadrado *et al.,* 2005; Tarantilis *et al.*, 2008; Garde-Cerdán *et al.*, 2010), distilled spirits (Palma and Barroso, 2002; Cocciardi *et al.*, 2005; Lachenmeier *et al.*, 2005; Lachenmeier, 2007), brewer's grits (Pojić *et al.*, 2009), wort (Titze *et al.*, 2009), beer (Llario *et al.*, 2006; Lachenmeier, 2007), Chinese rice wine (Yu *et al.*, 2009) and peat (for the production of Scotch whisky) (Chapman *et al.*, 2001; Harrison *et al.*, 2006). Similarly, FTIR has been successful in the quantitative determination of specific wine components (Gorinstein *et al.*, 1992; Vonach *et al.*, 1998; Moreira and Santos, 2004; Nieuwoudt *et al.*, 2004).

Other specific components, such as anthocyanins and polyphenols in wine (Fernández and Agosin, 2007; Soriano *et al.*, 2007; Jensen *et al.*, 2008) and carbohydrates in beer and wine (Coimbra *et al.*, 2002; 2005; Boulet *et al.*, 2007; Niu *et al.*, 2008) have received attention from FTIR spectroscopy. Both the near infrared and mid infrared regions are the widely used for the analysis of alcoholic drinks, unlike other areas of food science or agricultural science, where NIR spectrocopy tends to dominate.

The NIR region of the electromagnetic spectrum, situated between the visible and mid infrared regions, covers the wavelength range between *ca*. 780 nm and 2526 nm. Recently, NIR reflectance spectrometers with capability extending into the visible region have become available for research and industrial use, where they have proved to be of considerable value (McCaig, 2002).

Quality control methods that use FTIR spectroscopy generally require the construction of a database of optimized calibration models. Statistical analyses are used to correlate these data with IR data for the same set and to compute regression models and errors of prediction for the chosen parameters (e.g. total acidity, total sugars, percentage ethanol by volume, etc.). Validation is then carried out on a different set of samples. Differentiation/determination of origin methods generally follow a similar route, often using principal component analysis and other statistical analyses of a selected region of the IR data for each compound. It is in these areas that FTIR has proved to be an excellent screening method; it is fast, easy (with no or little sample preparation) and capable of indicating the possibility of fraud or inadequate quality. However, it is an indirect method in that it uses a calibration based on previously determined results and hence it generally lacks the confidence for the presentation of evidence of the fraudulent activities of alcoholic drinks producers. In these cases, reference or official methods (which are invariably lengthier and more demanding)

should be used to confirm those from FTIR analysis. Given the considerable advantages mentioned above, it is likely that FTIR spectroscopy will become more widely used for routine quality control screening in the alcoholic beverage and other food industries.

There appears to be only one recent report on the application of FTIR spectroscopy to the quality control of grape must (Swanepoel *et al.*, 2007). Here, total soluble solids (a measure of the sugar content, expressed as °Brix), pH and titratable acidity (expressed as g/l tartaric acid) were measured using an exploratory data analysis of the IR spectra of 1170 South African must samples (647 for °Brix, 252 for pH and 271 for titratable acidity). After optimization, the standard error of prediction was 0.46 °Brix, 0.05 pH and 0.49 g/l tartaric acid, thus indicating that FTIR is a useful method for the assessment of major grape must parameters, as well as for general quality control. Although these three parameters can be easily and rapidly measured by other methods, three separate experiments are required, whereas FTIR spectroscopy is able to measure all three rapidly in a single experiment.

Palma and Barroso (2002) were able to use FTIR data for the differentiation and classification of Sherries and Jerez brandies according to maturation age, as well as for the differentiation and classification of brandies from France, South Africa and Spain. It was possible to differentiate fino Sherries from all six 'scales' or levels of aging of a single aging batch of criaderas and solera (Section 2.10.2). Likewise Jerez brandies of three ages could be differentiated and these could be distinguished from French and South African brandies. The best differentiation of Sherries was obtained by utilizing the part of the IR spectrum that differed most between samples, the region ~930–3000 cm^{-1}. The major statistical techniques that were applied to the data were principal components analysis (PCA), linear discriminant analysis (LDA) and partial least squares regression (PLSR) analysis. The first principal component was related to the aging process, whereas the second principal component recorded another reason for the differences between sample spectra.

Near IR as well as mid IR spectroscopy was used to determine a variety of parameters (including % ABV, total acidity, total sulfur dioxide and lactic acid content) for 180 wines from different regions of Spain and from different vine varieties (Urbano Cuadrado *et al.*, 2005). The NIR spectra were obtained at 400–2500 nm using folded transmission through a ring cup with 0.1 mm path length. Reflection was provided by a gold surface placed at the bottom of the cup. The mid IR spectra were obtained at 3000–800 cm^{-1}, using attenuated total reflectance (ATR with a ZnSe crystal). PCA was used to correlate wine parameters for the samples (measured by a variety of methods) with the optimized NIR and/or MIR spectral data. After assessment of outliers, PLSR was used to generate correlation equations with a determination coefficient (R^2) and then validation was performed to generate standard error prediction. In general, NIR spectroscopy provided better results because of more favorable signal to noise ratios. However, use of both NIR and MIR data improved the determination of glycerol and total sulfur dioxide.

In the same year as above, Cocciardi *et al.* reported the application of a new FTIR method for the analysis of wine and distilled spirits. The method used a bench top FTIR instrument fitted with a single bounce attenuated total reflectance (SB-ATR) sample handling accessory (as opposed to a CaF_2 transmission cell or traditional multireflection ATR). The mid IR region was used for analysis (within 3000–850 cm^{-1}; the actual range used depended on the component or property to be analyzed) The new method applied to the determination of ethanol in distilled spirits (11 samples) gave results that were comparable with those obtained from transmittance FTIR (with a flow through cell) and superior to those obtained with FT-NIR. A PLS calibration of a 72 sample database for the prediction of 11 different components and wine parameters by SB-ATR/FTMIR spectroscopy was developed and validated using an independent set of 77 samples. Good coefficients of correlation (R^2) between reference and predicted values for the validation set were obtained for most parameters, except citric acid, total sulfur dioxide and volatile acids contents. It is possible that combined use of NIR and MIR data may have improved the correlation with total sulfur dioxide content, as for Urbano Cuadrado *et al.* (2005).

The highest quality tequila ('100% agave') must be bottled in Mexico, but the 'mixed' version (which can be made by distilling maguey juice with up to 49% (w:v) of added sugar) can be exported in bulk and bottled in foreign countries (Section 3.5.5). Although Tequila is protected under the North American Free Trade Agreement (NAFTA), adulteration and fraud (e.g. via addition of other types of alcohol, such as grain spirits, or by mixing different types of tequila) are commonplace. Principal component analysis was applied to ion chromatographic data (Cl^-, NO_3^-, SO_4^{2-}, $CH_3CO_2^-$ and oxalate $(COO^-)_2$ content) and FTMIR data from the region 4996–930 cm^{-1} (omitting the spectral regions of water absorption: 3696–2971 cm^{-1} and 1887–1447 cm^{-1}) (Lachenmeier *et al.*, 2005). Differentiation between Mexican bottlings (100% agave Tequila) and foreign bottlings (mixed Tequila) was observed, but no discrimination between categories of Tequila (añejo, blanco, reposado etc.) was possible from this data. Interestingly, the Mexican bottlings had high acetate contents and invariably possessed oxalate, whereas the foreign bottlings had lower acetate levels, higher chloride and sulfate levels and no oxalate. On the other hand, 100% Tequilas possessed significantly higher concentrations of methanol and isobutanol than mixed Tequilas.

Nieuwoudt *et al.* (2006) used FTIR to evaluate the major fermentation products of a variety of pure *Saccharomyces cerevisiae* cultures. Calibration equations for the quantification of ethanol, glucose, glycerol, reducing sugar and volatile acidity contents of South African Chenin Blanc fermenting musts and synthetic musts were derived from FTIR spectroscopy by the use of PCA and other statistical analyses of the data. A high degree of prediction (that is, with low standard error of prediction) were obtained for all the chosen parameters/components and the accuracies compared favorably with those associated with the respective reference methods used for the quantification of these parameters/components. Thus, FTIR spectroscopy was shown to provide a rapid and reliable screen for the fermentative properties of wine yeast strains.

Earlier, the same group had used PCA applied to FTIR for the design of calibration sets in order to predict glycerol levels in wine and to detect and classify outlier samples (Nieuwoudt *et al.*, 2004). Emphasis here was placed on the use of PCA to identify the major sources of variation in the FTIR spectra of wine samples and on the early detection and classification of poorly predicted and outlier samples. Judicious choice of calibration sets was considered necessary in order to design calibration sets that are robust and, at the same time, accurate.

The last mentioned aspects (above) were also investigated by Moreira and Santos (2004). Here poor accuracy of prediction (e.g. for total acid content, volatile acid content and total sugar content of dry wines) was attributed to spectroscopic interferences. Strongly absorbing bands due to abundant components, such as ethanol, organic acids and others produced major interferences in the analysis of low concentration components such as volatile acids and sugars in dry wines. The probable reason for poor prediction lies in the choice of samples for the calibration set; for example, sweet wines (with high sugar content) and dry wines (with low sugar content) were in the same set. It was suggested that a possible way of minimizing this problem would be to perform specific calibrations using different sample sets for different wine types (e.g. red, white, dry and sweet wines) thereby minimizing variation between samples and decreasing the extent of spectroscopic interference.

Although NIR spectroscopy has been used for some time for the determination of protein and water content, as well as the amino acid composition of barley and malt, more recent work has involved the application of information gained from wavelength studies of isolated barley hordein in order to improve prediction and reduce error in the estimation of total protein in barley and malt (Fox *et al.*, 2002). Strong correlations for grain protein (as determined by the Dumas method – see Section 4.6.3) and NIR wavelengths were found in the NIR region at six wavelengths between 1116 and 2300 nm (inclusive), indicating the usefulness of choosing a standard closely related to the parameter of interest in improving calibration robustness and hence the predictive ability of the method. Using a calibration set of 44 and a validation set of 19, multiple linear regression and partial least squares regression analysis applied to the results gave standard errors of prediction between 0.15% and 0.27% for barley and malt protein content. Clear differences could be seen in the NIR

spectra of barley and malted barley hordein, the largest difference occurring in the 1920–1940 nm region probably resulting from hydrolysis of hordein during malting and loss of moisture during kilning.

More recent work has suggested IR spectroscopy can be used for routine process control regarding the fat content of brewer's grits, an important consideration for brewers who use a high adjunct grain bill (Pojić *et al.*, 2009). Extensive statistical analysis showed the NIR method compared favorably with a standard chemical method, which cannot be readily applied to process control because of its high demand on time.

Similarly, FTIR spectroscopy has recently been evaluated for its ability to determine important quality parameters of wort (Titze *et al.*, 2009). All parameters relating to density could be determined with high accuracy, after accurate calibration using 256 'Congress' (EBC) wort samples. Additionally, total nitrogen content could be determined with good accuracy, but the method was of limited use in the determination of protein related parameters, because (for example) soluble nitrogen content was found to be dependent upon the harvest year during calibration of the that parameter. Other parameters, such as viscosity and color, could not be determined by this method. However, repeatability (over 130 days) was good and it was judged that FTIR spectroscopy has much promise as a routine wort and beer analyzer, saving both time and money.

FTIR spectroscopy has also been used for the rapid screening of beer samples (Duarte *et al.,* 2004; Llario *et al.,* 2006; Lachenmeier, 2007 and references therein), which must be degased prior to analysis. Llario *et al*. (2006) used ATR-FTIR spectroscopy to assess the important quality parameters of % ABV (by ethanol estimation), original extract and real extract (by carbohydrate estimation) (Section 2.6.2), using optimized spectral ranges for each component/parameter in order to minimize both prediction and calibration errors. Choice of ATR sampling minimized the influence on the overall spectra by the absorptions due to water molecules. The most important spectral region for all the parameters was 1200–1000 cm^{-1}, corresponding to C–O stretches. The calibration and validation sets were mostly pale bottom-fermented beers, whence the prediction errors were 1.5% for ethanol, 2.8% for real extract and 1.9% for original extract. Duarte *et al.* (2004), on the other hand, used FTIR only for classification of beers, using calibration and validation sets that included a wider variation of beers: bottom-fermented (Section 2.6.6), top-fermented (Section 2.6.5) and alcohol free beers (Chapter 2.13).

Lachenmeier (2007) used transmittance FTIR combined with multivariate data analysis as a rapid screen for quality control and assessment of authenticity of a range of spirits (including German fruit spirits) and beers (including bottom- and top-fermented beers). A partial least squares method was used to correlate the FTIR spectral data (which used the region 926–5012 cm^{-1}, but excluded the regions containing water absorptions) with results from reference methods. Validation using an independent set of samples showed strong correlations with reference values and high accuracies were obtained for the spirit parameters density, ethanol, ethyl acetate, isobutanol, methanol, 2- and 3-methyl-1-butanol and 1-propanol. Similar high accuracies were achieved for the beer parameters, density, ethanol content, lactic acid content and original gravity. Other beer parameters, pH, bitterness unit and color (EBC), showed lesser correlation and accuracy, but their determinations were still useful in screening analyses. Once again it was concluded that FTIR is useful for quality control of alcoholic beverages because quantitative assessment of important components or parameters as well as chemometric classification are simultaneously achievable.

In recent years, NIR spectroscopy (extended into the visible region) has been combined with fiber optics for the noninvasive quality control assessment of alcoholic drinks in intact bottles. For example, Nordon *et al.* (2005) have determined alcohol content in 200 ml flat clear glass bottles, Cozzolino *et al.* (2007) have assessed alcohol content, total SO_2, free SO_2 and pH of commercial wine in intact bottle, and Yu *et al.* (2007) have used this system to discriminate amongst rice wine samples in square brown glass bottles according to age. The specific spectrometer systems set up by these authors are suitable for on site wine quality determination, but the feasibility of visible-near infrared (Vis-NIR) spectroscopy and statistical analysis using least squares support vector machines (LS-SVM) for on line quality control determination of Chinese rice wine composition has been investigated by Yu *et al.* (2009).

Yu *et al.* (2009) designed a circle light fiber spectrometer system to determine transreflectance spectra of rice wine samples in unlabeled, sealed brown glass bottles on a conveyer belt. Statistical equations were established between reference data (% ABV, total titratable acidity and pH) and Vis-NIR spectra by LS-SVM. The statistical analysis method compared favorably with more widely used methods such as PCA, PCR and PLSR, with correlation coefficients for validation (r_{val}) of 0.915, 0.888 and 0.872, and lower root mean square error of validation (RMSEP) of 0.168 (% v:v), 0.146 (g/l) and 0.033 for the above-mentioned parameters. Based on the results, it was concluded that the Vis-NIR spectrometer system was suitable for on line wine quality determination, and LS-SVM was a reliable multivariate method for NIR analysis.

Using the methodologies described in the previous paragraphs, FTIR spectroscopy can be used to discriminate between wine samples of different grape varieties and also between red wines that have been subjected to different aging régimes. Tarantilis *et al.* (2008) have used similar techniques to classify Greek red wines according to grape variety using C-18 SPE extracts (Section 4.2.4) containing anthocyanins and polyphenols. AT/FTIR was used in the region 1800–900 cm^{-1} and spectra of extracts from wines of the varieties Agiogitiko, Merlot and Xinomavro were used in a library or data bank as 'fingerprints' for comparison with spectra of SPE extracts of unknown wines. The method was able to discriminate Greek wines made from these three varieties of *V. vinifera*.

NIR spectroscopy has been used to discriminate between Spanish red wines according to the extent of aging in oak casks: crianza $<$ reserva $<$ gran reserve; and according to type of oak cask used: American, French or combination (Garde-Cerdán *et al.*, 2010). NIR spectra of 510 samples and the concentrations of eight oak volatile compounds and ethylphenols (determined by SBSE-GC-MS; see Sections 4.2.4 and 4.3.2) were used as a database. Samples were grouped according to oak type used and also according to storage time, and partial least squares regression (PLSR) gave good calibration statistics ($R^2 > 0.86$) and allowed both discrimination of fresh samples and prediction of desirable oak volatile content and undesirable ethylphenol content.

All of the above examples involved measuring the IR spectra of alcoholic beverages, (or in one case, grape must), where the emphasis was on quality control, confirmation of origin (differentiation between samples according to type or origin) or prediction of component concentration. In the next examples, more emphasis was placed on quantitative determination of particular components of beverages, rather than on classification or discrimination. In an earlier report (Gorinstein *et al.*, 1992), FTIR (KBr discs; 4000–400 cm^{-1}) was used on lyophilized Israeli white wine samples (ethanol was removed at reduced pressure and the residue was freeze dried) to determine a number of components, including phenolic compounds. Polar phase HPLC, gel filtration and electrophoretic techniques (for protein assay) were also used in this study.

Real time HPLC-FTIR was applied for the first time to the analysis of alcohols, carbohydrates and organic acids in six Austrian wines (Vonach *et al.*, 1998). An anion exchange resin was used as the stationary phase, with 5 mM aqueous sulfuric acid as the mobile phase. A transmission flow cell of 25 μm pathlength and CaF_2 windows protected by a layer of low density poly(ethylene) from exposure to acidic solutions. The presence of a low wave pass filter allowed measurements in the spectral region 1600–900 cm^{-1}, where C–O stretches of alcohols and carbohydrates ($\sim$1050 cm^{-1}) and of carboxylic acids (1260 cm^{-1}) occur. The C=O stretching region of carboxylic acids ($\sim$1740–1700 cm^{-1}) was not used because of interference from water absorption at 1640 cm^{-1}. The results compared well with those from official methods, usually enzymic methods (a distillation method for ethanol and a gravimetric procedure for tartaric acid).

More recently, FTNIR (transmission, in the spectral range 800–2500 nm) has been used to identify and quantify the major four oligosaccharides (isomaltose, isomaltotriose, maltose and panose) in Chinese rice wine (Section 2.7.1) (Niu *et al.*, 2008). The reference method was HPLC in ion exchange mode, using pulsed amperometric detection, and the database was derived from the analysis of 40 rice wines from vintages spanning 1996–2005. PLSR with cross validation was used to build the calibration model. Although the calibration accuracy was satisfactory for the four sugars, the validation accuracy was not, indicating that

further studies are needed, possibly using a wider database to improve the specificity, prediction, accuracy and robustness of the models.

FTIR spectroscopy has been particularly focused on the identification and quantification of phenolic compounds in wine and in the analysis of carbohydrates in a number of alcoholic beverages. Fernandez and Agosin (2007) developed an FT/MIR spectrometric chemometric technique for the quantitative analysis of red wine tannins, via C-18 SPE extraction and elution with methanol. The IR sampling mode was ATR, whereby the extract (50 μl) was added to the ZnSe crystal and the methanol was evaporated in vacuum before running the spectrum. Calibration models were constructed using protein precipitation and phloroglucinolysis as analytical reference standards. After spectra preprocessing, different partial least squares models were tested, where PLS regression with full range second derivative spectra gave the most accurate determination of tannin concentration (root mean standard error of calibration = 6.7%, root mean standard error of prediction = 10.3%, $R = 0.958$). Moreover, the mean degree of polymerization of proanthocyanidins in the extracts could be estimated accurately by a similar method. It is expected that these models for tannins, along with other MIR calibrations for other important wine phenolic compounds, still to be developed, will in future be used as routine analyses in wineries.

The presence of higher concentration/strongly absorbing species (such as ethanol and organic acids) tends to complicate the direct analysis of phenolic compounds in wine by FTIR spectroscopy. Nevertheless, by discarding noninformative, 'noisy' spectral regions, Jensen *et al.* (2008) were able to limit the mid infrared spectral widow to 1485–1425 cm^{-1} and 1060–995 cm^{-1} for optimum quantitative analysis of both grape based polyphenols (largely proanthocyanidins) and hydrolyzable tannins derived from maturation in oak casks. The most important spectral regions for the analysis of wine tannins were deduced by the application of four different variable selection methods, including an iterative backward elimination of changeable size intervals partial least squares program, to standard 5012–926 cm^{-1} spectra. To help with the quantification of tannins in wine, the FTIR spectra of 20% aqueous ethanol solutions of (+)-catechin, grape tannin and oak tannin were recorded, along with a red wine spiked with different levels of grape tannin. The calibration model (using 128 red wines of wide variation) was based on the results of a tannin assay according to a slightly modified method of Harbertson *et al.* (2003) (Section 4.4.3). The four variable selection methods resulted in spectral regions that were used to develop calibration models and gave improved prediction of tannin content: RMSEP = 69–79 mg catechin equivalents (CE)/l; $r = 0.93$–0.94 compared with that derived from a calibration model developed using all variables: RMSEP = 115 CE/l; $r = 0.87$).

Turning the attention away from tannins, an FTIR spectroscopic method has been developed for the analysis of anthocyanins in young red wines (Soriano *et al.*, 2007). A reference HPLC method (using analytical standards of the most common grape/young wine anthocyanins) and a UV method were used to construct the calibration set from 350 young Spanish red wines from various regions and from a variety of vine varieties. The validation set was composed of 40 different young red wines covering the range of anthocyanin concentrations found in the calibration set. Partial least squares regression was used to perform the calibrations, where the prediction error (SEC) was 0.15–23.79 mg/l. Validation equations developed to correlate reference and FTIR results revealed a systematic error in the determination of specific anthocyanins (e.g. cyanidin 3-glucoside and petunidin 3-glucoside acetate), which had to be eliminated by application of a correction factor. Nevertheless, the method was considered suitable for measuring anthocyanin levels in young red wines.

Carbohydrates, especially polysaccharides, in alcoholic beverages have been determined by FTIR methods similar to those described above. Polysaccharides were extracted from wine by rather complex procedures involving firstly reduced pressure distillation (for removal of ethanol), dialysis (to remove tartaric acid and other small polar molecules) and then concentration, freezing and freeze drying to give a powder consisting of a mixture of polysaccharides (the 'polymeric material') (Coimbra *et al.*, 2002; 2005). Polysaccharides were then precipitated by the addition of different amounts of absolute ethanol to the polymeric material and, after

centrifugation, both residue and supernatant were kept for analysis, the residues being dissolved in water, rotary evaporated, frozen and freeze dried. The monosaccharide composition was determined by Saemon hydrolysis, conversion of the sugars to volatile alditol acetates, followed by GC analysis. Uronic acids were determined by colorimetry (Coimbra *et al.*, 1996). It was this data that was used to compose the calibration set by chemometric correlation with FTIR spectral data from the same samples. Boulet *et al.* (2007), on the other hand, used 15 polysaccharides with characterized structures previously purified from a red wine.

Single-reflectance ATR using a ZnSe crystal (Coimbra *et al.*, 2002; 2005) or a Ge crystal (Boulet *et al.*, 2007) appears to be the IR sampling mode of choice, with scans in the spectral region 4000–400 cm^{-1} (Coimbra *et al.*, 2002; 2005) or 1850–950 cm^{-1} (Boulet *et al.*, 2007). In the former reports, the 1200–800 cm^{-1} spectral region was used for analysis, whilst in the latter report, each spectrum was subjected to linear standardization at absorbance values from 0 to 1 for the wavenumbers 1800 and 1040 cm^{-1}, respectively. As in other cases, a variety of chemometric methods were used to analyze the data: PCA, canonical correlation analysis (CCA) and a PLS regression model (Coimbra *et al.*, 2002), PLS with orthogonal signal correction (OSC) (Coimbra *et al.*, 2005) and PLS (Boulet *et al.*, 2007). In all the cases outlined above it was possible to characterize wine polysaccharides, although quantification of the main families will need to overcome strong colinearity between the polysaccharide reference spectra and intrafamily spectral variability (intensified by the presence of esterified uronic acid units in the polymer chains) in order to achieve improved accuracy and robustness of the models (Boulet *et al.*, 2007). Similarly, it was necessary to use OSC-PLS to improve the predictive ability of the model for quantification of mannose from mannoproteins (Coimbra *et al.*, 2005).

Beta-glucans, oligomers or polymers of D-glucose, are produced by the action of hydrolytic enzymes on barley starchy endosperm cell wall cellulose during malting and subsequent processes involved in brewing. Oligomers can be released into the wort, and if not efficiently degraded, will be detrimental to general brewing performance (Section 2.6.2). NIR spectroscopy has been used to determine the β-glucan content of milled or homogenized samples of barley or malt, as well as in individual barley or malt grains, in an attempt to develop a rapid method for assessing endosperm modification of malt (de Sà and Palmer, 2006, and references therein). Three hundred and nineteen kernels were analyzed in reflectance mode in the spectral region 900–1700 nm and the same grains were analyzed for β-glucan content by an enzymatic/colorimetric reference method (Section 4.4.3). The standard of error of cross validation between the NIR method and the reference method was satisfactory, suggesting that NIR can be applied to β-glucan determination in whole grains, but is less reliable if the β-glucan content is very low.

Wine polysaccharides are derived from two sources: grape berry cell walls and yeast cell walls. In the former, arabinans and arabinogalactan proteins constitute the largest families, followed by rhamnogalactouronan II, whereas in the latter, mannoproteins and β-glucans are the most abundant. Winemaking procedures such as must clarification with added pectolytic enzymes, skin contact (maceration), fining and filtration can influence the polysaccharide content of the finished wine. Using the methods described above, Coimbra *et al.* (2002) were able to differentiate between extracts of white wines made by different methods (e.g. with and without clarification and/or maceration).

Peat is a very important factor in the production of Scotch whisky and a few other whiskies, since the inclusion of malt dried over peat fires or dried by hot air infused with peat smoke adds valuable aroma and flavor dimensions to the product (Section 3.2.3). In an earlier study, an attempt was made to use FTMIR spectra of surface peat layers from different areas within a specific location to distinguish between vegetative types of peat, to relate chemical and biological properties of peat and to predict chemical and microbiological properties of peat (Chapman *et al.*, 2001). Canonical variation analysis showed that the FTIR spectra of peat from three major vegetation zones were significantly different, indicating nonidentical chemical composition of peat at the three sites. PLS analysis gave a good correlation between the spectra and physicochemical properties such as pH, ash and total nitrogen content. In particular, it was found that variations in the spectral regions associated with the vibration of secondary amide groups accounted for much of the variation in total

nitrogen content. However, PLS models gave poor prediction of chemical and microbiological properties of moorland and forest peat.

It has long been suspected, but not known for certain, that peats originating from different areas of Scotland have different chemical constitutions and hence influence the organoleptic character of the whisky. FTIR spectroscopy has been used as a rapid screening method to assess the discrimination of a large number of peat samples from six different Scottish locations: four from basin or valley bogs (two from Islay, one from Aberdeenshire and one from Speyside) and two from blanket bogs (one from Islay and one from Orkney) (Harrison *et al.*, 2006). Peat samples were previously differentiated using Curie-point pyrolysis mass spectrometry, a destructive method that has serious reproducibility problems. In this study, FTMIR spectra of peats from both blanket and basin/valley bogs were analyzed by a supervized principal component analysis program (one that uses a priori knowledge about class structure within the modelling process), in particular, discriminant function analysis (DFA). Initially, without using a priori knowledge, the results did not cluster clearly, indicating that variability within geographic location was more significant that that between locations. However, encoding the data with the knowledge of the six locations of the peat samples led to a clearer differentiation, although the two basin peats from Islay could not be distinguished. These results suggested that the different chemical composition of the peat samples from different locations may contribute different chemical characteristics to peated malt and hence to peated Scotch whisky. However, it remains to be seen whether such methods can discriminate between the pyrolysis products of the same samples of peat; only then will a relationship between peat type and whisky aroma/flavor be demonstrated.

Like IR spectroscopy, Raman spectroscopy has great potential for multicomponent and other chemometric analyses used to distinguish samples and to determine authenticity of origin, as it readily provides structural fingerprinting data. Additionally, Raman spectroscopy is a rapid, nondestructive technique that requires little sample preparation. However, to date (2009) it has never had the popularity of IR spectroscopy for the analysis of alcoholic drinks. Frausto-Reyes *et al.* (2005) used Raman spectroscopy to distinguish silver Tequilas from aged Tequilas (nine samples and four references) with principal component analysis of the data. Fluorescence background of the Raman spectra (Raman spectra of organic compounds usually have a fluorescence background) was also used for classification. A Raman system with back scattering geometry was used, with linearly polarized radiation of 514.5 nm for excitation. A holographic filter was used to eliminate Rayleigh emission light and an interference filter was used to reject the plasma frequencies of the ecitation laser.

4.4.3 Colorimetry, UV-Visible Spectroscopy and Fluorometry

UV-visible spectroscopy involves the absorption of ultraviolet and/or visible light by molecules, which promotes electronic transitions in the molecules. In practice, radiation in the approximate range 190–800 nm (from the 'near UV' to almost the near infrared) is most useful; that is to say this range is widely applicable and gives most information. Spectroscopy involving the 'far UV' region of the electromagnetic spectrum, although useful, requires rather more specialized equipment. For general accounts on UV-visible spectroscopy, see Lambert *et al.* (1998) and Silverstein *et al.* (2005).

The wavelength of ultraviolet-visible light absorbed by a molecule depends on the electronic energy levels within the molecule, which in turn depend upon certain structural features in the molecule. The general term for a structural feature within a molecule that absorbs radiation is chromophore. In UV-visible spectroscopy, the chromophores are multiple bonds (e.g. C=C, C=O) (giving $\pi \rightarrow \pi^*$, $n \rightarrow \pi^*$ and other transitions), heteroatoms (e.g. O, S, I) (giving $n \rightarrow \sigma^*$ and other transitions) and transition metals (often as complexes with organic analytes). Single bonds (e.g. C–C, C–O) are also chromophores, but the transitions ($\sigma \rightarrow \sigma^*$, $n \rightarrow \sigma^*$) are so high in energy that absorption occurs well into the UV region (vacuum UV region), making them

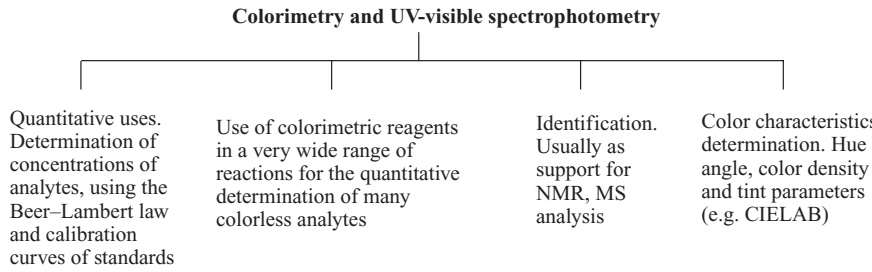

Figure 4.4.18 *Major applications of UV-visible spectrophotometry to the analysis of alcoholic beverages*

inaccessible by standard spectrophotometers (190–800 nm). The most amenable chromophores are those with extended conjugation (e.g. carotenoids) or aromatic character (e.g. porphyrins or phenolic compounds) or containing certain transition metal species; here the wavelength of absorption is either in the near UV region (say 210–350 nm) or visible region (360–800 nm). The study of colored analytes (those that absorb between 360 and 800 nm) is often known as colorimetry.

Of all the many spectroscopic techniques that are applied to the analysis of alcoholic beverages and their raw materials, colorimetry/UV-visible spectrophotometry (the last term often abbreviated to spectroscopy) is probably the most widely employed, even discounting its use as a major HPLC detection technique. Indeed, here the latter use will not be discussed, having been covered in Section 4.3.3.

The major ways in which UV-visible spectroscopy is used in the analysis of alcoholic drinks and their raw materials is summarized in Figure 4.4.18. To give a detailed account of the involvement of UV-visible spectroscopy in every aspect of alcoholic drinks analysis is beyond the scope of this book. Instead, focus will be on specific methods for the determination of specific analytes, with the emphasis being on colorimetric (or fluorometric) reactions (those that involve change of color, or introduction of a chromophore or fluorophore, such as that introduced by a chromogenic or fluorogenic reagent). Major uses of UV-visible spectroscopy and fluorometry (not including its use as a mode of detection in HPLC) in alcoholic beverage analysis include color assessment and quantitative analysis of specific compounds or families of compounds. The latter applications are numerous, so only a selected number of the more important ones will be discussed here in any detail.

Measurement of Color

Color can be measured most simply by use of a set of color standards, originally colored glass discs (comparator discs) developed by Lovibond for use with his early comparative colorimeter (the Tintometer – see Section 1.2.5) in the determination of the color of beer wort, beer and caramel or syrup adjuncts. Although updated versions of the Lovibond colorimeter are still used in breweries and wineries, and the American Society of Brewing Chemists has based its color scale for wort and beer on the Lovibond scale (°Lovibond/ASBC), more sophisticated ways for determining color are in use today. These methods involve the measurement of color intensity (absorbance) of the beverage at one or more wavelengths, using a spectrophotometer.

For the simple assessment of color, the European Brewery Convention (EBC) suggested 430 nm as being most appropriate for the pale Pilsner style beers that dominate continental Europe, whereas the Institute of Brewing (now the Institute of Brewing and Distilling) in the UK chose 530 nm because maximum variation in ale color occurs at this wavelength.

The SRM requires the measurement of the absorbance (A_{430}) of the sample in a 1 cm cuvette at 430 nm, in which case the SRM value is defined by Equation 4.4.7, where D is the dilution factor.

$$\text{SRM} = 12.7\, DA_{430} \tag{4.4.7}$$

SRM is related to the older Lovibond scale and the European EBC scale (which also uses A_{430} and a 1 cm pathlength) via Equations 4.4.8 and 4.4.9, respectively.

$$\text{SRM} = 1.3546\ \text{Lovibond} - 0.76 \tag{4.4.8}$$

$$\text{SRM} = 0.508\,\text{EBC} \tag{4.4.9}$$

Thus, pale lager beers, pale ales and pale wheat beers, brown beers, porters and stouts tend to have SRM values of *ca.* 2–6, 6–10, 12–24, 24–30 and 35+, respectively, with the corresponding EBC values being approximately double these.

These simple color assessments work well if there is no haze ($A_{700} < 0.039A_{430}$) and if the beer has 'average spectral characteristics,' which applies to the big majority of beers; the major exceptions are those, such as cherry or raspberry ales, that have been necessarily made with colored adjuncts.

A more recent approach has been to devise an augmented SRM that has no restriction on the spectral characteristics of beers and the color can be determined under any viewing conditions, unlike the CIE L*a*b* method (see below) (de Lange, 2008). Based on the absorbance spectra of 99 beers, the absorbance at any wavelength of any beer with average spectral characteristics can be computed from Equation 4.4.10.

$$A(\lambda) = \frac{\text{SRM}}{12.7}\left\{0.018747\exp\left(\frac{\lambda - 430}{13.374}\right) + 0.98226\left(\frac{\lambda - 430}{80.514}\right)\right\} \tag{4.4.10}$$

The transmission spectrum of any beer (without spectral restrictions) is given by Equation 4.4.11, where ζ_i are essentially eigenvectors of the covariance matrix of the normalized transmission spectra of the beers that were used to construct Equation 4.4.10. $A(\lambda)$ has the form shown in Equation 4.4.10.

$$T(\lambda) = \log^{-1}[A(\lambda) - c_1\zeta_1 + c_2\zeta_2 + \cdots] \tag{4.4.11}$$

The coefficients c_1 and c_2 are augmentation coefficients to account for the deviation of a particular normalized spectrum from the average normalized spectrum. For a beer with close to average spectral characteristics they are small, but for nonaverage beers, such as a cherry ale, they are much more significant and have to be included. Thus a simple SRM determination (via Equation 4.4.10) of cherry ale would give a value of around 15 (dark amber), with no indication of its red color, whereas application of Equation 4.4.11, with three coefficients (1.8, 0.8 and –0.1) yields a much accurate color assessment.

Red wine color can be described by measurements at 420, 520 and 620 nm, representing yellow, red and blue contributions to the overall color. Young red wines have strong absorbances at 620 nm, arising from the quinoid forms of anthocyanins (Figure 4.4.19) and their derivatives, whereas aged red wines have a greater absorbance at 420 nm, because of the presence of condensed polyphenols. Indeed the hue of a red wine can be described by the ratio of the absorbances at 420 and 520 nm (A_{420}/A_{520}) (Ribéreau-Gayon *et al.*, 2000a); it is ~0.5–0.7 for young wines and increases with aging, reaching ~1.3 as an upper limit. Also, a function known as brilliance (Equation 4.4.12) can be used to describe red wine color. It relates to the shape of the spectrum: young red wines have narrow maxima at 520 nm (bright red), whereas older samples have broader,

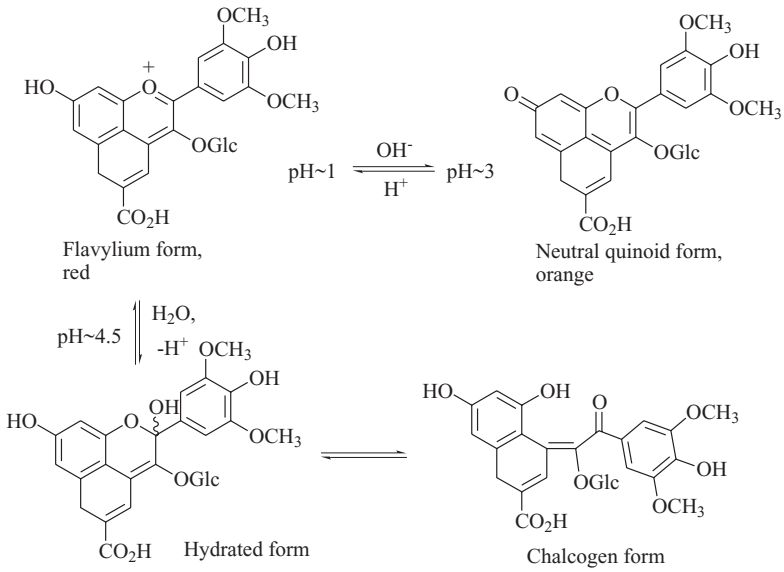

Figure 4.4.19 *Some molecular forms of anthocyanins in young red wines. Illustrated for vitisin A, an abundant anthocyanin derivative of young red wine. Asenstorfer and Jones (2007)*

less well defined maxima at 520 nm (brick red), giving brilliance values between 40 and 60 and below 40, respectively.

$$\text{Brilliance (\%)} = \left[1 - \left(\frac{A_{420} + A_{620}}{2A_{520}}\right)\right] \times 100 \tag{4.4.12}$$

More recently, tristimulus values (Hughes and Baxter, 2001) have been developed to describe the color of beverages in terms of the transmittance at three wavelengths that correspond to the maximum response of human retinal cone cells for red (600 nm), green (550 nm) and blue (450 nm) light perception. This system of measurement was devised by the Commission Internationale de l'Eclairage (CIE). The transmission spectrum of a beverage in a 10 mm cuvette relative to a water reference in a spectrophotometer with a standard illuminant light source (usually the D_{65} standard) is used to derive the three CIE color matching functions (tristimulus values). These are notated X (red), Y (green) and Z (blue). However, these values are usually transformed into three uncorrelated color parameters L^*, a^* and b^*, which give a representation of the color in three dimensions, known as the CIE L*a*b* space (Figure 4.4.20). In this representation, hue is a continuum of colors (between yellow and blue) around the equator of the sphere. Young red wines should have a red-blue hue, Pilsner beers a yellow hue and pale ales a yellow-red hue. Value, which is located along the North–South axis, measures the brightness of color. Many young red wines should have value measurements in the southern hemisphere. Finally, chroma, the distance from the North–South axis to the circumference, describes the depth or strength of color. A young wine from Chateau Latour should have a chroma measurement close to the circumference in the southern hemisphere, in the blue-red hue region. Lambrusco or young Valpollicella, on the other hand, will have a chroma characteristic closer to the North–South axis, indicating less depth of color.

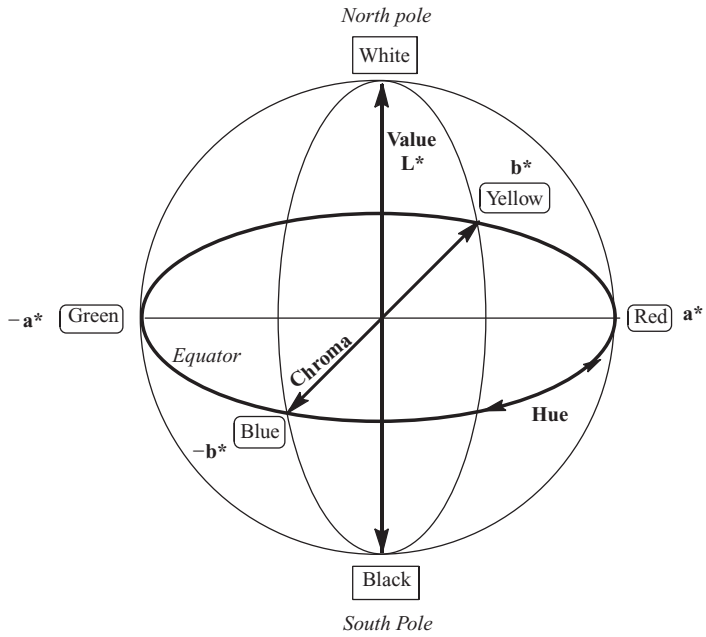

Figure 4.4.20 *The CIE L*a*b* color space. Hue is a continuum of colors around the equator. Value describes brightness and chroma relates to color strength :* $c = (a^* + b^*)^{1/2}$. *The hue angle is defined as* $h = tan^{-1}(b^*/a^*)$. *It describes the color nuance*

Color characteristics have been used to investigate new grape and wine anthocyanin pigments. One of the earliest studies involved the characterization of color stable anthocyanin derivatives in maturing red wines (Bakker and Timberlake, 1997; Romero and Bakker, 2000a; 2000b). Vitisins A and B, condensation products between malvidin 3-glucoside and pyruvic acid and acetaldehyde (respectively), were found to give UV-visible spectra that showed hypsochromic shifts (i.e. to lower wavelength) of ∼19 nm and ∼38 nm (respectively, depending on the solvent) from malvidin 3-glucoside, the major anthocyanin of grape juice. With increasing pH, the tristimulus L^* value increased for malvidin 3-glucoside, indicating loss of color intensity, whereas vitisins A and B largely retained their color between pH 2 and pH 5. Similarly, the hue angles for the two vitisins were constant between pH 2 and pH 4. Both these aspects demonstrated the superior color characteristics and color stability of the derivatives over the simple anthocyanin.

Similarly, tristimulus parameters have been used to study the aging of red wines (e.g. Port wines) (Romero and Bakker, 2000b). Generally, as red wines age their L^* values increased (indicating loss of color) and this was accompanied by an increase in hue angle from purple-red to brown-red. These observations are consistent with the slow formation of condensation oligomers from anthocyanins and flavan-3-ols. However, for the first stage of aging (∼6 months in 600 l oak casks), L^* values and hue angle decreased as anthocyanins reacted with fermentation carbonyl compounds (especially acetaldehyde and pyruvic acid) to produce vitisins. In the aging period beyond six months the vitisins gradually form oligomeric condensation products.

Determination of pK_a Values

Anthocyanins and their derivatives are important wine pigments. They can exist in solution as a number of species, depending primarily on the pH of the medium and the concentration of pigments. The earliest reliable

estimates of the ionization and hydration constants of native anthocyanins such as malvidin-3-glucoside were made by Brouillard and Delaport (1977 – see also earlier papers) using pH and temperature jump experiments and UV-visible spectroscopy. The complex equilibria existing in dilute solutions of anthocyanins and their derivatives over a range of pH have been studied recently by UV-visible spectrophotometry, ^{13}C NMR spectroscopy and paper electrophoresis (Asenstorfer *et al.*, 2003; 2006; 2007). Brønsted ionization constants for malvidin-3-glucoside, vitisin A and 8,8-linked malvidin-3-glucose-ethyl-catechin/epicatechin were determined by fitting absorbance data for each analytical wavelength to Equation 4.4.13 (Asenstorfer *et al.*, 2006).

$$A_{\mathrm{p}} = \frac{A_0 + A_1 10^{\mathrm{pH}-\mathrm{pK}(1)} + A_2 10^{2\mathrm{pH}-\mathrm{pK}(1)-\mathrm{pK}(2)+\cdots}}{1 + A_1 10^{\mathrm{pH}-\mathrm{pK}(1)} + A_2 10^{2\mathrm{pH}-\mathrm{pK}(1)-\mathrm{pK}(2)+\cdots}} \tag{4.4.13}$$

Here, A_p is the predicted absorbance at a particular wavelength estimated at a particular pH value. It results from the absorbance of the equilibrium mixture of the acid, A_0, and its ionization products, A_1, A_2, etc. and is determined by the sum of the respective absorbances and partial molar fractions of the acid and its ionization products.

The pK_a values were found to depend on structure: for example the first pK_a value, $pK_a(1)$, was 1.76 for the malvidin-3-glucoside, but 0.95 for vitisin A and 2.33–2.44 for the various dimer stereoisomers. These pK_a values were found to agree well with those determined by paper electrophoresis (Asenstorfer *et al.*, 2006) and the assignment of equilibrium species (flavylium, hydrated, quinoid base, etc.) was confirmed by ^{13}C NMR spectroscopy for vitisin A (Asenstorfer and Jones, 2007); at wine pH (~3.2–3.6) the most important structures are the flavylium ion the neutral quinoid forms, with the latter predominating (λ_{max} ~498 nm) (Figure 4.4.19).

In *dilute* solution at wine pH, the major forms of anthocyanins and their derivatives (such as vitisin A) tend to be colorless hydrated or orange quinoidal forms (Asenstorfer *et al.*, 2003; 2006; Asenstorfer and Jones, 2007). The obvious bright red color of young red wines is attributed to the much higher concentrations of anthocyanins and derivatives, resulting in extensive association, via π-stacking or dipole–dipole interaction, (or copigmentation) between a number of species, including the quinoidal forms of malvidin-3-glucoside and vitsin A.

Colorimetric and Fluorometric Reactions and Titrations

There are many colorimetric and fluorometric reactions that are utilized to determine the concentration of a specific component of an alcoholic beverage (e.g. acetic acid, D-glucose, (–)-malic acid, tartaric acid, (+)-lactic acid and (–)-lactic acid) or families of components (e.g. amino acids, phenolic compounds or reducing sugars). Additionally, there are colorimetric methods for the determination of most metals found in alcoholic beverages or their raw materials and precursors.

Many of the methods for individual organic components depend on an enzymic reagent carrying out the reaction that enables UV-visible absorption measurement. These can often be bought as kits (e.g. Boehringer Mannheim (now Roche), Fluka, Megazyme or Sigma), which contain the enzymic reagent, buffer solutions and other reagents required for the analysis, along with detailed instructions and standard solutions of the analyte to be determined. They are usually straightforward to operate and of good accuracy and precision, but they do suffer from limited shelf life, particularly of the enzyme reagent(s). As with any other analytical method, the test solutions will probably need to be diluted so that measurements fall within the calibration range of the kit.

Total Phenolic Content (TPC)

TPC of musts and beverages is usually measured by the Folin–Ciocalteu method, mostly the version developed by Singleton and Rossi (1965). A mixture of phosphomolybdic ($H_3PMo_{12}O_{40}$) and phosphotungstic acids ($H_3PW_{12}O_{40}$) in alkaline solution is known to oxidize most phenols to give a blue coloration which can be measured at 760 nm. The oxidizing agent is a polymeric species containing tetrahedral phosphate units linked to octahedral molybdate and tungstate units, where the metals in oxidation state +6 and are readily interchangeable. Upon oxidation of phenols (as the anions or phenoxides, in alkaline solution) some of the metal +6 oxidation states are reduced to +5 states and it is this combination of mixed oxidation state complexes that is thought to give rise to the coloration.

In one version of this method (Ribéreau-Gayon *et al.*, 2000a), red wine (1 ml), diluted five or tenfold with distilled water, is mixed with reagent (5 ml), 20% aqueous sodium carbonate and made up to 100 ml with distilled water. After 30 min, the absorbance of this solution in a 1 cm cell is measured at 760 nm and TPC is calculated according to Equation 4.4.14. Values lie between 10 and 100 for red wines.

$$\mathrm{TPC_{F-C}} = 20A_{760}(\mathrm{DF}) \tag{4.4.14}$$

where DF is the dilution factor.

In another version (Amerine and Ough, 1980b), red juice or wine samples are diluted × 5, whereas pale samples are used undiluted. To the sample (1.00 ml) in a 100 ml volumetric flask, is added distilled water (60 ml) and Folin–Ciocalteu reagent (5.00 ml). After 30 s, aqueous sodium carbonate (15 ml) is added and the solution is brought to volume with distilled water. After a 2 h stand at ∼20 °C, the absorbance is measured at 765 nm against a blank made up as above, but without the sample.

The total phenolic content of each sample (taking into account any dilution factor), is determined using the standard plot for gallic acid standards (e.g. 50–500 mg/l) and is expressed in terms of mg/l of gallic acid (gallic acid equivalents).

A much simpler, speedier method for measurement of TPC was suggested by Ribéreau-Gayon *et al.* (2000a). It does not involve the use of a colorimetric reaction, but is a simple measurement of absorbance at 280 nm (Equation 4.4.15, where DF is the dilution factor).

$$\mathrm{TPC_{280}} = A(280\,\mathrm{nm})(\mathrm{DF}) \tag{4.4.15}$$

$\mathrm{TPC_{280}}$ values lie between 6 and 120. The method relies on the fact that the benzene rings of the majority of phenols have an ultraviolet absorption at 280 nm. It is the simplest method for the determination of phenols, but is subject to error if the phenol does not absorb at 280 nm, as in the case of cinnamic acids and some of their biological derivatives, such as chalcones. Similarly, if there are nonphenolic aromatic compounds present that do absorb at 280 nm, then this will lead to an overestimate of phenolic content. In practice, for red wines, both these interferences are known to be very small.

Procyanidin Content

Procyanidins are polymeric flavanols, which yield anthocyanidins ($\lambda_{max} \sim 520$ nm) upon heating with hydrochloric acid under oxidative conditions (Section 5.8.6). They are important components of many alcoholic beverages, particularly red wines. The method of Glories *et al.* (1988) requires the preparation of two samples (red wine diluted × 50; white wine undiluted or diluted × 2). One sample (4.00 ml) is mixed with water (2.00 ml) and pure 12 M HCl (6.00 ml) and heated at 100 °C in a water bath for 30 min, after

which 95% ethanol (1.00 ml) is added to solubilize the red pigments that are formed and the absorbance at 520 nm is measured (A_1) (1 cm optical path length). The other sample is treated as above, but is not heated (absorbance A_2). By comparison with an oligomeric procyanidin solution derived from grape seeds, the procyanidin concentration of the sample is obtained by use of Equations 4.4.16 and 4.4.17.

$$\text{For young wines, } \mathrm{PC}(g/\mathrm{l}) = 16.16A_1 - 24.24A_2 - 1.71\mathrm{AC} \tag{4.4.16}$$

$$\text{For older wines, } \mathrm{PC}(g/\mathrm{l}) = 16.16\mathrm{A}_1 - 32.32\mathrm{A}_2 - 3.86\mathrm{AC} \tag{4.4.17}$$

where AC is the free anthocyanin content (in g/l), as determined by the method described below, for example.

Tannin Content

Estimation of tannin content (procyanidin and similar flavonoid polymers plus hydrolyzable tannins) can be carried out using a modification (Jensen *et al.*, 2008) of the method of Harbertson *et al.* (2003). This method involves the precipitation of tannins with bovine serum albumin (BSA). The precipitate is redissolved and the tannin concentration is measured by a color reaction with ferric chloride. Typically, the wine sample is diluted in a model wine solution containing 12% ethanol (v:v) and tartaric acid (5 g/l), whose pH has been adjusted to 3.3 with aqueous NaOH. The test solution and BSA are mixed and allowed to stand for 30 min before centrifugation at 14000g. The supernatant is poured off the tannin–protein pellet, which is redissolved in SDS/TEA buffer solution (1.5 ml) and a background absorbance measurement on the spectrophotometer is performed on this – A(BG). This solution (1 ml) is then reacted with $FeCl_3$ solution (11.4 mM $FeCl_3$ in aqueous 11.4 mM HCl) (125 μl) and the absorbance (A) is measured after 10 min. Dilutions of sample in the model wine solution are adjusted to give a tannin response (calculated as 1.125A – A(BG)) between 0.3 and 0.75. The tannin content is reported in mg of catechin equivalents/l from a linear plot of the color reaction between catechin and $FeCl_3$ (absorbance = 0.006258 × [catechin (mg/l]; $R = 0.9997$).

Anthocyanin Content

Estimation of anthocyanin content of musts and wines is important in many wineries. There are two widely used colorimetric methods, the pH shift method and the sulfur dioxide bleach method, of which the latter is generally thought to be more reliable (Ribéreau-Gayon *et al.*, 2000a). Purple colored beverages, like red wines, black raspberry juice and mulberry juice, contain anthocyanins as both free molecules and condensed or polymerized species. All of these species absorb at *ca.* 520 nm. This method relies upon the fact that bisulfite reacts with free anthocyanins, but not with the condensed species, to form products that do not absorb at 520 nm. So, by measuring the difference in absorption at 520 nm (i.e. before and after the addition of bisulfite), it is possible to estimate the free anthocyanin content of beverages (Amerine and Ough, 1980a). This method is insensitive to the presence of SO_2 in the beverage (a commonly used preservative in commercial juices and wines) and so is thought to be more reliable than the pH shift method (Ribéreau-Gayon *et al.*, 2000a).

The method of Amerine and Ough (1980a) is described in Figure 4.4.21. Firstly, all samples (but not standards) are accurately diluted × 5 and then 1 ml of this diluted solution is used in the procedure described in this figure. After 30 min, 3 or 4 ml of A and B are transferred separately to quartz cuvettes and the difference in absorbance at 520 nm, against distilled water blank is determined. The standard solutions of cyanidin hydrochloride of concentrations say, 100 mg/l, 50 mg/l, 25 mg/l and 10 mg/l, are used for calibration, without prior dilution. A standard curve is prepared and the anthocyanin content of each of the samples, using the standard curve. The results are quoted as mg/l of cyanidin, taking into account the × 5 dilution.

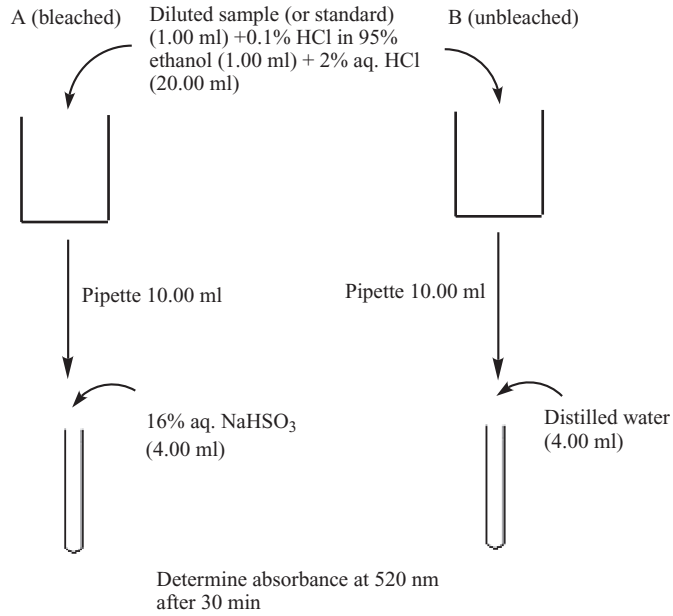

Figure 4.4.21 *Summary of bisulfite bleach method for estimation of anthocyanin content of musts and bevarages*

Individual Acids

Various colorimetric methods are available for the analysis of the important individual aliphatic acidic components of alcoholic beverages and musts, including acetic acid, citric acid, fumaric acid, α-ketoglutaric acid, L-malic acid, D- and L-lactic acids, pyruvic acid and succinic acid (Amerine and Ough 1980b). Similar methods also exist for the determination of sugar acids, such as gluconic acid. These all depend on a reaction of the analyte with a reagent to produce a product that absorbs either in the visible or near ultraviolet region of the electromagnetic spectrum.

Enzymic reagents are particularly favored for these assays and enzymic/colorimetric/UV methods (often using kits from companies such as Boehringer Mannheim, Fluka, Sigma or Megazyme) are widely used in analytical laboratories of the food and beverage industries. Figure 4.4.22 illustrates the principles of several of these enzymic methods. They usually involve the use of dehydrogenase enzymes in the presence of NAD^+ or $NADP^+$ coenzymes in buffered solution, whence the reaction is monitored at ∼340 nm by the formation of NADH or NADPH. An additional enzyme reaction is often used in the assay procedure in order to maximize NADH production, exemplified by the use of glutamate-oxaloacetate transferase in the L-malate assay (Figure 4.4.22) (Möllering, 1985). In the case of fumarate determination, fumaric acid in the sample is first hydrated to L-malic acid by fumarase and then the malate produced here is assayed by the malic acid method (Figure 4.4.22) (Boehringer Mannheim GmbH, 1989).

Samples should be clear and nearly neutral (pH ∼7); turbid samples need filtration before analysis and pH may need to be adjusted by the addition of a small quantity of mineral acid or alkali. Accurate sample dilution is usually necessary prior to analysis, unless the analyte in the beverage is present at low concentration (e.g. <0.2 g/l for malic acid). Lightly colored samples can be analyzed without further sample preparation, but highly colored samples, such as red wine or elderberry must (10 ml) should be stirred with PVP powder (0.1 g) for 1 min and filtered, the clear slightly colored solution being used for the assay. Bound acid concentrations

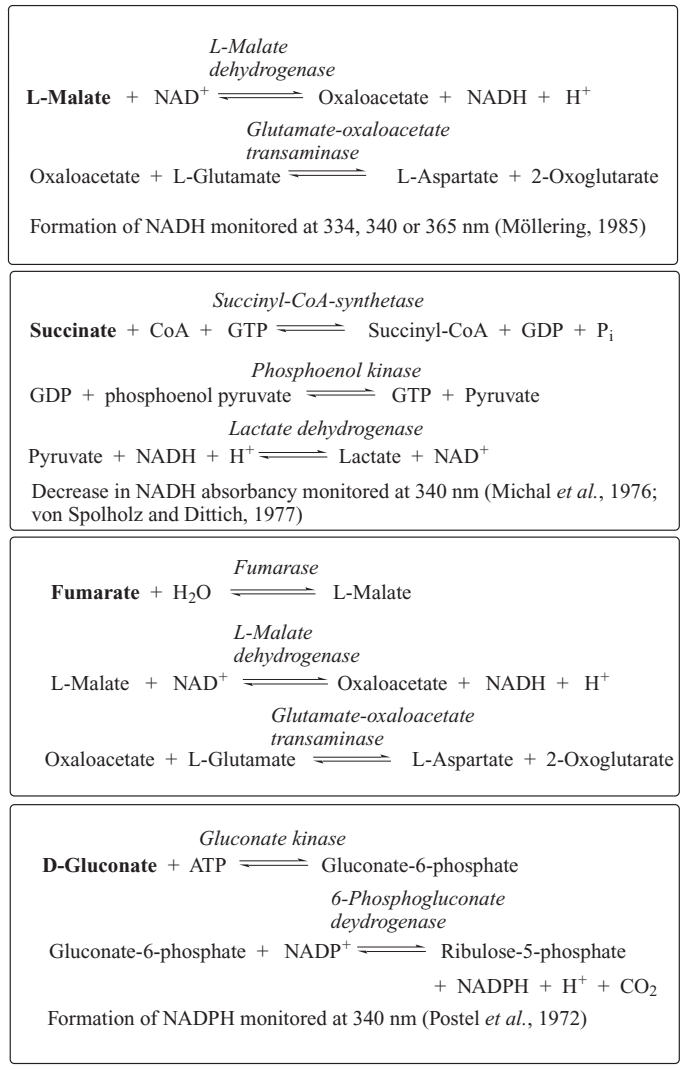

Figure 4.4.22 *Principles of some enzymic methods for the determination of individual acids*

(e.g. as esters) in beverage samples can be determined from the results of free acid and total acid assays. The latter are carried out on samples that have undergone alkaline hydrolysis, followed by neutralization. For example, in the case of malate determination, the sample (20.00 ml) and 2 M sodium hydroxide (6 ml) are heated under reflux (with stirring) for 30 min. After cooling, the solution is neutralized with 1 M sulfuric acid and made up to 50.00 ml with distilled water. This solution (already diluted × 2.5) is then used for the assay.

Sometimes, as in the succinate assay, use of the more direct method is unsatisfactory because of the instability of the dehydrogenase enzyme (here, succinate dehydrogenase), coupled with difficulty of its isolation in pure form (Michal *et al.*, 1976). In cases such as this, a series of coupled enzymic reactions were used and the reaction was monitored by following the fall in absorbance at 340 nm due to NADH (Figure 4.4.22).

Certain individual aliphatic acids are still sometimes determined by nonenzymic colorimetric methods, although in many laboratories chromatographic methods (especially HPLC – see Section 4.3.3) and CZE methods (Section 4.6.1) have largely replaced these. Tartaric acid can be determined by the Rebelein method, which uses the wine red coloration formed between tartrate and ammonium vanadate (Amerine and Ough 1980b and references therein). The standard method involves the following procedure. The sample (3.00 ml of must or 10.00 ml of wine) is mixed with 0.1 M silver nitrate solution in 30% aqueous acetic acid (15 ml) and (for colored samples) decolorizing charcoal (0.5 g). This solution is swirled for 15 s whilst ammonium vanadate (NH_4VO_4) solution (15 ml) is added. (The ammonium vanadate solution is made by mixing NH_4VO_4 (10 g), 1M NaOH (150 ml) and 27% aqueous sodium acetate (200 ml) and making up to 1000.00 ml with distilled water). The solution is filtered, the first 5 ml is discarded and the filtrate (∼10 ml) is allowed to stand for 30 min. Its absorbance is determined in a 1 cm cell at 530 nm against a blank made up as above, but using distilled water in place of the sample. The absorbances of samples are compared with a standard curve prepared using standard tartaric acid solutions carried through the same procedure. The decolorizing charcoal is used to adsorb anthocyanins in colored samples since these interfere with the method (they absorb around 520 nm). This procedure has been improved for colored samples by running further blanks rather than by using decolorizing charcoal (Amerine and Ough, 1980b).

Citric acid may be assayed using the diazo method of Rebelein (Amerine and Ough 1980b). The diazo solution (made from a glacial acetic acid-water solution of sulfanilic acid and aqueous sodium nitrite) needs to be prepared at 0 °C and must be used immediately. This feature, plus its numerous steps (i.e. its labor intensive nature), including centrifugation and the use of many reagents, make the diazo method compare unfavorably with HPLC or CZE methods, despite its good reliability.

Colorimetric methods for the determination of lactic acid involve the oxidation of both enantiomers (hence only total lactic acid can be assayed) to acetaldehyde by cerium (IV) sulfate. The acetaldehyde is then reacted with either sodium nitroprusside/piperidine or *p*-hydroxydiphenyl to give colored derivatives that have absorption maxima at 570 nm and 560 nm, respectively (Amerine and Ough, 1980b). Once again, although these methods generally give reliable results, their nonrobust and labor intensive nature make them unattractive compared with HPLC, CZE or enzymic methods, all of which are able to determine D- and L-lactic acid separately.

Sugars

Although reliable chromatographic methods (especially HPLC and CZE – see Sections 4.3.3 and 4.6.1, respectively) are available for the determination of sugars (including reducing sugars) in alcoholic beverages, musts and wort, colorimetric assays are still sometimes used. Total reducing sugar content of beverages can be determined by titrimetric techniques, such as the Lane–Eynon method (Section 4.6.3).

D-glucose can also be assayed individually using the Sigma D-glucose kit, as for the determination of D-glucose released by the hydrolysis of aroma precursor glucosides (Arévelo Villena *et al.*, 2006). The aforementioned kit involves the use of glucose oxidase to specifically oxidize D-glucose to D-gluconic acid, which after incubation of the test solution with the enzyme and adjustment of pH, the gluconic acid is reacted with *o*-dianisidine to give a red coloration (540 nm), whose absorbance is measured and related to concentration via a calibration curve.

There are enzyme kits available for the colorimetric determination of other sugars and carbohydrates (see catalogues of Boehringer-Mannheim (now Roche), Fluka, Megazyme and Sigma, for example). The Megazyme mixed linkage β-glucan kit can be used to assay the β-glucan content of malt flour, wort or beer. Here, the enzyme lichenase (specific, *endo*-(1-3)(1-4)-β-D-glucan 4-glucanohydrolase) is used to hydrolyze 3→4 links of β-glucan polymers to produce oligomers, which are then hydrolyzed by the enzyme β-glucosidase to give D-glucose. The last named is then oxidized by glucose oxidase and peroxidase to gluconic

acid, which in the presence of 4-aminoantipyrine gives a red coloration at 510 nm. As usual, absorbance measurements are made with respect to a blank carried through the same procedure and the method is regularly calibrated, in this case using either D-glucose standards or control flours of known β-glucan contents. This method forms the basis of a number of recommended or standard methods of various professional bodies, such as the Association of Official Analytical Chemists (AOAC) and the European Brewery Convention (EBC). A method similar to that described above was used to compare glucanase activities of two malting barley varieties and the β-glucan contents of the corresponding malts (de Sà and Palmer, 2004).

A nonenzymic fluorometric method for β-glucan determination uses the reagent Calcofluor in aqueous sodium chloride/glycine buffer at pH 9.5 to produce a fluorescent derivative of β-glucan after 30 min incubation, with excitation at 360 nm, followed by fluorescence at 420 nm (Kanauchi and Bamforth, 2002). Brewers have a special interest here, since extraneous β-glucans in beer wort can lead to processing problems (Section 2.6.2), but at the same time they are a useful source of dietary fiber, giving certain health benefits (Sections 5.7.4 and 5.11.2).

Ammonia, Amino Acids and Proteins

Ammonia is an important constituent of many alcoholic beverages, and particularly of raw materials, such as fruit juices and beer wort. Apart from column chromatography/titrimetric (Section 4.6.3), ion selective electrode methods (Section 4.5.1) and methods mentioned in the next paragraphs, ammonia may be determined using Nessler's reagent, a solution of 0.09 M potassium tetraiodomercurate (II) and 2.5 M potassium hydroxide. Small quantities of ammonia produce a yellow coloration due the formation of the soluble complex $HgO.Hg(NH_2)I$. Color formation can be monitored at 425 nm and its absorbance compared with those of standard ammonia solutions under identical experimental conditions.

Ammonia can also be determined colorimetrically by the phenate test, in which it reacts with sodium phenate (phenoxide) in the presence of hypochlorous acid (HClO) to give the blue soluble indophenol. The reaction is usually monitored at 630 nm. Both the above methods have been used to assay ammonia produced in Kjeldahl digestions for the determination of total nitrogen or protein content of foodstuffs (Section 4.6.3).

Yet another method for the determination of ammonia and urea in foodstuffs makes use of the Megazyme® kit, where ammonia (as NH_4^+) is combined with 2-oxoglutarate in the presence of glutamate dehydrogenase and NADPH to produce L-glutamate and $NADP^+$. NADPH consumption is measured by decrease in absorbance at 340 nm and is related to ammonia content. If urease is then added, urea is hydrolyzed to ammonia, which reacts as described above, so measurement of a further decrease in absorbance at 340 nm can be related to the urea content. All absorbance measurements are made with respect to a blank (with an extra water component in place of the sample) taken through the same procedure.

Total usable nitrogen is a measure of the yeast usable nitrogen content (ammonia, α-amino acids and small peptides) content of beverages, musts and worts. Free amino nitrogen (FAN) is the amino acid nitrogen available to yeast during fermentation. It is often determined by colorimetric methods involving ninhydrin, such as that of the European Brewery Convention, although in reality these methods actually measure ammonia and small peptide content as well as amino acid content. The EBC method involves making the ninhydrin color reagent from ninhydrin (0.5 g), anhydrous Na_2HPO_4 (4 g), KH_2PO_4 (6 g) and fructose (0.3 g) in 100 ml of aqueous solution. For FAN assay, beer (1.00 ml) is diluted to 50.0 ml with distilled water and the diluted sample (2.00 ml) is pipetted into a test tube. After addition of ninhydrin color reagent (1.00 ml), the test tube is heated in boiling water for 16 min, then cooled in cold water before the addition of a diluting reagent (KIO_3 (2 g) in water (600 ml), with ethanol (400 ml) added). The absorbance of this solution is measured at 575 nm against a blank, containing water (2.00 ml) in place of the sample. A glycine standard solution (107.2 mg glycine/100 ml of aqueous solutuion) is used for calibration, following the method described above.

Yeast assimilable nitrogen (YAN), a measure of the ammonia and amino acid content of wine must, is the sum of two separate determinations; ammonia and free amino acids. The former can be estimated by use of the 2-oxoglutarate method (Bergmeyer and Beutler, 1983), whilst the latter can be determined by formol titration (Shively and Henick-Kling, 2001) or by the *o*-phthalaldehyde/*N*-acetyl-L-cysteine spectrophotometric method (Dukes and Butzke, 1998; Shively and Henick-Kling, 2001). Kits are also available for the assay of ammonia and primary amino nitrogen (e.g. see www.megazyme.com).

Reduced volume versions of the ninhydrin method of FAN determination have been applied recently to beer and wine (Abernathy *et al.*, 2009), using ninhydrin solutions that were buffered either by sodium acetate (pH 5.5) for beer or grape juice, or phosphate buffer (pH 6.8, as for the EBC method, above) for beer. These procedures used just 30 μl of sample (or 20 μl of glycine standard) and 200 μl of the pH 5.5 ninhydrin solution or 1 ml of the pH 6.8 ninhydrin solution, thus being economical as well as rapid, accurate and applicable to large numbers of samples.

Data from these methods, along with total nitrogen content data (section 4.6.3) are useful in assessing the fermentability of wine must and beer wort, as well as checking the protein content of malted cereals.

Individual amino acids can be determined by a wide variety of HPLC (Section 4.3.3) and GC (Section 4.3.2) methods, but a routine automated method uses ion exchange column chromatography and an amino acid analyzer, with ninhydrin as a chromogenic reagent (Ribereau-Gayon *et al.*, 2000b) and a similar method uses picric acid solution (Kluba *et al.*, 1978).

There are well established individual colorimetric methods for the determination of arginine and proline in wines and other alcoholic drinks, via color formation with 8-hydroxyquinoline/alkaline sodium hypobromite and ninhydrin (respectively) (Amerine and Ough, 1980c), but these have largely given way to chromatographic methods. More recently, the individual amino acid (lysine and proline) content and biogenic amine (histamine and tyrosine) content of beers have been determined by fluorometric methods on beer extracts, using mostly *o*-phthalaldehyde (with 2-mercaptoethanol and Brij 35 for proline assay) for fluorophore formation (Gorinstein *et al.*, 1999). Absorption of the amino acid/amine *o*-phthalaldehyde complexes were at 340 nm and emission was measured at 430–450 nm. Tyramine was reacted with α-nitroso-β-naphthol and nitric acid containing 2% $NaNO_2$ to form the fluorescent analyte that absorbed at 465 nm and emitted at 540 nm.

Total soluble protein concentration, say of barley extract, malt extract or wort, can be determined using proprietary protein assay kits, such as the BCA kit of Pierce (Rockford, USA), which measures the absorbance of the sample at 562 nm, using bovine serum albumin (2 mg/ml) as the standard. The kit works on the principle that Cu(II) in alkaline medium can be chelated and reduced to Cu(I) by cysteine, lysine, tryptophan and tyrosine residues in proteins, in the presence of bicinchoninic acid (BCA), forming a purple coloration, the intensity of which is proportional to the protein concentration.

Other colorimetric methods for total protein determination include the biuret method, which uses the purple coloration (monitored at 540 nm) caused by interaction of the biuret reagent (often a 20% copper sulfate solution) specifically with peptide bonds, and the rather more sensitive Lowry method, which uses the biuret reagent combined with the Folin–Ciocalteu reagent. Proteins react with these reagents to give a blue solution that can be monitored at ~500 nm for samples with high protein content or ~750 nm for those with lower protein content.

More recently, a microwell plate ninhydrin assay has been applied to the determination of the total protein content of beer by hydrolyzing the protein to amino acids beforehand by heating the sample (200 μl) with 12 M HCl (200 μl) at 95 °C for 18 h (Abernathy *et al.*, 2009). Hydrolyzed bovine serum albumin was used as the calibration standard. The results were 30% lower than those of the Kjeldahl method (Section 4.6.3), which measures nitrogen from all sources. Also, by comparison of the results for undialyzed hydrolyzed beer with those for dialyzed hydrolyzed beer (cut off 3.5 kDa), it was found that only 25% of the total protein in beer is actually derived from peptides of molecular weight greater than 3500 Da.

There are specific colorimetric methods for the assessment of diastase (total amylolytic) activity and individual amylolytic enzyme (e.g. α-amylase, β-amylase and limit dextrinase) activities in malt samples – see also titrimetric methods (Section 4.6.3). Variants of the 3,5-dinitrosalicylic acid (DNSA) method can be used to assess all the aforementioned enzyme activities (see for example Osman, 2002). The general method depends on measurement of the absorbance at 540 nm of the DNSA derivative of reducing sugars released by the action of the enzymes (extracted from, say, malt) on a soluble starch solution. Details of the method are given in Figure 4.4.23. For α-amylase assay, β-amylase is deactivated by heating in the presence of 20 mM calcium chloride solution prior to analysis, whereas for β-amylase determination, α-amylase is deactivated by the presence of 20 mM EDTA in the equilibrated starch solution. A sample (600 μg) of maltose is used as the standard for the colorimetric determination. Standards and controls are treated similarly, except that the enzyme extract is added to the controls after quenching the reaction with 0.1 M NaOH solution.

Limit dextrinase activity can be estimated by the above method, using pullulan (not soluble starch) as the polysaccharide source of reducing sugars and after the deactivation of β-amylase by heating. It can also be estimated, perhaps rather more conveniently, by the limit-dextriZyme (Megazyme, Australia) method (Osman, 2002; McCleary, 1992).

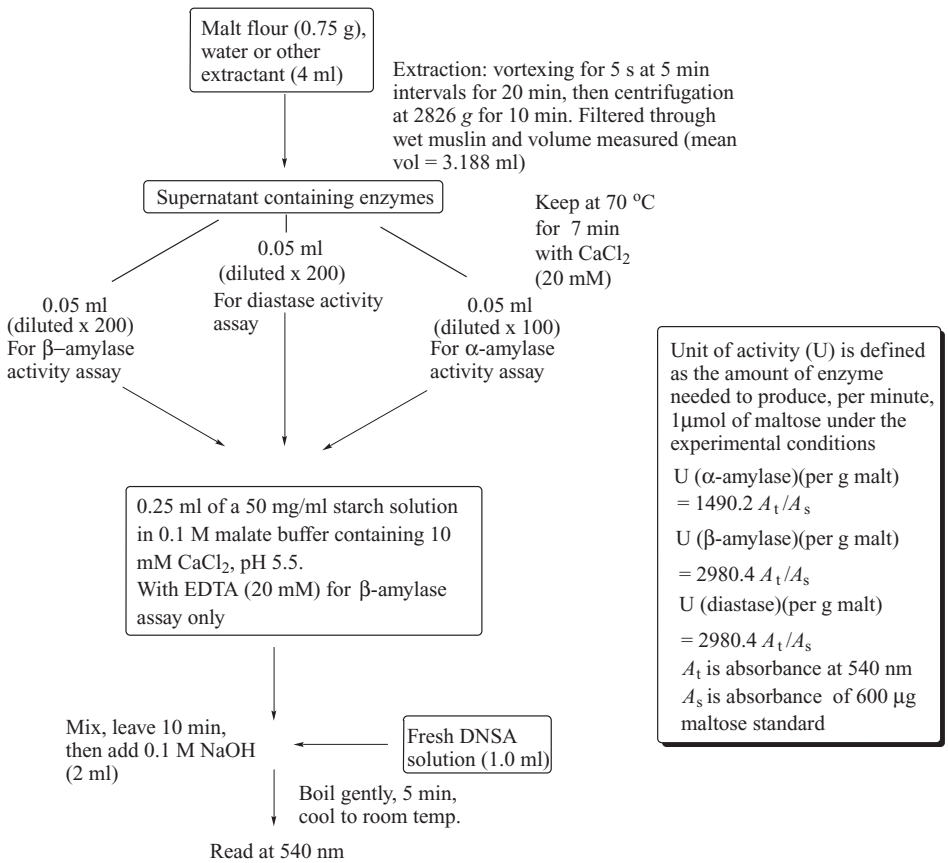

Figure 4.4.23 *Summary of DNSA colorimetric method for the determination of activity of malt amylolytic enzymes. Osman (2002)*

β-Glucanases are enzymes present in malted cereals that hydrolyze the cell wall β-glucans, forming soluble oligomers and β-D-glucose. β-Glucanase activity is important for the efficient release of starch and proteins and removal of oligomers that cause processing problems and can compromise haze stability (Sections 2.6.3 and 2.6.4). β-Glucanase activity can be measured by the Congo Red method, as described by Shengli *et al.* (2009). Here, a β-glucan (0.8 ml of a 30 μg/ml solution) was incubated at 40 °C for 10 min, followed by the addition of beer or wort sample (0.2 ml). After 30 min, the solution was heated to 100 °C for 15 min and then cooled to room temperature. Congo Red (0.2 ml of a 100 g/ml solution) was added and the mixture was diluted with buffer to 2 ml and the absorbance of the supernatant measured at 540 nm. β-Glucanase activity is defined as the amount of β-glucanase needed to hydrolyze 1 μg of β-glucan per min in 1 ml of culture fluid.

Metal Ions

Colorimetric methods are available for the determination of many metals – including those in different oxidation states, such as Fe(II) and Fe(III) – and nonmetals, such as P (as phosphate). Many of these methods have been or are still used as standard or reference (official) methods for alcoholic beverage analysis in certain countries, although for routine analysis, say for quality control purposes, they have been largely replaced by atomic spectrometric (Section 4.4.4) and electrochemical methods (Chapter 4.5). Since there is at least one colorimetric method available for most metal and nonmetallic species found in alcoholic drinks, only an outline of the more important methods that are still used as reference methods or for comparison purposes will be considered here.

Total Iron

Iron (III) reacts with excess of thiocyanates to give a series of soluble and intensively blood-red colored complex compounds. If carried out in the presence of persulfate, this method permits the determination of the total iron [Fe(II) + Fe(III)], since $K_2S_2O_8$ quantitatively oxidizes all the iron to the Fe(III) state.

In a typical experimental procedure for the direct determination of total iron content in alcoholic beverages, the sample, suitably diluted (5.00 ml), is placed in a screw capped bottle and the following reagents are added in sequence: 10% (v:v) H_2SO_4 (1 ml) aqueous 50% (w:v) KSCN (1 ml) and aqueous 1% (w:v) $K_2S_2O_8$. Finally, ethyl acetate (5.00 ml) is added and the bottle is vigorously shaken for 1 min. The biphasic system was allowed to stand for 5 min, to separate the phases into two transparent layers. Portions of 3 ml of the upper red organic layer are transferred into a quartz cuvette of 1 cm pathlength, after filtration using a Whatman No. 42 ashless paper. The absorbance was measured at 495 nm, against a reagent blank. The same procedure is carried out on standard Fe solutions (100–600 μg/l) to obtain a calibration curve.

Ferrous Iron

The nitro-PAPS reagent (Makino *et al.*, 1988), [2-(5-nitro-2-pyridylazo)-5-[*N*-*n*-propyl-*N*-(3-sulfopropyl)-amino]-phenol, disodium salt, dihydrate] has been introduced as a highly sensitive colorimetric reagent specifically for Fe(II), by forming the 1:2 water soluble complex $[Fe(C_{17}H_{19}N_5O_6S)_2]Na_4$ in the 3-8 pH range ($\lambda_{max} = 582$ nm).

In a typical experiment, the sample (1.00 ml) is transferred to a test tube with a pipette, and the following reagents are added in sequence: distilled water (5 ml), aqueous 1.0 M NaN_3 (1 ml), aqueous 1.0 M ascorbic acid (1 ml) and aqueous 1×10^{-4} M nitro-PAPS solution (2 ml). After 10 min, the absorbance of the colored complex is measured at 582 nm, against a reagent blank. Standard Fe(II) solutions are treated in the same way to obtain a calibration curve. The above assay should be carried out in conjunction with a total Fe assay.

Calcium

Numerous methods exist for the determination of this important component (as Ca^{2+}) of alcoholic beverages and their precursors, including EDTA titration (Section 4.6.3) and various complexometric and colorimetric methods, although nowadays the methods of choice tend to be either atomic spectroscopic (Section 4.4.4) or electrochemical (Section 4.5.1) methods.

A simple colorimetric method for the assay of calcium in drinks involves a pH 11 buffer (orthoboric acid (3.6 g) in water: ethanolamine (9:1 v:v)), a color reagent (8-hydroxyquinoline (1 g) + conc HCl (5 ml) + *o*-cresophthalein (40 mg) (in that order), made up to 100 ml with water) and EDTA (disodium salt; 50 g in 1 l of water) (Amerine and Ough, 1980d). To suitable Ca standard solutions (e.g. containing 0–3.0 mg/l) (1.00 ml) is added one drop of water, pH 11 buffer solution (5.00 ml) and color reagent (0.50 ml). After mixing well and allowing to stand for 10 min in a water bath at 25 °C, the absorbance is measured against a blank made as above, but using water (1.00 ml) in place of the standard. The above procedure is carried out on a pale sample (e.g. white wine), diluted 1:20. For a colored sample (e.g red wine, again diluted 1:20 v:v) a double procedure is performed, one exactly as above and the second as above, but adding one drop of the EDTA solution in place of the water. The absorbance value of the EDTA sample is subtracted from that of the water sample. The 8-hydroxyquinoline prevents interference by Mg, whereas the buffer prevents interference from other metal ions.

Copper

There are several colorimetric methods available for the estimation of copper, but those involving (red) complex formation with 2,2′-diquinoline (in the presence of hydroxylamine/sodium acetate to reduce Cu^{2+} to Cu^{+}) or complex formation with diethyldiothiocarbamate are probably the most satisfactory (Amerine and Ough, 1980d). Again, Cu in alcoholic beverages is more often determined by atomic spectroscopy (Section 4.4.4).

Phosphate

Total phosphate can be determined by ashing the sample, evaporating a solution of the ash in 1:5 hydrochloric acid to dryness, redissolving in 1:5 hydrochloric acid and treating aliquots of this solution with ammonium molybdate/aminonaphthosulfonic acid, measuring the absorbance at 600 nm after 30 min (Amerine and Ough, 1980d).

Colorimetric and fluorometric titrations are only occasionally used in the study of alcoholic beverages. Tanaka *et al.* (2002) conducted fluorometric titrations to determine the amount of charge (polyelectrolyte concentration) in whiskies. The amount of charge was attributed to polyphenols derived mostly from oak contact during maturation. The titrant was polydiallyldimethylammonium chloride (poly-DADMAC) and the fluorescence indicator was acriflavine hydrochloride.

Hop Bittering Agent Determination

There are several methods available for the determination of the α-acid and β-acid content of hops. α-Acids are the precursors of *iso*-α-acids, the major bittering compounds of beer (Section 2.6.3). An American Society of Brewing Chemists (ASBC) method involves extracting freshly ground hops with toluene and measuring the absorbance of the resulting filtered extract at 275, 325 and 355 nm (ASBC, 1999). Using the ASBC method with specified standards, the α-acid and β-acid contents of hop samples are calculated using Equations 4.4.18

and 4.4.19, where d is the dilution factor.

$$\alpha\text{-acid content } (\%) = d(-51.56A_{355} + 73.79A_{325} - 19.07A_{275}) \quad (4.4.18)$$

$$\beta\text{-acid content } (\%) = d(55.57A_{355} - 47.59A_{325} + 5.10A_{275}) \quad (4.4.19)$$

Since many hop constituents are prone to deterioration in the presence of oxygen (Sections 2.6.3, 2.6.7 and 2.6.12), it is useful to have a method (other than a sensory method) that can give some indication of the extent of deterioration of the hop sample. One such method (Bamforth, 2002) is based on the fact that the toluene extract of aged hops shows an increased absorbance at 275 nm relative to that at 325 nm. Hence, the hop storage index (HSI), defined as A_{275}/A_{325}, is a measure of deterioration.

Likewise, in Europe, the standard EBC spectrophotometric method for the determination of bitterness (expressed as IBU) in beer (EBC method 9.8) is performed by spectrophotometric determination of an acidified *iso*-octane extract of beer at 275 nm. The absorbance at 275 nm is the sum of the absorbances of all extracted substances, including bittering agents (*iso*-α-acids, unisomerized acids, etc.), as well as polyphenols and others that do not contribute to bitterness. Also a significant, but acceptable, variation in reproducibility results from the extraction process and related manipulations (Benard, 2000).

More recently, two spectrofluorometric methods using chemometrics have been applied to the determination of bitterness in both light and dark beers (Christensen *et al.*, 2005). Partial least squares (PLS) regression models, with full cross validation, were applied for the comparison of autofluorescence and europium induced delayed fluorescence spectra with IBU data generated by application of the standard EBC method to 21 beers. Bitterness uncertainty (reproducibility) was similar to that of the standard method, but the fluorescence methods have advantages in speed, robustness and not requiring solvents.

Dissolved Oxygen

Although a certain amount of contact between oxygen and red wine is thought to be beneficial (even to the extent of applying micro-oxygenation regimes to maturing red wine), giving reduction of astringency and enhancement of color, the quality of white wines is generally compromised by exposure to air because of unfavorable color and flavor changes. Likewise, dissolved oxygen as low as 1 mg/l in beer is bad news, since this quantity can lead to a number of off flavors and can significantly reduce the shelf life of the beer.

There are several colorimetric/spectrophotometric methods for the assay of dissolved O_2 in alcoholic beverages, although most of them were originally developed for testing water samples. These come in convenient kit form (e.g. Chemetrics, Hach, Thermo Scientific) and at least one has a color comparator (Chemetrics), for measurement, in place of using a colorimeter or spectrophotometer. The majority of these are based on the reaction between O_2 and the reduced ('leuco') form of indigo carmine dye, resulting in a color change from yellow to indigo, which can be monitored at 608 nm. Other methods rely on the pink coloration formed on reaction of dissolved O_2 with the reduced form of the dye rhodazine D. Neither method is subject to interference from dissolved gases such as CO_2 or from sulfites, and so can be applied to wine and beer. However, they are subject to interference from pigments and so are generally limited to dissolved oxygen assay of white wine and pale beers. These methods are also destructive of the sample and require careful sampling technique. See also Section 4.5.3 for a description of electrochemical (polarographic) probes for dissolved oxygen, which are widely used in the beer and wine industries.

There has been much interest recently in monitoring oxygen ingress through closures (corks, plastic stoppers, screw caps, crown caps, etc.) into bottled wine (Goode, 2009), as well as in changes in oxygen levels that occur in wine during various processing procedures.

Lopes *et al.* (2005) monitored the diffusion of oxygen into solutions of reduced indigo carmine contained in 375 ml bottles closed with various kinds of stoppers, from natural and technical cork of various grades and types to synthetic closures. The control bottles were sealed with a glass stopper via flame welding. Oxygen ingress was followed over a one year period of horizontal storage of the bottles, thus mimicking storage conditions of real bottles of wine. The oxygen concentrations were determined directly (without sampling) on the bottles using L^*, a^*, b^* measurements (CIELAB76) by scanning the bottles with a spectrocolorimeter equipped with a transmittance accessory. L^*, a^*, b^* values were collected using illuminant D65 and a 10° observer. Hue angle (H^*) was calculated from arctan (b^*/a^*). Oxygen diffusion was shown to be much greater in the first month for all stoppers (except the control, where there was no diffusion), but the overall rate of diffusion was dependent on the stopper material, first grade natural cork being the most resistant to long term oxygen ingress.

More recently, the German company PreSens Precision Sensing has produced a nondestructive probe that includes a photodiode to detect the blue light emitted by an oxygen sensitive sensor when red light is incident upon it. It can be incorporated into a reuseable dot that can be placed inside a bottle to monitor oxygen ingress through the stopper (Goode, 2009). Similar dissolved oxygen sensors (e.g. those of Electro-Chemical Devices Inc. and Mettler-Toledo AG) rely on the quenching of fluorescence emission, for example from a fluorescent layer sandwiched between a light emitter and a light detector (a kind of mini fluorometer). The greater the dissolved O_2 content of the sample the less intense is the fluorescence, and the more rapidly is quenched.

Antioxidant Ability Assays

There are several methods for assessing the *in vitro* antioxidant potential of foodstuffs, including juices, worts and alcoholic beverages. Most of these methods determine the ability of a whole beverage or fractions of a beverage, or even an individual component to quench a free radical species. This ability is usually measured with respect to quenching of the same radical by a reference antioxidant, often tocopherol (vitamin E) or Trolox® (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid). A selection of methods is outlined in the next paragraphs, followed by a commentary regarding their relative advantages/disadvantages, accuracy and precision and extent of intercorrelation.

The ferric reducing ability of plasma (FRAP) assay was developed in 1996 by Benzie and Strain (1996) in order to assess the antioxidant power of human plasma. It has since been applied to assess the antioxidant activity of a range of pure substances and mixtures, such as red wines (Lee *et al.*, 2004). The method compares the ferric ion reducing ability of the antioxidant under investigation with the ferric ion reducing ability of some standard. The original calibration standard was Fe (II), but lately Trolox (a water soluble synthetic vitamin E analog) has been used for this purpose (Lee *et al.*, 2004).

The antioxidant (A) being tested requires a redox potential that is less positive than that of the Fe(III)/Fe(II) half reaction, so that the overall reaction (Figure 4.4.24(a)) has a positive redox potential. The greater the antioxidant power, the more the above reaction lies to the right. The substance *s*-tripyridinyltriazine (2,4,6-tris(2-pyridyl)-1,3,5-triazine or TPTZ) forms complexes with both Fe(III) and Fe(II), but the Fe(II) complex has an intense blue color. Hence, it is possible to deduce the Fe(III) reducing ability of any substance by carrying out the reaction in the presence of TPTZ and by measuring the intensity of the blue coloration (i.e. the absorbance at 593 nm).

1,1-Diphenylpycrylhydrazyl ($DPPH^\bullet$) is relatively stable free radical that exhibits a purple color ($\lambda_{max} \sim 515$ nm) because of the extensive delocalization of the unpaired electron. It can react with hydrogen/electron donors (antioxidants) (Figure 4.4.24(b)). The further the reaction lies to the right, the greater is the radical scavenging ability (which can be related to antioxidant ability) of the antioxidant. Hence, measurement of loss of purple color can be used to estimate radical scavenging ability. One of the problems of this method is, because $DPPH^\bullet$ is a radical that is kinetically (steric hindrance) stabilized (as well as thermodynamically

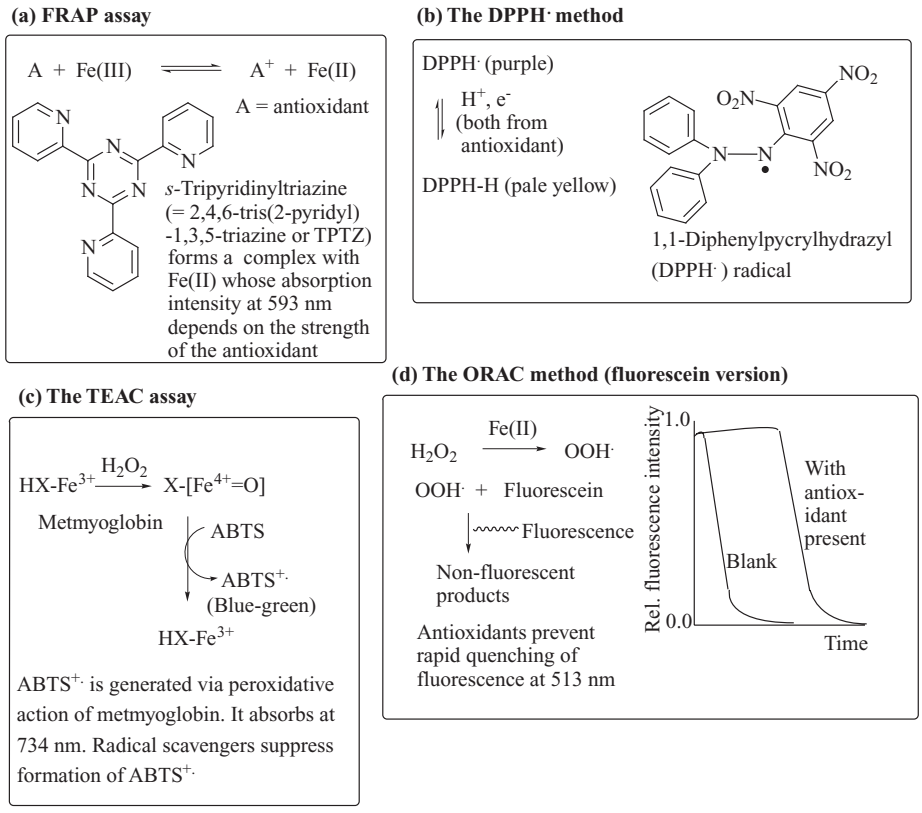

Figure 4.4.24 *Colorimetric methods of antioxidant power determination*

stabilized), it reacts with the wide range of scavenger phenols (and other types) at different rates. In the most basic method, the time interval of 90 min is chosen so that the reaction at room temperature is likely to be complete for all the radical scavenging substances that act as antioxidants in foodstuffs. However, a development of this method that involves measurement of reaction time T_{EC50}, as well as the amount of antioxidant needed to decrease by 50% the initial DPPH concentration (EC_{50}) has been described in the literature (Sánchez-Moreno *et al.*, 1998). The parameter antiradical efficiency ($AE = \{EC_{50}\ T_{EC50}\}^{-1}$) was suggested as being more discriminatory and generally a better measure of antioxidant power than EC_{50}.

The Trolox® equivalent antioxidant capacity (TEAC) assay was developed by Miller *et al.* (1993), and Miller and Rice-Evans (1996). It is based upon the generation of the $ABTS^{+\bullet}$ radical cation when 2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) is incubated in the presence of a peroxidase enzyme (metmyoglobin) and hydrogen peroxide or in the presence of hydroxyl, peroxyl alkoxyl or inorganic radicals. From the time ABTS, metmyoglobin, buffer and hydrogen peroxide are mixed, the absorbance of the blue-green $ABTS^{+\bullet}$ species is measured at 734 nm with respect to time (Figure 4.4.24(c)). If antioxidants are present before the hydrogen peroxide is added, these scavenge the ABTS radical cations, thus inducing inhibition of absorbance at 734 nm (suppression of color). The unit of measurement is the TEAC, namely the concentration in mmol/l of Trolox with the equivalent antioxidant capacity to a 1.0 mmol/l solution being investigated. The main problem with the TEAC assay is that it does not take the inhibition time into account, thus ignoring a component of antioxidant power (Cao *et al.*, 1995).

The oxygen radical absorbance capacity (ORAC) method was developed originally in 1993 (Cao *et al.*, 1993) from previous work of Glazer and modified to an automated method in 1995 (Cao *et al.*, 1995). It was further modified in 2001 (Ou *et al.*, 2001). In this method, 2,2′-Azobis (2-amidinopropane) dihydrochloride (AAPH) is used to generate peroxy radicals ($OOH^{\bullet}$), which quench fluorescence in β-phycoerythrin (Cao *et al.*, 1993) or a fluorescein salt (Ou *et al.*, 2001). The loss of fluorescence indicates the extent of reaction of the fluorescent probe with the generated peroxy radicals, hence when this reaction is performed in the presence of an antioxidant, the fluorescence will be quenched over a longer time period than without the antioxidant, depending on the potency and concentration of the antioxidant.

After mixing of reagents, fluorescence measurements are made at 37 °C at intervals of time for blank and sample until zero fluorescence. The results are quoted as the ORAC value, namely the net protection area under the fluorescence quenching curve when an antioxidant is present (Figure 4.4.24(d)). It is calculated (in Trolox equivalents) by dividing the area under the sample curve by the area under the Trolox (standard) curve, both being corrected by subtraction of the area under the blank curve. Many other methods for the assessment of antioxidant capacity have been developed over the years: some of these are summarized and compared by McAnalley *et al.* (2003).

Because each of these methods uses a different free radical mechanism (the FRAP method and TEAC assays use single electron transfers) and because of a variety of data analysis methods associated with these assays, it is often difficult to correlate results for the same foodstuff using different methods. At present (2009) the ORAC method seems to be the most favored, possibly because it uses the area under the fluorescence (quenching) versus time curve and hence combines two measurements (inhibition time and degree of inhibition). It is also the only method that directly assays the chain breaking antioxidant activity of substances and mixtures. For these reasons, the ORAC method is thought by many to give the best estimate of antioxidant ability. However, no single method can give a universal antioxidant value of a complex sample, and when choosing a method, many other factors are taken into consideration, such as relative cost (particularly with regard to reagents and instrumentation), time required for analysis and general methodology. Hence, there is plenty of work in this area being performed using the DPPH or FRAP assays, in particular, because of the relative simplicity and speed regarding these two methods.

Intercorrelation between these various methods is often either nonexistent or poor, making to difficult to compare results; indeed scatter plots of TEAC and ORAC antioxidant values for the same substrates show no linear correlation, and only a rather weak (but significant) correlation is observed in the FRAP versus ORAC scatter plot (McAnalley *et al.*, 2003).

There are many reports in the literature on the total antioxidant capacity of alcoholic beverages and musts. There are also reports on antioxidant potential of various fractions and of individual components, along with investigation of correlation of antioxidant capacity with phenolic or other content. The big majority of these reports have focused on phenolic components and the general observation is that highly colored musts and drinks exhibit higher antioxidant ability and have higher contents of phenolic compounds.

Total antioxidant potentials of wines were evaluated with the ABTS (TEAC) method, where a positive correlation between TEAC value and phenolic content (especially gallic acid, (+)-catechin and (–)-epicatechin) was found, as determined by capillary zone electrophoresis (Minussi *et al.*, 2003).

Que *et al.* (2006) have determined the total antioxidant activity, reducing capacity and free radical scavenging capacity of Chinese rice wines (Section 2.7.1) by the thiocyanate method of Mitsuda *et al.* (1966), the ferricyanide method of Oyaizu (1986), and the DPPH method respectively. There were good correlations between these parameters and total phenolic content and also between the concentrations of the ten most important polyphenols in rice wine. Nuomi had the highest and Foshou the lowest antioxidant activity of the wines tested; Guyuelongshan, Hongqu, Shousheng, Foshou and Nuomi.

The thiocyanate method is an older method that measures the prevention by antioxidants of peroxide induced linoleic acid oxidation. Rice wine (120 μl) in 0.04 M potassium phosphate buffer (pH 7.0) (2.5 ml)

was added to linoleic acid emulsion in 0.04 M potassium phosphate buffer (pH 7.0) (2.5ml). The control (5.0 ml) was linoleic acid (2.5 ml) emulsion and 0.04 M potassium phosphate buffer (pH 7.0) (2.5ml). Linoleic acid emulsion (50.0) ml) was prepared with Tween-20 (350 mg) and of linoleic acid (310 μl) and 0.04 M potassium phosphate buffer (pH 7.0) was added up to the volume. The mixed solution (5.0 ml) was incubated at 37 °C in the dark. The peroxide level was determined by reading the absorbance at 500 nm after reaction with 20 mM $FeCl_2$ (in 3.5% HCl) and 30% thiocyanate every 12 h. Inhibition of lipid peroxidation in percent was expressed as antioxidant activity.

The DPPH radical is frequently used for assessment of antioxidant activity, by virtue of its radical scavenging ability, as mentioned previously. The DPPH method, however, is a general method and is not selective with regard to the identities of the radical oxidants. Effectiveness of alcoholic beverages at scavenging *particular* oxidative radicals can be assessed by more specialist procedures, such as the xanthine/xanthine oxidase method for superoxide anion scavenging ability (Lu and Foo, 2001; Que *et al.*, 2006). Here a 0.5 ml of aqueous solution containing rice wine (60–240 μl) was added to a 1.0 ml mixture of 0.4 mM xanthine and 0.24 mM nitroblue tetrazolium chloride (NBT) in 0.1 M phosphate buffer (pH 8.0). A 1.0 ml solution of xanthine oxidase (0.049 units/ml), diluted in 0.1 M phosphate buffer (pH 8.0) was added and the resulting mixture was incubated in a water bath for 40 min at 37 °C. After this time, the reaction was quenched by adding 2.0 ml of 69 mM sodium dodecylsulfate and the absorbance of NBT was measured at 530 nm and compared with that of vitamin C and control (with no antioxidant present) taken through the same procedure.

The effectiveness of wine fractions in trapping peroxyl radicals has been measured using an azo initiator to generate a constant flow of peroxyl radicals (Ghiselli *et al.*, 1998) that cause loss of fluorescence upon reaction with (*R*)-phycoerythrin (R-PE). A 15 nM R-PE solution in 75 mM phosphate buffer (pH 7.0) was incubated at 37 °C with 4 mM 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) in the presence or absence of the wine fractions (80 μl of a 1:200 dilution, pH 7.0). The delay of loss of R-PE fluorescence (t_s) induced by the samples was continuously monitored in a spectrofluorometer. The delay induced by a known amount of trolox (t_T), the water soluble analog of vitamin E, was used as a standard to quantify the results according to the equation, sample antioxidant activity $= t_s - [\text{trolox}]/t_T$.

The ability of wine and wine fractions to scavenge the hydroxyl radical ($OH^{\bullet}$) can be measured by the deoxyribose method (Halliwell *et al.*, 1987) (e.g. Ghiselli *et al.*, 1998). Sample (100 μl of 1:10 dilution at pH 7.4) was added to 10 mM phosphate buffer (690 μl) at pH 7.4 containing 2-deoxyribose (2.5 mM). Iron ammonium sulfate (1.0 mM, 100 μl) premixed with 1.04 mM EDTA was added. The samples were kept in a water bath at 37 °C and the reaction was started by adding 1.0 mM ascorbic acid (100 μl) and 0.1 M H_2O_2 (10 μl). Samples were maintained at 37 °C for 10 min, and then cold 2.8% trichloroacetic acid (1.0 ml) was added followed by 1% thiobarbituric acid (0.5 ml). The samples were boiled gently for 8 min, then after cooling the absorbance was measured at 532 nm.

Because of increasing interest in the contribution of food phenolic components toward good health, much attention during the present decade has been placed on the analysis of total and individual phenols in highly colored fruits, and in the determination of antioxidant capacities of these fruits. Thus, Ehlenfeldt and Prior (2001) studied correlations between oxygen radical absorbance capacity (ORAC), total phenolic content (TPC) and total anthocyanin content (TAC) of the fruit and leaves of 87 highbush blueberry (*Vaccinium corymbusum* L.) varieties, some of which were hybrids of other varieties. ORAC leaf values did not correlate with ORAC fruit values, but significant correlations were found between fruit ORAC, TPC and TAC.

Antioxidant capacities of cultivated rowanberry and other fruit grown (bilberry and lingonberry) in Finland were determined by both the FRAP and DPPH methods (Hukkanen *et al.*, 2006). Antioxidant capacities and TPC of rowanberries were found to high (with the major phenols being chlorogenic acid and neochlorogenic acid), and on the basis their phenolic profiles, principal component analysis was able to separate the varieties of different origin into clusters. Rowanberries are used to for homemade wines and liqueurs, as well as commercial flavored vodkas (Section 3.4.3).

Much further south, measurement of antioxidant capacities, TPC, TAC and ascorbic acid content of blackberries, Cornelian cherries, gooseberries, raspberries and redcurrants showed all (except white gooseberry) to have high TPCs and all had high antioxidant activity, as measured by the FRAP method (Pantelidis *et al.*, 2007). TPC and TAC were highly correlated with antioxidant capacity. Although blackberries had the highest antioxidant capacity for the inhibition of free radicals, Cornelian cherry (a red skinned native wild cherry of Northern Greece) aroused interest because of its high ascorbic acid, anthocyanin and phenolic content. Also, sweet cherries grown in Slovenia had high TPCs and antioxidant capacities, as determined by the ascorbic acid equivalent antioxidant capacity (AEAC) method (Usenik *et al.*, 2008). This time, however, correlation between antioxidant capacity and TPC was found to be cultivar (variety) dependent, although, as in previous studies, darker skinned fruits had higher TACs, TPCs and antioxidant potentials.

Bilberry (*Vaccinium myrtillus*) and blueberry (*Vaccinium* spp.) are small dark skinned fruits that have attracted considerable attention because of their high phenolic contents. They are frequently used to make wines (Chapter 2.11) and liqueurs (Section 3.9.2). Faria *et al.* (2005) examined the ability of bilberry extracts to limit peroxidation (induced by 2,2′-azobis(2-methylpropanimidamide) dihydrochloride) of soybean liposomes, by measuring oxygen consumption and the formation of conjugated dienes (see Section 5.8.4). All the extracts provided protection from peroxidation, but this increased with increased polyphenol content and complexity of the anthocyanin derived pigments. Interestingly the antioxidant power of the extracts, determined using the DPPH and FRAP methods, correlated well with the results from the liposome membrane peroxidation protection assays.

Interest in antioxidant power is not entirely confined to phenolic compounds. Herbs, spices and spice essential oils are used in the preparation of a number of flavored alcoholic beverages, such as apéritifs, flavored spirits (Sections 3.4.2 and 3.4.3), liqueurs (Section 3.9.3) and vermouth (Section 2.12.2). The antioxidant capacities, determined by the DPPH and FRAP methods, of free terpenoid aglycones (mainly chavicol, eugenol, linalool and α-terpineol) from basil, the fresh herb itself and its essential oil were compared (Politeo *et al.*, 2007). The DPPH results suggested that together the free aglycones had good antioxidant properties – comparable with those of the essential oil and the synthetic antioxidant butylated hydroxytoluene (BHT). On the other hand, the FRAP results suggested that the compounds are less effective antioxidants than the essential oil or BHT.

Star anise (*Illicium verum*) and black caraway (*Carum nigrum*), and their powders and essential oils have been examined by the DPPH (and other) methods for their antioxidant activity (Padmashree *et al.*, 2007). Both powders and ethanol/water extracts, as well as their volatile oils, showed strong antioxigenic activity, with star anise volatile oil having higher activity than that of black caraway. Star anise is used to flavor various distilled spirits (Sections 3.4.3 and 3.5.6), some liqueurs (Section 3.9.3) and some vermouths (Section 2.12.2).

Essential oils of basil, cinnamon, clove, nutmeg, oregano and thyme (all important ingredients of some liqueurs and vermouths) were found to have good radical scavenging abilities in the DPPH assay at room temperature, with clove and cinnamon being the most effective (Tomaino *et al.*, 2005). Heating to 180 °C for a short time did not appear to adversely influence the essential oils' antioxidant capacity (except in the case of nutmeg oil: its antioxidant activity increased).

4.4.4 Atomic Absorption and Emission Spectroscopy

Atomic spectroscopy consists of a number of techniques for the determination of elements (mostly metals) in a sample. In principle, both absorption and emission modes are possible, but in practice the former is more widely used in the analysis of alcoholic beverages, so it will be discussed first. See Broekaert (2002) for general reading on flame and plasma atomic spectroscopy.

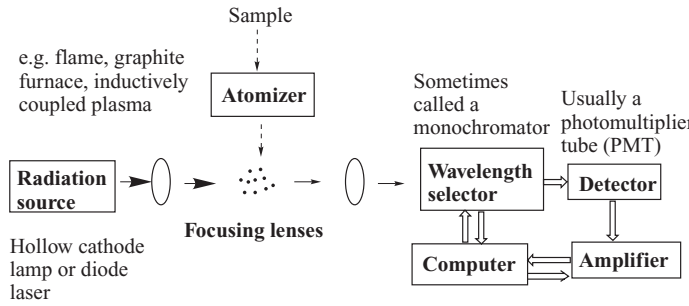

Figure 4.4.25 *Simplified block diagram of an atomic absorption spectrometer*

The basic parts of an atomic absorption spectrometer are shown in Figure 4.4.25. In atomic absorption spectroscopy (AAS), the elements in the sample to be analyzed need to be converted to gaseous atoms; this is done by atomization of the sample in an atomizer. The atoms of a particular element are then subjected to light from a radiation source of a wavelength that corresponds to the energy needed to promote an electronic transition in the atoms of that element. The atoms absorb this energy and are converted to excited electron states for a short time. The spectrometer measures the extent of absorption (by comparison with a blank sample) and relates it to the concentration of the element in the sample via the application of the Beer–Lambert law, once the data for reference solutions of the element have been acquired and the sample has been diluted so that the absorption falls within the range of absorption of the standards. The wavelength of incident radiation is specific to a particular transition in a specific element; radiation of a different wavelength must be used for another element.

The most common source of radiation in atomic absorption spectroscopy is the hollow cathode lamp, a cylindrical structure filled with neon or argon gas at low pressure and containing a cylindrical metal cathode and an anode rod. A high voltage placed across the electrodes causes some gas atoms to be ionized at the anode. Some inert gas cations collide with the cathode internal surface at high speed, causing the ejection of metal species in excited states from the surface. These emit light with the wavelength that is characteristic of that particular metal. It is possible to buy multimetal hollow cathode lamps, which can be tuned in to a particular metal by the operation of a switch on the lamp. Alternatively, diode lasers can be used as a source of radiation.

The mode of atomization generally gives its name to the type of atomic absorption spectroscopy; the major types are flame atomic absorption spectroscopy (FAAS), graphic furnace or electrothermal atomic absorption spectroscopy (GFAAS or ETAAS) and inductively coupled atomic absorption spectroscopy (ICPAAS). The latter atomization technique is more usually associated with atomic emission spectroscopy (ICPAES) or mass spectrometry (ICPMS) (Section 4.4.5). The atomization process produces atoms by a rather complex sequence of events that are summarized in Figure 4.4.26, for flame atomization.

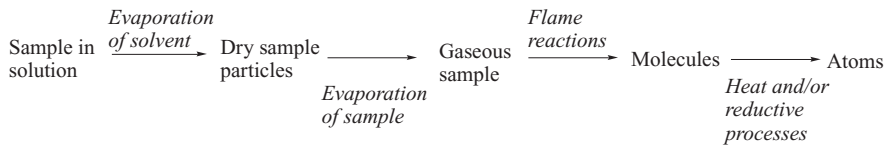

Figure 4.4.26 *Summary of processes leading to the production of atoms in a flame*

The majority of atomic absorption analyses of alcoholic beverages are performed using FAAS. Here, a flame ($\sim 10 \times 2$ cm) is produced from the combustion of a mixture of acetylene and air, giving a maximum flame temperature of ~2000 °C. For samples that need higher atomization temperatures (e.g. samples containing Al, Si and/or P), a nitrous oxide (N_2O)/acetylene flame will give ~3000 °C. The sample is introduced into the flame as a mist from a nebulizer and, provided there is continuous uptake of the solution by the nebulizer, the rate of atom production in the flame will become constant and a steady absorbance can be measured. Background emissions are minimized by a number of instrumental features, including deuterium lamp, Smith–Hieftje and Zeeman corrections. The first named is the most common, which automatically compensates for broadband absorption interferences. FAAS can usually achieve the determination of metals in the μg (10^{-6} g) to ng (10^{-9} g) range.

Graphite furnace atomic absorption spectrometry (GFAAS) – also called electrothermal atomic absorption spectrometry (ETAAS) – involves a flameless atomization method, using a graphite furnace that can achieve high temperatures very rapidly. It is more sensitive than FAAS, being able to determine metals in quantities as low as 1 pg (10^{-12} g). The sample (usually10 or 20 μl) is injected, either manually or via an autosampler into the cold graphite furnace and, by means of an automatic temperature programmer, the solvent and other volatile components are evaporated, usually over a period of a few seconds. The sample is atomized by heating the furnace to ~ 2000 °C over about 5 s. During this time the absorbance signal from the chamber is recorded and displayed on the screen as a function of time. After this, the furnace is heated for 5 s to around 2600 °C, in order to remove residues and prepare for the next sample. During this process, apart from when recording absorbance, the furnace is purged with argon.

Atomic emission spectroscopy (AES) uses the intensity of light emitted by excited atoms in an arc, flame, plasma or spark, while relaxing back to their lower energy states. The earliest and simplest form of AES is flame photometry, which is still used to determine alkali and alkaline earth metals (Na, K, Mg, Ca, etc.) in solution. Atomic emission detectors (AED) can be linked with gas chromatography (Section 4.3.2) and high performance liquid chromatography (Section 4.3.3), as discussed later.

The final atomization method considered here is that of the inductively coupled plasma (ICP), giving rise to ICPAES (or ICPOES) and ICPMS (Section 4.4.5). The plasma is produced in a torch that consists of three concentric tubes, usually made of quartz. The end of this torch is placed inside an induction coil supplied with a radio frequency electric current (~27 MHz). While argon is made to flow between the two outermost tubes of the torch, an electrical spark is applied briefly to introduce free electrons into the gas stream. These electrons interact with the rapidly oscillating magnetic field of the induction coil and are accelerated in alternating directions. These high energy electrons collide with argon atoms, and sometimes a collision causes ionization of argon atoms. These newly released electrons are in turn accelerated by the alternating magnetic field. The process continues until an equilibrium is reached between the release of new electrons in collisions and the recombination of electrons with argon ions. This produces a 'fireball' that consists mostly of argon atoms with a relatively small number of free electrons and argon ions at temperature between 6000 °C and 10 000 °C.

The rapid flow of gas between the two outermost tubes protects the walls from the destructive effect of the plasma, Likewise, a second (slower) flow of argon between the central tube and the intermediate tube keeps the plasma away from the end of the central tube. A third flow (again slower) of gas through the central tube forms a channel that is cooler than the surrounding plasma, but still much hotter than a chemical flame. Samples to be analyzed are introduced into this central channel, usually as a mist of liquid formed by passing the liquid sample into a nebulizer.

ICPEAS is even more sensitive than GFAAS and is similarly capable of determining trace metals and some nonmetals (such as S and Se), present in quantities well below 1 pg, in alcoholic beverages.

Metal species are present at low concentrations in all alcoholic beverages, and although they themselves make negligible direct contributions to flavor, the presence or absence of several species can have significant

effects on flavor and overall quality. For example, the presence of Cu^{2+}, Fe^{2+} and Mn^{2+} at certain levels promote premature staling of beer (Section 2.6.12) and the presence of extraneous Fe species causes a serious fault in wine known as 'casse' (Section 2.9.2). At concentrations higher than 10 mg/l, Fe(III) forms a blue colloidal suspension with tannins and phosphates, affecting both the color and flavor of wine. On the other hand, the presence of certain salts (e.g. $CaSO_4$, $CaCO_3$) in brewing water is known to be beneficial to the quality of certain kinds of beers (Section 2.6.2). Likewise, the presence of certain levels of Cu^{2+} in the wash used to make distilled spirits actually improves the organoleptic qualities by removing volatile sulfur compounds (see for example Section 3.5.3), but acts as a catalyst for the production of ethyl carbamate (Section 3.2.2) and can be present in high concentrations in distillery wastes, thus constituting an environmental problem (Sections 3.2.5 and 5.10.3). Quite apart from these factors, most so called heavy metal ions are harmful to health if present in alcoholic beverages above certain maximum levels (Section 5.10.3), defined by legislation, and hence their analysis is of prime importance. Also of importance are the speciation of metals (e.g. Cr^{3+} or Cr(VI)) present in a beverages, since this has a direct bearing on toxicity, and similarly, the bioavailability of a species (whether it is 'free' or bound to, say protein or polyphenolic compounds) also affects its toxicity (Section 5.10.3).

Generally, less alcoholic samples such as beer, cider and wine need to be treated in one or more of the following ways before analysis, especially if FAAS is used or if the analyte of interest is present at low levels:

- Preconcentration/separation (e.g. by solvent extraction, sorbent or other techniques, the analyte of interest (e.g. Cu) being first converted to a chelate complex, for example with diethylammonium-*N*,*N*-diethyldithiocarbamate)
- Digestion in strongly oxidizing reagents such as concentrated $HClO_4$, HNO_3 or H_2O_2
- Volatile hydride generation, usually using $NaBH_4$ (e.g. for the conversion of Pb species to PbH_4)
- Addition of matrix modifiers, such as $Mg(NO_3)_2$ or $Pd(NO_3)_2$.

These procedures are intended to lower the effect of the complex matrix (for beer, cider and wine this would be water, ethanol and a host of organic components of many different types) on the volatility and atomization of the analyte, thus increasing sensitivity and general quality of analytical method. Distilled spirits, such as rum, tequila or whisky, on the other hand, have much less complex matrices, and their analysis by AAS usually requires no more than dilution with a dilute nitric acid solution and/or the addition of modifiers.

There are many reports on the determination of toxic heavy metals (especially As, Cd, Cu and Pb) in alcoholic beverages by atomic spectroscopy (usually absorption) (Jaganathan *et al.*, 1997; Mena *et al.*, 1997; Azenho and Vasconcelos, 2000; Freschi *et al.*, 2001; Adam *et al.*, 2002; Cvetković *et al.*, 2002; Karadjova *et al.*, 2002; Paleologos *et al.*, 2002; Bakircioglu *et al.*, 2003; Moutsatsou *et al.*, 2003; Kim, 2004; Nascentes *et al.*, 2005; Nóbrega *et al.*, 2005; Husáková *et al.*, 2007; Jurado *et al.*, 2007; Neves *et al.*, 2007; Pohl and Prusisz, 2007; Ajtony *et al.*, 2008; Bramanti *et al.*, 2008; Dessuy *et al.*, 2008; Schiavo *et al.*, 2008; Elçi *et al.*, 2009; Monasterio and Wuilloud, 2009; Pohl, 2009). Similarly, investigation of the Fe content of drinks by atomic absorption spectroscopy has led to a number of reports (Costa and Araújo, 2001; Karajdova *et al.*, 2002; Riganakos and Veltsistas, 2003; Ferreira *et al.*, 2008; Pohl and Prusisz, 2009; dos Santos *et al.*, 2009). There are also several useful reviews on the determination of metals in wine (e.g. Aceto *et al.*, 2002) and other drinks.

Apart from the above, there are reports on the determination of selenium in wine by AAS (Jaganathan and Dugar, 1998), sulfur in grape must (Gump *et al.*, 1996), and on AES (including GC-AES) analysis of organosulfur compounds in wine and spirits (Swan, 2000; Campillo *et al.*, 2009), several wine components simultaneously (Paredes *et al.*, 2006) and haloanisoles in wine and cork (Campillo *et al.*, 2004; 2008).

Some investigators have studied metal profiles resulting from atomic spectroscopic investigation with chemometric techniques in order to differentiate alcoholic drinks and to establish authenticity (Peña *et al.*, 1999; Bellido-Milla *et al.*, 2000; Álvarez *et al.*, 2007; Moreno *et al.*, 2007).

Lead and cadmium in alcoholic beverages are common targets for atomic absorption spectroscopists, since unlike some other heavy metals like copper and iron, there should be no sources in any part of the production process and their presence indicates contamination due to pollution.

A graphite furnace atomic absorption spectrometry method with Zeeman background correction, using ammonium dihydrogen phosphate, magnesium nitrate, and palladium nitrate as matrix modifiers, for the direct determination of cadmium in wines was investigated by Jaganathan *et al.*, 1997. Aqueous nitric acid (10%) containing $Pd(NO_3)_2$ at 100 mg of Pd/l was the most satisfactory matrix modifier. The methodological detection limit was 0.03 μg/l and sensitivity, calculated as the characteristic mass, was 0.4 pg. The use of this matrix modifier also results in excellent reproducibility (10% RSD) at such low levels. Wines (16 worldwide samples) were found have 0.045–1.01 μg/l of Cd.

A method has been developed for the direct simultaneous determination of Cd and Pb in wine by electrothermal atomic absorption spectrometry (ETAAS), using a transversely heated graphite tube atomizer (THGA) with longitudinal Zeeman effect background correction (Freschi *et al.*, 2001). The method was satisfactory for red or white wine diluted 1:1 with 0.028 M HNO_3, but when diluted 1:1 with water containing $Pd(NO_3)_2$ (5 μg) and $Mg(NO_3)_2$ (3 μg) as the modifiers and then performing a two step pyrolysis (10 s at 400 °C and 10 s at 600 °C), the formation of carbonaceous residues inside the atomizer was avoided. The characteristic mass was approximately 0.6 pg for Cd and 33 pg for Pb. The limits of detection (LOD) based on integrated absorbance (0.03 μg/l for Cd, 0.8 μg /1 for Pb) were well within the requirements of the Brazilian Food Regulations, which established the maximum permissible level for Cd at 200 μg /1 and for Pb at 500 μg /1. Brazilian wines (six samples) were found to have <0.03–20 μg/l of Cd and 10.0–55 μg/l of Pb.

A method for the analysis of lead in water and wine using FAAS with a preconcentration step has been reported (Bakircogliu *et al*., 2003). Sample digests in 10% nitric acid were pumped through a column containing an immobilized crown ether with a cavity size selective for Pb^{2+}. The column was then rinsed with 2% HNO_3 and the lead was eluted with 0.1 M aqueous ammonium oxalate and delivered to the spectrometer at 4.0 ml/min by a flow injection valve. The procedure was optimized with respect to sample acidity and volume, loading and elution flow rates, eluent composition and volume, where it was shown that only small improvements in LoD (∼ 3 μg/l for 50 ml loaded at 4.0 ml/min) were obtained for volumes of digested wine greater than 50 ml and there were no advantages of loading at low flow rates. Hence using a loading flow rate of about 20 ml/min, 50ml would be loaded in approximately 150 s, corresponding to a sample throughput of 24/h. The method was evaluated through spike recovery for both water and wine. The lead content of three Port wine samples ranged from not detected to 190 μg/1.

Some years later, Monasterio and Wuilloud (2009) reported an FAAS method for cadmium assay in wine using a supported chelating agent to preconcentrate the analyte prior to spectroscopic analysis. The on line preconcentration system was a microcolumn packed with sheepwool on to which 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol was immobilized. The system was optimized, whence a preconcentration factor of 39 was obtained with 20 ml of sample. Good precision and reproducibility were claimed, and the accuracy of the method was good, as shown by comparison of the results with those obtained by ETAAS analysis along with a recovery study. An LOD of 0.037 μg/l was reported. Wine samples (six) had Cd contents in the range not determined to 2.14 μg/l.

Application of GFAAS, using Zeeman background correction, to the determination of lead and cadmium content of a large number of red and white wines (60) showed no statistically significant differences (Kim, 2004). The Pb content and Cd content ranges were 5–87 μg/l and <0.1–3.0 μg/l, respectively. All samples were microwave digested in concentrated HNO_3 and matrix modifiers were ammonium dihydrogen phosphate and magnesium nitrate.

Ajtony *et al.* (2009) have analyzed the As, Cd, Cu and Pb in wine simultaneously using both direct injection of samples and digestion based sample pretreatment methods (adding HNO_3 and/or H_2O_2). The direct injection method was optimized with the application of the chemical modifiers $Pd(NO_3)_2$ and $Mg(NO_3)_2$, giving better reproducibility and allowing the optimal 600 °C and 2200 °C temperatures for pyrolysis and atomization, respectively. A multielement graphite furnace atomic absorption spectrometer (GFAAS), with a transversally heated graphite atomizer (THGA) (as opposed to the more usual end heated graphite atomizer), end capped tubes and integrated graphite platforms (IGPs) was used for the analyses. Zeeman effect background correction was used. The detection limits (LoDs) were found to be 5.0, 0.03, 1.2, and 0.8 μg/l for As, Cd, Cu, and Pb, respectively, and the characteristic mass data were 24 pg, 1.3 pg, 13 pg and 35 pg for As, Cd, Cu and Pb, respectively. For the direct injection method, recoveries were 96–102% for all the metals except arsenic, where a compromise recovery of 45–85% was achieved. For the 35 red and white wine samples studied, the highest metal contents were observed for Cu ranging (20–640 μg/l), then for Pb (6–90 μg/l) and Cd (0.05–16.5 μg/l). Arsenic levels were below the LoD for all samples.

Other than ETAAS (GFAAS) methods or FAAS methods using treated or preconcentrated samples, like those described above, recent atomic spectroscopic determinations of lead, cadmium and other toxic heavy metals in less alcoholic beverages have tended to use more specialized methods that require little or no sample pretreatment or methods that enhance the sensitivity of FAAS toward the analyte (Dessuy *et al.*, 2008; Schiavo *et al.*, 2008; Elçi *et al.*, 2009).

An example of the latter kind can be found in the report of Elçi *et al.* (2009). Here, a flow injection hydride generation (FI-HG) system linked to a flame atomic absorption spectrometer with a flame quartz atomizer was developed for direct determination of lead in wine and rum samples. Samples were acidified to 0.40% (v:v) HCl for wine and to 0.30% (v:v) HCl for rum, which were then mixed on line with 3% (m:v) $K_3Fe(CN)_6$ solution in 0.03% (v:v) HCl prior to reaction with 0.2% (m:v) alkaline $NaBH_4$ solution. Sensitivity of FAAS was increased by the conversion of lead in the sample to volatile lead hyride (PbH_4), via reaction with potassium ferricyanide ($K_3Fe(CN)_6$) (as oxidant) and sodium tetrahydroborate ($NaBH_4$) (as reductant). The Pb contents of a rum and two different red wine samples determined by this method agreed with those obtained by an established ICP-MS method. A detection limit of 0.16 μg/l was achieved for a sample volume of 170 μl, which compares favorably with LoDs from other FAAS methods.

Another example is given by the direct determination of arsenic in beers by ETAAS with deuterium lamp background compensation (Husáková *et al.*, 2007). Here, the use of a Pd modifier, the atomization from platform and insertion of a cooling step before atomization resulted in a 40% increase of sensitivity in peak height measurements. Previously, Arsenic in foodstuffs was determined by much more time consuming and labor intensive AAS methods that involved ashing of samples or the use of hydride generation. Several modifiers were tested, but Pd was the best for the removal of phosphate interferences and it was able to stabilize As at charring temperatures of 1500 °C. Also, addition of the modifier to standards as well as samples made possible the use of matrix free standard solutions for the accurate analysis of diluted degassed beer samples. The accuracy of this method was checked by the comparison of results with those obtained from microwave digested samples measured by an inductively coupled plasma orthogonal acceleration time of flight mass spectrometer (ICP-oa-TOFMS) method. The accuracy was also confirmed by the analysis of certified reference samples. The arsenic content of beers (seven samples) was found to be 30.0–37.8 μg/l, well below the maximum limit of 200 μg/l set by the Czech government.

Thermospray flame furnace atomic absorption spectrometry (TS-FF-AAS) was evaluated for direct determination (without preliminary acid digestion of the sample) of Cu, Cd and Pb in wines and grape juices (Schiavo *et al.*, 2008). The main advantage of TS-FF-AAS was a significant increase in sensitivity. By using a nickel tube associated with a ceramic capillary, the sample was introduced into the flame, where the residence time of the atomic cloud in the atomizer was increased, thus improving the formation of analyte atoms and sensitivity. A sample volume of 150 μl was introduced into a heated nickel tube at a flow rate of 0.54 ml/min

and 0.14 M HNO_3 was used as sample carrier flowing at 2.5 ml/min. Recoveries, LoDs, accuracy (checked with addition recovery methods) and reproducibility compared favorably with the results of previous literature FAAS and GFAAS methods. Furthermore, the optimized method allowed a sample throughput of 45 per hour.

Dessuy *et al.* (2008) have developed a method for the determination of lead in wine by ETAAS without any sample preparation and using calibration against aqueous standards. Several matrix modifiers were tested, but addition of the equivalent of 7.5 μg Pd to the sample gave optimum results. The data obtained for seven wines using this method and a standard acid digestion procedure were compared, where a Student *t*-test did not show any significant difference. Atomization in a transversally heated filter atomizer (THFA) was compared with atomization in a conventional transversally heated platform furnace. The former proved to give higher sensitivity, lowering both the characteristic mass, LoD and reproducibility for aqueous solutions (injection volume of 20 μl). The Pb content found in seven arbitrarily chosen white and red wines was 6–60 μg/l.

Although Thalium compounds are very minor inorganic components of alcoholic drinks, the element is of interest because of its high toxicity (as either Tl^+ or Tl^{3+}). The problem is that the natural thallium contents of beverages are lower than detection limits claimed by both hydride generation AAS (HG-AAS) and electrothermal AAS (ETAAS). An extraction/preconcentration electrothermal atomic absorption spectroscopy (ETAAS) method has been developed for the determination of Tl in wine (Cvetković *et al.*, 2002). The wine sample was decomposed with a mixture of nitric acid and hydrogen peroxide and both Tl(I) and Tl(III) were extracted from 0.5 M KI solution into *iso*-butyl methyl ketone (IBMK). This procedure gave a 50-fold preconcentration and allowed the determination of 0.05 μg/l of Tl in wine. Tartaric acid, silver nitrate and ammonium tetrachloropalladate were used as matrix modifiers to give thermal stability to the highly volatile iodide complexes of Tl. The results using two different ETAAS instruments for this procedure were compared and it appeared that the behavior of the volatile species in the graphite tube during the temperature program depends not only on the chemical and thermal properties of the compound, but also on the tube geometry, internal gas flow, platform type, etc. It was thus recommended that careful optimization of the instrumental parameters is carried out. The Bulgarian and Macedonian wine samples (three) had Tl contents of 0.1–0.8 μg/l.

Both FAAS and GFAAS have been used to estimate a range of metals (other than or including Cd and Pb) in alcoholic beverages. Generally, both techniques are most effective for the analysis of beer or wine (where there are complex organic matrices) when matrix modifiers are employed, but often, distilled spirits can be analyzed without additives. Copper, iron, manganese and zinc in Portuguese wines were determined by FAAS using sequential injection analysis (Costa *et al.*, 2000). Selecting volume samples of up to 750 μl allowed analysis of all the metals above trace levels, but the assay of Cu at trace levels (<0.20 mg/l) required the conversion of free Cu^{2+} to the chelate complex with diethylammonium-*N*,*N*-diethyldithiocarbamate, its retention on and then elution from a C_{18} column coupled to the system. In this case a 2 ml sample allowed the determination of Cu between 0.05 and 0.50 mg/l. Although results using this method compared well with those from reference methods at that time, nowadays there are similar methods with higher sensitivities.

Jurado *et al.* (2007) and Moutsatsou *et al.* (2003) were able to analyze aniseed spirits (Section 3.5.6) and Greek anis type beverage distillery wastes (respectively) without sample pretreatment (other than dilution) for a range of metals, including Pb and Cd, using GFAAS with deuterium background correction and FAAS, respectively. In the case of aniseed spirits, samples were diluted in a dilute aqueous-ethanolic solution of nitric acid. Copper was present in the range 6-473 μg/l, whereas Pb and Cd were present at concentrations less than 6 and 1.4 μg/l, respectively. The high Cu levels were thought to arise, at least in part, from the use of copper stills. The distillation process is well known to give wastes that are high in both toxic organic and metallic residues (see, for example, Sections 3.2.5 and 3.5.3) and consequently disposal of large quantities of waste pose serious environmental problems. The main source of metals in the distillery wastes was the bronze pot stills commonly used for distillation, but another source was the botanicals (aniseed, fennel, star

anise, etc.) (Section 3.5.6) added to the pomace before distillation. Likewise Adam *et al.* (2002) used GFAAS to determine a range of metals in Scotch whisky using 10 μl of sample with neither sample pretreatment nor the use of matrix modifiers.

Direct determination of Cu, Mn, Pb and Zn in Brazilian beers was carried out using thermospray flame furnace AAS (Nascentes *et al.*, 2005). By introducing a sample volume of 300 μl into the hot Ni tube at a flow rate of 0.4 ml/min using 0.14 M nitric acid solution or air as carrier, the sensitivity was increased, leading to low LoDs compared with a standard GFAAS method, which also required the use of a matrix modifier. The beers were directly analyzed after ultrasonic degasification. Results were in agreement with those obtained by GFAAS, at a 95% confidence level.

The determination of iron, manganese and zinc in alcoholic beverages by AAS has received considerable attention, partly because of potential health hazards and partly because of the involvement of Fe and Mn in certain spoilage processes. Cerdeira *et al.* (2001) used sequential injection analysis (SIA) with FAAS for the sequential determination of Fe(III) and total Fe in Portuguese table wines. The sampling rate was 18 samples per hour. The determination of Fe(III) was based on the extraction of the complex formed between Fe(III) and thiocyanate into methyl *iso*-butyl ketone using an on line continuous liquid–liquid extraction device. Following this, the determination of total iron was carried out by sending a small sample aliquot (83–333 μl) directly to the nebulizer. The injection of about 1.8 ml of sample enabled the determination of Fe(III) ranging between 0.10–6.00 mg/l, whereas injection of sample volumes of up to 333 μl enabled the assay of total Fe in the range 0.25–5.00 mg/l. The results compared well with those obtained by reference methods. The speciation of Fe in the nine wine samples was generally somewhat in favor of Fe^{2+} and there appeared to be no correlation of Fe^{2+}/F^{3+} and wine color.

Riganakos and Veltsistas (2003) used FAAS (direct method and an $HNO_3/HClO_4$ digest method) to measure the total Fe content of 36 Greek wines, as a comparison with colorimetric methods for the determination of Fe^{2+} and Fe^{3+}. Agreement between the methods was good, the wines having a range of total Fe between 1.0 and 10.0 mg/l.

More recent determinations of iron in wine have also used FAAS (Ferreira *et al.*, 2008; dos Santos *et al.*, 2009). Manganese and iron in wine were determined by fast sequential FAAS, using the reference element technique to correct for matrix effects (Ferreira *et al.*, 2008). Cobalt, silver, nickel and indium were tested as references, but cobalt and indium at concentrations of 2 and 10 mg/l (respectively) were best for quantification of manganese and iron, respectively, which could be determined with quantification limits of 27 and 40 μg/l, respectively. The content of manganese in 16 tested wines varied from 0.78 to 2.89 mg/l and that of iron from 0.88 to 9.22 mg/l. The analytical results agreed (at the 95% confidence level) with those obtained by ICPOES after complete mineralization of the samples using acid digestion.

A different approach to the analysis of Fe and Mn in wine was recently suggested by dos Santos *et al.* (2009). Here, photo-oxidation with UV radiation/H_2O_2 was used as a sample pretreatment for the determination of iron and manganese in wines FAAS. The method was optimized according to pH, concentration of the buffer solution, concentrated hydrogen peroxide volume and UV irradiation time. The evaluation of sample degradation was monitored by measuring the absorbance at the maximum wavelength of red wine (530 nm). This allowed the determination of Fe and Mn with LoDs of 30 and 22 μg/l, respectively, for a 5 ml volume of digested sample. Accuracy was determined by standard addition/recovery tests and the results were in agreement (at the 95% confidence limit) with those obtained by a standard FAAS acid digestion procedure. Application of this method to six wines found Fe and Mn concentrations of 1.58–2.77 mg/l and 1.30–1.91 mg/l, respectively.

Occasionally, organic compounds in samples can be determined indirectly by AAS. For example, tannins in wines were estimated by FAAS, using a continuous precipitation system (Yebra *et al.*, 1995). Tannins were precipitated by injecting copper acetate complex into the sample, and the unprecipitated copper was determined by atomic absorption spectrometry. The detection limit was 0.7 pg/ml. The results were consistently

lower than those for the same samples obtained by the official Folin–Ciocalteu method (Section 4.4.3), but the latter method is often considered to overestimate total phenolic content.

More recently, total thiol contents of wines have been determined by a method that uses a commercially available flow injection cold vapor mercury analyzer (based on vapor generation of Hg° by $NaBH_4$ reduction) and atomic absorption detection (Bramanti *et al.*, 2008). Instrumental detection limits are as low as 2.5 pg, permitting sample dilution, therefore, minimizing interferences occurring with complex real wine matrices. The results from this method were compared with those from an HPLC method, where agreement was found to be good. Total thiol contents of wine (eight samples) were found to be in the range 11.0–28.2 μmol/l.

Other investigations of the iron, manganese and other metal contents of alcoholic drinks have focused on the partitioning of the metal species in the sample and hence involve fractionation of the sample before AAS analysis (Karadjova *et al.*, 2002; Paleogolos *et al.*, 2002; Pohl, 2007; Pohl, 2009; Pohl and Prusisz, 2009). Karadjova *et al.* (2002) used FAAS to determine Fe, Cu and Zn in different fractions of eight Macedonian and Turkish red and white wines. The charge of the metal species was established using cation and anion exchange separation based on solid phase extraction, XAD-8 resin was used for the separation of wine polyphenols in complexes with wine proteins and polysaccharides and Dowex ion exchange resins were used for the separation of cationic and anionic species of the three metals. The results indicated that almost 30% Fe, about 45% Cu and about 15% Zn are present in wine complexed with polyphenols and proteins, with only a few % of these metals bound to the carbohydrate fraction. The remainder of the metals were present as unbound ('free' or 'labile') cationic species, with Fe(II) being more abundant than Fe(III), as suggested by other studies.

Threefold fractionation of Mn and Zn species in beer was carried out using a column of hydrophobic adsorbing Amberlite XAD7 resin connected in series with a column containing a strong cation exchanger, Dowex 50Wx4 (Pohl and Prusisz, 2007). The fractions (containing hydrophobically bound metal, cation forms and residual neutral or anionic species) were digested in concentrated HNO_3 and H_2O_2 and then subjected to analysis by FAAS. For both Mn and Zn, the major form of the metal in the majority of beers was as cationic forms, but significant fractions of the total metal contents exist as polyphenolic complexes and low molecular mass, hydrophilic, neutral or negatively charged species. A nonionic adsorbing resin Amberlite XAD-16 and a strong cation exchange resin Dowex 50W-x8-200 linked in series was used for the fractionation of Mn in wine and its subsequent analysis by FAAS (Pohl, 2009). The major form of Mn in six wines was found to be the cation form.

A similar tandem arrangement of columns (Amberlite XAD-7HP and Dowex 50W-x8-200) was used to study the fractionation of Fe species in wine (Pohl and Prusisz, 2009). This time the fractions were polyphenol-bound Fe, cationic Fe and neutral/anionic complexes of Fe with organic acids. An Fe(III) single element standard solution made up in a medium imitating wine, containing citrate, tartrate, Ca^{2+}, K^+, Mg^{2+} and Na^+ was used as standard working solution for the calibration of Fe in wine. The big majority of Fe in the wines was present as cationic forms: hydrated cations or cations complexed with hydroxyacids and amino acids.

Since it is known that simple metal ions and complex cations with low molecular weight organic compounds are readily absorbed in the intestines, the above studies suggest that a high percentage of Fe, Mn and Zn in alcoholic beverages (as cationic forms) is readily bioavailable.

A FAAS method using a nonionic surfactant to trap polyphenol bound iron has been used to determine bound and free iron in 10 Greek commercial and homemade wines (Paleogolos *et al.*, 2002). The method makes use of precipitation of polyphenols and bound iron in the micelles of the surfactant. After centrifugation, the surfactant rich phase containing the tannin bound iron was directly aspirated into the nebulizer of an FAA spectrometer after its uptake with a methanolic solution of HCl, KCl and 8-hydroxyquinoline. The supernatant was subjected to the same procedure in the presence of ammonium pyrrolidine dithiocarbamate (APDC), which chelates free iron. The total iron content was also determined by conventional methods for comparison;

agreement between the two methods was good. Less than 10% of the iron in commercial wines was in tannin bound form, whereas this figure for the two domestic wines rose to 23.8% and 30.2%.

Atomic absorption spectroscopy has been used to determine the metal profiles of beers, wines and spirits for discrimination amongst samples and the determination of origin or type, by chemometric analysis (Peña *et al.*, 1999; Bellido-Milla *et al.*, 2000; Álvarez *et al.*, 2007; Moreno *et al.*, 2007). As far as wines are concerned, minerals are very useful composition elements for discrimination according to geographical origin, since the mineral profile should bear a direct relationship with the composition of the soil, although climatic factors and agricultural practices can also affect the mineral profile. The situation is a rather more difficult for beers, because it is likely that many beers are brewed using cereals that may have been be grown in different locations, although some brewers tend to buy their malted cereals from particular maltsters, who in turn tend to buy their grains from particular farmers.

Peña *et al.*, 1999 used FAAS data for Fe, Co, Mn, Ni and Zn, along with product data to discriminate between red wines of the same grape varieties from Ribeira Sacra and Valdeorras regions (Galicia, Spain) (39 samples in total), using principal component analysis (PCA), linear discriminant analysis (LDA) and K nearest neighbors (K-NN). Atomic emission spectroscopy was used to determine K, Li, Na and Rb. The method was able to discriminate between samples, but with a little overlap, suggesting that improvement could be made by use of a bigger reference set.

Atomic emission spectroscopy (AES) is often used in conjunction with inductively coupled plasma (ICP), gas chromatography or high performance liquid chromatography in the determination of a wide range of elements in alcoholic drinks, including nonmetals (such as B, C, Cl, P, S, Se, Si etc.), which are often difficult to determine by other atomic spectroscopy methods. An atomic emission spectrometer linked to a gas chromatograph has proved to be a highly sensitive and selective instrument (GC-AED) for the determination of certain nonmetals (such as Cl, S and Se) in organic compounds. The organic compounds are atomized in the AED and characteristic emission lines for the elements of interest are used for detection and quantification.

For example, the determination of organosulfur and organoselenium compounds in wine has been achieved by GC-AED (Swan, 2000; Campillo *et al.*, 2009). Swan (2000) analyzed red wines for dimethyl sulfide (DMS) and its precursors using this technique. Free DMS present in wines was purged from diluted samples to an adsorbent composed of gold coated glass wool. This was thermally desorbed to a valving and cryogenic trap system coupled to the GC-AED instrument. Permeated methylethylsulfide (MES) was used as an internal standard because the detector showed a compound independent response (at 181 nm) for sulfur from short chain alkylated sulfur compounds. There was no interference from SO_2 because of the high specificity of gold for sulfides. Release of DMS from precursors caused by the addition of aqueous NaOH depended on the concentration of NaOH and hence could only be estimated.

GC with a microwave induced plasma AED has been used to determine eight volatile organic sulfur and selenium compounds in beers, wines and spirits, using headspace SPME (carboxen/polydimethylsiloxane fiber) (Section 4.2.4) to extract and preconcentrate the analytes before GC-AED analysis (Campillo *et al.*, 2009). The scavenger gases in the AED were hydrogen and oxygen, and S and Se were determined simultaneously at 191 nm and 196 nm, respectively. Ethyl methyl sulfide and isopropyl disulfide were used as internal standards. Detection limits ranged from 8 ng/l to 40 ng/l, depending on the compound and the beverage sample analyzed, with a fiber exposure time of 20 min at ambient temperature. The optimized method was successfully applied to 40 different samples, where organosulfur compounds DMS, DMDS and/or methyl propyl sulfide (MPS) were found in half of them, detection levels being in the range 0.04–152 ng/l.

Possibly the most important development in this area was the application of HPLC-ICPAES to the simultaneous determination of alcohols, carbohydrates, carboxylic acids and metals in a range of foodstuffs, including wine (Paredes *et al.*, 2006). Using cation exchange chromatography, chromatograms were obtained by monitoring the carbon emission signal at 193.09 nm. A relatively high RF power (1350 W), with a high

outer gas flow rate (15 l/min) and low intermediate and nebulizer gas flow rates (0.2 and 0.6 l/min, respectively were used in the ICP-AES detector. Five sugars and polyols (fructose, glucose, lactose, sorbitol and sucrose), five carboxylic acids (acetic, citric, lactic, malic and tartaric), three alcohols (ethanol, methanol and glycerol) and seven metals (Al, Ba, Cu, Fe, Mn, Ni and Zn) could be determined in a single chromatographic run. The quantification of these species was in good agreement with results from other methods (HPLC-UV, FI and ICPMS, for example) and LoDs compared favorably with those of existing methods.

Other examples include the determination of 2,4,6-trichloroanisole (TCA) and haloanisoles in wines and cork stoppers (Campillo *et al*., 2004; 2008). Here the organohalogen components were atomized in the AED and were detected and quantified (simultaneously) using the 478 nm and 479 nm emission lines for Br and Cl, respectively.

For the analysis of TCA (Campillo *et al*., 2004), oxygen at 20 psi was used as reagent gas (scavenger gas), whereas oxygen at 5 psi was used for the analysis of haloanisoles (Campillo *et al*., 2008). The LoD for TCA was 25 pg/g for cork and 5ng/l for wine, whereas the LoDs for haloanisoles in wine were in the range 1.2–18.5 ng/l, illustrating the high sensitivity of this method compared with many other methods that have been used to estimate halophenols and haloanisoles in cork and wine. Campillo *et al.* used a purge and trap method of analyte preconcentration for TCA analysis (2004) and SPME for haloanisole analysis (2008).

Dietary intake of silicon is important mainly for the maintenance of bone mineral density. As the element (as silicates) is prevalent in the husk of cereal grains, it is probably this source that gives beer its relatively high silicon content compared with most other alcoholic beverages. Recently, ICP-AES has been used in the determination of Si in a wide range range of beers, produced by a variety of breweries using different cereals or combinations of cereals (barley, rice, sorghum, wheat) (Casey and Bamforth, 2010). The Si content was 6.4–56.5 mg/l, with the highest values generally being associated with the beers of smaller independent breweries, which usually use higher proportions of malted barley in their grist bills (barley husks have high levels of silica). Analysis of the change in Si content during a typical trial brew indicated that much of that element is lost in the spent grains, but significant levels are extracted into the wort and survive into the finished beer. A nitric acid, hydrogen peroxide, hydrofluoric acid digestion was required for ICP-AES analysis of Si in solid samples.

ICP-AES is particularly useful in the determination of metals in alcoholic beverages or in the determination of authenticity (in conjunction with statistical analysis) as the following examples demonstrate.

ICP-OES (AES), ^{1}H NMR and HPLC (ion chromatography) data combined with chemometrics was used to classify 33 red and white wines from three regions of Slovenia and three regions of Apulia (Italy) (Brescia *et al.*, 2003). AES analysis was performed on Al, B, Ba, Cu, Fe, Mn and Zn after mineralization (ashing) of the samples and digesting the ashes in 70% aqueous HNO_3 and 40% aqueous H_2O_2. Differentiation was possible between wines from Slovenia and Apulia, but was unsatisfactory for wines in different regions, probably because of small geoclimatic conditions.

Wines produced at different origins in the Western Cape area (96 samples) were differentiated on the basis of their elemental composition using ICP-AES and stepwise discriminant analysis, canonical discriminant analysis and linear discriminant analysis (Minnaar *et al.*, 2005). Seven grape varieties were used to make the various wines, so classification accuracy was 38–75% for red wines, 68% for Chardonnay white wines and 93% and 100% for Sauvignon Blanc and Chenin Blanc white wines, respectively.

More recently, Álvarez *et al.* (2007) used ICP-AES to study the mineral profile of Montilla-Moriles fino wines (50 samples), according to their content of Zn, P, Mn, Fe, Mg, Cu, Ca, Al, Sr, Ba, Na and K. Samples were digested in H_2O_2, followed by HNO_3 before analysis. The initial results indicated that mineral data sets were non-normally distributed and so nonparametric statistics (median, interquartile range) were applied. The interrelation of element couples was studied using the Spearman nonparametric sample correlation method. Correlations were established between P/Mg, P/Ca, Ca/Al, Ca/Na and Al/Na, thus allowing discimination between Montilla-Moriles wines and similar wines from other regions.

ICP-AES (as well as GFAAS) was used to study the metal content (Al, Ba, Cu, Fe, Mn, Sr, Zn, Ca, K, Na and Mg; and Ni, Pb, respectively) of 54 commercial wines from the Canary Islands (Moreno *et al.*, 2007). Samples were processed by dry ashing followed by solution with 5% nitric acid. Supervised learning pattern recognition procedures were applied and linear discriminant analysis (LDA) led to about 90% of correct classification of wines from two regions in the Canary Islands. Probabilistic neural networks gave better results; sensitivities and specificities higher than 95% for the two classes.

FAAS was used to determine Al, Ca, Cu, Fe, Mg, Mn and Zn in a range of beers, including ales, lagers, stouts and wheat beers (Bellido-Milla *et al.*, 2000). Na and K were determined by FAES. A sample preparation method for AAS, based on treatment with HNO_3 and H_2O_2 in a microwave oven, was developed for this study. UV-visible molecular absorption spectra were used as an index for the organic matter content, and along with conductivity and pH data were used in chemometric analysis. Analysis of variance (ANOVA) showed statistically significant differences among the four types of beers studied were found for Fe, Cu, Mn, Mg, Ca and Na content, conductivity and molecular absorption spectrum. ANOVA also revealed differences between canned and bottled beers, the former having higher Cr and Cu contents. Linear discriminant analysis (LDA) proved capable of grouping the samples correctly, although there was overlap between ales and stouts.

The 16 most abundant metals in 68 distilled spirits from a number of different countries were determined by ICP-AES and the results were analyzed using canonical discriminant analysis and classification binary tree methods in order to establish which of the analyzed metals present the best diagnostic parameters for the determination of authenticity of traditional Cypriot zivania (Kokkinofta *et al.*, 2003). It was found that Cu, Mg and Zn concentrations provided promising parameters for differentiation of zivania from various other spirits, including ouzo, tsipoura, tsikoudia (all Greek), arak, brandy, gin, grappa and vodka.

On the other hand, calcium, copper, iron, magnesium, potassium, sodium, strontium, sulfur and zinc levels were found to be the most discriminant elements, determined by ICP-AES, in the differentiation between silver, gold and aged mescal and Tequila (Section 3.5.5) (Ceballos-Magaña *et al.*, 2009). The application of probalistic neural networks to the data allowed 100% success, thereby providing a reliable method for the authetication of origin and detection of fraud, which is a serious problem regarding Tequila in particular.

4.4.5 Mass Spectrometry

Mass spectrometry (MS) has long been useful in wine analysis as a sensitive mode of detection for GC and HPLC separations, as GC-MS (Section 4.3.2) and LC-MS (Section 4.3.3). In this way, components can be identified by digital comparison of their mass spectra with those in mass spectral libraries (either proprietory ones, like the Wiley or NIST libraries, or in house libraries). Also, new compounds can often be identified from their fragmentation patterns, although other spectroscopic analysis (especially NMR) can be of great help, as in the identification of new pigments in port wine. Similarly, tandem mass spectrometry (especially MS-MS) is very useful at unraveling the structures of more complex components, such as condensed polyphenols. Because of rapid scanning abilities, quadrupole (Q) and ion trap (QIT) mass spectrometers are probably still the most widely used types in GC-MS and LC-MS, despite their disadvantages regarding low resolution and low m/z limits. The reader is referred to Lambert *et al.* (1998), Silverstein *et al.* (2005) and Lee (1998) for general accounts on mass spectrometry and to Smith (2004) and de Hoffmann and Stroobant (2002) for more specialist texts.

For GC-MS and LC-MS, information regarding the chromatographic and interface aspects will be found in Sections 4.3.2 and 4.3.3, respectively, along with a brief account of MS aspects in some cases. The present will be more or less confined to aspects of mass spectrometry.

A schematic layout of a mass spectrometer is shown in Figure 4.4.27, where it can be seen that the essential parts are the ion source, the analyzer, the detector and the computer. Ion sources and analyzers are discussed

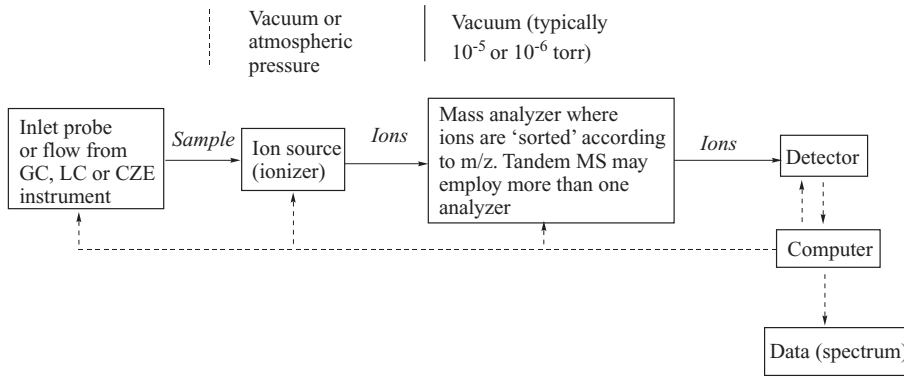

Figure 4.4.27 *Essential features of a mass spectrometer*

in the next paragraphs. The computer and data system are very important in modern MS instruments. The computer not only processes the mass spectral output from the detector, but also controls each section of the instrument in both real experiments and in 'tuning.'

Ionization

This is fundamental to all MS methods: the substance being studied needs to be ionized and its ions subsequently selected (analyzed) and detected. Because ion selection and detection is carried out at high vacuum (10^{-5}–10^{-6} torr; 10^{-3} torr for ion trap analyzers), ionization must occur in the gas phase. Either the substance must be vaporized prior to its ionization (as in EI and CI) or it is vaporized and ionized at the same time (as in ESI).

Electron Ionization (EI)

This is the oldest ionization technique still in use with commercial mass spectrometers; it is still used in GC-MS, but not LC-MS. Electrons are emitted from a hot filament and are accelerated through an electric field of potential difference typically 70 V, after which they have energies of around 70 eV. Fast electrons graze the analyte molecules (which must be in the gas phase) and cause ionization, usually to form molecular radical cations, but sometimes radical anions may be formed by electron capture.

Electrospray Ionization (ESI)

This mode of ionization is most commonly used with HPLC (including capillary column HPLC) and CZE, using mixed aqueous organic solvents (e.g. H_2O/MeCN) and (sometimes) added (volatile) buffer salts, acids or bases to aid ionization. The HPLC or CZE eluent containing the sample is converted to an aerosol by the action of a nebulizing gas and a high voltage applied to the capillary nebulizer tube (Figure 4.4.28). Although ESI is a 'soft' ionization technique (it gives a high abundance of molecular ions), some fragmentation often occurs, especially at higher voltages. In cases where fragmentation needs to be suppressed, ESI can be performed at lower capillary voltages.

An outline mechanism of positive ion production in an electrospray ion source is shown in Figure 4.4.29. The tiny droplets that make up the aerosol contain many protonated solvent and analyte molecules (as well

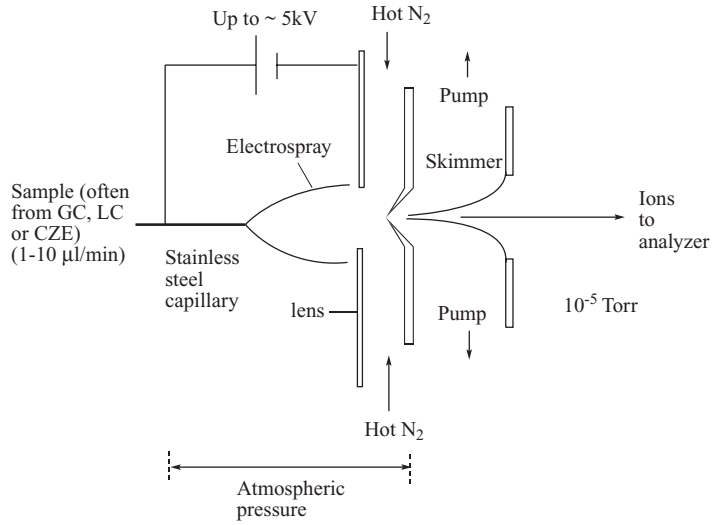

Figure 4.4.28 *Schematic diagram of electrospray ion source. Electospray is a plume of ionized solvent droplets, containing the analyte*

as a great many unprotonated, neutral molecules). A stream of hot gas rapidly vaporizes large numbers of neutral (mainly solvent) molecules, until the droplets become too small for the number of ions they contain. They then explode, releasing their ions, which enter the high vacuum region where any remaining neutral molecules are pumped to waste. The ions are subsequently focused and accelerated (and often gated) using skimmers and octapole lenses into the analyzer space.

Multiple charged ions are formed if there are many ionizable sites in the molecule, as in peptides and proteins, so that the formula masses of large molecules can be determined by ESI – another big advantage over EI. Most analyzers have limits on the size of m/z that can be measured with acceptable accuracy. For example, if a sample molecule has M = 10 000, it would be difficult to measure its m/z value if the ion was merely M^+ or MH^+, but if it has 20 ionizable groups it can form $[M + 20H]^{20+}$ in ESIMS, with an m/z value of 10 020/20 = 501, which is readily measured by a quadrupole or ion trap analyzer.

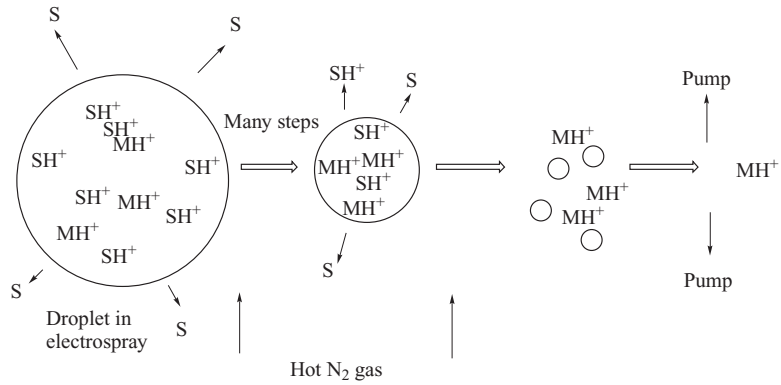

Figure 4.4.29 *Simplified scheme for formation of ions by ESI. Operation here is in positive ion mode*

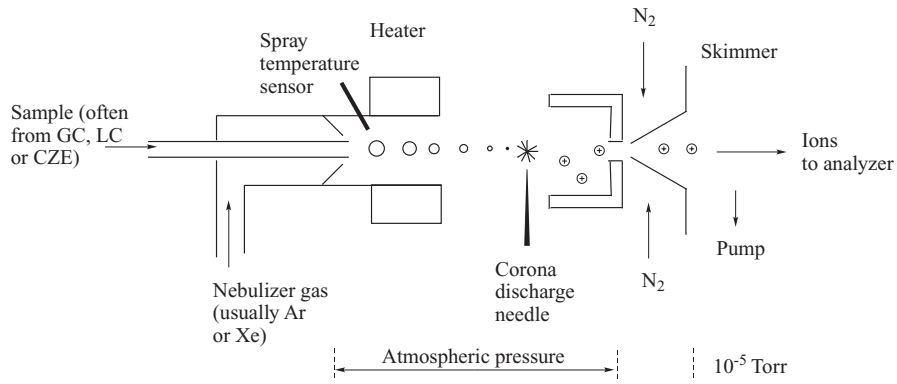

Figure 4.4.30 *Schematic diagram of an APCI source. Chemical ionization of analytes occurs in the micro droplets due to corona discharge*

Atmospheric Pressure Chemical Ionization (APCI)

This method (again popular in LC-MS) is similar to CI (it uses ion–molecule reactions), except that it operates at atmospheric pressure and the primary ions are produced by corona discharge on the eluent spray emerging from the HPLC capillary (Figure 4.4.30).

Analyzers

Mass spectrometers are usually classified according to the nature of their analyzers, where the ions are sorted, irrespective of the type of ion source employed. The two categories are:

- *Dispersive Instruments.* These are capable of separating gas phase ions according to their m/z ratios
- *Nondispersive Instruments.* These detect the presence of ions of selected m/z ratios by a resonance technique, without actually separating them.

The most common analyzers are: (a) magnetic sectors (B), (b) electric sectors (E), (c) electric + magnetic sector (double focus), (d) quadrupoles (Q), (e) ion trap (QIT), (f) time of flight (TOF) and (g) ion cyclotron resonance (ICR). All are dispersive, except (g). Nowadays, many mass spectrometry experiments on alcoholic beverages are carried out using a mass spectrometer that is attached to the outlet capillary of a GC, HPLC or CZE instrument. In these cases, the most widely used analyzers are quadrupole and ion trap, but TOF analyzers are sometimes used, either coupled to a quadrupole in a QTOF tandem mass spectrometer or for specific analysis of macromolecules using matrix assisted laser ionization (MALDI).

Quadrupole Analyzers (Q)

A quadrupole mass analyzer is made up of a set of four exactly straight and parallel metal rods, as shown in Figure 4.4.31. These are cylindrical (though the ideal shape is hyperbolic). Diametrically opposed rods are connected together electrically and both pairs are linked to a direct source of potential (V_{DC}) and an alternating radiofrequency source (V_{RF}). For the two pairs of rods, the DC voltages (V_{DC}) are of equal amplitude and opposite polarity, whereas the RF voltages (V_{RF}) are of equal amplitude and are 180° out of phase. Optimally, $V_{DC}/V_{RF} \leq 0.168$, where V_{DC} is typically 0–200 V and V_{RF} is typically 0–1200 V (peak to peak).

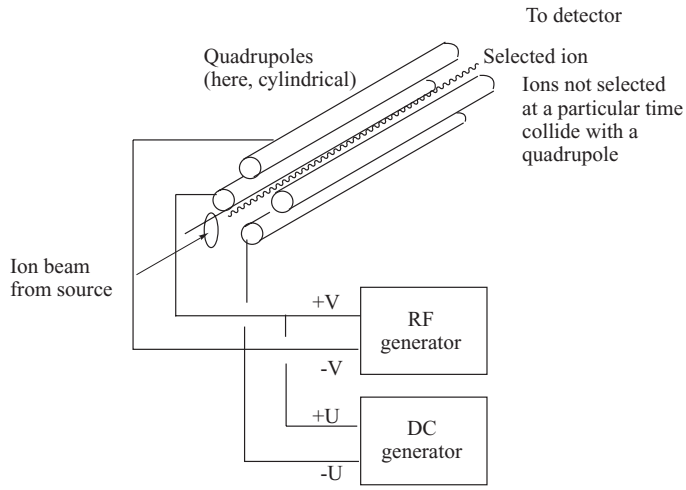

Figure 4.4.31 *Simplified diagram of a quadrupole analyzer*

The combination of DC and RF has no effect on the forward (z) motion of the ions, but instead they are subjected to complex sideways (x and y) motions, due to an electric potential (F) resulting from varying electric fields $+(U + V\cos\,\omega t)$ and $-(U + V\cos\,\omega t)$ and given by Equation 4.4.20.

$$F = \left(\frac{x^2 - y^2}{r^2}\right)(U + V\cos\omega t) \tag{4.4.20}$$

where r is the internal radius, ω is the frequency of the RF field (rad/s) and t is time, U is the DC voltage and V is the RF voltage.

For a fixed m/z value and fixed value of r, there is only a very narrow range of voltages (frequency is usually fixed) for which a stable ion trajectory is available (i.e. a trajectory that allows the ion through the quadrupolar space to the detector). This is called the resonance condition. Otherwise the ions eventually strike one of the rods. Ions of different m/z values can be allowed through to the detector successively very rapidly, so that scanning speeds of 6000 amu/s are routine. High precision engineering and placing of the rods ensures a unit mass resolution for up to 2000 amu.

Ion Trap Analyzers (QIT)

Strictly, these are quadrupole ion traps (hence the abbreviation QIT), since four charged electrodes are used to trap ions (Figure 4.4.32). Some QIT analyzers employ only an RF voltage of fixed frequency but of variable voltage, others allow the application of a DC voltage as well, like quadrupole analyzers. In concept, a QIT analyzer resembles a Q analyzer bent back on itself to form a closed loop, so that ions entering the space between the electrodes are trapped in three dimensional trajectories which are prevented from excessive motion (ions repel) by the presence of helium in the trap at *ca.* 10^{-3} Torr. A resonance condition exists for each m/z for a particular value of V, but a slight increase in V will cause the trajectory to become unstable and the ion is ejected out of the ion trap space to the detector. Alternatively, if an RF voltage at the secular frequency of a particular ion is applied to the end caps (i.e. in the z direction), the ion will come into resonance and its oscillations will be so large that it will be ejected from the trap in the z direction. Like quadrupole

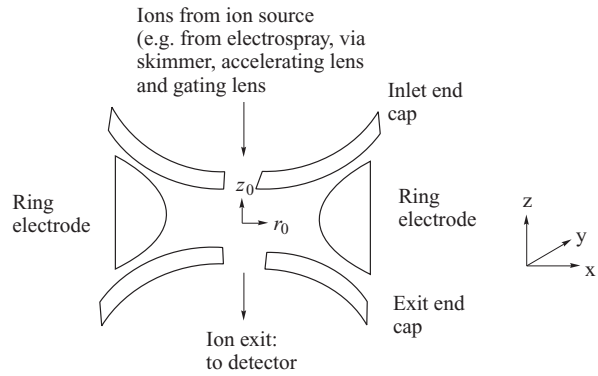

Figure 4.4.32 *Schematic view of an ion trap analyzer. Not to scale*

analyzers, scanning is very rapid. Tandem MS experiments (of the 'in time' type) can be carried using QIT analyzers by collision with helium atoms, which are always present. Fragmentation can be improved by excitation of selected ions at their secular frequency.

Tandem Mass Spectrometry

Sometimes known as MS/MS (or MS^n), tandem MS refers to instruments in which at least two independent stages of m/z analysis are used. This can be done either with the same analyzer (MS/MS 'in time') or using additional analyzers (MS/MS 'in space'). The most common use of tandem MS is in structure determination. Ions produced in one space or at one time undergo fragmentation (usually by collision induced decomposition (CID) with an inert gas), whence the fragment ions are analyzed in a different space or time. CID can be carried out at various energies, using various gases at various pressures, thus controlling fragmentation pathways and maximizing the information available.

The practical limit to the number of analyzers used in MS/MS in space experiments is three or four (MS^3/MS^4). Typical in space tandem MS arrangements are QqQ, QqTOF, BEqQ, BqQ. Tandem MS of the 'in time' type can be performed using quadrupole ion trap (QIT), ion cyclotron resonance (ICR) and time of flight (TOF) analyzers. The practical limit to the number of determinations that can be carried out using in time MS/MS is eight (MS^8).

The most common type of MS/MS instrument is the 'triple quad,' with three quadrupole analyzers, although only two are used for mass spectrometry (see next): its symbol is QqQ. The most usual kind of MS/MS experiment, known as 'product ion scan' is described next in relation to this type. The first quadrupole (Q) is used to select ions (precursor ions) of a particular m/z value. The middle one (q) is used for excitation (usually collisional activation) of these ions. The last quadrupole (Q) analyzes the fragment ions produced by decomposition of the precursor ions in the middle quadrupole space. Product ion scan and other MS/MS experimental types are outlined in Figure 4.4.33.

Mass spectrometry has two major uses in the analysis of alcoholic beverages:

- Identification of components from molecular weight and fragmentation data. Here it is usually combined with GC, LC or capillary electrophoresis, but sometimes direct inlet MS is used and NMR often provides support.
- Isotope ratio mass spectrometry (IRMS). Biological and geographical history influence isotope ratios and hence their determination can provide evidence of origin.

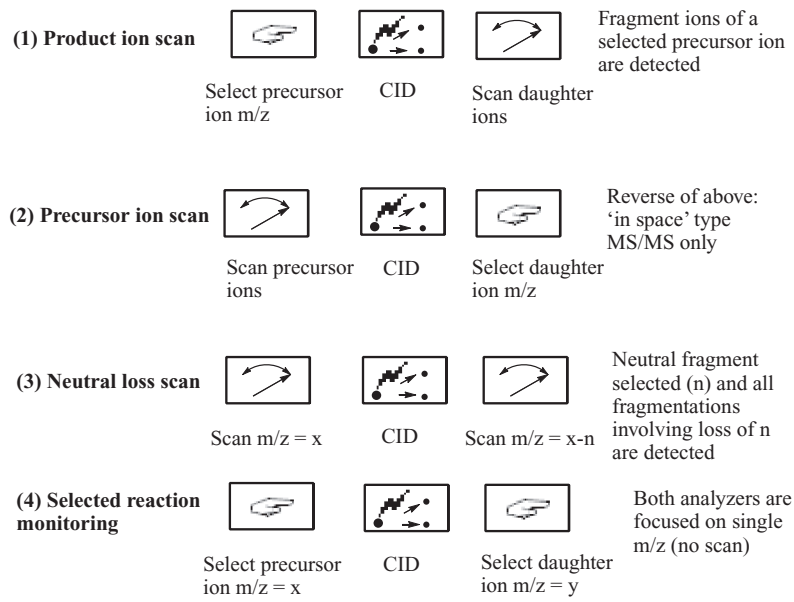

Figure 4.4.33 *Select and scan sequences for tandem MS. These are typical sequences used with QqQ and other tandem MS techniques, with (1) being the most common. (4) is analogous with SIM mode in GC-MS*

Identification and Quantification of Components

The biggest area of application of mass spectrometry (particularly tandem MS) is in the study of polyphenols in fruits and wines, where the big majority of analyses are conducted using LC-MS (Section 4.3.3). Earlier studies used mostly single analyzer MS instruments and many relied on NMR for unambiguous structure determination of new polyphenols. Identity of known polyphenols was achieved by comparing fragmentation with those of standards and/or those in the literature. More recent MS studies often involve tandem instruments, where QqQ and QIT configurations are the most common. Product ion scanning, neutral loss scan and selected reaction monitoring are the most usual modes (Figure 4.4.33), usually MS^2, but occasionally MS^3. Mass spectrometers with QTOF configurations are gaining in popularity, because when operating in product ion scan mode, accurate masses of daughter ions can be used for fragment identification and hence can be a great help in elucidation of the structure of the molecular ion. The application of tandem mass spectrometry to the study of flavonoid phenols has been extensively reviewed (March and Brodbelt, 2008), although there are relatively few examples involving alcoholic beverages or their raw materials.

Direct inlet MS experiments, using a medical syringe infusion pump for example, are comparatively rare in this field, but procyanidin polymers in pear skins (Guyot *et al.*, 1996b), oligomeric anthocyanins in grape skins (Vidal *et al.*, 2004a) and polyphenol standards (Wolfender *et al.*, 1998) have been studied in this manner. The negative ion ESI spectra of pear skins extracted with 0.25% (v:v) aqueous acetic:methanol (75:25) (the acid aided ionization) showed a family of polymeric epicatechin-based procyanidins (Figure 4.4.34) up to a polymerization degree of 17 (Guyot *et al.*, 1996b). The suggestion of epicatechin, rather than catechin monomeric units, was deduced from thioacidolysis experiments. Epicatechin units of mass 290 lose two protons for every interflavan linkage, so that ions at m/z 1153.0, 1441.0 and 2305.5, for example, are consistent with $(M - H)^-$ of tetrameric, pentameric and octameric ions (respectively), for example. Similarly, ions with multiple negative charges were identified; for example the ion at m/z 1663.2 was unambiguously

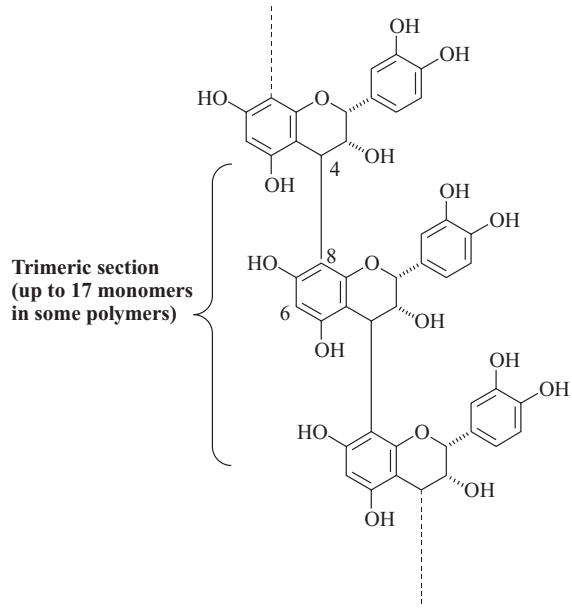

Figure 4.4.34 *General structure of epicatechin based polymeric proanthocyanidins. The existence of 4→6 linkages cannot be excluded. MS alone cannot distinguish between these possibilities. Guyot* et al. *(1996b)*

assigned to $[17\text{-mer} - 3H]^{3-}$. Also, enlargement of the spectrum peaks revealed isotopic clusters that were compared with computer calculated isotopic distribution diagrams for particular molecular formulas. Thus the isotope distribution of the peak at m/z 1585.0 corresponded to that of a molecular formula $C_{165}H_{132}O_{66}$; a doubly charged undecamer ($[11\text{-mer} - 2H]^{2-}$).

Similarly, direct introduction of a multilayer counter current chromatography fraction of a black grape skin extract into the mass spectrometer, using ESI, showed this fraction was composed almost entirely of oligomers, in support of the results of LC-MS analysis, color-bleaching tests with SO_2 and thiolysis (Vidal *et al.*, 2004a). The oligomers were direct condensation products extending as far as trimers, although it was unclear whether the anthocyanin units were linked by a carbon-carbon bond (as in B type proanthocyanidins) or by a carbon–carbon bond and an ether bond as in A type oligomers (see Figure 5.8.7, Section 5.8.6). The terminal unit was in the flavylium form, but the extension units would be in the flavene form for the B type oligomers and the flavan form for the A type oligomers.

The majority of LC-MS studies on polyphenols use electrospray ion sources, although isorhamnetin glycosides were detected and characterized in apple extracts using negative ion APCI (Schieber *et al.*, 2002). In this study, collision induced dissociation spectra were obtained at 20 eV, using xenon as the collision gas (9.1×10^{-4} Torr). Dissociation of a pseudomolecular ion ($[M - H]^-$) at m/z 477 gave a peak at m/z 315, which was assigned to isorhamnetin (aglycone). Isorhamnetin and rhamnetin could be differentiated by performing MS^2 and MS^3 product ion scans on the pure standards and comparing the results with those of LC-MS analysis: CID of isorhamnetin yields an ion at m/z 300 as the most abundant, whereas rhamnetin gave an intense fragment at m/z 165. The presence of isorhamnetin 3-*O* -glucoside was confirmed in apple extracts of the Brettacher variety on the basis of retention time, UV spectra and MS analyses. Tandem MS was able to assign a component that coeluted with quercetin 3-rhamnoside as isorhamnetin 3-*O*-galactoside.

Phenolic profiles of commercial apple juices and the juice of crushed whole eating apples and German cider apples, were determined using LC-MS with negative ion ESI and a triple quadrupole (QqQ) MSD (Kahle *et al.*, 2005). MS^2 experiments were performed at a collision energy of 20–40 eV with argon at 2.0×10^{-3} Torr pressure serving as the collision gas. Model solutions of pure reference compounds were used for identification via MS^2 and/or retention times. The pseudomolecular ion was chosen for either low energy or high energy CID fragmentation studies, according to identity. Thus, collision energies of 15–20 eV were used for chlorogenic acid and other hydroxycinnamic acids, 27–35 eV for dihydrochalcones, 20–30 eV for flavan-3-ols (including dimeric procyanidins) and 26–40 eV for flavonols.

In general, quadrupole (Q) tends to be used rather more than ion trap (QIT) MS instrumentation in the LC-MS analysis of beverage polyphenols (despite the capability of performing MS^3 and MS^4 experiments with QIT), but ion trap MSD is common and has been used to study the phenolic components of colored fruit extracts (González Paramás *et al.*, 2006; Sadilova *et al.*, 2006; Seeram, 2006a; 2006b) and wine (Salas *et al.*, 2004) and also for the detection and characterization of phenolic oxidation products of cider apple juice (variety: Kermerrien) (Bernillon *et al.*, 2004). In the latter study, negative ion ESI spectra were acquired using full scan (m/z 50–2000) and selected ion monitoring (SIM). Monomeric phenols and one dimeric proanthocyanidin (B_2) were identified using HPLC retention times of pure standards. The major polyphenols in unoxidized juice were caffeoylquinic acid, procyanidin B_2, (–)-epicatechin, *p*-coumaroylquinic acid, phloretin xyloglucoside and phlorizdin, as confirmed by their pseudomolecular ions ($[M - H]^-$) at m/z 353, 577, 289, 337, 565 and 435, respectively. Caffeoylquinic acid (CQA) plays a central role in the mechanism of oxidation of cider apple juice; study of oxidized apple juice in the SIM mode at m/z = 641, 705 and 929, showed seven chromatographic peaks corresponding to CQA-catechin dimers, two peaks corresponding to CQA dimers and six peaks corresponding to CQA-procyanidin B_2 dimers. Oxidation increased the number of polymeric proanthocyanidins, as indicated by the broadening and intensification of the unresolved baselines of the HPLC-UV chromatograms.

More recently, Lin and Harnly (2008) used LC-ESI-MS (as well as HPLC-DAD) to characterize the phenolic compounds (flavones, flavonols, flavan-3-ols, hydroxycinnamic acids, hydroxybenzoic acids and others) in the skin extracts of 16 pear varieties. Aglycones in the hydrolyzed skin extracts were also studied. ESI was conducted in both negative and positive modes and at high and low fragmentation voltages. In order to study less concentrated components in the hydrolyzed skin extracts, negative and positive selective ion monitoring detection was used at m/z 271/269 (for trihydroxyflavones), 287/285 (for tetrahydroxyflavone), 303/301 (for pentahydroxyflavone) and 317/315 (for tetrahydroxymethoxyflavone). As a result of this work, phenolic profiles were constructed for 16 pear varieties, whose subclasses (Asian, Yali, fragrant and Bartlett) could be grouped according to principal component analysis of the pear skin phenol data. Pears of the Bartlett group (*P. communis* L.) contained higher levels of isorhamnetin glycosides (including malonyl forms) and lesser amounts of quercetin glycosides, whereas Asian pears contained arbutin and chlorogenic acid, with only traces of flavonoids. Yali pears were richer in 3,5-dicaffeoylquinic acid (rather than chlorogenic acid) and had significant caffeic acid content. Fragrant pears had significant rutin, quercetin 3-*O*-2″-xylosyl-6″-rhamnosylglucoside and isorhamnetin 3-*O*-rutinoside contents.

All the above examples focused on negative ion ESI (and in one case APCI), since the mass spectra of polyphenols generally show more intense peaks in this mode, as the phenolic OH groups are easily ionized. Anthocyanins, on the other hand, are best studied in positive ion mode, because at fruit and wine pH they exist largely in the cationic form. In the following examples of the LC-MS determination of phenolic compounds in red or purple colored fruit or red wine, positive ionization modes are generally used for anthocyanins (and derivatives) (Burns *et al.*, 2003; Dugo *et al.*, 2003; 2004; Salas *et al.*, 2004; Vidal *et al.*, 2004b; Tian *et al.*, 2005; González-Paramás *et al.*, 2006; Sadilova *et al.*, 2006; Seeram *et al.*, 2006a; 2006b; Morata *et al.*, 2007) and negative ionization modes for polyphenols, (Vivas de Gaulejac *et al.*, 2001; Urpí-Sardà *et al.*, 2005; Seeram *et al.*, 2006a; 2006b; Lin and Harnly, 2007), respectively.

LC-MS (using +ESI and –ESI and a QIT analyzer) and HPLC-DAD was used to identify phenolic compounds in strawberries (Seeram *et al.*, 2006a). Here differentiation between ellagic acid and quercetin ($[M-H]^-$ = 301 amu for both aglycones) was achieved by MS^2; the former gives daughter ions at m/z 257 and 229, whilst the latter yields fragments at m/z 179 and 151. Tandem MS was also used to characterize complex hydrolyzable tannins, such as galloyl-bis-hexahydroxydiphenic acid (MS m/z = 935.0; MS^2 m/z = 898, 633, 463, 301, 257, 229) (molecular weight 936). Seeram *et al.* (2006b) also used a similar instrumentation to characterize the phenolic compounds in blackberry, black raspberry, blueberry, cranberry, red raspberry and strawberry extracts. MS^2 fragmentation was carried out at 50% energy and zoom scan analysis was used to determine the charge state of some of the ellagitannin components, which are more common in the *Rubus* species (red raspberry especially) and strawberry (*Fragaria ananassa*). As in many other cases, identities of the components were deduced by matching their molecular ions obtained from LC-MS and LC-MS^2 with literature data for phenolic compounds of small colorful berries (e.g. Maatta-Riihinen *et al.*, 2003; 2004; Wu and Prior, 2005; Zadernowski *et al.*, 2005).

LC-MS using positive ion electrospray has been used to characterize the anthocyanins of Silician blood oranges (Dugo *et al.*, 2003), Cabernet Sauvignon wines and red wines from hybrids (Burns *et al.*, 2003), black raspberry (Tian *et al.*, 2005), thermally degraded black carrot, elderberry and strawberry extracts (Sadilova *et al.*, 2006) and red wines (Dugo *et al.*, 2004). Furthermore, similar techniques have been used to study vitisins A and B, and their vinylphenol adducts in red wine (Section 2.9.2) (Morata *et al.*, 2007), flavanol-anthocyanin adducts in red wine (Salas *et al.*, 2004), flavanol-anthocyanin condensed pigments (González-Paramás *et al.*, 2006).

Determination of complete anthocyanin profiles by LC-MS has been demonstrated to be a more reliable means of differentiating between wines of Cabernet Sauvignon and those from hybrid grapes (without tasting them), rather than use the ratio of acetylated to *p*-coumaroylated derivatives of nine characteristic anthocyanins (Burns *et al.*, 2003). Thus examination of full anthocyanin profiles may lead to detection of adulteration of Cabernet Sauvignon wines.

Anthocyanin adducts and condensation products have received considerable attention from LC-MS. Morata *et al.* (2007) used positive ESI and a single quadrupole analyzer to study anthocyanin–pyruvic acid and anthocyanin–acetaldehyde adducts (vitisin A and B, and their coumaroylated derivatives) (Section 2.10.7) in red wine. The compounds were identified by their molecular ions and their major fragments, which are produced by loss of the sugar moiety, as shown in Figure 4.4.35. Using a QIT mass detector, González-Paramás *et al.* (2006) showed that two minor pigments in the first part of HPLC chromatograms of black grape skin extracts were flavanol–anthocyanin condensation products. Their molecular ions (m/z = 751 and 781) yielded MS^2 fragments that indicated the loss of a hexose moiety (m/z = 589 and 619). MS^3 fragments suggest loss of water (m/z = 571 and 601), loss of $C_6H_6O_3$ (m/z = 463 and 493), flavanol RDA fission (m/z = 437 and 467), partial loss of flavanol (at m/z = 343 and 373) and loss of a flavanol unit (m/z = 301 and 331). The condensation products from this data, were shown to be (epi)catechin-peonidin 3-glucoside and (epi)catechin-malvidin 3-glucoside (Figure 4.4.36). This work was in general agreement with earlier work of Salas *et al.* (2004) on flavanol-anthocyanin pigments in wine.

Although most LC-MS^n studies of phenolic compounds have used product ion scan, Tian *et al.* (2005) used selected reaction monitoring (Figure 4.4.36)(along with selected ion monitoring) to determine the anthocyanins in freeze dried black raspberry juice extracts.

SRM was carried out by measurement of m/z 449→287 for cyanidin 3-glycoside, m/z 581→287 for cyanidin 3-sambubioside, m/z 595→287 for cyanidin 3-rutinoside and m/z 727→287 for cyanidin 3-(2G-xyloylrutinoside). Cyanidin 3-arabinoside (m/z 419→287) was used as an internal standard during extraction and analysis. Although, the majority of this work was carried out using ESI in the positive ion mode, negative ion LC-ESI/MS showed the pseudomolecular ions to be of the type $[M-2H]^-$ and $[\text{aglycone}-2H]^-$. Presumably, the more usual $[M-H]^-$ are formed, but are not detected because of the positive charge residing on anthocyanidins and anthocyanins.

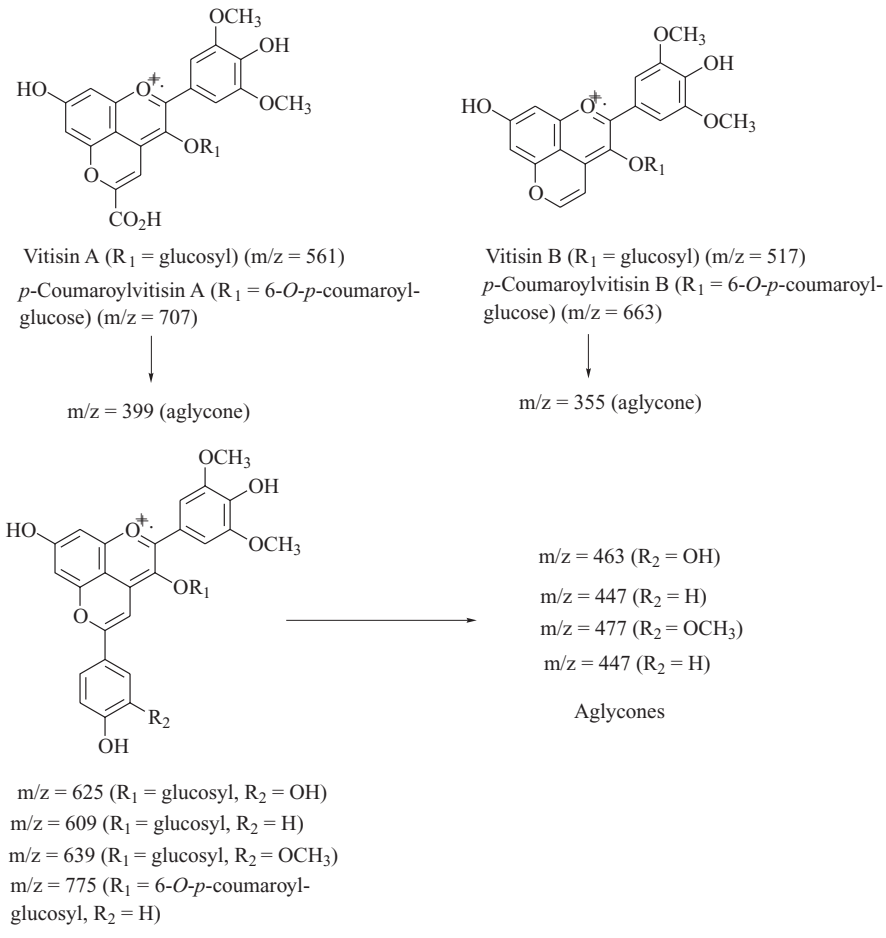

Figure 4.4.35 *Fragmentation of vitisins A and B,* p-*coumaroylvitisins A and B, and their 4-vinylphenol adducts*

Using multiple standard reaction monitoring and negative ESI, Urpí-Sardà *et al.* (2005) were able to identify and quantify resveratrol metabolites in human low density lipoprotein (LDL) for the first time after moderate consumption of red wine, thus giving support to the theory of dietary phenols preventing oxidation of LDL and hence minimizing development of atherosclerosis (Section 5.8.9). Five transitions were monitored for each analysis: resveratrol (m/z 227→185), resveratrol glucosides (389→227), resveratrol glucuronides (403→227) and resveratrol sulfates (307→285). Taxifolin (m/z 303→285) was used as an internal standard and dwell time for each transition was 350 ms with a 5 ms pause between mass ranges. Although several metabolites were found in LDL, the highest concentrations were of *trans*-resveratrol-3-*O*-glucuronide (up to 278.32 pmol/mg of LDL protein), which is known to be synthesized in the liver from dietary *trans*-resveratrol (Tang *et al.*, 2003).

LC-MS has been applied to the study of reactions involving phenolic compounds, as in the thermal degradation of anthocyanins (Sadilova *et al.*, 2006) and the oxidation of red wine (Vivas *et al.*, 2001). In the first mentioned study, MS^2 and MS^3 product ion scans with a QIT analyzer were used to identify the decomposition products of anthocyanins in black carrot, elderberry and strawberry. Upon heating, Cyanidin 3-glucoside ($M^+ = 449$) gave protocatechuic acid (MS^3: m/z (MH^+) 155→111→111) and phloroglucinaldehyde

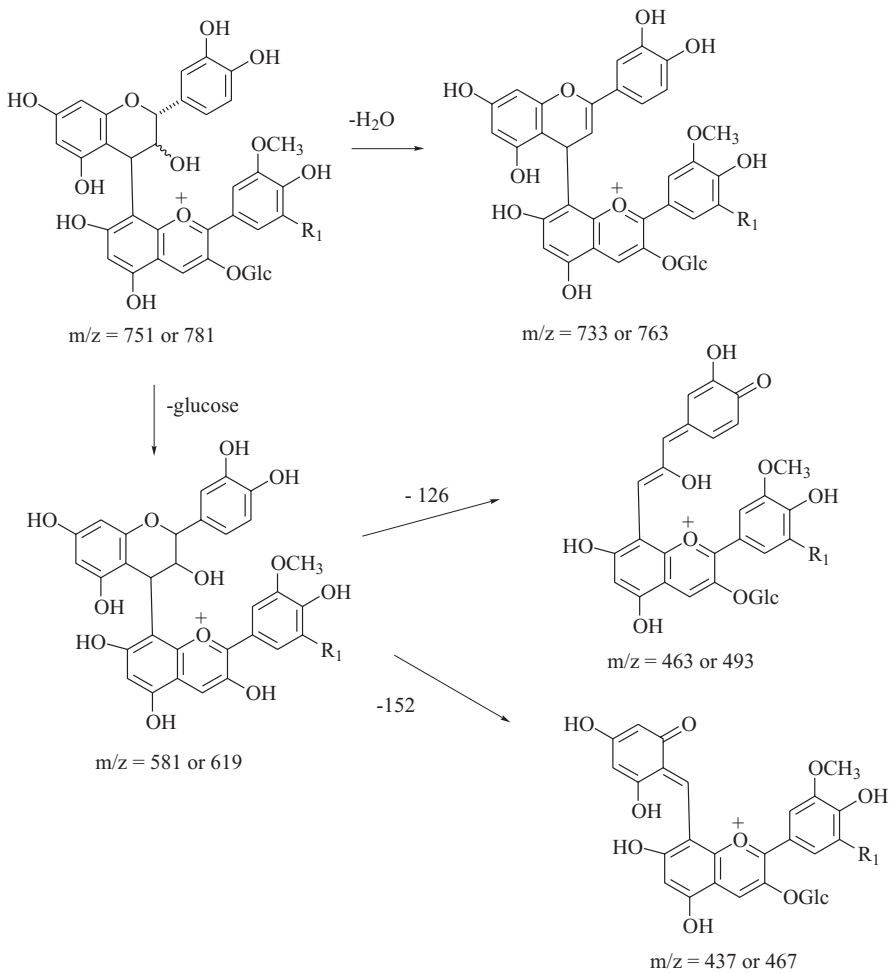

Figure 4.4.36 *Tandem MS fragmentation scheme for flavanol-anthocyanin grape skin pigments. R1 = H or OCH_3 (Gonzalez-Paramas* et al.*, 2006; Salas* et al.*, 2004)*

(MS^2: m/z 155 (MH^+)→127), whereas pelargonidin 3-glucoside ($M^+ = 433$) gave phloroglucinaldehyde and 4-hydroxybenzoic acid (MS^3: m/z 139 (MH^+)→95→95). Also, adducts between thermal decomposition products (e.g. 4-hydroxybenzoic acid) and an original anthocyanidin (e.g. pelargonidin 3-glucoside) (MS^3: m/z 553 (M+)→391→297) were tentatively assigned (e.g. M = 553 ≡ 433 + 138 – 18). In the latter study, low voltage negative ESI was used to identify the quinonic forms of monomeric flavan-3-ols and dimeric procyanidins with regard to their oxidation in red wine. Enzymic oxidation (using laccase or tyrosinase) and chemical oxidation (in the presence of Cu^{2+}or Fe^{2+}) were used as model reactions on pure phenolic compounds. The quinonic forms themselves were unstable, rapidly polymerizing and precipitating, so they were also studied as their stabilized sulfones, produced by reaction with benzenesulfinic acid. Quinonic forms of flavan-3-ols (m/z = 289; sulfonated forms, 429), but not procyanidins, were found in five year old red wine. Interestingly, LC-MS analysis of oxidized model solutions of procyanidin B_2 showed that enzymic oxidation produced just one quinone ring (monosulfonated m/z = 717), whereas chemical oxidation

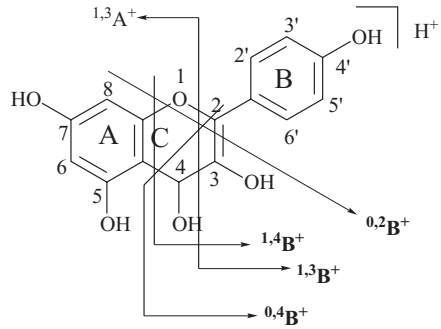

Figure 4.4.37 *Fragmentation (positive ionization mode) nomenclature for flavones, flavanones and isoflavones, illustrated for kaempferol. March and Brodbelt (2008); Ma* et al. *(1997)*

gave two products; one as for enzymic oxidation and the other with two quinonic functions (disulfonated m/z = 855.9).

As seen in the two examples above (Figures 4.4.35 and 4.4.36), anthocyanins and their adducts, and dimeric condensation products with flavanols fragment via a variety of pathways. Likewise, flavonoid aglycone pseudomolecular ions follow many fragmentation routes, as indicated in Figure 4.4.37, which also shows the fragmentation nomenclature commonly used to describe the fragmentation of flavones, flavanones and isoflavones (March and Brodbelt, 2008; Ma *et al.*, 1997).

The astringency of many alcoholic beverages with high polyphenol content (such as red wine) is thought to occur by the precipitation of protein–polyphenol complexes, the proteins originating from the lubricating salivary proteins in the mouth, including PRPs (proline-rich proteins) of the protid and submandibular glands. These proteins are characterized by high proline content and repetitive Pro-Gln-Gly-Pro-Pro sequences. Energy resolved mass spectrometry (ERMS) has been used to study interactions between various flavonoids (monomeric and dimeric) and synthetic segments of PRPs, particularly $IB7_{14}$ (^{1}SerProProProProGlyGlyLysProGlnGlyProProProGlnGlyGly^{14}). DE_{50} values (obtained by monitoring the additional energy needed to separate the partners of a complex) represent the relative affinity of flavonoids for the peptide in the gas phase and present data suggest flavonoid aglycones form weaker 1:1 complexes than the various glycosides (March and Brodbelt, 2008). This data showed epicatechin to be more effective than catechin in binding to $IB7_{14}$, in agreement with sensory analysis, which attributes greater astringency to epicatechin (Thorngate and Noble, 1995; Kallithraka *et al.*, 1997). Also, the data shows procyanidin B_3 (a catechin dimer) to have a much higher affinity for $IB7_{14}$ than catechin, again in agreement with sensory analysis regarding the higher astringency of oligomers over monomers (Simon *et al.*, 2003; Vidal *et al.*, 2003; Vidal *et al.*, 2004b; Preys *et al.*, 2006).

In practice, tandem MS has shown that flavonoid-$IB7_{14}$ complexes with stoichiometries of 1:1 to 4:1, even up to 16:1 for flavan-3-ol- $IB7_{14}$ complexes, suggesting stacking of the flavan-3-ol units, as well as flavanol–peptide interactions.

Other important components of alcoholic beverages have been studied by mass spectrometry. Volatile components (such as aroma compounds) have been determined mainly by GC-MS and are discussed in Section 4.3.2, whereas less volatile constituents are have been studied mostly by LC-MS and discussed here and in Section 4.3.3. These include pentacyclic triterpenes (Arramon *et al.*, 2003), chlorophyll catabolites (Müller *et al.*, 2007; Mendes-Pinto *et al.*, 2005), carotenoids (Mendes-Pinto *et al.*, 2005), proteins (Marangon *et al.*, 2009; Wigand, 2009), Maillard intermediates (Silva Ferreira *et al.*, 2007) and proteins (Marangon *et al.*, 2009; Wigand *et al.*, 2009).

Negative ion electrospray using selected ion monitoring was used to identify pentacyclic triterpenoids in wine and brandy (Armagnac), which are derived from oak casks during the maturation period (Arramon *et al.*, 2003). A cone voltage in the ion source of 30 eV or 75 eV was used, the latter to encourage fragmentation of the pseudomolecular ions ($[M - H]^-$). Four major triterpenoids were characterized: 2α,3β,19α-trihydroxyolean-12-ene-24,28-dioic acid (m/z = 517) and its 28-β-D-glucopyranoside (m/z = 679), 2α,3β,19α, 23-tetrahydroxyolean-12-ene-24,28-dioic acid (m/z = 533) and its 28-β-D-glucopyranoside (m/z = 695). Fragmentation of the two glycosides yielded main daughter ions at m/z 517 and 533, corresponding to the two aglycones. Interestingly, for the two aglycones, there were abundant high mass peaks at m/z 1035 and 1067, corresponding to dimeric quasimolecular ions ($[2M - H]^-$).

Nonfluorescent chlorophyll catabolites (NCCs) (degradation products) in the skins and flesh of apples and pears have been characterized by positive ion ESI MS (Müller *et al.*, 2007). Two major catabolites from pear were found to have accurately measured pseudomolecular ions ($[M + H]^+$) at m/z 807.341 and 645.292, which corresponded to $C_{41}H_{50}N_4O_{13}$ (m/z calc.) = 807.345) and $C_{35}H_{40}N_4O_8$ (m/z calc.) = 645.292), respectively, the former being the glucoside of the latter (see Figure 5.11.1, Section 5.11.2).

Chlorophyll, chlorophyll derived compounds and carotenoids in grapes and Port wine have also been characterized by positive ESI MS (Mendes-Pinto *et al.*, 2005). Eight carotenoids and six chlorophyll derived components isolated from Port wine grapes were discovered by LC-MS. Many of these survived the conversion into wine and identified compounds in Port wine included (with m/z) pheophorbide b (607), (all-*E*) lutein ($M^+ - H_2O$ = 551), (13*Z* or 13′*Z*)-lutein ($M^+ - H_2O$ = 551), pheophytin b (885), pheophytin a (871), (all-*E*)-β-carotene (537) and (13*Z*)-β-carotene (537). Several unknown compounds were classified as either chlorophyll degradation products or carotenoids and several compounds were identified by comparison of UV spectra of standards, but not by MS. Comparison of the HPLC profiles of grape juice and wine showed that wine had higher levels of chlorophyll degradation compounds and no chlorophyll. Also, aged Port wines had lower total carotenoid contents than younger wines, some of the carotenoids presumably having been converted to norisoprenoid flavor components during the aging process.

Application of both APCI and ESI (both in negative and positive ion modes) to the identification of Maillard reaction intermediates in oxidatively aged (which in many cases, is equivalent to spoilage) wine has been carried out by Silva Ferreira *et al.* (2007). The focus here was on certain keto acid and dicarbonyl intermediates, which were analyzed as their quinoxalinol/quinoxaline derivatives. Identification of key intermediates was carried out using product ion scan MS^2, based on fragmentation of pseudomolecular ions, as follows (for negative ion mode): phenylpyruvic acid (m/z 163→91); oxobutyric acid (m/z 100.8→57); ketoglutaric acid (145→101); methylthiobutyric acid (m/z 163→91), optimizing the operational parameters (including collision energy) for maximum intensity of pseudomolecular ions (see Section 4.3.3 for details of LC-MS and Section 2.6.2 for details of the Maillard reaction).

Although proteins are minor components of wine, they can influence wine quality by affecting haze formation, so for this reason alone they are worthy of investigation. The usual method of analysis is to prepare the sample – usually by dialysis and lyophilization and other treatments (Wigand *et al.*, 2009) or by separation into fractions using chromatography (Marangon *et al.*, 2009) – and then to separate the proteins first using SDS-PAGE (Section 4.6.1). The bands from SDS-PAGE separation, after reduction and alkylation, are then subjected to MS analysis, usually via HPLC. In a recent study (Marangon *et al.*, 2009), positive ion electrospray was used to produce ions that were analyzed using a QTOF system. The TOF-MS was set to scan m/z 370–1600 (1.0 s) and the three most abundant multiply charged ions (counts >50) in the scan were sequentially subjected to MS^2 analysis, where spectra were accumulated for 2 s (m/z 100–1600). The resulting mass data were matched against data base searches with a fragment mass tolerance of 0.6 Da, allowance of one missed cleavage per peptide and a number of variable modifications.

In another recent study (Wigand *et al.*, 2009), tryptic peptides were analyzed using positive mode ESI with a NanoLockSpray source, with the lock mass channel being sampled every 30 s. The instrument was

run in data directed acquisition mode, with the three most intense peaks selected for MS^2 fragmentation analysis and fragmentation of the precursor ion being achieved by collision with argon atoms. Collision energy was varied between 15 and 35 eV, depending on the precursor ion mass and charge, and the TOF analyzer integration time was 1 s, with an interscan delay of 0.1 s. The MS data were processed and searched using software and databases containing all known protein sequences from *V. vinifera*, *S. cerevisiae*, known possible contaminants (e.g. trypsin, human keratins) and typical fining agents (e.g. casein, collagens, etc.). The maximum mass error was 15 ppm for precursor ions and 30 ppm for fragment ions, and as in the previous study, one missed cleavage per peptide and certain variable modifications were allowed. All identified peptide sequences were verified by manual interpretation of the fragment spectra.

Tandem MS (again mostly via LC-MS) has been applied extensively to the analysis of pesticide residues in crops, food and beverages, including wine and other alcoholic beverages (Budde, 2004; Picó *et al.*, 2004). ESI and APCI are the major ionization techniques and many analyses are performed using QqQ analyzers, where all modes of MS^2 are used, with product ion scan and neutral loss scan perhaps being the most common. However, the QIT analyzer is particularly sensitive and its MS^n capability makes it especially attractive for analysis of residues, despite less reliable quantification for difficult matrices. So called hybrid instruments, such as Waters/Applied Biosystems QSTAR XL (QTOF), have gained in favor in this area of study, partly as a result of increased availability and increased performance since their inception at the turn in the 1990s. They offer big advantages of accurate mass determination of product ions and very high sensitivity for product ion scan. For example, determination of two insecticides (buprofezin and hexythiazox) in fruit skins used LC-QTOF, with lowest calibration levels of 0.075 and 0.01 mg/kg, respectively (Grimalt *et al.*, 2007). Up to 21 identification points (IPs) were earned by the QTOF system at the highest insecticide level (5mg/kg), and there were 11–21 IPs at the 0.1 and 1 mg/kg levels, thus demonstrating the very high potential of QTOF for identification purposes.

APCI in positive ion mode was used to determine a number of fungicide residues in wine grapes, since one of the fungicides (bitertanol) did not give a signal in ESI and APCI in general was 25–100 times more sensitive for these particular compounds (Juan-García *et al.*, 2004). Full scan LC-MS chromatograms were obtained by scanning from m/z 80–340 (0.68 s). Time scheduled selected ion monitoring of the most abundant ions of each compound was performed as follows (in order of retention times): carboxin (m/z 236, 143), flutriafol (302), pyrimethanil (200), triadimefon (294, 197), tebuconazole (308) and bitertanol (338, 269).

Mycotoxins in foodstuffs, arising via fungal infection, constitutes another area of application of mass spectrometry (again mostly by LC-MS). Deoxynivalenol (DON) and T-2 toxin are just two mycotoxins found in cereal and cereal products that are produced when the crops are infected with *Fusarium* species (Section 5.11.4). Modern mass detectors, such as Finnigan Surveyor MSQ types are able to collect scanning data and SIM data from the same run, thus allowing simultaneous quantitative and qualitative survey data to be obtained from one run (Moncur, 2004). SIM was based on m/z 319 for DON and 489 for T-2 toxin. The ionization method was positive electrospray, giving pseudomolecular ions of the type $(M + Na)^+$. Similarly, a Thermo Scientific TSQ Discovery Max instrument (QqQ type) using heated ESI in positive ion mode was able to determine 12 mycotoxins extracted from food matrices, via LC-MS (Huls *et al.*, 2004). Selected reaction monitoring (SRM) was used, with collision energies being optimized (22–42 eV) (like other MS conditions) using auto tune software. Two product ions were measured for each mycotoxin, one a quantifier ion, the other a qualifier ion, so that identity of the analytes could be confirmed from the ion ratios. The SRM details were (precursor ion, quantifier ion and qualifier ion m/z values): aflatoxin B1 (313, 241, 285); aflatoxin B2 (315, 259, 287); aflatoxin G1 (329, 243, 283); aflatoxin G2 (331, 245, 275); fumonisin B1 (722, 334, 352); fumonisin B2 (706, 336, 318); ochratoxin (404, 239, 221); zearalenon (319, 187, 185); deoxynivanenol (297, 249, 231); diacetoxyscripenol (367, 307, 289). See Figure 5.11.3 in Section 5.11.4 for the structures of some of these mycotoxins.

Inductively coupled plasma-mass spectrometry (ICP-MS) is a highly sensitive technique capable of determining a range of metals and some nonmetals below the picogram level. The fundamentals of ICP are outlined in Section 4.4.4. Like most spectroscopic methods, it can be linked with a chromatographic method, particularly HPLC, thus providing a very sensitive detector. Another advantage of using an ICP-MS detector is its mass selectivity; peaks can be identified and quantified for a particular element even if coelution with other components (containing different elements) is occurring. Often, a quadrupole MS instrument is combined with the ICP source, but TOF and double focusing magnetic sector instruments have also been used.

There are many reports of the application of ICP-MS to the determination of metals and other species in wine. For example, the technique has been used to measure isotope ratios for the determination of origin (Almeida and Vasconselos, 2001), to determine multiple elements for discrimination of origin (Perez-Trujillo *et al.*, 2003; Taylor *et al.*, 2003), anisoles (Gómez-Ariza *et al.*, 2005), lead (Myors *et al.*, 2005) and arsenic species (Wangkarn and Pergantis, 2000).

The Sr isotope ratio $^{87}Sr/^{86}Sr$ in wines (10 samples) was determined by ICP-MS in order to distinguish the wines, which were from a total of six different regions (Almeida and Vasconselos, 2001). After sample preparation by UV irradiation and the removal of Rb interference by a cation exchange process, the sample was evaporated to near dryness, digested in conc. HNO_3, evaporated again to near dryness and the residue was dissolved in dilute aqueous HNO_3 for ICP-MS analysis. After corrections for instrumental and sample bias were applied, the results were able to distinguish between the wines.

Mineral profiles determined by ICP-MS have also been used to characterize wines according to origin. Thirty-nine trace and ultratrace elements (including several rare earth metals) were analyzed in 153 samples of wine from the Canary Islands (Perez-Trujillo *et al.*, 2003). It was found that, using LDA and back propagation artificial neural networks (BP-ANN), it was possible to classify the wines according to the island of origin: the wines of La Palma, Lanzarote and El-Hierro could be distinguished according to their Sr, Rb and Pb content, respectively.

Likewise, simultaneous determination of 34 trace elements in 95 Canadian wines by ICP-MS and treatment of the results with discriminant analysis allowed 100% accuracy using 10 of these elements in the classification of according to origin: Okanagan Valley (British Columbia) and Niagara Peninsular (Ontario) (Taylor *et al.*, 2003). Once again, the Sr level was found to be a good indicator of likely origin. In the ICP part of the method, a high RF power (1500 W) was used to maintain a stable plasma in the presence of ethanol in the samples, even though the samples had been diluted 1:1 with 0.2 M aqueous HNO_3 before analysis. Because of the higher than normal power used, a plasma gas flow rate of 14 l/min was used. In order to determine precision and accuracy, five water reference materials were matrix matched to the wine samples.

In the analysis of important wine contaminants such as Pb, reference methods around the world need to give interconsistent results. The Comité Consultatif pour le Quantité de Matière (CCQM) is an international organization that evaluates primary methods and measurement techniques of high accuracy by making international intercomparisons in many measurement areas. An exact matching isotope dilution mass spectrometric (IDMS) method using ICP has been applied to the determination of Pb in wine (Myors *et al.*, 2005). Isotopic levels (^{206}Pb and ^{208}Pb) in the samples, after digestion in conc. HNO_3, were measured using a magnetic sector instrument at low resolution (300) in order to approximate simultaneous determination. Mass bias correction was made using standard isotope ratio reference materials. Exact matching IDMS is an iterative process in which the initial estimated concentration of the analyte is subjected to iteration and is refined to allow improved matching of the analyte and calibration standard in the next iteration. This process is continued until there is no significant difference between results.

As with other spectroscopic methods, ICP-MS has been used to investigate speciation of elements in samples. Narrow bore ion paired RPHPLC-ICP-MS was used to separate four arsenic species (arsenite, dimethylarsinic acid, monomethylarsonic acid and arsenate), which were determined as As by the quadrupole MS instrument operating in the single ion monitering mode (m/z = 75) (Wangkarn and Pergantis, 2000).

Arsenite at trace levels was the only As species found in eight different wines. The ion pairing agent tetrabutylammonium hydroxide was used to improve the HPLC resolution.

A combination of SPME-GC (Section 4.2.4) with ECD and ICP-MS detectors was used to determine haloanisoles (contaminants that give rise to an off odor in wine known as cork taint) at low levels (ng/l) in wines, using a chemometric method to obtain the highest sensitivity for all analytes simultaneously (Gómez-Ariza *et al.*, 2005). The haloanisoles were analyzed in the mass spectrometer as ^{35}Cl and ^{79}Br after ionization in the plasma with 8.8% oxygen added to the plasma gas to ease the formation of ions.

Isotope Ratio Mass Spectrometry (IRMS)

This technique involves measuring the isotope ratio (typically $^{2}H/^{1}H$, $^{13}C/^{12}C$, $^{15}N/^{14}N$ and $^{18}O/^{16}O$) of an analyte that has been converted to a simple gas prior to analysis. This gas (typically, CO, CO or H_2O) must be isotopically representative of the original analyte. The method relies on the fact that the isotope ratios of carbon, hydrogen, nitrogen and oxygen in natural products, such as grape or wine components (e.g. sugars, ethanol and water), depend upon their biological and geographical origins and are influenced by processing conditions, such as additions of sugar, water or the use of must concentration methods. Thus IRMS can be used to check authenticity and to detect fraud. In particular, ethanol and wine water isotopic parameters have been used since the 1980s to check wine authenticity and wine isotopic measurement is now an official EC method that can be used by all wine producing member states of the European Union (EC, 1990; 1997). In general, D/H ratios are measured by SNIF NMR (Section 4.4.1), whereas $^{13}C/^{12}C$ and $^{18}O/^{16}O$ ratios are determined by IRMS, sometimes involving combustion or pyrolysis of more complex components to simple gases, as mentioned above.

In practice, for the determination of $^{13}C/^{12}C$ and $^{18}O/^{16}O$ ratios, gas chromatography-isotope ratio mass spectrometry (GC-IRMS) is often used, with on line combustion/pyrolysis units (GC-C/P-IRMS) for the production of simple gases (e.g. CO_2 from ethanol by combustion, CO from ethanol by pyrolysis) (Aguilar-Cisneros *et al.*, 2002). Alternatively, the IRMS instrument can be linked to an elemental analyzer and equipped with a dual gas inlet system from a combustor/pyrolyzer so that IRMS data can be checked against elementary analysis data (Guyon *et al.*, 2006). In all cases, daily system stability checks need to be carried out by measuring reference samples (e.g. ethanol) with known isotope ratios. Also stability checks on working references gases (e.g. CO) need to be performed regularly by measurement of IAEA standards (VPDB, VSMOW, IAEA-CO-9, etc.).

The areas most investigated by IRMS are:

- Addition of exogenous sugar to grape must before or after fermentation
- Dilution of must or wine with water
- Addition of ethanol derived from extraneous sources
- Addition of exogenous glycerol to wines
- Use of exogenous CO_2 for sparkling wines.

Nowadays, for sugar enrichment analysis, isotopic data of the controlled samples are compared to reference points in data banks held by each EU member state (EC, 2000). Data bank maintenance and data collection are supervized by BEVABS, part of the European Commission.

Photosynthesis (the conversion of CO_2 and H_2O in green plants into essential biomolecules, including sugars) occurs by two routes, according to how CO_2 is incorporated into the plant metabolism ('fixed'): the C_3 pathway (the Calvin cycle, via 3-ribulose diphosphate) and the C_4 pathway (the Hatch–Slack pathway, via oxaloacetate). Grapevines and sugar beets use the C_3 pathway, whereas maize ('corn') and sugar cane use

the C_4 pathway. The carbon isotope ratio is defined by Equation 4.4.21.

$$\delta^{13}C\,(‰) = 10^3 \left\{ \frac{R_s}{R_{std}} - 1 \right\} \tag{4.4.21}$$

Here R_s and R_{std} are the $^{13}C/^{12}C$ ratios of the sample and standard, respectively. The references are international standard ratios; for example, VPDB for $^{13}C/^{12}C$ and VSMOW for $^{18}O/^{16}O$, although in many cases, reference gases of known isotopic ratios are used (working standards) and then related to international standards (International Atomic Energy Agency (IAEA) standards).

For components of C_3 plants, $\delta^{13}C$ lies in the range –22‰ to –33‰, whereas for C_4 plant products it is in the range –10‰ to –20‰. Using such methods, it is possible to detect prefermentation addition of cane or 'corn' sugar in still wines (Košir *et al.*, 2001; Ogrinc *et al.*, 2003) and sparkling wines (Martinelli *et al.*, 2003) (including Champagne) by measurement of $\delta^{13}C$ in ethanol and CO_2, respectively. It was also possible to detect added beet sugar in sparkling wines, but not in still wines; for these, measurement of δ^2H is needed and is best done in conjunction with NMR (Ogrinc *et al.*, 2003). Hence IRMS has been useful in the detection of illegal additions of sugar, before fermentation (where the process is called 'chaptalization,' after its inventor, Jean Chaptal – Napoleon Buonaparte's minister of agriculture) and to the finished wine (see Ogrinc *et al.*, 2003 and references therein). However, it should be noted that addition of sugar is often legal, but only in clearly defined situations and in strictly regulated ways, which differ considerably from region to region, and from country to country.

In a study of the $^{13}C/^{12}C$ and $^{18}O/^{16}O$ ratios in the ethanol of samples of commercial and authentic tequila, using GC-C/P-IRMS (Aguilar-Cisneros *et al.*, 2002), it was found that $\delta^{13}C_{VPDB}$ and $\delta^{18}O_{VSMOW}$ data for authentic samples were much more homogeneous, especially the latter, which varied between +22.1 and +22.8‰ for 100% pure Agave tequilas and between +20.8 and 21.7‰ for mixed tequilas (for definitions of Tequila see Section 3.5.5). Most commercial Tequila evidently had a considerable content of exogenous ethanol, probably derived from grain neutral spirits. However, IRMS was unable to distinguish between white, rested and aged categories of authentic 100% agave and mixed Tequilas. The $^{13}C/^{12}C$ isotope ratios were measured in CO_2 produced by combustion of ethanol in an Al_2O_3/Cu/Ni/Pt oxidative reactor and $^{18}O/^{16}O$ ratios were determined in CO produced by pyrolysis of ethanol in an Al_2O_3/Ni/Pt reactor, using a 1% H_2-He auxilliary gas.

In a study of $^{13}C/^{12}C$ isotope ratios in sparkling wines, a needle device with two valves and a connector to a vacuum line was used to obtain samples of CO_2 from the headspace above the wine in unopened bottles of Cava, Granvás, Aguja (semi-sparkling) and gasified wines (González-Martin *et al.*, 1997). The standard $^{13}C/^{12}C$ ratio was that of the international PDB standard. For the Cavas, values of $\delta^{13}C$ ($‰_{PDB}$) ranged between –9.48 and –21.17‰, indicating the presence of CO_2 from two sources: added cane sugar and nutural grape sugar. The lower the numerical values reflect greater the amounts of CO_2 derived from added sugar. The Granvás and Aguja samples had similar values of $\delta^{13}C$, but the gasified wines had generally much higher numerical values (between –28.24 and –39.71‰, much closer to $\delta^{13}C$ values associated with commercial 'food quality' CO_2 (derived from fossil fuel combustion) (from –20.56 to –36.22‰, with most close to 30‰).

The above study analyzed CO_2 in the wine headspace, but a later report describes $\delta^{13}C$ values for the wine and the CO_2 bubbles produced during secondary fermentation for 75 sparkling wines from around the world (Martinelli *et al.*, 2003). Lower numerical values of $\delta^{13}C$ for American, Australian and Brazilian wines (–15.8 to –20.5‰) (n = 28), suggested use of maize or cane sugar in the manufacture of these wines, whereas Argentine, Chilean and European sparkling wines had average $\delta^{13}C$ values of –26.1 ± 1.6‰ (n = 5) and –25.5 ± 1.2‰ (n = 12), respectively, suggesting either less chaptalization or the use of beet sugar. The isotopic composition of the CO_2 bubbles followed similar trends. Thus, the average $\delta^{13}C$ (CO_2) value

for most Brazilian and Argentine wines was –10.8 ± 1.2‰ (n = 23), whereas the average value for most Chilean and European wines was –22.0 ± 1.2‰ (n = 13), suggesting the use of sugar cane (or maize sugar) and beet sugar, respectively, in the promotion of secondary fermentation.

More recently, reports have been made on the influence of enoligical practices on isotope ratios, particularly the newer practices of reverse osmosis (RO) and high vacuum evaporation (HVE) to enrich the must prior to fermentation (Guyon *et al.*, 2006). In the European Union, EC regulation 1493/99 (EC, 1999) states that concentration of must by use of RO or HVE should not exceed 20% and the subsequent increase in alcohol content should not exceed 2%. Ethanol obtained from laboratory fermented wines by distillation was subjected to $^{13}C/^{12}C$ isotope ratio measurement using IRMS and based on CO_2 released upon ethanol combustion. Water $^{18}O/^{16}O$ ratios were measured in CO_2 previously equilibrated with wine or the extracted water. The $\delta^{13}C$ and $\delta^{18}O$ ratio values were given in reference to VPDB and VSMOW, respectively. Measurements were carried out in duplicate with the difference between the two measurements not exceeding 0.1‰ or 0.2‰ for $\delta^{13}C$ and $\delta^{18}O$, respectively. A reference sample was analyzed after every eight samples to control instrument drift. The isotopic ratios of musts and laboratory fermented wines from control musts were compared with those of wines fermented from RO- or HVE-enriched musts. No isotopic fractionation (at sugar or water level) was found for the RO wine, but the HVE process increased wine $\delta^{18}O$ with regard to the initial must.

Determination of $\delta^{18}O$ values for wine water has been used for the assignment of wine origin and as evidence of aldulteration by addition of water to wine. However, data from authentic references wines for the evaluation of measured $\delta^{18}O$ values are not always available and there were no empirical (or model) relationships that give independent estimates of $\delta^{18}O$ for wine water until Hermann and Voerkelius (2009) used a model based on the meteoerological parameters relative humidity and mean temperature for this purpose. The performance of this model was tested on measurement of wine water $\delta^{18}O$ for 775 German wines from six vintages, where differences between computed and mean measured values were $\leq 0.4\%$.

4.5

Electrochemical Methods

Electrochemical (or electroanalytical) methods depend on the analytes in solution having electrochemical properties; either they are ionized in solution or can be oxidized (lose electrons) or reduced (gain electrons) at electrode surfaces, so that interaction occurs between the analytes and an external measuring electric circuit via the electrodes. It is important that the sample solution containing the analytes is electrically conducting; electrolytes such as potassium chloride or sulfate ('background electrolytes') can be added to boost the conductivity.

Conductance is the simplest electrochemical property of a solution – it is a measure of the inverse of the electrical resistance to the passage of an electric current through a solution. It is not so much used in the analysis of alcoholic beverages, apart from the minicontact test for assessing the tartrate stability of wines (Ribéreau-Gayon *et al.*, 2000), and ion chromatography (Section 4.3.3), which normally uses a conductometric detector. Also, in brewing, there are conductometric methods (e.g. EBC, 1998) for the estimation of the α-acid content of hops and hop products, based on the decrease in conductivity occurring via precipitation of lead ions by bittering substances.

In the minicontact test, the wine is kept at 0–0.1 °C with 4 g/l of potassium hydrogen tartrate added over a maximum period of 18 min. The result of the test is the decrease in the conductivity (in μS/cm) of the wine after this treatment. In experiments on the tartrate stability of Sherry, it was shown that a value of 10 μS/cm was the upper limit for a range of Sherries kept at +4 °C and –4 °C; a wine with test result of 10 μS/cm or less would not form a sediment under these conditions (Gómez Benítez *et al.*, 2003).

Conductance measurements can be used to check the absence of ions in purified water or change in conductance can be monitored during the course of a reaction in which the number of ions in solution changes, or a change in ion mobility occurs.

Potentiometry and voltammetry, in their various forms, are the electrochemical techniques that have wide application to the analysis of alcoholic drinks and other foodstuffs. Potentiometric methods are passive – they measure the solution potential as a function of various physicochemical variables, whereas voltametric methods are active (or dynamic) – they monitor redox behavior as a function of dynamic potential changes. The main electrochemical methods used for the determination of certain analytes in alcoholic beverages are summarized in Figure 4.5.1, where the various versions depend both on the physical characteristics of the instrumentation (e.g. on the type of electrode) and on the parameters that are being measured.

Electrochemical methods for the analysis metals in alcoholic drinks possess some notable advantages over other methods, such as atomic spectrometric or chromatographic methods. They are generally fast, sensitive

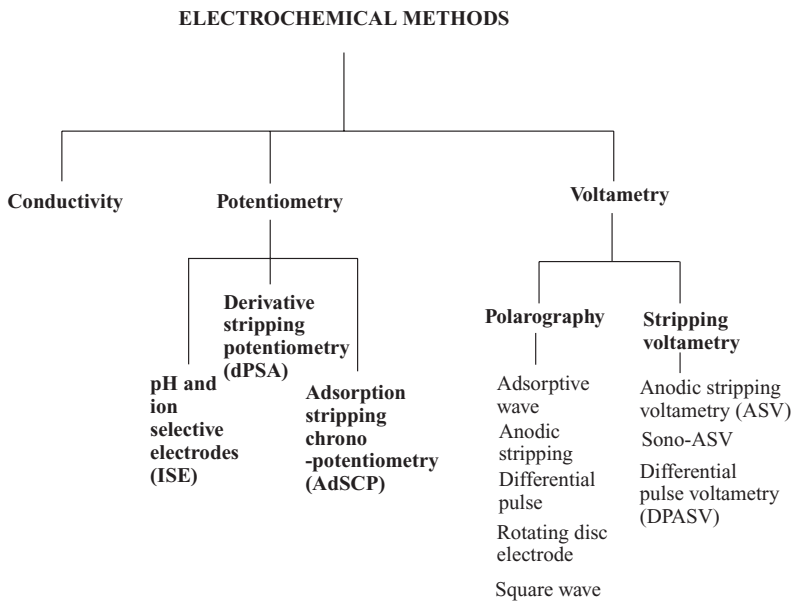

Figure 4.5.1 *Family tree of electrochemical methods used in alcoholic beverage analysis*

and inexpensive, often requiring relatively straightforward instrumentation and manipulation techniques, with little sample pretreatment, other than dilution or matrix modification (additives). Precision and accuracy are often very good and many of the methods are capable of the simultaneous determination of several metals in samples. Although the many variations of electrochemical methods differ in their advantages/challenges, some of them (e.g. potentiometric stripping analysis and related methods) are not affected by high concentrations of organic compounds in the sample and are well suited to the analysis of metals in nondistilled alcoholic beverages, the sample often only requiring slight modification before analysis. On the downside, many of the methods use toxic mercury and mercury (II) compounds and some suffer from interference by other ions (e.g. ion selective electrode methods) or by organic compounds (e.g. some voltammetric methods) in the sample. Also, in some voltammetric experiments, oxidized or reduced analyte can precipitate at the working electrode, thus causing problems by altering the electrode surface and redox characteristics and hence necessitating frequent cleaning of the working electrode. Additionally, potentiometric cells such as ion selective electrodes (ISE) generally need frequent calibration.

Like most chapters of Part 4, the electrochemical analysis chapter assumes a basic undergraduate knowledge of the subject, but an outline of the more important aspects is undertaken during discussion of specific examples relating to alcoholic beverages. Electrochemical methods applied to the analysis of metals in wines and other drinks and foodstuffs have been reviewed by Ibanez *et al.* (2008). For background and further information, the reader is referred to a specialist text on electrochemistry (Brett and Oliveira Brett, 1994), and to a paper on terminology for electrochemical stripping analysis (Fogg and Wang, 1999), as well as to general analytical chemistry texts, such as Skoog *et al.* (1994; 1998) and Tyson (1991).

4.5.1 Potentiometric Methods

Potentiometric methods make use of potential difference caused by redox reactions occurring at the electrodes of an electrochemical cell. These occur at the solid surface of the electrodes via electron transfer between ions

in solution and atoms of the electrode materials [reduction: $M^{n+} + ne^-$ (from electrode) $\rightarrow$ M (at cathode); oxidation: $X^{n-} \rightarrow X + ne^-$ (to electrode, at anode)]. The two electrode systems are connected in the cell via a salt bridge, which is often a concentrated solution of potassium chloride in an agar gel. The bridge provides electrical contact (but not physical contact) between the two electrode systems by allowing transport of K^+ and Cl^- ions across the bridge and at the same time prevents the passage of any other ions.

If the cell is connected to a voltmeter, that instrument will record the net potential difference between the two electrode systems and so all potentiometric measurements are relative. However, if one of the electrodes is a reference electrode, designated as having a potential difference of zero volts, the potential difference of the second electrode system can be can be measured directly from the voltmeter as a 'single electrode potential.' This second electrode is selective to particular ions (M^{n+}/M or X^{n-}/X) and is sometimes known as an ion sensitive electrode, whereas the reference electrode is ion insensitive, being separated from contact with the solution containing M^{n+} or X^{n-} ions. The standard hydrogen electrode (SHE) designated zero potential is that in which H_2 gas at a pressure of 1 atm and temperature of 20 °C is in contact with a 1.228 M solution of H^+ ions (provided by hydrochloric acid and also at 20 °C), via bubbling over a platinum electrode coated with platinum black (finely divided Pt) that dips in the solution.

A much more convenient standard electrode is the saturated calomel electrode (SCE), which has a potential of –0.242 V with respect to the SHE. In practice, a number of reference electrode systems are used, their actual potentials being known accurately with respect to the SHE.

Electrode potentials are related to the concentration (strictly the activity) of ions in solution by the Nernst equation (Equation 4.5.1).

$$E = E^0 \pm \frac{RT}{nF} \ln [X] \tag{4.5.1}$$

where E^0 is the potential (in V) under standard concentration and temperature conditions, R is the gas constant, T is the temperature (in K) and n is the ionic charge (+ for cation, – for anion).

Converting ln to log (base 10) and inserting appropriate values for R, T (298.15 K or 25.00 °C) and F reduces Equation 4.5.1 to the more convenient Equation 4.5.2.

$$E = E^0 \pm \frac{0.059}{n} \log [X] \tag{4.5.2}$$

The main method of using electrochemical cells for analytical measurements is to change the concentration of the ion being determined, keeping all else constant. For direct measurements, the cell needs to be calibrated with a series of standards of accurately known ionic concentrations and then the potential of unknown solutions of the same ion can be obtained and related to concentration via the calibration curve. Cells have a very wide calibration range or 'dynamic range,' since $E \propto \log$ (concentration); a range of 10^5 or 10^6 is not unusual and the pH electrode has a range of $\sim 10^{13}$.

Ion Selective Electrodes (ISE)

The majority of electrochemical cells are of the ion exchange membrane type, where the membrane acts as an ion sensitive electrode, and a reference electrode (usually Ag/AgCl) plus a potential measuring device (usually a voltmeter) complete the circuit. The reference electrode, say of the Ag/AgCl type, is a strip of Ag immersed in a solution containing both AgCl and the ion of interest (e.g. H^+ from aqueous HCl or Ca^{2+} from aqueous $CaCl_2$), which is also in contact with the inner surface of the membrane. As ion exchange occurs, a potential is set up across the interface between the solution containing the ions of interest and the liquid ion exchanger and even though there are no redox reactions here, the Nernst equation is obeyed. If the

ion exchange material is selective toward exchange of a particular ion the cell is known as an ion selective electrode (ISE).

The membranes used in ISE fall into three broad categories:

- *Liquid membrane* (based ion exchange or ion carrier material, neutral or charged)
- *Solid membrane* (e.g. glass, crystal or solid polymer membrane)
- *Membrane in a special electrode* (gas sensing or enzyme electrode). Typically such a membrane contains an analyte-selective component that is responsible for the recognition process

In liquid membrane electrodes (still the most common type of ISE), liquid organic ion exchangers or ion carriers are supported on inert polymers such as cellulose acetate, or in transparent films of polyvinyl chloride. The binding sites are distributed throughout the matrix, the number and type of which determine the polarity, lipophilicity, transport mechanism and other properties of the membrane.

An example of this type is the potassium sensitive electrode, where the membrane is usually a thin PVC disc impregnated with the macrocyclic antibiotic valinomycin. This compound has a hexagonal ring structure with an internal cavity (rather like a crown ether), which is similar to the K^+ ion in size. It forms host–guest complexes with this ion and preferentially conducts it across the membrane. Unfortunately, like the majority of ISE, it is not 100% selective and can suffer interference from cesium, ammonium and other cations, especially if they are present in the sample at high concentrations. Also, such electrodes usually also suffer from low chemical and physical durability and have rather short working lives. Additionally, like other ion selective electrodes, they need frequent calibration.

Crystalline membranes are made from mono- or polycrystallites of a single substance, such as AgCl (selective for Ag^+/Cl^-) or Ag_2S (selective for Ag^+/S^{2-}), respectively, or of two substances, such as PbS/Ag_2S (selective for Pb^{2+}). They generally have good selectivity, which can be for either the cation or the anion of the membrane forming substance. An example of a crystalline membrane electrode is the fluoride selective electrode, which is based on LaF_3 crystals. Unlike most ISE, the fluoride electrode has only one serious interference, from OH^- ions, but this can be minimized by adjusting the pH of the medium to below 7. Table 4.5.1 gives a list of ion selective electrodes commonly used in alcoholic beverage analysis, along with their major interferences.

Ion selective electrodes have been used to routinely determine many inorganic species in must and wine. For a more specialist use, see, for example, Turbow *et al.*, 2002, where ammonia in must and wine was determined with ISE and an enzymic method. Ammonium selective electrodes are sometimes used (in place

Table 4.5.1 *Some ion selective electrodes used in alcoholic beverage analysis*

Electrode = analyte ion measured	Type	Typical concentration range/M	Main interferences
Ca^{2+}	Liquid membrane	$1–5 \times 10^{-7}$	Fe^{2+}, Hg^{2+}, Ni^{2+}, Pb^{2+}, Sr^{2+}
Cl^-	Liquid membrane	$1–5 \times 10^{-6}$	I^-, OH^-, $SO_4{}^{2-}$
Cu^{2+}	Crystalline membrane	$10^{-1}–10^{-8}$	Ag^+, Cd^{2+}, Hg^{2+}
F^-	Crystalline membrane	Saturated–10^{-6}	OH^-
K^+	Liquid membrane	$1–10^{-6}$	Cs^+, $NH_4{}^+$, Tl^+
Pb^{2+}	Crystalline membrane	$1–10^{-6}$	Ag^+, Cd^{2+}, Hg^{2+}
Water hardness (Ca^{2+} and Mg^{2+})	Liquid membrane	$1–6 \times 10^{-6}$	Ba^{2+}, Cu^{2+}, Fe^{2+}, Ni^{2+}, Sr^{2+}, Zn^{2+}

of distillation and titration) to determine the ammonium content of the Kjeldahl digest (Section 4.6.3) in the determination of total nitrogen or protein content of fruit juice, wort and alcoholic beverages. See also Couto *et al.* (1998), where a homogeneous crystalline silver double membrane tubular electrode operating with a flow injection unit was able to analyze chloride in wine samples at the rate of 90–200 samples per hour.

Easily the most widely used membrane electrode is the glass electrode or pH electrode. The glass membrane is composed of 63% SiO_2, 28% Li_2O, 5% BaO, 2% La_2O_3 and 2% Cs_2O soaked in a hydrated gel ion exchanger that is highly selective toward hydrogen ions. Schematic diagrams of a glass (pH), a liquid membrane and two solid membrane ion selective electrodes are shown in Figure 4.5.2. Measurement of pH is one of the most common routine measurements in the food and alcoholic beverage industries. Not only is pH itself a useful check on quality, but it can be used, along with other parameters, in chemometric discrimination and authentication of origin studies (see, for example, Sections 4.4.1, 4.4.2 and 4.4.4). Additionally, many methods used for the analysis of alcoholic beverages need the pH of the medium containing the analyte to be carefully adjusted (see, for example, the bovine serum albumin assay of total tannin content, Section 4.4.3) for proper functioning of the method.

Although pH measurement by itself it will not necessarily give a definitive indication of quality, it can give the winemaker or brewer an indication of possible trouble and a guide to what needs to be done to prevent or rectify the problem. For example, low pH (high acidity) is required for biological stability, so musts or wines of high pH need acidification, but too low a pH in must indicates immature grapes and a low wine pH may suggest the presence of too much volatile acidity (Chapter 2.4). Similarly, pH measurement of beer wort

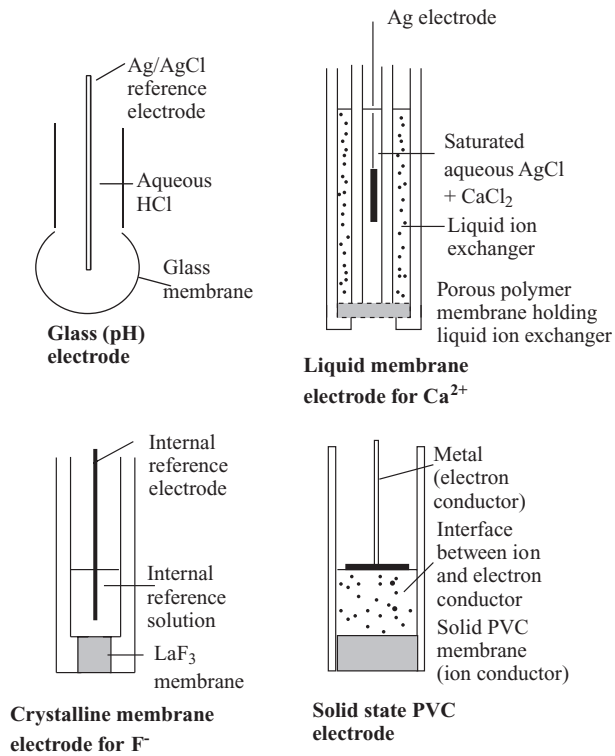

Figure 4.5.2 *Schematic diagrams of common membrane ion selective electrodes. Not drawn to scale*

will indicate whether acidifying salts (such as $CaCl_2$ or $CaSO_4$) or acidifying bacteria (such as *Lactobacillus delbruckii* – see Section 2.6.2) or alkali forming salts (such as $CaCO_3$) need to be added, according to the type of beer being brewed (Section 2.6.2).

Wines and other nondistilled alcoholic beverages, such as beer and cider, are essentially acid–basic buffer solutions, consisting of a number of weak organic and inorganic acids and metal ions. The major acids of wine (in order of decreasing acid strength) are tartaric, malic, lactic and succinic acids; the inorganic acids phosphoric and sulfuric acids are also present at low levels. The major metal ions in wine are ammonium, calcium, potassium and sodium. The superior buffering effect of the unfermented media (e.g. apple juice or grape must) over the corresponding alcoholic drink (e.g. cider or wine) can be seen in the comparison of the pH titration curves, when a strong base is added in portions to medium or wine. The curve for the juice or must is of shallower gradient (Ribéreau-Gayon *et al.*, 2000) than that of the alcoholic beverage, especially around the equivalence point (pH 8–10).

The buffer capacity of a wine or similar beverage is defined, Equation 4.5.3, as the number of base (or acid) equivalents (usually measured in milliequivalents, meq) needed to raise (or lower) the pH by one unit.

$$\beta(\text{buffering capacity}) = \frac{\Delta\,[\text{base}]}{\Delta\,\text{pH}} = \frac{-\Delta\,[\text{acid}]}{\Delta\,\text{pH}} \tag{4.5.3}$$

Although pH, total acidity (TA) and alkalinity of ash (AA) are not related in a simple way (partly because most wine acids are not monoprotic), the approximate Equation 4.5.4 is useful in giving the winemaker an initial idea of the number of milliequivalents of acid or base needed to lower or increase the pH by one unit.

$$\beta = \frac{2.303(\text{TA})(\text{AA})}{(\text{TA}) + (\text{AA})} \tag{4.5.4}$$

For the determination of the total titratable acidity of wine and other beverages, potentiometric titration is often recommended as an alternative method to acid/base titrations with phenolphthalein indicator (Section 4.6.3). The end point is defined as alkali consumption up to pH 7.0 in Europe and the USA or pH 8.2 in Japan.

Hence, a pH meter, with its glass electrode, is an essential piece of equipment for any brewery or winery. The schematic glass electrode shown in Figure 4.5.2 is the conventional type, with a spherical membrane, but versions exist with cylindrical membranes or low surface area membranes that can be used to measure the pH of solid or semi-solid foodstuffs and even the pH of a single grape or fruit. Likewise, hand held battery powered pH meters mean that pH can be measured anywhere in the field, brewery or winery.

Miniaturized and disposable potentiometric electrodes and their application to the analysis of alcoholic drinks (such as in electronic tongues) are dealt with in Section 4.5.3.

Potentiometric Stripping Analysis (PSA)

This technique involves a cycle of events that include electrochemical reduction of cations at the working electrode (cathode) (the enrichment step) and (after a certain time) their chemical oxidation back to cations (the stripping step), as outlined in Figure 4.5.3. A typical PSA instrumentation consists of a glassy carbon working electrode in the electrochemical cell, plated with a mercury film, with an enclosed Ag/AgCl reference electrode and platinum wire counter electrode immersed in a saturated solution of potassium chloride, saturated with silver chloride. This provides an electrical connection to the outer glassy carbon disc of the working electrode via a porous ring. All potentials are measured with respect to the Ag/AgCl (KCl(sat)/AgCl(sat)) reference electrode. The working electrode is coated with a thin mercury film by an electrolysis process, such as of

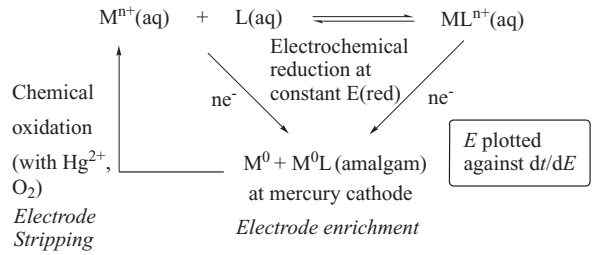

Figure 4.5.3 *Basis of derivative potentiometric stripping analysis (dPSA). Shown for mercury plated glassy carbon working electrode*

a mercury (II) chloride solution (1 g/l) in 1 M hydrochloric acid at –900 V for 1 min against an Ag/AgCl (KCl(sat)/AgCl(sat) reference electrode (Mayer *et al.*, 2003).

A typical method, say for the determination of Cu in wine is as follows. The matrix modifying solution – aqueous HCl and $CaCl_2$, which may also contain the stripping oxidant, such as Hg(II) – and diluted wine sample are mixed in the electrochemical cell. An enrichment potential of –700 mV is used for, say 30 s (although this is dependent on the analyte concentration in the sample under test), with stirring at approximately 2000 rpm and for a further 30 s without stirring. The potentiostat is switched off and the stripping curve recorded over the potential range say –900 to –100 mV. Once stripping had been executed, the electrode is set at a potential of –100 mV for 15 s to clean and restabilize the mercury film.

Often PSA can be carried out on the beverage without sample pretreatment, although matrix modifiers are added to the sample before analysis. For example, HCl and $CaCl_2$ were added to wine samples in order to convert all Cu in the sample to the same species ($CuCl_4^{2-}$) (Green *et al.*, 1997). Matrix modifiers may also be substances that remove interferences, such as potassium metabisulfite added to beer samples in order to oxidize sulfur containing proteins reacting with the thin mercury plating on the working electrode (Mayer *et al.*, 2003). More usually, the sample was merely mixed with hydrochloric acid to lower the pH to ~2 (thereby ensuring the metals are present as free ions) and then filtered (Dugo *et al.*, 2005). In other cases, such as the simultaneous analysis of Cd, Cu and Pb in wine, the samples were digested in concentrated HNO_3 before analysis (Ostapczuk *et al.*, 1997).

Chemical oxidants are often either Hg(II) as in the determination of Cu in wine (Green *et al.*, 1997; Ensafi *et al.*, 2001), the determination of Cu in beer (Mayer *et al.*, 2003) and in the analysis of several metals in Marsala (Dugo *et al.*, 2005), or oxygen as in the simultaneous determination of Cd, Cu and Pb in wine (Ostapczuk *et al.*, 1997) and in the simultaneous analysis of several metals in wine (Salvo *et al.*, 2003).

Mercury film working electrodes have been much used in laboratory potentiometric stripping analyses of alcoholic beverages, but in view of the toxicity of mercury and its compounds, there has been considerable interest in alternative electrodes. In particular, recordable compact disks have been used to make working PSA electrodes and these (CDtrodes) have been used to analyze the Cu content of sugar cane spirits such as cachaça (Section 3.5.2) (Richter *et al.*, 2001). CDs are made of a polycarbonate base on which a thin layer of photosensitive organic dye is deposited. A uniform, mirror-like film (50–100 nm) of very pure gold is fixed on this, followed finally by one, or two layers of protective polymer films. To make CDtrodes, a CD is cut into many slices and the protective films are removed by treatment of each slice with concentrated nitric acid or organic solvents. After washing in a jet of water and drying, a layer of enamel or PVC resin was placed on each strip to determine the electrode area. Electrical contact is supplied by wrapping firmly the bare end of a wire to an electrode with Teflon tape, or by use of a conducting adhesive. These are much cheaper than commercial gold electrodes used for PSA, but give comparable performance and are more versatile (Richter *et al.*, 2001).

A gold working electrode, along with a platinum secondary electrode and a built in Ag/AgCl reference electrode in saturated KCl were used in an automated chronopotentiometric method for the determination of SO_2 in beer (Dvořák *et al.*, 2006). Free and bound SO_2 (Section 2.5.2) were converted to sulfite anions by alkaline hydrolysis of the sample, which was then acidified so that the released SO_2 was separated on line through a semi-permeable membrane and transported to the electrochemical cell by an electrolyte solution. This method had a reproducibility (%RSD) of 8.6% for levels of SO_2 in beer and the results compared well with the official European Brewery Convention method, although the latter method is much slower and more complex.

The stripping step in PSA sometimes suffers interference from organic species present in the test sample, as in the case of alcoholic beverages, especially nondistilled samples. The organic species may alter the surface characteristics of the electrode surface. One way of eliminating this interference is by addition of matrix modifiers such as metabisulfite (Mayer *et al.*, 2003) or complexing agents (Sánchez Misiego *et al.*, 2004). Another way is known as medium exchange PSA. As the name implies, a change of medium from the enrichment to stripping steps is used, sometimes with a series of washes and rinses between the two (Green *et al.*, 1997; Clark and Scollary, 2006). The stripping medium can be water or an aqueous salt solution, such as 4.0 M ammonium acetate (Clark and Scollary, 2006).

However, a regular medium exchange procedure can cause an unpredictable loss of material due to oxidation of analyte in or on the working electrode. To avoid this, the deposition potential can be maintained simultaneously as the exchange solution is introduced into the cell, with stirring (Mikkelsen and Schrøder, 2002).

A version of PSA that is frequently used is derivative potentiometric analysis (dPSA). The stripping potential data are digitally derivatized; E versus t data are converted to E versus dt/dE data, thus presenting a maximum at the point where the conventional PSA curve shows a sharp change of E with t. In this way, resolution and sensitivity are improved. This technique was used to determine Cu in sugar cane spirit (Richter *et al.*, 2001), where the detection limit was found to be 30 ng/l (10 min deposition time) with standard deviation of 1.8% for 20 repetitive measurements using 25 μg/l of Cu with 1 min deposition time. Mayer *et al.* (2003) also used dPSA to determine Cu in beer, where the detection limit was 0.8 μg/l. Dugo *et al.* (2004; 2005) also used derivative potentiometric stripping analysis and derivative adsorption chronopotentiometry to determine Ni^{2+} and a number of metal species, respectively, in alcoholic beverages. The electrochemical parameters for the simultaneous determination of Cd(II), Cu(II), Pb(II) and Zn(II) in Marsala wine (Section 2.10.8) (Dugo *et al.*, 2005) were: –1200 mV electrodeposition potential for 240 s, 0 mV the final acquisition potential, and 120 rpm the agitation speed. For the analysis of Marsala wine, the sample (0.3 ml), ultrapure water (10 ml), Hg(II) (1.0 mg/l) (1.0 ml) and Ga(III) (1.0 mg/l) (0.1 ml) were placed in the electrochemical cell, the Hg(II) being the chemical oxidant. Limits of detection ranged from 0.05 to 0.07 μg/l, reproduciblity was (%RSD) 1.1–2.0% and accuracy expressed in terms of recoveries was 96.8–99.8%.

Another variant of PSA is adsorptive stripping chronopotentiometry (AdSCP), which involves a different enrichment/stripping mechanism rather than different analytical data treatment, as above. The basic mechanism is summarized in Figure 4.5.4. The major differences between PSA and AdSCP are the use of a complexing agent for the analyte and the use of a small stripping current for reduction, rather than a chemical oxidant. Like PSA, glassy carbon mercury film electrodes are frequently used. Adsorptive stripping chronopotentiometry often enables the determination of trace metal concentrations, with a judicious choice of complexing agent and without the need for any sample extraction procedure and preconcentration step that increase the amount of sample handling and may lead to contamination or loss of analyte. However, dilution of the sample prior to analysis minimizes loss of sensitivity toward the analyte caused by the presence of ethanol, sugars and other organic compounds.

AdSCP has been used to determine Ni (II) in many beverages (including wine and spirits) using dimethylglyoxime (DMG) as complexing agent and a glassy carbon mercury film electrode as the working electrode (Dugo *et al.*, 2004). The Ni $(DMG)_2$ complex was adsorbed onto the mercury film of the working electrode

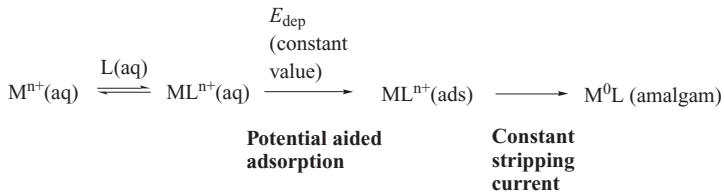

Figure 4.5.4 *Basic mechanism of adsorptive stripping chronopotentiometry*

at an electrolysis potential of –500 mV for 1 min and then reduced by a –5 μA constant cathodic current. The detection limit was 0.2 μg/l at pH 9.5 in ammonia buffer, and the instrumental precision (as %RSD) was 1.5. Accuracy, expressed as recoveries from certified and uncertified matrixes, ranged from 93.0 to 95.5%. Among alcoholic beverages, red wines had the highest Ni (II) content (55.5–105.0 μg/l), whereas white wines, beer and spirits (brandy, vodka and whisky) had 12.0–21.0 μg/l, 10.9–23.4 μg/l and negligible amounts of nickel, respectively.

4.5.2 Voltammetric Methods

Voltammetry is the name that describes a big family of potentiodynamic electrochemical methods, which unlike potentiometric methods, involve changing the working electrode potential at will and measuring the current originating from the system as it responds to the changing potential via redox reactions at the electrode. Linear sweep voltammetry is the simplest form of voltammetric analysis, where the current at a working electrode is measured while the potential between the working electrode and a reference electrode is swept linearly in time. As the analyte undergoes oxidation or reduction, peaks or troughs are observed in the current signal at the working electrode.

Voltammetric methods can be used to study the speciation of metals in alcoholic drinks. Many metals, especially Cu(II) and Zn(II) exist in these beverages as 'free' ions, as labile complexes (those with low formation constants, that easily dissociate) and as tightly bound complexes. In general, metals in the first two of the above forms can be detected using voltammetric methods in samples that need little or no pretreatment (see polarography, later). On the other hand, tightly bound metal concentrations can be found only by substracting the levels of free and labile ions from the total concentration of that ion in the sample. The latter can be found by AAS (Section 4.4.4) or by voltammetric analysis on samples digested in nitric acid.

Apart from the determination of metals in beverages, voltammetry has been used to study redox interactions between different components, such as the sulfur dioxide-ascorbic acid antioxidant system in wine (Bradshaw *et al.*, 2004). By use of square wave voltammetry of ascorbic acid/sulfur dioxide mixtures in model wine solutions and visible spectrophotometric monitoring of the production of yellow catechin polymers under forced oxidative conditions, Bradshaw *et al.* (2004) showed that the presence of ascorbic acid led to enhanced consumption of SO_2 and hence to compromised protection of the wine from browning. This suggested that if winemakers wish to use an ascorbic acid/sulfite mixture to preserve bottled wine from browning, a higher (not lower) amount of sulfite will be needed.

Voltammetric methods have also been used in the indirect analysis of components with relatively high redox potentials, such as ethanol and aliphatic acids, by the use of added oxidants, such as peroxodisulfate ($S_2O_8^{2-}$) (Song *et al.*, 2000) or added reductants such as benzoquinones (Ohtsuki *et al.*, 2001). Polarographic analysis (see later) of the influence of the presence of ethanol on the catalytic current of the sulfate radical anion ($SO_4^{-\bullet}$) was used to assay the ethanol content of distilled spirits (Song *et al.*, 2000). This radical anion

was generated at the electrode surface where it oxidized ethanol to the α-radical, and reduction of this at the electrode produced a polarographic reduction wave. In ethanolic samples in phosphate buffer solution (pH 5.6), in the presence of $K_2S_2O_8$, the first derivative peak current was proportional to ethanol concentration in the range 1×10^{-4}–9×10^{-4} mol/l.

Ohtsuki *et al.* (2001) used a three electrode voltammetric system (plastic formed carbon working electrode, a platinum auxiliary electrode and a standard calomel electrode) to determine the total acid content wines by measuring the reduction prepeak current of 3,5-di-*t*-butyl-1,2-benzoquinone (DBBQ) due to the presence of acids in a nonbuffered model wine solution. The height of the prepeak was proportional to the total acid concentration. The method was tested on 23 wine samples and the results compared well with a reference potentiometric titration method, with the former being superior in sensitivity and consumption of sample.

The most popular method generally is cyclic voltammetry. In a cyclic voltammetry experiment the working electrode potential is ramped linearly versus time. When this potential reaches a set value, it is inverted and inversion can occur several times during the course of a single experiment. The current at the working electrode is plotted versus the applied voltage to give the cyclic voltammogram trace. The usefulness of cyclic voltammetry is highly dependent on the analyte of interest, which has to be redox active within the experimental potential limits. It is also highly desirable for the analyte to display a reversible wave; one in which an analyte is reduced or oxidized on a forward scan and is then reoxidized or rereduced in a predictable way on the return scan.

Cyclic voltammetry was used for the indirect determination of reductones in beer (Section 2.6.2), using the redox dyestuff 2,6-dichlorophenol-indophenol (DCI) (Sobiech *et al.*, 1998). Reductones are antioxidants in beer, originating from hops (bittering substances, polyphenols) and malt (polyphenols, Maillard reaction products). Firstly, a cyclic voltammogram (0–1.1 V at 0.4 V/s) of the sample was recorded and then DCI and ascorbic acid internal standard was added to the sample, where DCI was reduced in quantities that depended on the reductone concentration. Its reduced form was electrochemically reoxidized in the voltammetric experiment, using a constant oxidation working potential of 0.625 V and with no stirring during the reaction of DCI or ascorbic acid with the reductones. After each measurement, the electrode surface was strongly passivated (mainly by DCI and polyphenolic compounds). This necessitated the reactivation of the electrode by use of a square wave generator, which gave a rapid activation at a high redox potential.

Voltammetric methods in general use a three electrode set up: a reference electrode, a working electrode and a counter electrode. Common materials for working electrodes include mercury plated glassy carbon, gold, platinum and silver. The counter electrode is often a platinum wire and the reference electrode is commonly an Ag/AgCl (KCl(sat)/AgCl(sat) electrode or standard calomel electrode. Other working electrode materials have been tested, such as a dental silver amalgam type used for the analysis of heavy metals in wine (Mikkelsen and Schrøder, 2002) and a platinum microdisk electrode used to assay the total acidity of distilled spirits (Baldo *et al.*, 2001). Voltammetry based on the reduction of weak acids at a platinum microelectrode was used for the determination of the total acid content in ethanol–water mixtures of 40–50% (v:v) ethanol content (Baldo *et al.*, 2001). The method was then applied directly to crude samples of distilled spirits (gin, grappa, rum, vodka and whiskey) without sample pretreatment or addition of a supporting electrolyte. The results compared well with those obtained using the AOAC official titrimetric method.

More recently, a titrimetric linear sweep voltammetric analysis of free sulfite in wine samples at a bare glassy carbon electrode has been reported (Scampicchio *et al.*, 2008). The method was based on the reaction of sulfite with Ellman's reagent and voltammetric detection of the equivalence point, either from a plot of electrode current versus concentration or the first derivative of this plot.

Additionally, chemically modified electrodes (CMEs) have been for various analyses (Ijeri and Srivastra, 2000; García *et al.*, 2005; da Silva *et al.*, 2008). Ijeri and Srivastra (2000) used carbon paste electrodes modified with 3% benzo-15-crown-5 crown ether in differential pulse voltammetric experiments to determine Cu(II) in rum. The electrode was constructed by mixing the crown ethers into a graphite powder–paraffin oil

matrix. It gave better voltammetric responses than unmodified electrodes, with a detection limit of 0.05 ppm. By differential pulse anodic stripping voltammetry Cu(II) could be quantified over the range 1 to 100 ppb, with no significant interference from metal ions like Fe(II), Co(II), Mn(II) and Ni(II).

A preactivated glassy polymeric carbon electrode containing a stable electroactive poly(caffeic acid) thin film (containing a quinone moiety), formed by the electrochemical oxidation of caffeic acid (3,4-dihydroxycinnamic acid) (da Silva *et al.*, 2008). The redox properties of the film were investigated at different solution pH values using cyclic and differential pulse voltammetry (DPV), where pH 3.5 was found to give optimum current versus potential curves. The electrode was used in DPV experiments to determine the caffeic acid content of a red wine, the sample being diluted with ammonium acetate buffer (pH 3.5). The concentration determined was 1.08×10^{-5} mol/l, in the range normally associated with red wine, but there was no comparison with established methods for caffeic acid determination reported.

Glassy carbon electrodes modified with films of Prussian Blue (iron hexacyanoferrate) have been used for the determination of free sulfur dioxide in wine (García *et al.*, 2005). The films were electrodeposited and the modified electrodes showed a reversible redox response originating from the oxidation/reduction of iron atoms in the electrode film; it was the Fe(II)-CN-Fe(III)/Fe(III)-CN-Fe(II) redox couple of potential +0.82 V (against SCE) that showed high catalytic activity for the oxidation of sulfite. The detection limit was 5.12 mg/l and there was a precise linear relationship between sulfite concentration and catalytic current. Results for three wines compared well with those from a standard iodometric method.

Stirring or agitation of the solution occurs at some stage in most voltammetric experiments, but during a cyclic voltammetry experiment, the solution is not stirred, resulting in this method's characteristic diffusion controlled peaks. However, stirring the solution between cyclic voltammetry experiments is important so as to supply the electrode surface with fresh analyte for each new experiment. Ultrasound can be used in place of stirring, as in the determination of copper in beer (Agra-Gutierrez *et al.*, 1999) and audible sonication was applied to the analysis of Pb and Zn in wine (Mikkelsen and Schrøder, 2002) by stripping voltammetry. Unlike stirring, which is used only during the deposition step of stripping voltammetry, sonication can be used throughout the entire experiment, and in the case of ultrasound, can be used to clean the working electrode between experiments.

Pulsed techniques, such as normal pulsed, differential pulsed and square wave voltammetry, by monitoring current changes at the working electrode for many analyte redox reactions over a short period of time, are highly sensitive techniques that can used to determine trace amounts of analytes. The peak current is proportional to the analyte concentration. Pulsed voltammetric methods were used to determine Cu in rum (Ijeri and Srivastra, 2000), Pb and Zn in red and white wine (Mikkelsen and Schrøder, 2002), and copper in beer (Agra-Gutierrez *et al.*, 1999)

Stripping Voltammetry

A particularly important group of voltammetric methods in the analysis of alcoholic beverages are the stripping techniques: anodic stripping voltammetry (ASV), cathodic stripping voltammetry CSV) and adsorptive stripping voltammetry (AdSV). These methods have their pulsed and/or differential versions. Like potentiometric stripping (Section 4.5.1), stripping voltammetry involves two steps. The first step is the preconcentration or deposition step, where in ASV, the electrode is held at a suitable negative potential so that the target analyte is reduced onto the electrode surface to form either an amalgam, if using a mercury or mercury coated electrode, or a layer if using a solid electrode. In the second step, the electrode is subjected to a positive potential sweep (in ASV) causing the analyte on or in the electrode to be oxidized, resulting in an anodic current peak that is characteristic of the analyte; its position (E) is related to the analyte identity and its height or area is related to analyte concentration. In favorable circumstances, stripping voltammetric techniques can measure analyte levels down to 10^{-11} M.

Stripping voltammetric methods have been used to determine Cu, Cd, Pb and Zn in wine (Daniele *et al.*, 1989), Cu, Pb and Zn in rum (Barbeira and Stradiotto, 1997), Cu in wine (Wiese and Schwedt, 1997), Cu, Pb and Zn in whiskey, (Barbeira and Stradiotto, 1998), Cu in distilled spirits (Barbeira and Stradiotto, 1999), Cu in beer (Agra-Gutierrez *et al.*, 1999), the analysis of Pb and Zn in wine (Mikkelsen and Schrøder, 2002), Pb and Zn in wine (Mikkelsen *et al.*, 2004), Cu and Zn in wine (Esparza *et al.*, 2007), Pb in wine (Salles *et al.*, 2009) and Cu in tequila (Carreon-Alvarez *et al.*, 2008). The first four reports above describe polarography experiments – using a specific kind of working electrode, known as a hanging mercury drop electrode – and hence will be discussed later.

Mercury thin film and unmodified glassy carbon electrodes were used for the analysis of Cu in beer, by anodic stripping voltammetry with ultrasound agitation, rather than stirring (Agra-Guttierez *et al.*, 1999). Measurable signals were not observed in the absence of ultrasound because of electrode passivation by organic species and lower rates of mass transport. Ultrasound was used for *in situ* cavitational cleaning of the electrode. Results from experiments using either electrode under ultrasound conditions were in excellent agreement with values obtained using atomic absorption spectroscopy, performed by an independent laboratory. Moving on to less hazardous electrode material, a silver–mercury amalgam electrode was used to determine Pb and Zn in several wines and one brandy sample by DPASV, using audible sonication or stirring (Mikkelsen and Schrøder, 2002). Using a similar method, Mikkelsen *at al.* (2004) were able to determine the Pb and Zn contents of 10 wines (red and white), in the ranges 9.7×10^{-8} M–2.4×10^{-7} M for Pb and 2.1×10^{-6}–11.7×10^{-6} M for Zn, with reproducibility (as %RSD) of 3.5% in both cases. The results were verified against atomic absorption spectroscopic results, where correlation was good.

More recent work in stripping voltammetry includes investigations with different electrodes, such as bismuth modified gold microelectrodes (Salles *et al.*, 2009). Bismuth was electrodeposited by an *in situ* procedure in alkaline solution on gold microelectrodes for the determination of Pb(II) in wine square wave anodic stripping voltammetry (SWASV). Even though the deposition time for Pb(II) was relatively high with this electrode, the repeatability of the method was similar to other electrochemical methods, whilst a more extended dynamic concentration range was obtained in comparison with other stripping methods: a linear calibration plot for Pb(II) in the concentration range 40 to 6700 nmol/l was obtained. The detection limit was 12.5 nmol/l.

Recent work has also tended to involve more specialized investigations into speciation and metal–polyphenol or metal–protein complexes. ASV has been used to monitor the fate of Cu and Zn during alcoholic fermentation of wine (Esparza *et al.*, 2007). The Cu concentration dropped from 0.958 to 0.158 m/l and zinc levels decreased from 0.446 to 0.223 mg/l during the course of 32 days of fermentation, presumably as the metal ions formed complexes. Titration results suggested that, on average, natural ligands present in wine produce dissociable 1:1 complexes with Cu and Zn, polyphenols and proteins complexing with Cu(II) and polyphenols with Zn (II). Theoretical calculations suggested that hydrated and chalcone forms of anthocyanins can form viable 1:1 complexes with both Cu and Zn, acting as bidentate ligands, with the remaining four coordination places being occupied by water ligands.

Polarography

This is a special form of voltammetry, where the working electrode is a polarizable dropping mercury electrode (DME), whereas the reference (and also the counter electrode for three electrode systems) is a solid nonpolarizable electrode. The electrochemical response at the DME is determined by combined diffusion/convection mass transport between the analyte and mercury drops regularly falling from a capillary tube. In its simplest form, polarography is a special kind of linear sweep voltammetry where the electrode potential is altered in a linear fashion from its initial to its final potential. Commonly in polarography (e.g. with three electrode systems), the experiment is potentiostatic; it is potential controlled, so that the polarographic curve is a plot of the current passing through the system against the voltage applied to the electrodes, or

on the electrode potential of the dropping electrode. Nowadays, all the variations that apply to voltammetry also apply to polarography, so there is adsorptive wave, anodic stripping, differential pulse, square wave polarography and others.

Despite environmental pressure to curtail the use of mercury, polarography is still a popular technique and has several advantages. Mercury is an effective working electrode because it has a high overpotential toward evolution of hydrogen compared with many other electrode materials and hence many metals can be analyzed, although some metals cannot be analyzed because the positive potential required causes oxidation of mercury. The mercury provides a fresh electrode surface in each drop, thus minimizing contamination caused by adsorption and 'carry over' interferences from previous determinations. This aspect eliminates the need to clean the electrode surface between experiments. Against these advantages, we have the severe toxicity of the metal and the need to use very pure mercury (triple distilled), which is expensive.

Polarography has been widely used in the analysis of alcoholic beverages and indeed it is the oldest electrochemical technique for such purposes. Daniele *et al.* (1989) used DPASV with a mercury microelectrode for the analysis of Cd and Zn in wine at its natural pH, without any sample pretreatment, whereas acidification of the sample with hydrochloric acid to pH 1 allowed simultaneous determination of Cd, Cu, Pb and Zn. Polarographic DPASV was also used to determine Cu in white wine, and in conjunction with ISE analysis and kinetic photometry, the speciation of Cu between ionic, labile and tightly bound forms could be determined (Wiese and Schwedt, 1997). DPASV itself could determine free copper ions and labile Cu(II) species (with complex formation constant $K < 10^{10}$) in nondigested samples. The levels of tightly bound complexes of copper could not be measured in this way, but could be calculated by subtraction of the concentration of ionic and labile species from the total Cu concentration. The latter was determined by DSPASV of concentrated HNO_3/microwave digestions of the samples and by FAAS on the same samples, where agreement was good. In most of the wine samples the dominant form of Cu was as labile species, but tightly bound species were significant in most of the samples and dominant in a few.

Similarly, Barbeira and Stradiotto (1997) used anodic stripping polarography to determine Cu, Pb and Zn in Brazilian sugar cane spirits, without any sample pretreatment or addition of supporting electrolyte. Optimum conditions, using linear sweep ASV were Hg drop size 0.52 mm^2, deposition potential –1.3 V (against Ag/AgCl(sat)), deposition time 10 min., conditioning time 20 s and anodic scan rate 50 mV/s. Detection limits were 0.09, 0.2 and 0.02 mg/l, respectively for Cu, Pb and Zn, considerably lower than the AAS method with which the results matched reasonably well. A similar method was used to analyze the same three metals in whisky, again without any sample pretreatment (Barbeira and Stradiotto, 1998).

Determination of sulfites in alcoholic and other beverages is always of much interest because of the wide use of this useful antioxidant and microbiological stabilizer (Section 2.5.2) and because of the regulations in force that relate to its maximum allowed concentration, due to its possible harmful effects, such as allergenic-like reactions in asthmatics (Section 5.10.2). Several voltammetric methods exist for the analysis of SO_2 and its derivatives in alcoholic beverages. A polarographic method for the determination of free and total sulfur dioxide in beer has been described by Almeida *et al.* (2003). Beer samples were made alkaline, and the aldehyde components were purged from the sample with nitrogen, collected in an electrolyte trapping solution and after derivatization with hydrazine they were determined by polarography. Next, the same sample was strongly acidified and the total SO_2 was purged from the solution, collected and analyzed by polarography, as before. The free SO_2 concentration was calculated from the difference between total SO_2 and aldehyde concentrations. Results were in good agreement with those obtained by the *p*-rosaniline reference method (Section 4.4.3).

Sulfite was determined in wine and fruit juice samples using an indirect amperometric flow injection method (Section 4.6.2) that incorporated a glassy carbon working electrode, a platinum wire auxiliary electrode and an Ag/AgCl (saturated NaCl) reference electrode (Lowinsohn *et al.*, 2004). The current was measured at an

applied potential of 0.0 V, and was proportional to the amount of the Cu^{3+} species chemically generated by the autoxidation of the Cu^{2+} tetraglycine complex induced by sulfite in the presence of traces of Ni^{2+}. The method utilized gas diffusion separation of sulfite (as SO_2) through a PTFE membrane, thereby minimizing matrix interferences. The donor stream at the membrane was deionized water, sample (containing sulfite) and 1 M H_2SO_4, while the acceptor stream consisted of 1mM Cu(II)-tetraglycine solution in a supporting electrolyte solution. The dynamic concentration range was 20–100 mM with a detection limit of 2 mM, with recoveries in the range 92–98%.

Oxygen Electrode

Dissolved oxygen in alcoholic beverages needs careful monitoring, since excessive levels can contribute to a more rapid oxidative deterioration in stored beers (especially) and wines. Probably the most widely used oxygen probe is the 'Clarke oxygen electrode,' which consists of a platinum electrode covered with a polymer membrane (usually Teflon) that is permeable to oxygen, but not to water or electrolytes, and a silver electrode. The poles are connected by a saturated potassium chloride bridge (Figure 4.5.5). Some versions have the platinum electrode in contact with a silver chloride electrode, without the intervening potassium chloride bridge. A constant voltage (~0.6 V) is held across the electrodes so that the Pt electrode is negatively charged (cathode) with respect to the silver electrode (anode). Orbisphere probably produces the best known series of D.O. probes and ancillaries, but battery powered hand held instruments, such as those provided by Hanna, are useful for measuring dissolved oxygen in samples from around the brewery or winery.

When the probe is placed in a sample solution, electrons are donated from the Pt electrode to dissolved oxygen molecules that have permeated the membrane, thus reducing them to hydrogen peroxide, or in the presence of hydrogen ions, to water (Figure 4.5.5). Consequently, electrons flow from the Ag electrode through the electrical circuit to the Pt electrode to regain electrical balance. This current is converted to a voltage that is measured, its magnitude depending on the level of dissolved oxygen. At the same time, chloride ions from the salt bridge combine with Ag^+ to form AgCl at the silver electrode, thus maintaining electrical balance in the probe.

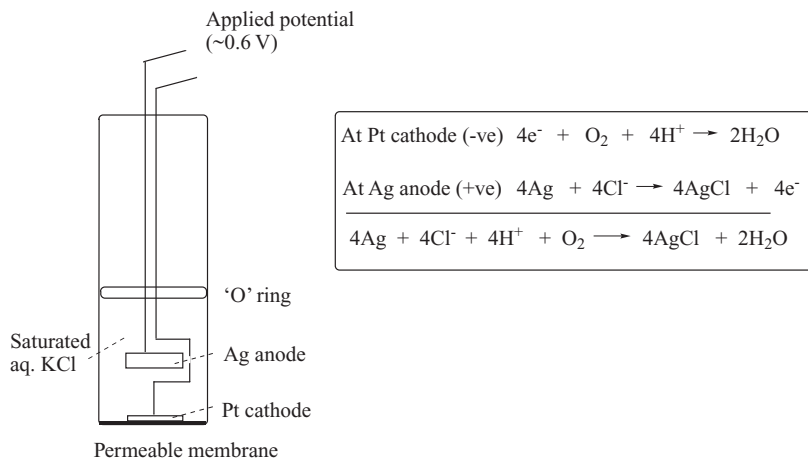

Figure 4.5.5 *Schematic section of a Clarke oxygen electrode and summary of reactions at cathode and anode*

4.5.3 Electrochemical Sensors

A chemical sensor is a device that converts chemical energy (e.g. of redox reactions) to electrical energy or other form of energy, so on this basis the experimental systems discussed in Section 4.5.1 and 4.5.2 (potentiometric methods and voltammetric methods) are sensors. Usually, an analyte recognition process takes place followed by the conversion of chemical information into an electrical signal. Among various classes of chemical sensors, ion selective electrodes (ISE) are one of the most frequently used potentiometric sensors during laboratory analysis as well as in industry, process control, physiological measurements and environmental monitoring.

Discussion here will be limited to electrochemical sensors as miniaturized analytical devices, which can deliver real time and on line information on the presence of specific compounds or ions in complex samples. This includes microelectrode systems developed by photolithographic techniques, giving reduced instrument size, small sample volume requirements, high uniformity and good definition. Also included here are systems based on interdigitated electrodes, which have been used as highly sensitive electrochemical detectors because of their ability to offer large current and higher sensitivity than typical macroelectrodes.

In the analysis of alcoholic beverages and other foodstuffs, electrochemical sensor devices can be divided into two types; those that contain a single electrochemical cell (transducer) that is selective for a single analyte and those that contain an array of nonselective (but cross sensitive) electrochemical cells, as found in electronic tongues and noses. The first type is used to determine the concentration of a specific component, while the second type is used to give a response profile (a 'fingerprint') and, by using chemometric software, can be matched to a sample type, leading to identification of origin or discrimination amongst types. Also, the second kind of sensor may be used to quantify various components (e.g. ethanol, malic acid) and parameters (e.g. pH, °Brix) by training/prediction (calibration/validation) techniques.

Electrochemical sensors use changes in conductometric, potentiometric and voltammetric properties of materials exposed to samples. Sensors of the first variety are often found in electronic noses, of which there are several commercial versions. They typically consist of an array (say 32) of organic polymer based electrically conducting sensors that have adsorptive surfaces, which display changes in electrical resistance on the adsorption of certain components in headspace samples of alcoholic beverages. Such devices have been used to monitor the production of aroma compounds during the fermentation of Muscatel grapes (Pinheiro *et al.*, 2002; 2005) (Figure 4.5.6). In these studies it was found that, without sample pretreatment, the electronic nose could only monitor the formation of ethanol during fermentation. On the other hand, if organophilic pervaporation (with a modified silicone rubber composite membrane) (Section 2.13.3) was used as a concentration sample pretreatment step, the nose was able to detect the aroma compounds, even in the presence of ethanol. Thus under these conditions the nose was able to discriminate between samples and could be used in line to monitor the evolution of aroma compounds during fermentation. The dense, nonporous, hydrophobic membrane separates the upstream side (feed) that contains the feed solution (must/wine) from the downstream side (permeate) containing the compounds to be recovered. The hydrophobic membrane acts as a selective transport barrier, facilitating or preventing sorption and subsequent diffusion of particular components.

Electronic tongues have been devised to discriminate between wine samples and to quantify certain wine parameters, such as ethanol content, pH, shikimic acid content, tartaric acid content and total acidity (Legin *et al.*, 1999). An array of 29 potentiometric sensors that showed poor selectivity, but good cross sensitivity was tested on 22 wines with known parameters (measured by standard methods), mostly from the *V. vinifera* variety Barbera. The sensors were cells with chalcogenide glass and PVC membrane electrodes, including metal ion selective types and ion selective (H^+, Na^+, Cl^-, etc.) types.

Sensor potential values were measured against a conventional Ag/AgCl reference electrode. Partial least squares regression, principal component analysis and self-organising map methods were used to process the results.

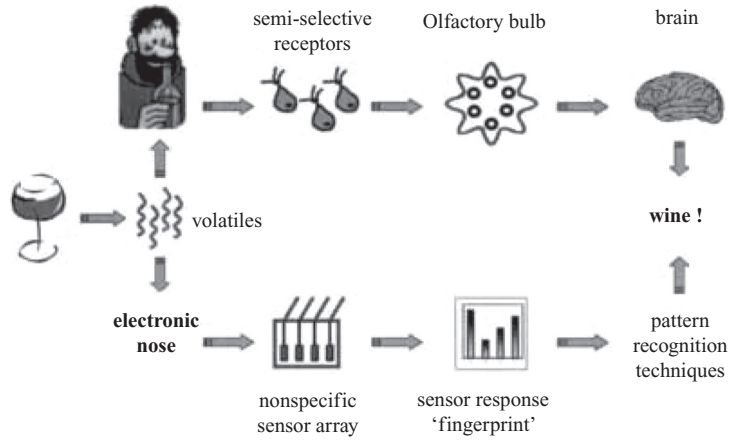

Figure 4.5.6 *Comparison of operation of human olfactory system and electronic nose in identifying wine. Reproduced from Pinheiro* et al. *(2002), with permission of John Wiley & Sons Ltd*

A multisensor system with six ion sensitive field effect transistor (ISFET) sensors monolithically integrated in silicon has been applied as an electronic tongue to discriminate between must and wine samples and to quantify certain must and wine parameters, such as % ABV, °Brix, pH, total acidity and volatile acidity (Moreno i Codinachs *et al.*, 2008). Two sets of multisensors were prepared by depositing ion sensitive membranes on IFSETs: one set with photocurable polymeric membranes sensitive to Ca^{2+}, Cl^{-}, K^{+}, Na^{+}, NH_4^{+} and ions, and the other set with chalcogenide glass membranes sensitive to heavy metal ions (Ag^{+}, Cd^{2+}, Cu^{2+}, Pb^{2+}, Tl^{+}). Both multisensor chips contained a pH ISFET sensor. Principal component analysis (PCA) and soft independent modelling class analogy (SIMCA) were used on the data for the pattern recognition and classification of samples and partial least squares (PLS) regression for quantification of the wine parameters.

More recently, an electronic tongue composed of 18 potentiometric chemical sensors was applied to the quantitative analysis of 50 Belgian and Dutch beers of a wide range of styles (Polshin *et al.*, 2010). The main physicochemical parameters (bitterness, CO_2 content, color, ethanol content, pH, polyphenol content, real extract and real fermentation degree) of the same samples were analyzed by standard methods, and relationships between the potentiometric and physicochemical data sets were investigated using canonical correlation analysis. Calibration models with regard to the physicochemical parameters using the electronic tongue were calculated by partial least squares regression. The electronic tongue was capable of prediction of several parameters relating to beer quality, including bitterness, ethanol content, polyphenol content and real extract, with mean relative errors of 10–17%. The lowest error was for bitterness, so in this respect alone, the electronic tongue offered an attractive alternative to the standard spectrophotometric method (Section 4.4.3), being much simpler, more rapid and of similar precision.

An electronic tongue based on pulse voltammetry was used to predict concentrations of bisulfites in wine samples (Labrador *et al.*, 2008). The sensor array consisted of four working electrodes – gold, rhodium, platinum and stainless steel, all of 99.9% purity and of 1 mm diameter – encapsulated into a stainless steel cylinder, which acted as both the body of the ET system and the counter/reference electrode. The ET device was additionally equipped with a self-polishing system, which was used for 30 s between experiments. A white wine whose sulfite content was known from HPLC measurements was used for calibration and 20 wine samples were used as the validation set. Multivariate analysis including cross validation and partial least square (PLS) techniques are applied for data management and prediction model building. Accuracy was good; ascorbic acid and histamine were included in the predictive analysis, but here accuracy was only moderate.

A sensor system using an array of carbon paste electrodes modified with rare earth complexes, including lutetium(III), gadolinium(III) and praseodymium(III) bisphthalocyaninates (Parra *et al.*, 2004). The sensors showed high cross selectivity and responses were evaluated by cyclic voltammetry or square wave voltammetry. The sensor array was tested on six Spanish red wines made from the same grape variety, but of varying ages and geographic origin. The data was analyzed by principal component analysis, where it was found that the sensor array was able to discriminate between the samples, agreeing closely with a PCA analysis of selected red wine taste parameters (e.g. % ABV, dry extract, glycerol content, reducing sugar content, tannin content, tartaric acid content, total acidity and volatile acidity) associated with the tested wines.

Although not an electronic tongue as such, an electrochemical sensor device was used for the very rapid determination (~4 s) of the acidity of juices and alcoholic beverages (Wen *et al.*, 2004). The device actually performed electrochemical titrations ('flash' or 'nanotitration') in the media, with only a small fraction of the sample being titrated (in the immediate vicinity of the electrode), thus leading to an insignificant change in the total acidity. The titration curve was recorded by video and the results were in good agreement with those obtained by standard volumetric titration.

Although ascorbic acid is not a major component of most alcoholic beverages (except perhaps in certain mixers and cocktails) it is sometimes used along with sulfites to prevent premature browning in white wines and it is used extensively in other areas of the food industry. Consequently, there has been considerable interest in developing sensor devices for the electrocatalytic determination of ascorbic acid (Pauliukaite *et al.*, 2005; Nassef *et al.*, 2008). Oxidation of ascorbate to dehydroascorbate is a two electron process that can be catalyzed by a number of reduction processes of electrode modifier substances. This, and the subsequent electrochemical reoxidation of the modifier, constitute the basis of some determinations of ascorbic acid (Figure 4.5.7).

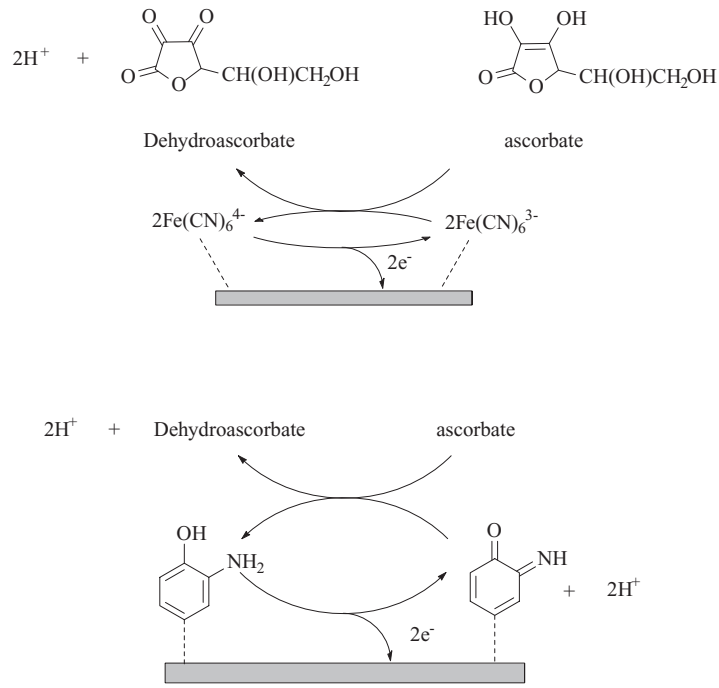

Figure 4.5.7 *Redox coupled systems at modified electrodes used for the electrochemical determination of ascorbic acid. Pauliukaite* et al.*, 2005; Nassef* et al.*, 2008*

Carbon films modified by copper hexacyanoferrate were used as electrodes for detecting ascorbic acid in red and white wines (Pauliukaite *et al.*, 2005). They were made from carbon film resistors, produced from ceramic cylinders (1.5 mm o.d. × 4.0 mm) by pyrolytic deposition of carbon, in such a way that the exposed geometric area was ~0.2 cm^2. Copper hexacyanoferrate was deposited from a solution of 10 mM Cu(II), 10 mM $K_3Fe(CN)_6$ and 100 mM KCl by either chemical (immersion) or electrochemical methods. The chemically deposited films performed best and were used as amperometric sensors at +0.05 V against SCE.

Disposable screen printed electrodes modified with an electrografted *o*-aminophenol film were constructed for the amperometric sensing of ascorbate in various beverages (Nassef *et al.*, 2008), against an Ag/AgCl reference electrode. The film was prepared via the electrochemical reduction of the *in situ* prepared *o*-aminophenol diazonium salt in aqueous solution. The modified electrodes showed pronounced electrocatalytic activity towards the oxidation of ascorbic acid, and the catalytic oxidation peak current was linear with respect to ascorbate concentrations in the range 2–20 μM, with good precision (%RSD = 1.98, n = 8).

Many wines or wine categories are regulated according to their residual sugar content (e.g. Marsala – see Section 2.10.8), which is mostly glucose. Although there are several methods for the analysis of residual glucose and reducing sugars, such as enzymic/colorimetric (Section 4.4.3) and chemical techniques (Section 4.6.3), the use of electrochemical biosensors in this area has resulted in some effective rapid screening methods. Electrochemical biosensors are similar to other sensors, but having at least one biological redox component linked with a physicochemical detector component. They are usually three electrode systems that involve the analyte in a redox enzyme reaction that produces ions at the working electrode. The product ions give rise to a potential, which is subtracted from that of the reference electrode to produce a signal.

Ulasova *et al.* (2003) used Prussian Blue based sensors with a flow injection system (Section 4.6.2) to determine the glucose levels of 10 Italian red and white wines, after a 1:1000 dilution, where agreement with a standard spectrophotometric method was good. The wines had glucose levels in the range 0–60 mg/l. The working electrode was made by depositing a membrane of Nafion®, containing immobilized glucose oxidase on a Prussian Blue modified glassy carbon electrode. An auxiliary electrode made as above, but with bovine serum albumin in place of glucose oxidase, and an Ag/AgCl reference electrode completed the electrochemical cell, which showed a linear response to glucose at an applied potential of 0.0 V in the range 10^{-6}–10^{-3} M.

Biosensors often have two biological redox systems linked, as in one based on platinum chips for the determination of glucose (Alonso Lomillo *et al.*, 2005). Briefly, the biosensor was produced by metallation of (3 × 3 mm) silicon chips, giving a platinum working electrode. Horseradish peroxidase (HRP) and glucose oxidase (GOX) were coimmobilized on this microelectrode by electropolymerization of pyrrole, and hexacyanoferrate or Meldola's blue was used as mediator for electron transfer between the enzymes and electrode (Figure 4.5.8). The sensor was able to quantify glucose in grape juice, with repeatability (%RSD) of 7.1% (n = 4) and so could be used as a tool for the rapid screening of glucose in ripening grapes.

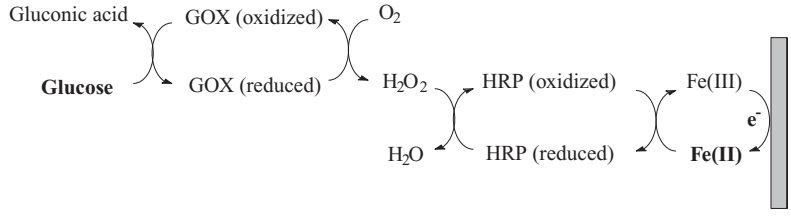

Figure 4.5.8 *Coupled GOX-HRP enzymic reactions and hexacyanoferrate reactions at the working electrode of a glucose biosensor. Alonso Lomilla* et al.*, 2005*

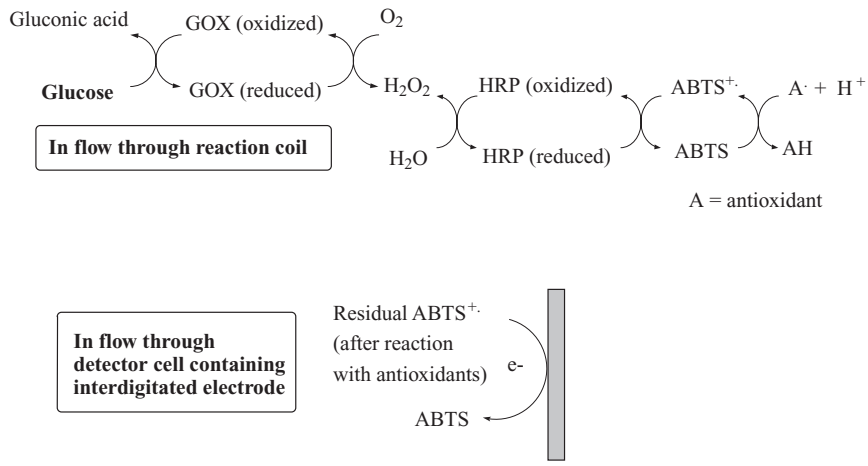

Figure 4.5.9 *Redox reactions associated with biosensor method for the determination of the total antioxidant capacity of alcoholic drinks. Milardovic* et al.*, 2007*

A similar method using flow injection analysis (FIA) was reported for determination of total antioxidant capacity of alcoholic beverages by bienzymatically produced $ABTS^{+\bullet}$ (Section 4.4.3) and an electrochemical detector using an interdigitated gold electrode (IDE) (Milardovic *et al.*, 2007). $ABTS^{+\bullet}$ is produced from ABTS by the glucose oxidase-peroxidase enzyme system immobilized on polyacrylamide gel in the tubular flow through reactor coil. The method is based on electrochemical (biamperometric) measurements using the $ABTS^{+\bullet}$/ABTS redox couple. The biamperometric technique is based on electrochemical detection using two identical working electrodes, upon which is imposed a small potential difference. This indirect method relies on a homogeneous reaction between the analyte and a reversible redox couple as indicator. The reactions involved with this system are shown in Figure 4.5.9. The results, 0.04–0.59 Trolox equivalents for spirits and one liqueur, and 1.23–17.38 Trolox equivalents for wines, were in good agreement with those from a spectroscopic method.

4.6
Other Methods

4.6.1 Electrophoretic Techniques

The process of electrophoresis can be described as the differential migration of ions by attraction or repulsion in an applied electric field. The simplest form of electrophoresis involves positive (anode) and negative (cathode) electrodes placed in a solution containing ions. When a voltage is applied across the electrodes, anions (negative ions) and cations (positive ions) move through the solution towards the electrode of opposite charge. For general reading, the reader is directed to Westermeier (2005).

Separation by electrophoresis relies on differences in the migration velocity (v) of ions, which is given by Equation 4.6.1.

$$v = \mu_e E \tag{4.6.1}$$

where v is in m/s, μ_e is the electrophoretic mobility (in m^2/V/s) and E is the electric filed strength (in V/m).

The electric field strength is the applied voltage divided by the total capillary length. Electrophoretic mobility expresses the balance of forces acting on each ion; the electrical force in favor of motion and the frictional force against motion. For a particular ion in a given set of conditions, electrophoretic mobility is constant during an electrophoresis experiment.

Electrophoretic mobility is given by Equation 4.6.2.

$$\mu_e = \frac{q}{6\pi\eta r} \tag{4.6.2}$$

where q is the ionic charge, η is the medium viscosity and r is the ionic radius.

At one time, high voltage paper electrophoresis (HVPE) was a fairly popular method for the identification of amino acids and low molecular weight carboxylic acids in fruit juices and alcoholic beverages, but this technique gradually gave way to other electrophoretic methods (especially capillary electrophoresis) and to chromatographic methods. However, recently HVPE has been used to determine the pK_A values and acid–base equilibria of anthocyanins and derivatives such as 5-carboxypyranomalvidin-3-glucoside (vitisin A) in dilute solution (Asenstorfer *et al.*, 2003; 2006; Asenstorfer and Jones, 2007). Paper electrophoresis has been used to study the charge dependent electrophoretic mobility of malvidin-3-glucoside in a variety of buffers over the pH range 1.2 to 10.4 (Asenstorfer *et al.*, 2003). Apparent pK_A values of pK_A (1) 1.76 ± 0.07, pK_A (2)

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

5.36 ± 0.04, and pK_A (3) 8.39 ± 0.07 were determined for malvidin-3-glucoside. It was deduced that the major forms of malvidin-3-glucoside and similar anthocyanins at wine pH (∼3.6) were the neutral hydrated (hemiketal) and quinoidal base forms. In view of these results, coupled with information from UV-visible spectra (Section 4.4.3) and ^{13}C NMR spectra (Section 4.4.1) it was suggested that, at wine pH (3.2–3.8), vitisin A exists as a complex mixture of neutral, anionic, hydrated and nonhydrated species, with the major species being the orange neutral quinonoidal base (Asenstorfer *et al.*, 2006; Asenstorfer and Jones, 2007). See Section 4.4.3 for further discussion on the implications of these results regarding young red wine color.

In these experiments a gel electrophoresis unit was used, with glass fiber paper folded over a glass rod and dipping into two wells containing buffer solutions. A voltage gradient of 7.5 V/cm was applied and the unit was cooled to 15 °C to counter the heat generated. The buffers used were 0.1 M formic/acetic acid (pH 1.0–2.4), 0.1 M citric acid (pH 2.8–7.2), and 0.5 M citric acid/0.5 M sodium pyrophosphate (pH 7.4–10.0).

Oligosaccharides and polysaccharides are important constituents of beer, being present in different proportions depending on production methods and beer style (e.g. ale, lager, light, porter and stout). They cannot be analyzed easily by electrophoretic methods because they are not appreciably ionized, except in very strongly basic media. However, if firstly derivatized with the fluorescent and anionic dyestuff 8-amino-1,3,6-naphthalene trisulfonate, they can be separated and detected with fluorescence assisted carbohydrate electrophoresis (FACE). Oligosaccharides in a wide range of beers were identified via comigration of standards (e.g. oligosaccharides derived from β-glucan, pentosan and purified starch) using such a method (Thomas *et al.*, 2000).

Gel Electrophoresis

Several techniques of this type are regularly applied to the study of macromolecules associated with alcoholic beverages or their raw materials, as well in relation to production processes, including fermentative microorganisms. Polyacrylamide gel electrophoresis (PAGE) is probably the most common analytical technique used to separate and characterize proteins. These, and other macromolecules, dissolved in a buffer solution, are separated by their differential movement through the cross linked gel upon the application of a potential gradient.

Electrophoretic mobility depends on the applied potential difference, the molecular weight and the number of electrical charges on the macromolecule. However, if the sample solution is treated before electrophoresis with sodium dodecyl sulfate (SDS), an anionic detergent, the proteins are denatured into more or less linear molecules containing roughly one absorbed SDS molecule for every two amino acids. The native charge of each protein is hidden by the negative charges of the SDS units, thus the denatured proteins tend to have similar shapes and similar mass to charge ratios. Consequently during SDS-PAGE electrophoresis, proteins are separated largely according to their molecular weights. Proteins with large numbers of disulfide bridge links can be further denatured before electrophoresis by reaction with 2-mercaptoethanol or dithiothreitol. The resulting technique is known as reduced SDS-PAGE.

A solution of acrylamide and bisacrylamide is polymerized, usually in Tris-Cl buffer solution (pH ∼7–9), using ammonium persulfate as an initiator and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED) as a free radial stabilizer (promoter). A cross linked gel is formed (acrylamide alone tends to produce linear polymers), the extent of cross linking ('pore size') being determined by both the concentration of acrylamide and the ratio of acrylamide to bisacrylamide. A high acrylamide concentration and a high ratio of bisacrylamide to acrylamide give a highly cross linked (low pore size) polymer, which results in low electrophoretic mobility during electrophoresis. A typical composition for a resolving gel (see below) is 12–16% (w:v) total acrylamide with ∼3–6% of this being bisacrylamide crosslinker. This gives highly cross linked (small pore) gels, typically used as resolving gels for the separation of relatively high molecular weight proteins.

Polyacrylamide gels are polymerized in a gel caster, where the separating (resolving) gel is poured and allowed to polymerize, as described above. Next a thin layer of isopropanol is added, the loading (stacking) gel is poured over this and a comb is placed to create the wells. After the loading gel is polymerized the comb can be removed and the gel is ready for electrophoresis.

The loading gel is a large pore polyacrylamide gel (~4% w:v acrylamide concentration), which is usually prepared in Tris/HCl buffer pH 6.8; 2 pH units lower than that of the common electrophoresis buffer (usually Tris/glycine). These conditions allow SDS-coated proteins to be rapidly concentrated several fold and to form a thin starting zone of less than 20 μm. Sometimes a spacer gel, of pore size intermediate between those of the loading and resolving gels, is used.

The electrophoresis apparatus is set up with cathode buffer covering the gel in the upper negative electrode (cathode) chamber, and with the anode buffer in the lower positive (anode) electrode chamber. The (usually) denatured protein samples are added to the wells at one end of the gel plate and a calibration reference solution containing denatured proteins of known molecular weights is added to a well at the other end. A potential difference is then applied, under which the negatively charged proteins move at different rates down the gel plate toward the anode. Higher voltages give faster migration, but at the cost of poorer resolution: an SDS-PAGE experiment can be expected to take an hour or more. Visualization of the migration progress can be achieved by including bromocresol in the electrophoresis medium.

After a suitable separation has been achieved, the voltage is switched off and the gel plate is removed and usually stained with either Coomassie Brilliant Blue R-250, an anionic dye that binds to proteins nonselectively (although only weakly with some glycoproteins) or a silver nitrate solution, for greater sensitivity.

Many researchers still use the Tris-glycine or Laemmli procedure (1970), described above, that stacks at pH ~6.8 and resolves at pH ~8.3–9.0. However, the latter high pH values promote disulfide bond formation between cysteine residues in the proteins, especially if the protein is rich in such residues, because the pK_A of cysteine residues is 8–9 and because the reducing agent present in the loading buffer does not comigrate with the denatured proteins. To minimize this problem, some researchers carry out the electrophoresis by using a bis-Tris buffer medium of pH ~6.5, which is well below the pK_A of cysteine. The medium also includes sodium bisulfite reducing agent that moves into the gel ahead of the proteins, thus maintaining a reducing environment during electrophoresis. Additionally, acrylamide gels are more stable in lower pH buffers and hence can be made in advance and stored for a considerable time before use.

The most frequently and widely applied form of gel electrophoresis is sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), used mainly for the characterization of proteins and their breakdown products (Soares and Sato, 2000; Singh and MacRitchie, 2001; Blanco Gomis *et al.*, 2003; Osman *et al.*, 2003; Liesegang and Stahl, 2005; Gambuti *et al.*, 2006, Cilindre *et al.*, 2007; Hégrová *et al.*, 2009; Marangon *et al.*, 2009; Wigand *et al.*, 2009).

Additionally, gel electrophoretic techniques are used for the identification of plant species and microbial strains via nucleic acid (microsatellite or molecular markers) analysis of plant material, rather than via analysis of native proteins (Viti *et al.*, 2000; Gimble, 2001; Coulon *et al.*, 2006; Larisika *et al.*, 2008; Maestre *et al.*, 2008 and İşçi *et al.*, 2009). Identification of plant species is an important aspect of authentication of wine origin and in the detection of fraud.

A common technique for the analysis of grape vine plant material is restriction fragment length polymorphism (RFLP), whereby the DNA is first extracted from fresh tissue, purified and then amplified by polymerase chain reaction (PCR). The DNA is then cut into restriction fragments using suitable endonucleases, which cut the DNA molecule only at specific base sequences. The restriction fragments are then separated according to length (and molecular weight) by gel electrophoresis, often agarose gel electrophoresis with enhancement by Southern blotting. Alternatively, fragments can be visualized by pre- or posttreatment of the agarose gel with ethidium bromide or silver solutions.

Although such techniques have been applied to must (e.g. see Baleiras-Couto and Eiras-Dias, 2006; Faria *et al.*, 2008), there are problems with DNA analysis in wine (İşçi *et al.*, 2009). Firstly, the levels of DNA in wine are very low, secondly, some degradation occurs during the production process, thirdly, contamination with microbial DNA can occur and fourthly, wine contains many potential inhibitors (e.g. polyphenols and carbohydrates) of the PCR process.

PAGE analysis of proteins is often accompanied by other separation techniques, such as capillary gel electrophoresis (Blanco Gomis *et al.*, 2003) or gel filtration (Osman *et al.*, 2003), and is sometimes carried out on chromatographic fractions (e.g. Soares and Sato, 2000; Singh and MacRitchie, 2001; Osman *et al.*, 2003), as well as extracts. Also, PAGE protein bands, after destaining and possibly other treatments, are frequently subjected to mass spectrometric analysis, such as MALDI-TOF (e.g. Hégrová *et al.*, 2009) or LC-MS (e.g. Marangon *et al.*, 2009; Wigand *et al.*, 2009).

SDS-PAGE can be used to probe native cereal protein structures and their breakdown mechanisms, as in the case of controlled depolymerization of wheat gluten and glutenin subunits by ultrasound (Singh and MacRitchie, 2001). Here, highly pure glutenin (free of gliadins) reduced and unreduced chromatographic fractions were subjected to analysis on 10% SDS-PAGE minigels in a discontinuous (isoelectric focusing) system at pH 6.8, with staining by Coomassie Brilliant Blue R-250. The results (protein profile), coupled with SH content determination, indicated that proteins vary in their ease of breakdown via disulfide (SS) bridge fission and that intramolecular SS bonds are readily reformed in the breakdown of protein subunits.

Interest in protein composition is often in relation to the effects of processing (Osman *et al.*, 2002: 2003), foam promotion or haze formation in beer (Sections 2.6.2 and 2.6.3) (Liesengang and Stahl, 2005), cider (Section 2.8.2) (Blanco Gomis *et al.*, 2003) and wine (Brown *et al.*, 2007; Cilindre *et al.*, 2007) or the 'gushing' phenomenon in beer (Hégrová *et al.*, 2009).

In beer, the major proteins involved in foam production are 'protein Z' (molecular weight $\sim$ 40 kDa) and lipid transfer protein 1 (LTP1) (molecular weight $\sim$ 9.6 kDa), which are normally found in concentrations of 50–200 mg/l and 59–90 mg/l, respectively (Liesengang and Stahl, 2005). SDS-PAGE (and RPHPLC) has shown that beer LPT1, but not barley native LTP1, is hydrolyzed by proteinase A enzymes excreted by yeast during wort fermentation, thus suggesting this protein is modified during malting and or mashing to a more susceptible form (Liesengang and Stahl, 2005). Protein Z was not affected by proteinase A. The gel electrophoresis experiments were carried out on protein fractions, using a standard Laemmli procedure and visualized by Coomassie Brilliant Blue R-250 staining, as well as by an immunoblot technique. Hence, since some the foam promoting protein in beer is degraded by proteinase A and most of this enzyme is released by autolyzed yeast cells, it was suggested that foam quality may be maintained by use of yeasts with low proteinase A activity and conducting the fermentation at low temperatures with rapid separation of the beer from the yeast after fermentation.

On the other hand, SDS-PAGE analysis of barley, wort and beer proteins, using the Laemmli procedure and 'low range' standards (molecular weight 14.4–97.4 kDa), combined with gel filtration has demonstrated the generally similar protein profile of barley malt and beer (Osman *et al.*, 2003), confirming the assumption that beer proteins descend from barley, some unchanged and some modified by processing, as described above. Although most barley proteins are water insoluble, it was found that the process of malting doubled the concentration of soluble proteins (from 20% to 40% of total protein content).

It has also been shown that some proteinases survive the kilning process and are active during mashing, some breaking down insoluble proteins into soluble ones, and others hydrolyzing these further to ammonia, small peptides and amino acids. These are known as free amino nitrogen (FAN). Nondenaturing PAGE (i.e. without SDS and using Tris-HCl buffer of pH 8.5) separation of native barley endoproteases at different points in the malting/kilning process indicated that active endoproteases (as determined by their action on glutelein and haemoglobin substrates) were formed during germination, and 90% of them were still active in the kilned malt (Osman *et al.*, 2002). In this study, Amido Black was used as the staining agent.

Sorghum (*Sorghum bicolor* (L.) Moench) is an important cereal in semi-arid regions of Africa and Asia. It is malted and used to produce a range of alcoholic beverages in both continents, particularly Africa (Section 2.7.2). Recently, SDS-PAGE has been applied to the analysis of proteins at different stages of sorghum germination during the malting process (Correia *et al.*, 2008). Proteins extracted in *tert*-butanol were dried under N_2 and the residues were dissolved in the electrophoretic buffer (SDS, Tris, glycerol and bromophenol blue), and were run under nonreducing and reducing conditions (with added 2-mercaptoethanol) at 170 V for 1.5 h using the Laemmli method, after heating in a boiling water bath for 5 min. The gels were stained with Coomassie Blue R and destained with methanol and acetic acid.

The results indicated an increase in high molecular weight protein aggregates during the first few days of malting, followed by significant degradation by proteases, suggesting that, as with other cereals, germination significantly increases the concentration and availability of proteins, peptides and amino acids.

Certain peptides are produced by barley kernels in response to attack by fungi, such as *Fusarium* spp. (Section 5.11.4). These stress peptides may survive through the brewing processes and their presence in the beer, along with fungal metabolites, is thought to contribute the phenomenon of gushing. Hégrová *et al.* (2009) used SDS-PAGE to show that proteome changes occurred during barley infection, but the basic hordothionin type peptides and LPT1 (important in foam quality) concentrations did not correlate with the degree of gushing.

Blanco Gomis *et al.* (2003) used capillary gel electrophoresis and standard SDS-PAGE to show that Spanish cider contained five major proteins of molecular weight 16–110 kDa. The major protein (16.4 kDa) was known to be involved in haze formation in apple juice and hence it was suggested that the other proteins could contribute to the sensory value of cider – with respect to foam quality, an important quality parameter applied to Spanish cider.

As with beer and cider, proteins are required for good foam (mousse) characteristics of sparkling wines, such as Champagne (Section 2.9.3). It is has been shown that infection of grapes by *Botrytis cinerea* (causing grey mold) adversely influences foam quality (foamability and foam stability) of the resulting wine (Cilindre *et al.*, 2007). SDS-PAGE and two dimensional electrophoresis (2-DE), with immunodetection, showed that *B. cinerea* infected grapes gave wines with a different protein profile to normal wine (i.e. with fewer and different proteins). This suggested that certain grape proteins are proteolized during infection by this fungus and new proteins are synthesized, either by the fungus or by the grape (in response to fungal infection), or are breakdown products of original grape proteins. Loss of good foaming characteristics could be due to a combination of loss of foam promoting proteins and the presence of foam preventing proteins, as a result of *B. cinerea* infection.

Wigand *et al.* (2009) have used SDS-PAGE in conjunction with LC-MS (see Section 4.3.3) to analyze the protein content of wine after enrichment by dialysis and lyophilization. Generally, the method of Laemmli was used, but for comparison of the different wine varieties and homemade 12.5% polyacrylamide gels and for the further identification with mass spectrometry, 10–17.5% gradient polyacrylamide gels were used, each with 3% stacking gels. Protein samples were denatured with 2-mercaptoethanol and applied in a Tris buffer at pH 6.8, containing 4% SDS and bromophenol blue. Coomassie Brilliant Blue R-250 or silver nitrate was used as the stain, although glycoproteins (being insensitive to the above staining methods) were stained with periodic acid-Schiff's reagent (PAS) solution.

In the broader context of improving our understanding of protein haze formation in white wine, Marangon *et al.* (2009) identified Semillon juice proteins by taking five hydrophobic interaction chromatographic (HIC) fractions after RPHPLC separation (see Section 4.3.3) and subjecting them to nonreducing SDS-PAGE, using the method of Laemmli, with Bio-Safe Coomassie or silver stain procedures. All 24 bands of the SDS-PAGE electrophoretogram were subjected to nano LC-MS/MS, where all samples were shown to contain proteins from *V. vinifera*, using plant protein sequence databases. The juice proteins were PR (pathogenisis related) and TL (thaumatin-like) proteins, chitinases, (possibly) ripening related protein, LPT protein isoform1 and

vacuolar invertase 1, G1N1. Semillon wine was treated in the same way, giving a similar protein profile with respect to TL proteins, but had fewer chitinase proteins, indicating that some of these are hydrolyzed by yeast proteases during fermentation. PR and TL type proteins, as well as chitinases are known to be responsible for protein hazes in wine.

Haze protective factors are mannoproteins secreted by yeasts. They prevent protein haze formation in white wines by binding solutes, such as metal ions and polyphenols, which are required for the aggregation of denatured proteins into large particles. Brown *et al.* (2007) used a variety of techniques, including SDA-PAGE to characterize a 6xHis-tagged mannoprotein of molecular weight 178 kDa, which demonstrated haze protection when present in white wine. This offers the possibility of using proteins of this type to prevent haze formation, thereby reducing the need for fining agents such as bentonite (Section 2.9.4), which in the long term are costly and can cause disposal problems.

SDS-PAGE (using the Laemmli procedure on 12% w:v gels and with Coomassie Blue G-250 stain) and gel filtration chromatography have been used to characterize the killer protein (secreted to subdue the activities of other yeasts) of the *S. cerevisiae* strain Y500-4L (Soares and Sato, 2000). The purified killer protein had a molecular weight of 43 kDa, but a band corresponding to 18–20 kDa was found in the PAGE electrophoretogram, suggesting it is a dimer, like other killer proteins.

There has been much interest in the literature on polyphenol–saliva protein interactions, since formation complexes are believed to be responsible for the important sensory attribute known as astringency (see Section 4.7.1). SDS-PAGE (Laemmli procedure, with 14% resolving gel and 4% stacking gel and Coomassie Brilliant Blue R-250 staining), densitometry and sensorial analysis showed that four saliva proteins (amylase, lactoferrin, PRPbg1 and PRPbg2) were best able to distinguish tannin solutions according to different levels of astringency (Gambuti *et al.*, 2006). The Coomassie Blue destaining step (by incubation in 30% acetic acid – methanol or ethanol was omitted) distinguished PRPs, which stained pink-violet, from other proteins, which stained blue. The electrophoretograms showed a greater depletion of free saliva proteins with the more astringent grape seed tannin solution, as opposed to the grape skin tannin solution of Aglianico grapes.

Capillary Zone Electrophoresis (CZE)

This technique, sometimes known simply as capillary electrophoresis (CE) performs electrophoresis in a buffer- filled, narrow bore capillary, normally from 25 to 100 μm in internal diameter (ID), using a potential difference of typically up to 30 kV between the electrodes. The capillary is usually made of fused silica or quartz glass, protected by an external covering of polyimide. A schematic representation of a basic native CZE instrument is shown in Figure 4.6.1. Typically, the detector is situated ~50 cm from the anode. The

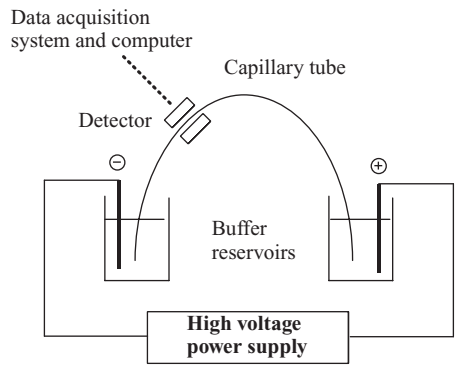

Figure 4.6.1 *Schematic representation of a capillary electrophoresis instrument*

sample may be introduced into the capillary tube by either electrokinetic or hydrodynamic injection. The former is carried by placing one capillary end (with the other capillary end in the cathode reservoir) in the anode buffer reservoir containing the sample and applying the voltage for a few seconds. A plug of buffer with sample moves a little way up the capillary due to electro-osmotic flow (see below). Hydrodynamic injection is carried out using application of pressure or vacuum at the appropriate end of the capillary for a few seconds (no voltage is applied), in which time the pressure differential causes movement of sample and buffer into the capillary. In either case of injection technique, this is repeated with the sample capillary end in a vial of pure water, which is then moved to an anode buffer reservoir containing no sample and the experiment is performed.

The mechanism of separation depends upon the existence of a double layer of counter ions (cations) to balance the overall charge of ionized silanol groups on the surface of the silica or quartz capillary wall (Figure 4.6.2). Under the influence of an applied potential gradient, the outer (diffuse) layer of counter ions migrates in the direction of the electrode of opposite polarity (the cathode) carrying its solvation shell, containing neutral analytes, and the rest of the medium, along with it. This migration is known as the electro-osmotic flow (EOF) (Figure 4.6.2). Ionic analytes will move at different rates, according to their charge densities, solvation spheres and masses, and hence will be sequentially monitored as they pass by the detector (CZE has a similar range of detector types to HPLC). Even most anions migrate in the same direction, since the EOF rate is greater than their reverse migration rates.

Since samples are normally introduced at the anode and EOF moves in the direction of the cathode, cations have positive effective electrophoretic mobility, neutral species have zero mobility and anions have negative mobility. In other words, cations migrate faster than the EOF, neutrals migrate with the same velocity as the EOF and anions migrate more slowly than the EOF. Mesityl oxide is often used to measure the EOF under the experimental conditions, according to buffer type, concentration, pH and temperature.

Cations have the lowest migration times, since their speed is augmented by the electro-osmotic flow. Anions have the highest migration times because although electrically attracted towards the anode, they are dragged towards the cathode by the EOF. In between the two extremes, neutral components migrate with the EOF, but are unresolved by the native CE technique. Cations with the highest charge densities (e.g. Al^{3+}) migrate first, followed by cations with lower charge densities (e.g. Na^+). Conversely, anions with lower charge densities (e.g. Br^- or RCO_2^-) migrate earlier than those with greater charge densities (e.g. F^- or SO_4^{2-}).

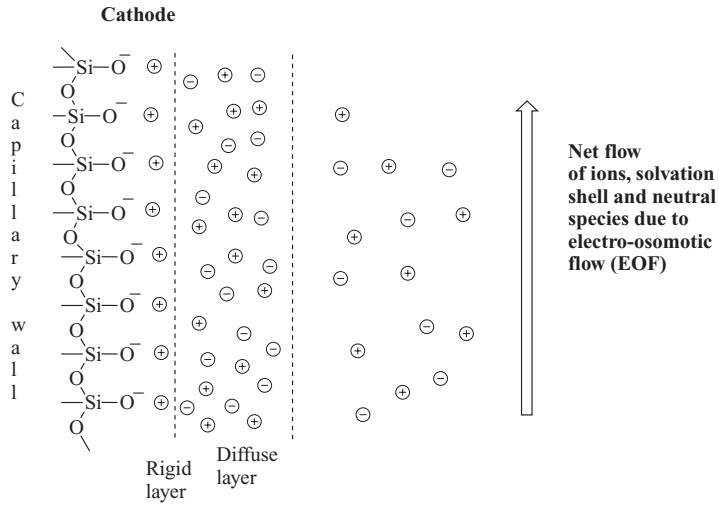

Figure 4.6.2 *Stern's model of double layer and EOF*

It is possible to change the charge density of many ions by adjustment of the buffer medium pH, thus influencing their relative migration rates. Also, EOF modifiers, such as cationic surfactants cetyltrimethylammonium bromide (CTAB) or hexadimethrin bromide (HDB), can be used to reverse the direction of the EOF, so making analysis of anions easier. On flushing the capillary with cationic modifier solution, the additive is physically adsorbed onto the capillary surface by ionic interactions, thus providing a dynamic, but reproducible coating. Such a technique is often used in the CE analysis of carboxylate and other anions in alcoholic beverages.

The selection of a background electrolyte (BGE) in capillary electrophoresis is a very important – for good resolution and high sensitivity, the mobility of BGE should be similar to that of the analytes, and where indirect UV detection is used, the BGE should have high molar absorptivity. As in HPLC, UV-visible detectors are popular, but many ionic analytes do not absorb strongly in the more readily accessible near UV region of the electromagnetic spectrum (say 190–300 nm). These analytes can be determined indirectly by adding chromophore containing counter ions to the sample. The counter ions form UV or visible light absorbing ion pairs with the analytes, which migrate at different velocities during electrophoresis.

Capillary electrophoresis has been widely applied to the determination of organic acids in juices and alcoholic drinks, the analytes generally being studied as their anions at relatively high pH. Indeed, in the case of organic acids, there are more CE reports than HPLC reports in the literature over the last decade (Mato *et al.*, 2005). Most of the CE reports involve the use of an EOF modifier or a coated capillary (Castiñeira *et al.*, 2000; Saavedra and Barbas, 2003; Esteves *et al.*, 2004; Simonet *et al.*, 2004; Bianchi *et al.*, 2005; Mardones *et al.*, 2005; Cortacero-Ramírez *et al.*, 2005; Mato *et al.*; 2007; Peres *et al.*, 2009), rather than native CE (Castiñeira *et al.*, 2000). The organic acids are generally separated as anions at pH ∼6.4–9.2, but there is at least one report on their separation as derivatives (Santalad *et al.*, 2007). There is also a report that uses zone electrophoresis on a poly(methyl methacrylate) chip, with integrated conductivity detection (Masár *et al.*, 2005a).

Generally, running negative potentials of 14–30 kV have been used for CZE analysis of acids in juice and alcoholic beverages (Mato *et al.*, 2007). Reproducibilities (determined as %RSD) are usually less than 3%, with recoveries generally in the range 90.0–103.0% and LoDs between 0.04 mg/l and 25 mg/l, thus comparing well with HPLC. The majority of reports deal with the simultaneous determination of a number of acids.

Castiñeira *et al.* (2000) examined the capillary electrophoretic analysis of acids in wine, using both uncoated and myristyltrimethylammonium bromide (MTAB) coated capillaries and a variety of background electrolytes (BGEs). Detection was by direct or indirect UV spectroscopy, depending on the BGE. The optimum conditions, electrolyte containing containing 3 mM phosphate (BGE) and 0.5 mM MTAB (as EOF modifier) at pH 6.5, allowed the determination of acetic, malic, lactic, succinic and tartaric acids were determined simultaneously in ∼6 min, with precision better than 1% and limits of detection in the range 0.015–0.054 mg/l.

There were some problems relating to poor peak shape, lack of sensitivity and limited ranges of linear detector response associated with some of the earlier CE determinations of short chain organic acids of wine. A background electrolyte of 2,6-pyridinedicarboxylic acid, along with EOF modifier cetyltrimethylammonium bromide (CTAB), have been found to be useful in the CZE analysis of low molecular weight wine acids (de Villiers *et al.*, 2003; Esteves *et al.*, 2004). De Villiers *et al.* (2003) used 7.5 mM pyridine dicarboxylic acid (PDC) as BGE, containing 0.5 mM CTAB as well as 0.5 mM EDTA at pH 5.60 to determine the six most important acids in 20 red and white South African wines. The samples required no pretreatment other than ×80 dilution (and addition of formic acid internal standard) and the analytes were detected indirectly at 350 nm (due to the presence of PDC as the BGE), with a reference wavelength of 210 nm. EDTA was present to improve the peak shape and quantification of citric acid. Limitations regarding linearity were shown to be the result of a lower sample pH than that of the BGE. Esteves *et al.* (2004) used a similar running electrolyte (5 mM PDC with 5 mM CTAB, but no EDTA, at pH 5.6) to determine five organic acids in 21 red and white

Port wines. Peres *et al.* (2009), on the other hand, preferred to use 10 mM 3,5-dinitrobenzoic acid (DNB) as background electrolyte at pH 3.6 (containing 0.2 mM CTAB EOF flow reverser). DNB was considered to be a good BGE because of its similar mobility to the analytes at pH 3.6 and also because it was a good chromophore, it allowed indirect detection of six acids at 254 nm in 23 Brazilian wines.

Direct UV detection at 185 nm was chosen by Mato *et al.* (2007) for the CE analysis of six organic acids in grape juice and wines. For this, the electrolyte was aqueous 7.5 mM NaH_2PO_4 and 2.5 mM Na_2HPO_4, with added 2.5 mM tetradecyltrimethylammonium hydroxide (TTAOH) as electro osmotic flow modifier and 0.24 mM $CaCl_2$ as selectivity modifier, at pH 6.40. Using this running electrolyte and a running potential of –25 kV, it was possible to determine six acids in less than 3 min. Likewise, direct UV detection (at 210 nm) was chosen for the analysis of 19 low molecular weight organic acids in seven beer samples (Cortacero-Ramírez *et al.*, 2005). The running buffer was 50 mM sodium phosphate in water:propan-2-ol (3:1) with added hexadimetrine bromide (HDB; 0.001%) as EOF modifier; this concentration caused a fast anodic electro-osmotic flow. The 19 acids could be determined in 22 min, with reproducibilities (%RSD) of 2.4–5.9% and LoDs of 0.04–3.3 mg/l.

Analysis of the shikimic acid content of Chilean red wines by CZE was undertaken by Mardones *et al.* (2005) in order to assess this as a means of varietal differentiation. Two methods were used, one at pH 7.5 using *p*-aminobenzoic acid for indirect detection of the analyte at 260 nm and the other at pH 7.0 with direct detection at 213 nm. In both cases the buffer system was bis[2-hydroxyethyl]imino-tris[hydroxymethyl]methane (Bis-Tris), with added $CaCl_2$ or LiCl and trimethyl(tetradecyl)ammoniumbromide (TTAB) as EOF modifier. Cabernet Sauvignon wines were found to have a higher shikimate content than other varietal wines from Chile (Merlot and Carmenère). Interestingly, Carmenère has all but disappeared from the Bordeaux area, where it once was an important red wine variety. It generally produced high quality wine, and possibly following the initiative of the New World (particularly Chile), it may experience a modest revival in France (2009).

Rather than using an EOF modifier in the electrolyte solution, the internal capillary walls can be coated with a modifier, such as polyacrylamide or HDB (Saavedra and Barbas, 2003; Bianchi *et al.*, 2005). Eight organic acids, as well as nitrate and sulfite were determined in Rioja red and white wines using a polyacrylamide coated capillary with 200 mM phosphate buffer as BGE (pH 7.5), using direct UV detection at 214 nm (Saavedra and Barbas, 2003). Bianchi *et al.* (2005) used a dynamically coated capillary, although the coating required a fairly lengthy process and had to repeated after 10 determinations. A new fused silica capillary was treated by rinsing at high pressure (20 psi) with 0.5 M NaOH for 20 min, with water for 5 min, followed with 0.1 M hydrochloric acid for 20 min. This procedure was followed by a second treatment with water for 5 min, 0.1 M sodium hydroxide for 20 min, and water for 5 min. Aqueous HDB (0.1% (w:v)) was then flushed through the capillary at 20 psi for 5 min. Using this capillary with a running electrolyte consisting of 35% (v:v) methanol in a solution of 22 mM benzoic acid at pH 6.10 adjusted with 1.0 M Tris-base buffer, determination of acetic, malic, lactic, succinic and tartaric acids in 12 Italian wines was carried out in less than 4 min for each sample.

Derivatization (Section 4.3.3) is not often used these days in either HPLC or CZE analysis of organic acids, but such a method was used to good effect in the analysis of as many as 11 acids in grape wines, indigenous Thai wines, fruit juices, vegetable juices and beer (Santalad *et al.*, 2007). Preanalysis derivatization was carried out with 2-nitrophenylhydrazine (2-NPH) in the presence of *N*-(3-dimethylaminopropyl)-*N′*-ethylcarbodiimide hydrochloride (EDC.HCl). The running buffer was 30 mM borate in water:acetonitrile (9:1). Results were comparable with those in the literature and, in terms of repeatability, accuracy and LoDs, the method was similar to other CZE methods.

Zone electrophoresis, using a miniaturized chip based system (lab on a chip), has been applied to the analysis of 22 inorganic and organic acids in Slovakian wines of independently known composition (Masár *et al.*, 2005a). The chip was poly (methylmethacrylate) (PMMA) of 115 mm length with channels for injection,

separation and waste, and with two integrated platinum conductivity detectors. Careful control of pH (5.6 and 5.9), using Bis-Tris or Bis-Tris/Bis-Tris propane, 2-[*N*-morpholino]ethanesulfonic acid as carrier ion and PVA as EOF supressor and ionic strength, as well as the use of cyclodextrin complexing agents, allowed the resolution of 22 acids (oxalate and fluoride comigrated).

Capillary electrophoresis has also been much used in the determination of phenolic substances in alcoholic drinks and their raw materials. Much of the interest has been inspired by reports of health benefits, particularly with regard to antioxidant action (Chapter 5.8). There are reports on flavan-3-ols and nonflavonoid phenols in white wines (Andrade *et al.*, 2001), nonflavonoid phenols in wine (Dobiášová *et al.*, 2002; Spanilá *et al.*, 2005; Saenz-Navajas *et al.*, 2009), flavonoid phenols in wine (Wang and Huang, 2004), in apple juice and cider (Peng *et al.*, 2005), in grape skins (Priego Capote *et al.*, 2007), anthocyanins (and derivatives) in wine (Saenz-Lopez *et al.*, 2003; Asenstorfer *et al.*, 2003; 2006; Asenstorfer and Jones, 2007; Saenz-Navajas *et al.*, 2009), in grape skins (Priego Capote *et al.*, 2007), wood derived phenolic aldehydes (Panossian *et al.*, 2001) and total phenolic contents of wine (Minussi *et al.*, 2003; Pazourek *et al.*, 2005). Because many phenolic compounds are present in comparatively low concentrations in alcoholic beverages and their raw materials, some kind of preanalysis focusing (e.g. using solvent extraction or solid phase extraction) is generally required.

Nonflavonoid and flavonoid phenols can be well resolved by native CZE (cathodically driven migration, using uncoated fused silica capillaries and applied voltages of *ca.* +20 kV) using sodium tetraborate buffers (pH ~9–10) as running electrolyte (e.g. Andrade *et al.*, 2001; Dobiášová *et al*., 2002; Spanilá *et al.*, 2005), sometimes with added organic solvent, such as 10% methanol (Saenz-Navajas *et al.*, 2009). Generally, the phenols are detected by UV absorption at 305 nm, or if a diode array detector (DAD) at more than one wavelength.

Tyrosol, a number of benzoic acid and hydroxycinnamic acid type phenols and (–)-epicatechin were determined by CZE after solvent extraction from some Portuguese and Spanish white wines of the *V. vinifera* varieties Albariño, Alvarinho and Loureiro (Andrade *et al.*, 2001). The electropherograms were considered to be rather superior to reversed phase HPLC chromatograms of the same samples, having better resolution, better peak shape and shorter experimental time. The variety Loureiro had a greater total amount of these phenols than Alvarinho.

More recently, reactions between individual hydroxycinnamic acids (caffeic, *p*-coumaric and ferulic acids) alone and in the presence of malvidin 3-glucoside in model wine solutions were studied over a period of six months storage using CZE with UV detection (Saenz-Navajas *et al.*, 2009). The running buffer was 50 mM sodium tetraborate buffer solution (pH 9.4) containing 10% methanol (v:v) as modifier and, unusually, the capillary temperature was kept at 10 °C. LC-MS was used to confirm the structures of product compounds detected by CZE. A number of derivatives corresponding to self-condensation products of the hydroxycinnamic acids and cocondensation products of hydroxycinnamic acids and malvidin 3-glucoside were detected and given tentative structures.

Both diasteroisomers of the stilbene phenols *cis*- and *trans*-resveratrol were determined in red and white wines (Dobiášová *et al*., 2002; Spanilá *et al.*, 2005). Solid phase extraction (SPE – see Section 4.2.4) with ODS columns was used to focus the stilbenes prior to analysis by CZE. For both Alsace (Dobiášová *et al*., 2002) and Australian wines (Spanilá *et al.*, 2005), the *tran*s isomer was generally more abundant and total resveratrols were higher in red wines (up to 5.61 mg/l for Alsace Pinot Noir and 6.27 mg/l for New South Wales Cabernet-Shiraz).

Resveratrols were determined in 47 Czech and Australian red and white wines by CZE after preconcentration by SPE (Pazourek *et al.*, 2005). The running buffer was 25 mM sodium tetraborate (pH 9.38) at 25 °C and the applied potential was +20 kV. Mesityl oxide (0.1%) was used as an OEF marker. Detection was by UV absorption at 305 nm. The electropherogram data were used as fingerprints, which were subjected to a chemometric treatment known as artificial neural networks. This allowed the prediction of vine variety and vintage within the limits of the tested wines (eight varieties and three vintages) with greater than 90% success.

Flavonoid phenols (Section 5.8.6), distributed widely throughout the plant kingdom, have been determined by CZE in wine (Andrade *et al.*, 2001; Wang and Huang, 2004), apples and cider (Peng *et al.,* 2005) and grape skins (Priego Capote *et al.*, 2007). Wang and Huang (2004) studied flavones and flavonols in wine using a running buffer of 35 mM borax (pH 8.9) with applied field strength of 240 V/cm on a fused capillary of 70 cm (effective length 45 cm) × 75 μm (≡ 16.8 kV applied voltage). The flavonols quercetin, kaempferol and myristin, determined by UV detection, were the most abundant of nine flavonoid phenols in the wine sample, where CZE percentage recovery and reproducibility (as %RSD) ranges were 90.1–99.8 and 0.43–5.68, respectively.

The chalcone phloridzin, along with chlorogenic acid (a hydroxycinnamic acid derivative), the flavan-3-ol (–)-epicatechin and the flavone myricetin were determined in commercial apple juice and Chinese ciders by CE with amperometric (voltammetric) detection (Peng *et al.*, 2005). The running buffer was 50 mM borate buffer (pH 8.7) and using an applied voltage of 18 kV, the analytes could be separated within 20 min in a 75 cm length capillary, with good accuracy (recoveries 95–98%) and precision (%RSD 1.8–3.6).

All the above studies used either solvent extraction or SPE for preconcentration of sample and most of the CE experiments were run with purely aqueous buffers. In contrast, a superheated ethanol-water extraction (120 °C, 80 bar) procedure followed by centrifugation was used to extract phenolic compounds from pomace grape skins to be determined by CE using an aqueous/organic buffer with both UV and fluorescence detection (Priego Capote *et al.*, 2007). Sodium tetraborate (50 mM) with 10% methanol (pH 8.4) solution was used as background electrolyte with an applied potential of 25 kV to separate 10 polyphenolic compounds (kaempferol, myricetin and quercetin, (+)-catechin, (–)-epicatechin, resveratrol and four anthocyanins) within 10 min. Intraday variability of results ranged from 3.49 to 6.27%. Pomace grape skins are those remaining after fermenting and pressing red wine (Section 2.9.2). They were high in malvidin 3-glucoside, delphinidin 3-glucoside, kaempferol, myricetin, quercetin and resveratrol, but low in other anthocyanins and the flavan-3-ols, those compounds probably having been leached from the skins in the winemaking process.

Anthocyanins in wines have been determined by CZE with UV-visible detection, using sodium tetraborate buffer background electrolyte with 15% methanol at an applied potential of 25 kV (Saenz-Lopez *et al.*, 2003). Reproducibility (%RSD <8%) and accuracy (% recoveries: 94–107%) were comparable with those of solvent gradient HPLC methods, although CZE experimental time was less and there was no need for solvent gradient.

The above research was largely concerned with the phenolic compounds originating from raw materials (e.g. grapes or apples) and perhaps some produced from these during fermentation and storage. Phenolic compounds that originate from wood make important contributions to the mouthfeel of many alcoholic drinks. Wood maturation derived aromatic phenolic aldehydes, coniferaldehyde, sinapaldehyde, syringaldehyde and vanillin, have been determined in brandy and wine by CZE using an uncoated silica capillary, 50 mM borate buffer (pH 9.3) and diode array detection (DAD) at 348, 362, 404 and 422 nm (Panossian *et al.*, 2001). Detection limits were 0.1425–0.275 μg/l.

Preservatives play an important role in some alcoholic drinks, notably wine, but because of potential health problems, their use is strictly regulated (Section 5.10.2) and hence regular determination is necessary. Sulfites in wine have been determined by CZE (Masár *et al.*, 2005b) and sorbate in wine has likewise been analyzed by CZE (Dobiášová *et al.*, 2002; Huang *et al.*, 2005). Sorbic acid has been determined in wine by CZE directly, without a pretreatment step, with a good precision and a detection limit of 0.03 mg/l (Dobiášová *et al*., 2002). Alsace white wines were found to have sorbic acid levels of 7.4–185.8 mg/l.

In-sample hydrogen peroxide oxidation of total sulfite in wine at high pH (∼10) to sulfate with the separation and quantification of the latter anion by zone electrophoresis (ZE) on line coupled with isotachophoresis (ITP) on a column coupling chip, with integrated conductivity detection (Masár *et al.*, 2005b). The ITP-ZE separations were carried out in a hydrodynamically closed separation compartment of the chip at pH 3.5–4.0

in an electrolyte consisting of chloride or citrate, β-alanine, Bis-Tris propane buffer with suppressed electroosmotic flow due to added methyl hydroxyethylcellulose. ITP extensively eliminated the matrix, allowing high accuracy (recovery: 99–100%) and a detection limit of 90 μg /l.

Again, inspired largely by possible health hazards and existing regulations, biogenic amines in alcoholic beverages have received some attention from CE analysts (Jayarajah *et al.*, 2007; Cortacero-Ramírez *et al.*, 2007).

A portable microfabricated capillary electrophoresis instrument (lab on a chip) was used for the determination of biogenic amines, particularly histamine and tyramine, in a variety of wines and sake (Jayarajah *et al.*, 2007). The analytes were determined with fluorescamine labels on their primary amine groups and analyzed on a microfabricated glass CE device containing 21.4 cm long separation channels. Samples were injected by applying –2.5 kV at the waste reservoir and earthing the sample and cathode reservoirs, while floating the anode during the injection period (10 s). The sample and waste reservoirs were then held at –2.65 kV, the anode at 0 V, and the cathode at –15 kV during CE runs. Tyramine was found mainly in red wines (<1–3.4 mg/l), which had histamine levels of 1.8–19 mg/l. The highest levels of histamine (20–40 mg/l) were found in sake. Analysis of a wine undergoing a typical winemaking process indicated that the biogenic amines were formed during both alcoholic and malolactic fermentation.

Conventional CZE was used for the simultaneous determination of 10 biogenic amines in beer samples, using laser induced fluorescence detection (Cortacero-Ramírez *et al.*, 2007). Sample amines were first derivatized with fluorescein isothiocyanate (FITC), filtered and then subjected to CZE using an uncoated capillary with an applied potential of 30 kV and 50 mM sodium borate and 20% acetone electrolyte at pH 9.3. It was possible to analyze biogenic amines in brewing process samples and in beer samples in less than 30 min, obtaining detection limits in the range 0.3–11.9 μg/l.

CE has been used in the analysis of a number of other components of alcoholic beverages, such as the fungal contaminant ochratoxin A (González-Peñas *et al.*, 2006), and pesticide residues (Rodríguez *et al.*, 2003).

The presence of ochratoxin A in wine due to contamination of grapes (mainly by *Aspergillus spp.*, see Section 5.11.4) is a problem and since the EU has established a maximum level of tolerance in wine of 2 ng/ml, its regular determination in wine is important. Ochratoxin A (extracted from samples in chloroform) was determined in a number of fortified wines by CZE using fused silica capillary with a 'bubble cell' of 48.5 cm total length (40 cm effective length) and 50 μm i.d. at 10 °C (González-Peñas *et al.*, 2006). The electrolyte was sodium tetraborate (10 mM) (pH 9.3) and the applied potential was 20 kV. UV detection was used and fixed at 380 nm. Although the method compared well with an established HPLC-fluorescence detection method in terms of accuracy and precision, it was considered unsuitable for routine analysis of real samples because of its high detection limit; a situation that could be rectified by using a fluorescence detector.

CZE offers several advantages over the most popular chromatographic method of wine analysis (HPLC), amongst which are greater speed, higher resolution and lower solvent usage. However, two limitations of CZE (in its native form, as described above) are its inability to resolve uncharged analytes and its inability to resolve ionic analytes of similar electrophoretic mobilities. These two limitations can be eliminated by the introduction of a second mode of separation – partition – either by the addition of a small amount of surfactant (which forms micelles) or by using a capillary that is packed with a typical HPLC reversed phase. The first of these modifications is known as micellar electrokinetic chromatography (MEKC), whereas the second is called capillary electrochromatography (CEC).

Micellar Electrokinetic Capillary Chromatography (MECC OR MEKC)

MEKC is a mode of electrokinetic chromatography in which a surfactant, such as sodium dodecylsulfate (SDS), is added (at concentrations that favor micelle formation) to the electrolyte solution. The separation

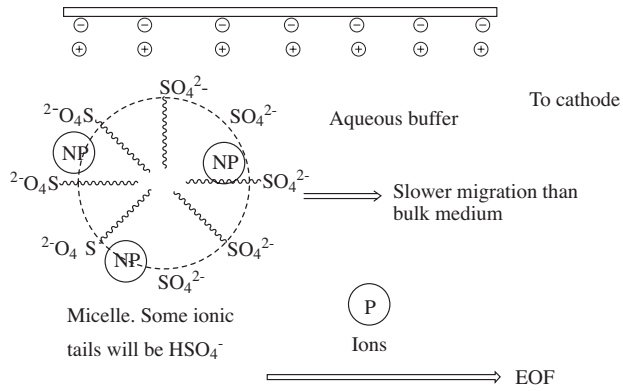

Figure 4.6.3 *Simplified mechanism of separation of neutral analytes by MEKC. NP = nonpolar analyte, P = polar analyte. Ions differentially interact with micelles*

principle of MEKC is based on a differential partition of both ionic and particularly neutral analytes between the micelles and the solvent as the micelles migrate toward the cathode with the electro-osmotic flow – more slowly than the bulk of liquid (Figure 4.6.3). The micelles thus constitute a pseudo or moving stationary phase: hydrophobic (nonpolar) neutral molecules are closely associated with the hydrophobic interiors of the micelles and migrate with the micelles, whereas hydrophilic (polar) neutral molecules associate only weakly the micelles and migrate more quickly, at about the same rate as the bulk flow.

Capillary Electrochromatography (CEC)

This technique is essentially a hybrid of CE and HPLC; it can be regarded as capillary HPLC in which flow of mobile phase is caused by electro-osmotic drive, rather than by pump action (Figure 4.6.4). The stationary phases, mostly particulate silica based reversed phases of the C_{18} and C_8 type, are similar to those of HPLC. It has most of the advantages of reversed phase HPLC, but with higher efficiencies, because of the longer columns (up to 100 cm) with smaller particles (down to 0.5 μm). Efficiencies of 700 000 or more plates per meter are not uncommon. Resolution may also be improved, because of the flat 'plug' flow through the stationary phase produced by the EOF, as opposed to parabolic flow produced by pump action. Finally, because no pump is used, there is no back pressure problem, and very small stationary phase particles can be used. On the negative side, packing of capillaries with stationary phase material requires much skill and consequently reproducibility of CEC column performance has been problematic.

Five common food preservatives (benzoic acid, butyl paraben, methyl paraben, propyl paraben and sorbic acid) in foodstuffs, including Taiwanese wine, were analyzed by CEC using a methacrylate ester based monolithic capillary, rather than a particulate silica based column (Huang *et al.*, 2004). Optimal separation of the five preservatives was obtained within 7.0 min with a mobile phase composed of aqueous phosphate buffer: acetonitrile (35:65 v:v) at pH 3.0.

4.6.2 Flow Injection Techniques

Flow injection analysis (FIA) is basically an automated sample and reagent handling technique. It was developed in the 1970s to cut down the manual handling of solutions, to minimize the amount of materials

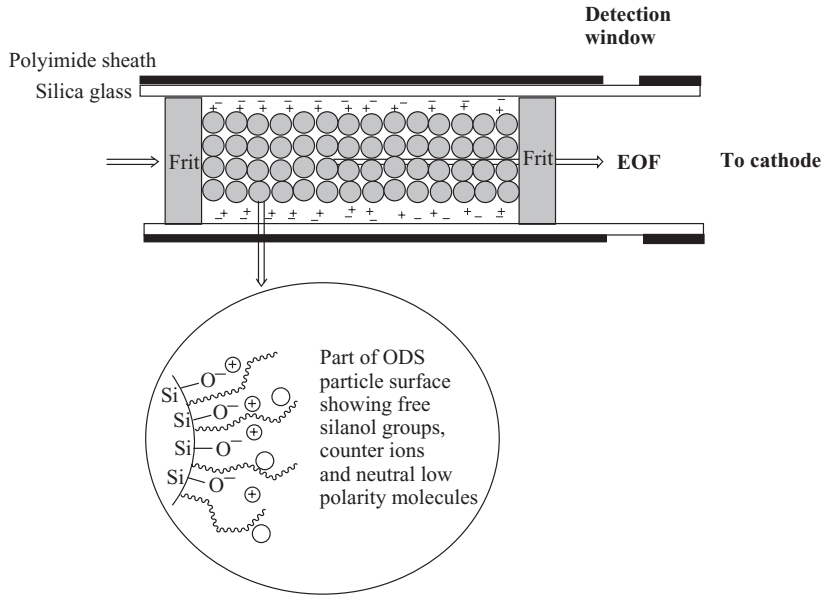

Figure 4.6.4 *Principle of capillary electrochromatograhy. Not drawn to scale*

handled (and therefore the amount of waste) and to increase sample throughput. It was originally devised for serial assay of large numbers of samples, as in quality control, but since the method allows automated handling of sample and reagent solutions under strictly controlled reaction conditions, its versatility made it suitable for a wide range of situations. Nowadays, FIA has been applied to the study of live cells, monitoring chemical processes in real time, biotechnology, immunoassays, including antibody/antigen reactions, and the determination of a wide range of components in alcoholic beverages and other foodstuffs.

The original technique (Figure 4.6.5) is still probably the most widely utilized. In its simplest form, the sample is injected into a flowing carrier stream of reagent, although this can be performed the other way around (inverse flow injection analysis). As the injected zone moves downstream, the sample solution disperses into the reagent steam, where reaction occurs and the product is formed, which now has a desired physical parameter for detection purposes (e.g. an UV-visible chromophore, a fluorophore or a redox group). A flow through detector placed downstream records the desired physical parameter, such as UV-visible absorbance, fluorescence absorbance or electrochemical characteristics.

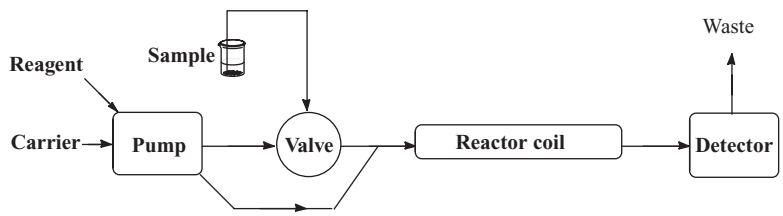

Figure 4.6.5 *Schematic diagram of basic flow injection set-up. Filters and degassing units can be placed online and an additional reagent and reactor coil can be used*

A standard FIA system usually consists of a high quality multichannel peristaltic pump, an autosampler, an injection valve, a coiled reactor and a detector such as a photometric flow cell (Figure 4.6.5). Additional components may include a flow through heater to increase the speed of chemical reactions, columns for sample reduction, degassing units and filters.

The typical FIA flow rate is 1 ml/min, typical sample volume consumption is 100 μl per sample, and typical sampling frequency is two samples per minute. With regard to precision, FIA determinations are usually comparable with other techniques, such as chromatographic methods, typically having reproducibilities (expressed as %RSD) of a few percent.

A summary of FIA methods used in the assay of alcoholic beverage components is given in Table 4.6.1. In essence, FIA methods are superautomated versions of manual or semi-automatic methods for specific analytes (such as ammonia, ethanol, glucose, glycerol, metal ions, sulfite, tartaric acid and urea) or families of analytes (such as nitrogen compounds, polyphenols and reducing sugars). Detection usually requires reaction of analyte(s) with a reagent that confers properties to the analyte(s) suitable for a specific detector, such as UV-visible, fluorometric, or electrochemical properties. Furthermore, FIA has been instrumental in the development of miniaturized electrochemical sensor and biosensor devices used for field work and routine quality control. Some FIA methods require more than one reagent, whereas a few involve direct detection, such as in the assay of metal ions in wine (Lapa *et al.*, 1996; Segura *et al.*, 1999; Wangkarn and Pergantis, 1999; Chuachad and Tyson, 2005; Elçi *et al.*, 2009) and beer (Fernandes and Rangel, 1997; Segura *et al.*, 1999; Ampana *et al.*, 2002), determination of total soluble solids (density) of wines by refractive index measurement (Mataix and Luque de Castro, 2001a), the assay of ethanol in wine by density measurement (González-Rodríguez *et al.*, 2003) and the assay of total phenolic content by the 280 nm absorbance method (Section 4.4.3) (Mataix and Luque de Castro, 2001b).

Lapa *et al.* (1996) used flow injection zone sampling technique to determine Ca, K, Mg and Na in wines by flame photometry and flame atomic absorption spectroscopy, whereas the same elements in beer were determined in beer by Fernandes and Rangel (1997) using flame atomic emission and atomic absorption spectroscopy. Computer operated rotatory valves allowed a wide range of reproducible dilutions and also permitted the most appropriate dilution level according to the analyte concentration for each sample during the same analytical run (Lapa *et al.*, 1996). Thus, identical dilutions for samples with different concentrations of analytes were avoided.

Flow injection has been combined with hydride generation atomic absorption spectroscopy (see Section 4.4.4) for the direct determination of arsenic in beers and wines, without sample pretreatment (Segura *et al.*, 1999), and combination of FI with inductively coupled plasma mass spectrometry (ICPMS – see Section 4.4.5) was used to determine ultratrace levels of arsenic in wine (Wangkarn and Pergantis, 1999).

More recently, cadmium in wine, and lead in wine and rum were determined by FI using an electrothermal AAS detector with chemical vapor generation from a BH_4 anion exchanger (with in atomizer trapping) and flame quartz atomizer AAS detector with hydride generation, respectively (Chuachad and Tyson, 2005; Elçi *et al.*, 2009). Lead hydride (PbH_4) was generated using potassium ferricyanide as oxidant and sodium tetrahydroborate ($NaBH_4$) as reductant Elçi *et al.*, 2009). For lead in wines (diluted prior to analysis) and rum (assayed neat), the detection limit was 0.16 μg/l, recoveries were in the range 95–110% and reproducibility (as %RSD) ranged from 6.1% (wine) to 12.0% (rum).

In the determination of total soluble solids (Mataix and Luque de Castro, 2001b), the sample/carrier concentration gradient produced on injection created a refractive index gradient, which was detected by a UV-visible spectrophotometric detector. The magnitude of this gradient was measured by allowing a nonabsorbed light beam to pass through the detector volume. Using a simple manifold, the total phenolic index (measured by absorbance at 280 nm – see Section 4.4.3) could be determined sequentially to the total soluble solids assay.

Table 4.6.1 *Examples of the use of flow injection analysis in the determination of alcoholic beverage components*

Analyte(s)	Beverage	Detector/sensor	Comments/references
Density	Wine	Refractive index	Mataix and Luque de Castro (2001a); total soluble solids.
Metal ions And other elements	Wine	AAS/flame photometry	Lapa *et al.* (1996); Ca, Mg, Na, K.
	Beer	FAES/FAAS or spectrophotometric	Fernandes *et al.* (1997); Fernandes *et al.* (2000); Ampan *et al.* (2002).
	Wine	Electrothermal-AAS	Chuachad and Tyson (2005); Cd.
	Wine/rum	HG-AAS	Elçi *et al.* (2009); Pb.
Ethanol	Wine	Density detector	González-Rodríguez *et al.* (2003).
	Wine	UV-visible	Segundo and Rangel (2002). Enzymatic.
	Wine	UV-visible	Borges *et al.* (2006).
Glucose	Wine	Electrochemical	Schachl *et al.* (2002). Biosensor.
	Wine	Electrochemical	Ulasova *et al.* (2003); residual glucose.
Reducing and other sugars	Wine	UV-visible	Oliveira *et al.* (2001).
	Wine	Electrochemical	Esti *et al.* (2003). Amperometric biosensor.
	Beer	ESI-MS	Mauri *et al.* (2002).
Glycerol	Wine	UV-visible	Segundo and Rangel (2002). Enzymatic.
Polyphenols	Wine	UV-visible	Mataix and Luque de Castro (2001b).
	Red wine	UV-visible	González-Rodríguez *et al.* (2002a). TPI and TAI
	Wine	Chemiluminescence	Costin *et al.* (2003).
	Wine	UV-visible	Schoonen and Sales (2002).
Ascorbate Sulphite and other preservatives	Beer	UV-visible	Luque-Peréz *et al.* (2000).
	Wine	UV-visible	Segundo *et al.* (2000).
	Wine	Electrochemical	Alipázaga *et al.* (2002).
	Wine	Electrochemical	Corbo and Bertotti (2002).
	Wine	UV-visible	Tzanavaras *et al.* (2009); total sulphite.
	Wine	UV-visible	Rivero-Molina *et al.* (1999); sorbic acid.
Nitrogen compounds	Wine	UV-visible	González-Rodríguez *et al.* (2002b); ammonia, involving pervaporation.
	Must and wine	UV-visible	González-Rodríguez *et al.* (2002c); readily assimable nitrogen.
	Wine	Chemiluminescence	Costin *et al.* (2004); Proline
	Wine	CE/ESI-MS	Santos *et al.* (2004); biogenic amines.
Tartaric acid	Wine	UV-visible	Silva *et al.* (2002).
Multiple	Wine	Electrochemical	Esti *et al.* (2003). Fermentation monitor.

González-Rodríguez *et al.* (2003) used pervaporation for separation of ethanol from the sample and a vibrating tube type detector (Section 4.6.3). Pervaporation is a nonchromatographic membrane separation technique that selectively separates volatile components of liquid mixture by partial vaporization through a nonporous polymeric membrane (Section 2.13.3); it has been used in many FI methods for the determination of more volatile components, such as ammonia, SO_2 and ethanol. Good correlation was achieved between

the FIA method and a reference distillation method, the latter being much more labor intensive and somewhat less precise.

The majority of flow injection (FI) techniques use at least one reagent to convert the analyte to an easily detectable product. In many cases, the reagent type, reaction conditions and method of determination are similar to those used in nonautomated reference methods, but FI has inspired a large number of modified or new methods, particularly with regard to the use of electrochemical sensors (Section 4.5.3).

UV-visible detection of derivatized or oxido reduced analytes is frequently used in FIA. Total phenolic content/index (TPC/TPI) of red and white wines has been determined by FI versions of the Folin–Ciocalteu method (Section 4.4.3) (Celeste *et al.*, 1992; Mataix and Luque de Castro, 2001b). Alternatively, TPC of wines has been determined using the colored complex formed between phenols and 4-aminoantipyrine in the presence of oxidizing agents, such as ferricyanide, peroxodisulfate or periodate (Schoonen and Sales, 2002). Interferences from sugars, tartaric acid and others suffered by the Folin–Ciocalteu method, were not observed for this method, which was precise (RSD $< 3.9\%$) and accurate (relative error, by the Folin–Ciocalteu method $<5.1\%$).

Total anthocyanin index was simultaneously determined with the total phenolic index of red wines using an FI version of the SO_2 bleach method (absorbance at 520 nm) and 'I_{280}' method (absorbance at 280 nm) (Section 4.4.3), respectively (González-Rodríguez *et al.*, 2002a). The valve in the injection mode allowed monitoring absorbances at 520 and 280 nm. After this, a switching valve supplied potassium metabisulfite to the stream and a new sample aliquot was injected. The absorbance at 520 nm was now lower because of bleaching of free anthocyanins. The difference of absorbance between the two measurements at 520 nm gave the free anthocyanin index value.

The determination of ethanol, glycerol and sugars in alcoholic beverages are of fundamental importance, particularly in the case of ethanol and sugars, since legislation imposes certain limitations on the content of these two components, depending on beverage type, area of production and country. Also the extent of tax or duty is dependant on the ethanol content, usually expressed as a percentage (v:v).

Ethanol in beverages can be determined by flow injection analysis with electrochemical detectors, provided that interferences such as carboxylic acids are removed beforehand. Such a method, using an oxidized nickel wire was used to analyze the sample eluent of from a strong anion exchanger (Chen *et al.*, 1997). The optimal conditions for the detection of ethanol were an applied potential of $+0.60$ V (versus Ag/AgC1) in a carrier of 100 mM sodium hydroxide solution. The recoveries of ethanol from wines spiked with standards ranged from 101 to 103 % with an LoD of 10^{-5} M.

Ethanol has been determined in Portuguese wines and fortified wines by combining FI with an immobilized alcohol dehydrogenase reactor and NAD^+ cofactor. The ethanol content was calculated from the absorbance of NADH produced by the enzyme reaction, but ethanol was first separated from the sample medium by gas diffusion, thus maximizing dilution and minimizing matrix intereference (Rangel and Toth, 1999). More recently, ethanol, glycerol and reducing sugars have all been determined in wine using a flow injection version of the appropriate enzymatic essays (Segundo and Rangel, 2002). Immobilized ethanol and glycerol dehydrogenase enzymes, in the presence of NAD^+, were used as the reagents, with determination of NADH at 340 nm after oxidation of the analytes. Relative deviations between the FI method and reference methods were $<3.7\%$ for ethanol and $<3.4\%$ for glycerol, but as always the FIA, the analysis rate was far higher at 45 determinations per hour.

An FI method that uses neither immobilized enzymes nor chromogenic reagents has been developed for the assay of ethanol in wine (Borges *et al.*, 2006). This procedure is based on a falling drop system that is supplied by employing a flow injection manifold. The detection system comprised an infrared LED and a phototransistor. The sample drop grew between these two devices, thus causing a decrease in the intensity of the beam of radiation coming from the LED. The size of the drop was related to the ethanol content of the sample and hence this could be related to the intensity of radiation reaching the phototransistor.

Reducing sugars in wines were determined by oxidation of glucose and fructose with potassium ferricyanide in alkaline solution, using microwaves to increase dispersion and reduce hydrodynamic pressure, by observing the reduction of the absorbance at 420 nm due to the reduction of ferricyanide (Oliveira *et al.*, 2001). Good precision (%RSD = 1.9), good accuracy (% recovery in the range 99.2–104.6) and good agreement with a reference method, with a sampling rate of 54 per hour, were obtained with this method.

Certain oligosaccharides in beer (α-glucans or dextrins) (Section 2.6.2) make important contributions to organoleptic character and hence their analysis is of considerable interest. Oligosaccharides in beer have been determined by a flow injection procedure linked to an electrospray ionization-mass spectrometer (Mauri *et al.*, 2002). The method allowed characterization and quantification of six maltooligosacchirides (up to maltoheptaose) from 1 μl injections of 1000-fold diluted beer samples, thus eliminating matrix effects.

Urea has been shown to be a major precursor of the potentially carcinogenic ethyl carbamate (EC) in alcoholic drinks and hence its assay is of importance. UV-visible detection has also been used in the determination of nitrogen compounds, tartaric acid and sulfites in alcoholic beverages by FIA. A flow injection–pervaporation method for monitoring urea and ammonia in must and wine has been developed (González-Rodríguez *et al.*, 2002b). The method was based on separation of the ammonia from the sample matrix by pervaporation using a PTFE membrane followed by reaction with salicylate, hypochlorite and nitroprusside to form a diazonium salt with maximum absorption at 647 nm. Urea was converted to ammonia by the enzyme urease prior to pervaporation and analysis. The method had double the sampling rate of a reference method, with adequate reproducibility (1.34 versus 0.21 mg/l) and limit of detection (0.90 versus 0.15 mg/l) for urea determination. Readily assimilable nitrogen (RAN) due to ammonia, ammonium and amines in wines was determined by a very different FI method (González-Rodríguez *et al.*, 2002c). Here, the reaction of analyte amine functions with formaldehyde reagent caused a change in medium pH, which was monitored by the corresponding change in absorbance of bromothymol blue indicator (at 616 nm) present in the reagent stream. The detection limit was 10 mg/l and the RAN content of 120 samples of must and wines was found to be 25–35 mg/l.

A multisyringe FI system for the determination of sulfur dioxide in wines, using UV-visible detection, was developed by Segundo *et al.* (2000). The method is based on the *p*-rosaniline method: reaction of SO_2 with formaldehyde and *p*-rosaniline. The manifold included a gas diffusion unit with a hydrophobic membrane (0.22 μm pore size) in order to prevent the color interference of red wines with the spectrophotometric measurement. The method was successfully applied to the determination of free and total SO_2 in wines. A sampling rate of 25–30 samples per hour was possible with good repeatability for 10 consecutive injections of wine samples (%RSD <3.2). Reaction of SO_2 (after its diffusion through a teflon membrane into an alkaline stream at pH 8) with malachite green and detection of the product at 620 nm has also been used to determine the sulfite content of white wine (Melo *et al.*, 2003).

Tartaric acid is generally the most abundant acid of grape must and wine and as it makes an important contribution to wine quality, it needs frequent determination. A flow injection method using a cellulose acetate dialysis unit was developed to analyze tartaric acid in wine by reaction with vanadate in acetate buffer at pH 5 (Silva and Álvares-Ribeira, 2002). Tartrate was included in the reagent stream to reduce background noise, and the UV-visible detector was set at 490 nm. The method was compared with the modified Rebelein method (Section 4.4.3), which uses metavanadate rather than vanadate. Agreement between the two methods was good, with the FI method giving tartaric acid concentrations in 17 Portuguese table wines in the range 0.37–3.19 g/l and in 13 Port wines in the range 0.72–1.89 g/l. The factorial designs and simplex chemometric techniques were used to optimize the operating parameters of the method.

Electrochemical sensors of a wide variety of types have been extensively used in FIA for more easily oxidizable components of alcoholic beverages, such as glucose, reducing sugars and sulfites. Ulasova *et al.* (2003) used a Prussian blue type biosensor (Section 4.5.3) for the determination of residual glucose in wines

and Schachl *et al.* (2002) used a carbon paste electrode modified with glucose oxidase as the biocomponent and manganese dioxide as the mediator working at 0.48 V versus Ag/AgCl reference electrode. The sensor could be operated for 12 h without signal loss under FI conditions: flow rate 0.2 ml/min of 0.2 M phosphate buffer (pH = 7.5) at 21 °C. Both methods were used to assay the glucose content of white wines.

Antioxidant and antibacterial agents, such as sulfite and sorbic acid respectively (see Chapter 2.5), are very useful, but highly regulated additives in the alcoholic drinks industry and hence need regular assessment. FIA involving a variety of electrochemical detection methods have been widely applied to the assay of sulfites. Most of these methods include a membrane system for diffusion of SO_2 from the sample and use either potentiometric (Araujo *et al.*, 1998) or amperometric detection (Azevedo *et al.*, 1999; Cardwell and Christophersen, 2000). Araujo *et al.*, (1998) used a homogeneous crystalline tubular electrode as the potentiometric detector for SO_2 in wine, whereas Azevedo *et al.* (1999) used a glassy carbon electrode modified with electrostatically assembled films of tetraruthenated porphyrin working at +0.90 V (versus Ag/AgCl (saturated KCl)). In contrast, a platinum electrode, set at +0.90 V (versus Ag/AgCl), was used by Cardwell and Christophersen (2000) to determine SO_2 in wine, while ascorbic acid (sometimes used as an additive in conjunction with sulfite) was assayed simultaneously at a glass carbon electrode, working at +0.42 V (versus Ag/AgCl).

A sensor consisting of a copper electrode working at 0.60 V (versus Ag/AgCl (saturated NaCl) has been developed to determine sulfite in wine in an alkaline (1 M NaOH) medium (Corbo and Bertotti, 2002). The flow injection manifold included a PTFE membrane to extract sulfite from the sample as SO_2. Changing the pH of the donor stream allowed determination of ethanol (which is electroactive and permeates the membrane) only, then ethanol plus sulfite were assayed and the sulfite concentration was determined by difference. Agreement between the FI method and a recommended method for sulfite assay was excellent.

Another indirect FI method for the determination of sulfite in wine is based on the amperometric measurement (E = 0.1 V) of Cu(III) chemically generated by the sulfite induced oxidation of Cu(II)/tetraglycine by dissolved oxygen (Alipazaga *et al.* 2002). SO_2, displaced by a stream of argon through the acidified sample, was collected in water and injected into the acceptor stream. The detection limit of the method was 1 μM and the precision (as %RSD) for the determination (10 μM) was 1.4% (n = 20). The results compared favorably with those from a standard iodometric method.

Sequential injection analysis (SIA) is a recent development of FIA. The apparatus usually consists of a single channel high precision bidirectional pump, a holding coil, a multiposition valve and a flow through detector. The system is initially filled with a carrier stream into which a zone of sample and a zone of reagent(s) are sequentially injected into a holding coil. These zones soon become overlapped and flow reversals and flow acceleration promote mixing and hence reaction between sample and reagent. The multiposition valve is then switched to the detector position, and the flow direction is reversed, pushing the sample/reagent zones through the flow cell. SIA only uses a small fraction of sample and reagent(s) compared to FIA, and therefore produces less waste. Typical reagent consumption is only around 20–30 μl per assay. This often makes SIA more suitable for remote site and online process monitoring. On the down side, SIA methods generally have lower sampling frequencies than FIA methods. Segundo and Rangel (2002) partially resolved this problem by incorporating an additional pump into their SI system for the analysis of ethanol and glycerol in wine, thus enhancing the flow rate and reducing analysis time by 30%.

All the above examples involve the determination of one or two analytes (sequentially or simultaneously), using a single detector or sensor. An array of electrochemical biosensors has been used to monitor wine fermentation in industrial-scale wineries by a flow injection method (Esti *et al.*, 2003). The electrodes were platinum based, coated with enzymes for the determination of ethanol, fructose, glucose and glycerol. Before analysis, the biosensors were validated on musts and wines using spectrophotometric methods.

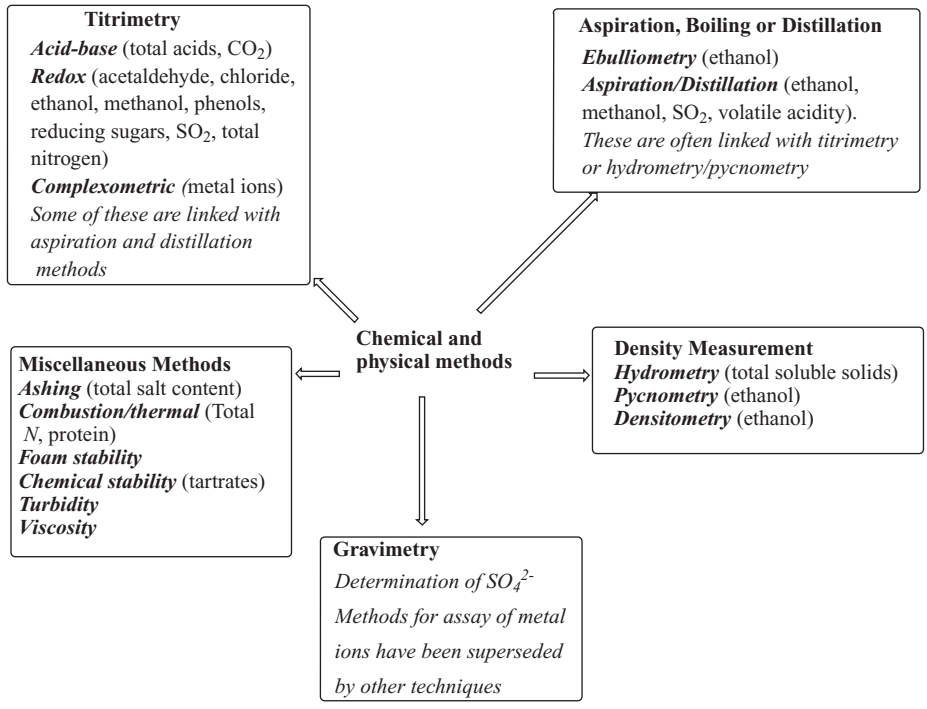

Figure 4.6.6 *Summary of chemical and physical methods*

4.6.3 Chemical and Physical Methods

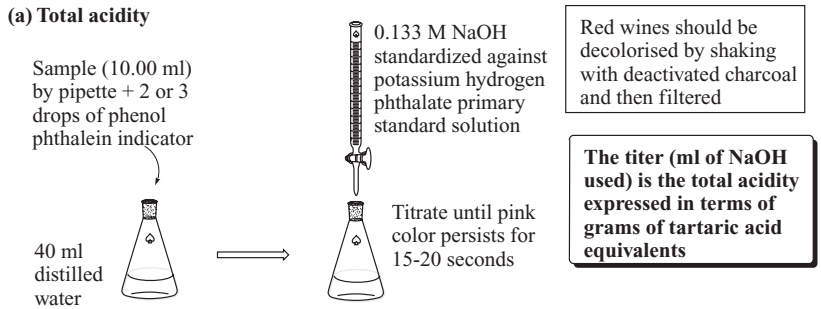
For the purposes of this section, chemical methods are defined as those that involve the use of chemical reactions that are monitored by eye and do not involve the use of spectrometers, chromatographic or electrochemical equipment. Likewise, physical methods are defined here as those that involve the measurement of physical parameters, without the use of such instruments. Many of these methods are still in routine use and some are standard reference procedures, although many others have been replaced by instrumental and/or automated methods. This account is not intended to be exhaustive, rather it is meant to be a summary of the more important or more widely used chemical and physical methods, as outlined in Figure 4.6.6.

Volumetric and Gravimetric Methods

Titrations and gravimetric methods were once much used in the determination of a range of components in alcoholic drinks. Some titrimetric methods are still used today, but gravimetric procedures have been replaced by methods that are quicker, more reliable, more sensitive and more robust.

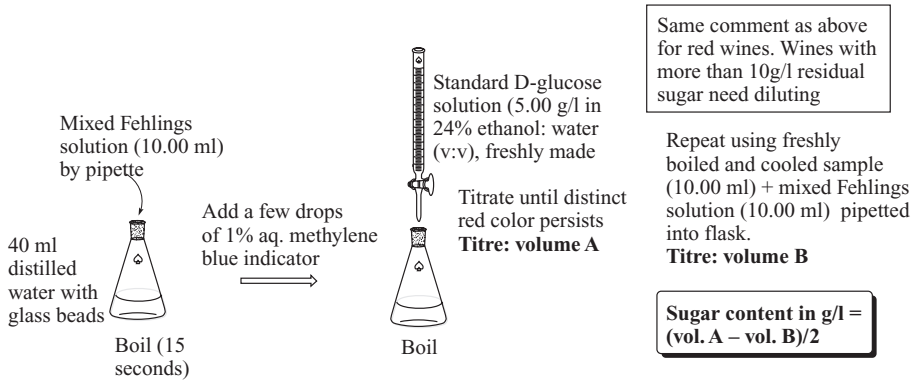
Acid–base titrations using chromogenic indicators are still in use for the determination of total acidity, but even here, in larger wineries or breweries, automated pH titrations (Section 4.5.1) or automated flow injection spectrophotometric techniques (Gaiao *et al.*, 1999) are often preferred. For the smaller winery, the procedure described by Jackson and Schuster (1981) is convenient (Figure 4.6.7(a)).

The majority of titrimetric procedures still used in alcoholic beverage analysis are of the redox type. Residual reducing sugars in drinks can be assayed using Fehlings solution. Although there are many versions



(b) Sugar levels below 2.2 ^{o}Brix (1 ^{o}Baume): Lane and Eynon method

Fehlings solution A [$CuSO_4.7H_2O$ (69.2 g/l)]; Fehlings solution B [sodium potassium tartrate (346 g/l) and NaOH (100g/l)]. Mix 1:1 immediately before use.



(c) Total and free sulfur dioxide content: Ripper method

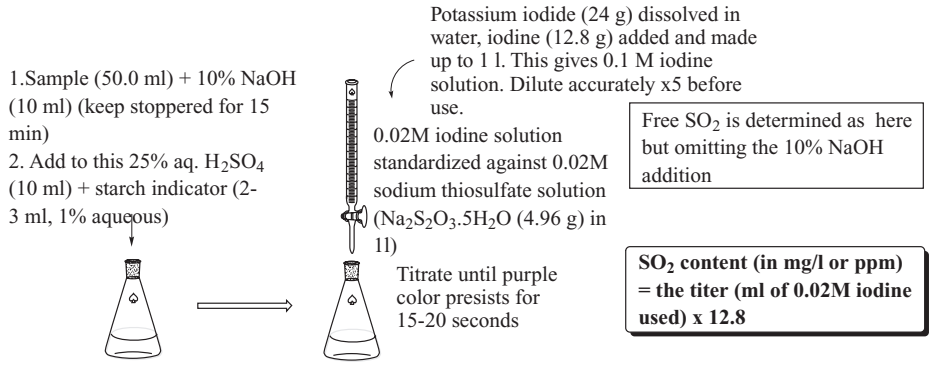


Figure 4.6.7 *Some important convenient titration procedures, suitable for a small winery*

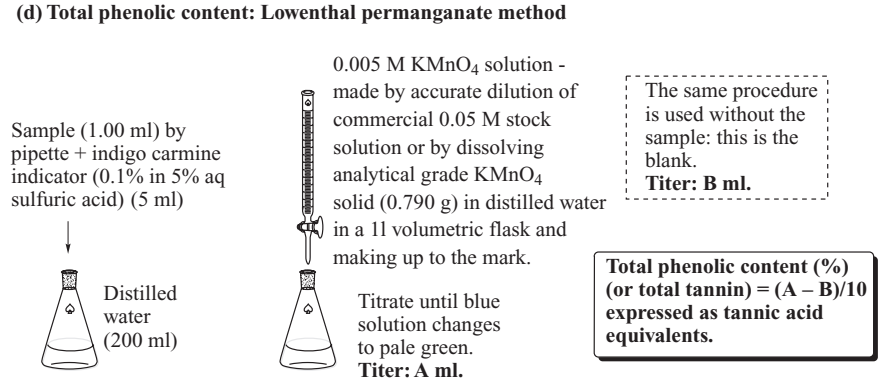

Figure 4.6.7 *(Continued)*

based on this solution (Amerine and Ough, 1980a), they all involve the reduction of blue Cu(II) to red-brown Cu_2O and the Lane and Eynon method is probably the best known (Jackson and Schuster, 1981). For a small winery or brewery, a summary of the Lane and Eynon procedure is given in Figure 4.6.7(b).

The diastatic power of malt (its ability to hydrolyze starch to sugars) can be measured by use of titrations involving Fehlings solution or a modification of it made by Soxhlet (JECFA, 1992). It is often expressed in units of degrees Lintner, defined as follows (JECFA, 1992): 'a malt has a diastatic power of 100 °Lintner if 0.1 ml of a clear 5% infusion of malt, acting on 100 ml of a 2% starch solution at 20 °C for 1 hour, produces sufficient reducing sugars to reduce completely 5 ml of Fehling's solution.' European brewers often use Windisch–Kolbach units (°WK) rather than °Lintner units (°L), the two being related by Equation 4.6.3. See also Section 4.4.3 for colorimetric methods for the determination of overall diastatic power and the activity of individual amylolytic enzymes.

$$^{\circ}\mathrm{L} = \frac{^{\circ}\mathrm{WK} + 16}{3.5} \tag{4.6.3}$$

In the JECFA procedure, which refers to standard procedures of the American Society of Brewing Chemists (ASBC), the Soxhlet solution is standardized using a solution of pure sucrose of accurately known concentration. A filtered malt infusion (prepared in 0.5% sodium chloride solution), after dilution with sodium chloride solution, is allowed to saccharify a buffered starch solution for 30 min, after which time sodium hydroxide solution is added to stop the diastasis. A blank is prepared in the same way, but adding the sodium hydroxide to the diluted malt infusion before the adding the starch solution. The saccharified starch solution (in the burette) is titrated against the gently boiling soxhlet solution, adding methylene blue late in the titration to determine the end point (blue to lavender). An identical procedure is performed on the blank. The diastatic power determined by this method is not strictly the Lintner value, because of the 0.5% NaCl solution, rather than water, used for extraction of diastase.

The official methods of the Institute and Brewing and Distilling and the American Society of Brewing Chemists use a procedure that gives results in Lintner units, whereas the European Brewery Convention (EBC) has a somewhat different procedure that gives results expressed as Windisch–Kolbach units, as mentioned above. Yet other procedures exist (particularly involving other malted cereals, such as sorghum), which involve other units – see EtokAkpan (2004) for a comparison of the IoB/ASBC, EBC methods for malted

barley and the South African Bureau of Standards (SABS) method for malted sorghum (this gives diastatic activity as sorghum diastatic units, SDU).

The grain bill of a beer mash (Section 2.6.2) should have a diastatic power of at least 40 °Lintner to ensure efficient conversion of starch to sugars in the mash; most pale barley malts have a diastatic power up to 160 °Lintner.

Total and free sulfur dioxide, mostly arising from the use of some form of sulfite as a preservative (Section 2.5.2), can be determined by a number of iodometric procedures (Amerine and Ough, 1980b), of which the Ripper method is probably the best known (Jackson and Schuster, 1981). See Figure 4.6.7(c) for a summary of this method, suitable for a small brewery or winery. The Ripper method suffers from interferences due to reactions between iodine with aldehydes, phenols and sugars and the iodine solution needs to be freshly prepared. More reproducible results are obtained using aspiration (aeration) methods, discussed later (Figure 4.6.10), or by an iodate titrimetric method (Amerine and Ough, 1980b), but for routine analysis, particularly of dry white wines, the Ripper method is satisfactory.

Ethanol, after a suitable distillation procedure (Figure 4.6.9 – see later), can be determined by oxidation with excess acidified standard dichromate, the unreacted dichromate being titrated against iodide, which produces iodine that is then titrated with standard thiosulfate solution (Amerine and Ough, 1980c). Acetaldehyde can be assayed using a similar distillation apparatus (Figure 4.6.9), but distilling the sample (containing less than 30 mg of acetaldehyde) from saturated sodium borate solution (pH $\sim$ 8) into a solution of potassium metabisulfite, with which it forms the bisulfite addition compound (Amerine and Ough, 1980c). The distillate is then acidified and titrated against 0.1 M iodine, using starch indicator. This removes excess bisulfite. Sodium borate solution is then added and the liberated bisulfite is titrated against 0.02 M iodine solution.

The chloride ion content of alcoholic drinks or water is of interest because of legal restrictions in the EU ($<$152 mg/l) on chloride levels in wine and because of beneficial influences of low to moderate levels in brewing water. Chloride is nowadays assayed mostly by ion chromatography (Section 4.3.3), capillary electrophoresis (Section 4.6.1) or by electrochemical methods (Section 4.5.1), but can be determined volumetrically by precipitation of silver chloride in the presence of ferric nitrate solution and titration of the excess silver nitrate with potassium thiocyanate solution to a persistent brick-red endpoint, in the presence of diethyl ether (Amerine and Ough, 1980d). Highly colored samples (e.g. red wines) should be passed through a strong anion exchange resin before titration (as the color masks the endpoint), eluting with 1 M nitric acid. Residual color can be removed acidifying the eluent with 20% aqueous nitric acid and a few drops of saturated $KMnO_4$ solution.

Calcium is an important constituent in wine because of the problem of precipitation of calcium tartrate and oxalate; these salts are slow to precipitate and usually form in the bottled product. Calcium is also important in the brewing water of certain beers (Section 2.6.2), giving beneficial pH effects in the mashing step, which is also of benefit in subsequent brewing steps. Calcium in beverages is derived from the soil (via the raw materials) and water, and from various beverage production processes (e.g. addition of $CaSO_4$, $CaCO_3$; treatment with calcium bentonite; storage in concrete tanks etc). Nowadays, it is mostly determined by atomic spectroscopic techniques (Section 4.4.4), but it can be assayed by ion chromatography (Section 4.3.3), electrochemical methods (Section 4.5.1) and colorimetric methods (Section 4.4.3). Volumetrically, calcium may be determined by passing the beverage through a strongly basic anion exchange column (to remove interferences), evaporating the eluent to dryness, ashing and titrating the ash (dissolved in dilute acid) with EDTA solution, in the presence of ethanolamine (to prevent interference from Al^{3+}, Fe^{2+}/Fe^{3+} and Mn^{2+}) and with calcon indicator (color change: red-blue) (Amerine and Ough, 1980d).

Sulfate is present in most nondistilled alcoholic drinks and may be legally added (as gypsum, $CaSO_4 \cdot 2H_2O$) to must for the production of flor Sherry and similar wines (Sections 2.10.2, 2.10.3) or to the mash in the brewing of certain beer types (a process known as 'Burtonization' – see Section 2.6.2). Today, sulfate is generally analyzed by ion chromatography, capillary electrophoresis or potentiometric methods, but it may

be determined in desulfited drinks by a gravimetric procedure involving its precipitation with barium chloride solution (Amerine and Ough, 1980d).

Total nitrogen is of importance to winemakers and brewers, since ammonium salts and amino acids are required for effective yeast function and certain proteins contribute to the formation of hazes, whereas others are important in foam formation. Total nitrogen content is determined by the Kjeldahl or Dumas methods (see also the last paragraphs of Section 4.6.3), the former of which involves conversion of all N in the sample to NH_4^+, by 'digestion' of the sample in concentrated sulfuric acid in the presence of selenium oxychloride or copper sulfate catalyst and with added sulfate salts to increase the boiling point. After vigorous heating, the clear solution (initially charring occurs) is cooled and concentrated sodium hydroxide solution is added until alkaline. This converts ammonium salts to ammonia, which in the original method is distilled directly into a 4% boric acid solution, where the ammonia is converted to ammonium borate. In a titration reaction, ammonium borate behaves like free ammonia and is determined by titration against standard hydrochloric acid. Alternatively, the ammonia can be distilled into excess standard hydrochloric acid solution and the unreacted HCl is determined by titration with standard alkali, such as NaOH. A blank is taken through exactly the same procedure, with pure water instead of the sample.

Some Kjeldahl instruments involve determination of NH_4^+ in the digestion mixture (without distillation) by use of Nessler or Biuret color development reactions, with manual or automatic colorimetric monitoring (Section 4.4.3). Also, instead of the distillation step followed by titration, the ammonium salts formed in the digestion step can be determined by use of an ammonia specific ion electrode (Section 4.5.1). In these cases, a set of standards is analyzed under identical conditions and a standard curve is used for the determination of ammonium or ammonia in the sample. An account of a manual Kjeldahl determination is given in Amerine and Ough (1980e), but nowadays, automated versions of the procedure are generally used.

Ammonia content (as NH_4^+) of alcoholic beverages can be determined by volumetric methods (Amerine and Ough, 1980e), even though ammonia is mostly analyzed by ion chromatography, capillary electrophoresis, colorimetric or ion selective electrode methods these days. Ammonia may also be assessed by use of a weak cation exchange/distillation process, followed by acid–base titration (Amerine and Ough, 1980e) (Figure 4.6.8).

Total α-amino nitrogen can be estimated using column chromatography to remove ammonia, followed by evaporation of the eluate to dryness, drying the residue and performing a formol titration on it, to a pH 9.0 endpoint (Amerine and Ough, 1980e).

The Kjeldahl or similar methods, such as the Dumas method, are still used to assay total N (see last paragraphs of this section), whereas amino acids are determined by chromatographic (Sections 4.3.2 and 4.3.3) or colorimetric (Section 4.4.3) methods, and total proteins may be estimated by a number of colorimetric methods including one that uses the biuret color reaction – see Section 4.4.3, or by NIR spectroscopy (Section 4.4.2). In the latter mode of analysis, data for construction of a database of optimized calibration models usually comes from Kjeldahl or Dumas determinations.

Distillation, Aspiration (Aeration) and Ebulliometric Methods

Certain volatile constituents of alcoholic beverages may be analyzed by methods that involve distillation, aspiration or ebulliometric (boiling) procedures. Classic amongst these are the determination of ethanol and volatile acidity by distillation, sulfur dioxide by aspiration and ethanol by ebulliometry. Although these methods are still in use, they have been largely replaced by less labor intensive and more rapid instrumental methods (e.g. GC for ethanol, HPLC or CZE for acetic acid).

Ethanol may be assayed by use of distillation equipment similar to that shown in Figure 4.6.9. The specific gravity of the distillate can be measured using a Brix specific gravity hydrometer or a pycnometer, adjusting for temperatures other than 20 °C by using the correction table (Table 2) in Appendix 2. Distillation removes

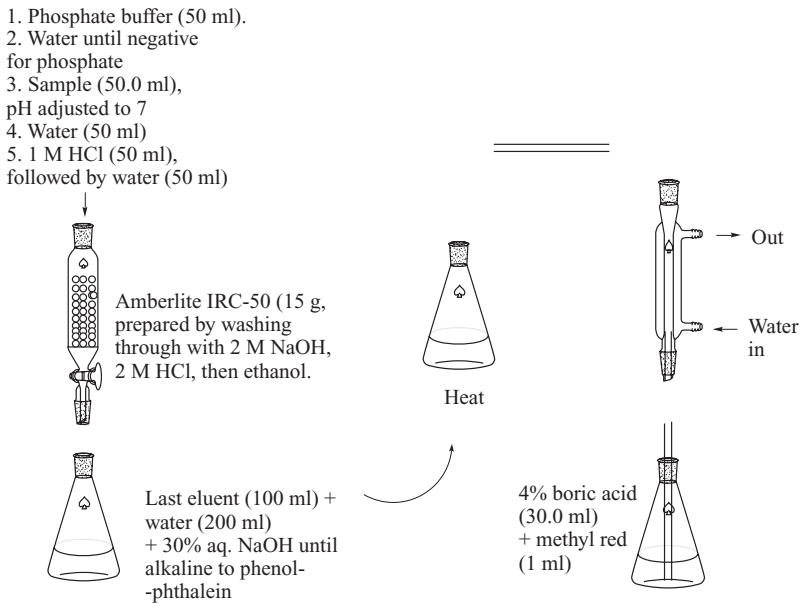

Figure 4.6.8 *Determination of ammonia content of beverages by titration*

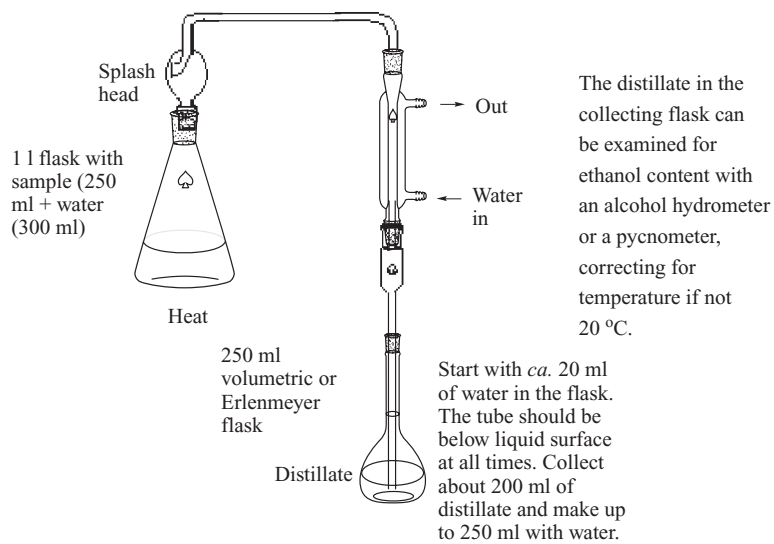

Figure 4.6.9 *Assay of ethanol content by distillation*

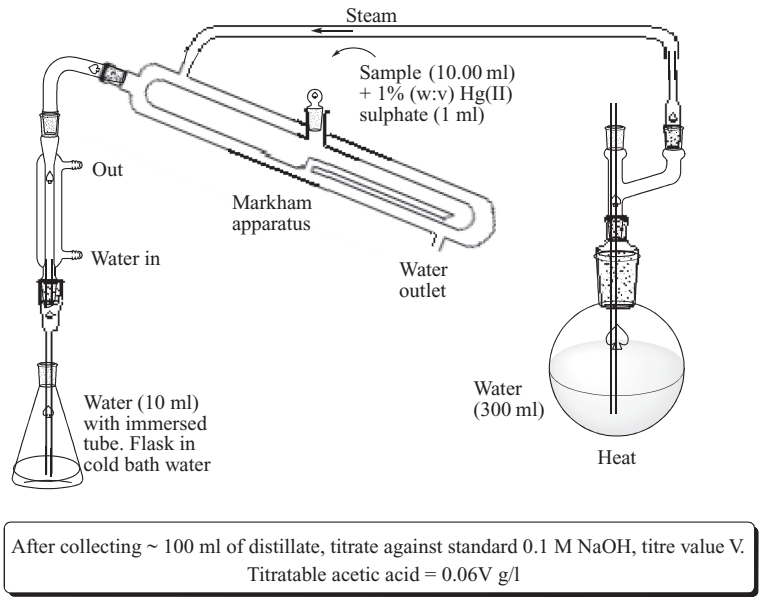

Figure 4.6.10 *Determination of volatile acidity using Markham apparatus*

interferences from dissolved constituents, such as salts and sugars. A rather more elaborate distillation set up, using a Markham apparatus, is required for the determination of volatile acidity (Jackson and Schuster, 1981) (Figure 4.6.10). Volatile acids (mainly acetic acid) are driven off as the steam bubbles through the sample in the Markham apparatus. They are collected in the receiver flask, where after addition of phenolphthalein indicator, they are titrated with standard 0.1 M sodium hydroxide solution.

The aspiration method (Figure 4.6.11) (Jackson and Schuster, 1981) is still used to determine free and bound sulfur dioxide in beverages, as it is more accurate than the standard Ripper method, which can be used

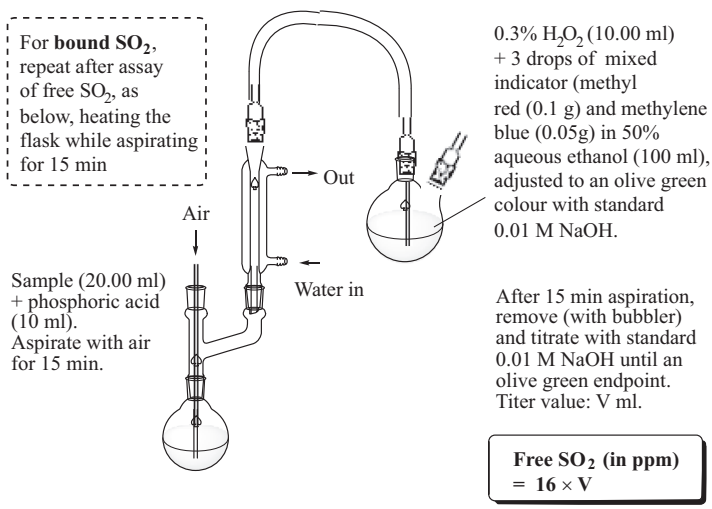

Figure 4.6.11 *Apparatus and outline of aspiration method for the determination of free and bound SO_2*

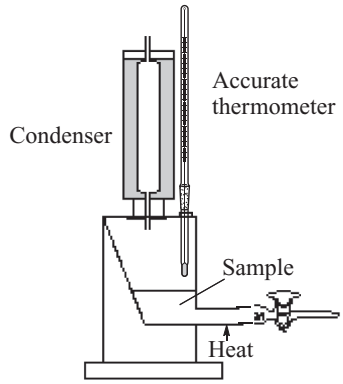

Figure 4.6.12 *Schematic representation of a typical ebulliometer*

for routine checks throughout the production process. Before bottling, or as a final check, it is better to use the aspiration method. Regular assay of known sulfur dioxide standards should be used to check the method accuracy.

Ebulliometry is based on the elevation of the boiling point of a liquid caused by the presence of solutes. It is used primarily for the determination of the ethanol content; mainly degassed beers, ciders and wines, but samples with high sugar content and spirits should be diluted before determination, in which case the result is multiplied by the dilution factor. The instrument used is known as an ebulliometer or ebullioscope, of which there are many commercial versions, those of Braun and Dujardin-Salleron probably being the best known (see Figure 4.6.12 for a general example). The boiling point of pure water is first determined and the instrument calculator is set at 0.00. The condenser and thermometer are removed, the ebulliometer chamber emptied and then rinsed well with the sample. Sample (50 ml) is added to the chamber, the thermometer is reinserted, the condenser (filled with fresh cold water) is screwed down and the steady boiling point of the sample is determined. The ethanol content (as % ABV) is read on the calculator.

Ebulliometer readings can be corrected for the presence of other solutes, such as sugars (say, in sweet wine) by a number of refinements, two of which are shown in Equations 4.6.4 and 4.6.5, the latter being specifically suggested for the Malligand instrument.

$$\text{Ethanol \% (v:v)} = E\% - 0.05S\% \tag{4.6.4}$$

$$\text{Ethanol \% (v:v)} = E\% \left(\frac{100 = 0.62S\%}{100} \right) \tag{4.6.5}$$

where $E\%$ is percentage ethanol (v:v) determined by ebulliometer and $S\%$ is percentage sugar (w:w).

Density and Viscosity Measurements

Density measurements are important in the determination of soluble solids in fruit must and beer wort, as well as in the determination of ethanol content. Additionally, progress of fermentation or distillation can be judged by density measurements. The time honored instrument for measuring relative density or specific gravity (the density of a liquid compared with the density of pure water; 1.000 g/ml at 20.0 °C) is the hydrometer. It comes in many shapes and sizes with different calibrations (sometimes with two or more calibrations): specific gravity (e.g. 1.097), °Oechsle (97); °Brix/Balling or Plato (22.8); °Baumé (12.7); % sugar (22.8); or

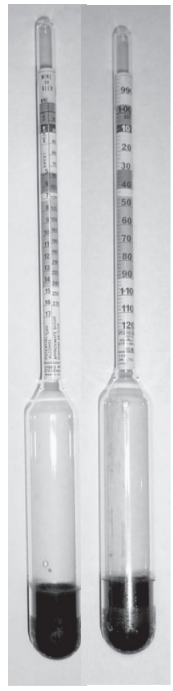

Figure 4.6.13 *Hydrometers and a pycnometer. These hydrometers are calibrated in specific gravity, potential alcohol (% ABV) and sugar equivalent (g/l). Other hydrometers are calibrated in °Baumé, °Brix or °Plato*

(potential) % alcohol (13.4) (see Appendix 2, Table 1 for interconversions). Hydrometer readings are subject to error by the presence of suspended solids and must be corrected for temperatures other than 17.5 °C or 20.0 °C, depending on the manufacturer and type of hydrometer (see Appendix 2, Table 2). Figure 4.6.13 shows some hydrometers and a pycnometer.

The pycnometer is considered by many to be more accurate than the hydrometer in the measurement of sugar or ethanol content: the pycnometer is weighed empty on an analytical balance (to four decimal places), filled with water, reweighed, then filled with sample (after thorough rinsing) and reweighed. The specific gravity (with temperature correction) is calculated according to Equation 4.6.6.

$$\text{Specific gravity} = \frac{\text{Mass of pycnometer with sample} - \text{Mass of empty pycnometer}}{\text{Mass of pycnometer with water} - \text{Mass of empty pycnometer}} \tag{4.6.6}$$

Density detectors (densitometers) are well suited to the in line monitoring of ethanol content, say of an alcoholic fermentation or a distillation. Two major kinds are the vibrating tube and ultrasound velocity types. In the case of the vibrating tube density detector a vibrating (usually) U shaped tube causes mechanical resonant vibrations in a liquid contained in the tube. The square of the resonance frequency is inversely proportional to the sum of the mass of tube and tube contents (Equation 4.6.7). Since both the tube mass and the tube inner volume are known values, the vibrating tube method is able to measure the density of an unknown fluid in a single measurement. Previously, the instrument will have been calibrated with two fluids, usually water and air, which give low and high tones for high and low density, respectively. The U tube is kept oscillating continuously at the characteristic frequency, which depends on the density of the sample.

The oscillation period is measured and converted into density by the equation of the mass-spring-model equation (4.6.7)

$$f = \frac{1}{2\pi}\sqrt{\frac{k}{(m + \rho V)}} \tag{4.6.7}$$

where f is frequency of resonant vibration, k is the spring force constant, m is the mass of the tube and contents, ρ is the density of the liquid and V is the volume of the liquid.

This method has been used in conjunction with flow injection to measure the ethanol content of wine (González-Rodríguez *et al.*, 2003).

An ultrasonic transmitter/receiver type density detector is based on the principle that the sound velocity depends on the density of the medium. The time an acoustic echo takes to travel a fixed path length in the detector element is used to determine sound velocity. The detector is calibrated using a series of ethanol-water standards over a range of temperatures; if a wide range of ethanol contents need to be measured, the detector must be calibrated separately for high ethanol content (say 95–40%) and low ethanol content (say 25–0%). The percentage ethanol (v:v) is calculated by a computer from a complex polynomial of velocity and temperature, using least squares or similar methods. An ultrasound detector has been used to monitor the ethanol content of batch (pot still) distillation run off (Forrest and Taylor, 2004). The detector element was installed just before the spirit safe, along with a temperature sensor. The precision of the instrument was $\pm 0.05\%$ (v:v), or better and its accuracy was sufficient to enable diversion of spirit at the foreshots and feints cut off points – very important in batch distillations (Section 3.2.4). The instrument, linked up to automated systems, has been used in several Scotch malt whisky distilleries.

Viscosity (symbol η, units millipascals per second) measurement is especially important in grain whisky distilleries that use cooked wheat prior to mashing with malted barley, since this can produce high viscosity starches (Section 3.2.3). High viscosity can cause problems during cooking, filtration and evaporation stages, leading to longer process times and higher production costs. There are many kinds of viscometers (instruments for the measurement of viscosity), such as the Ostwald and Ubbelohde U tube capillary, falling sphere, falling piston, bubble, vibrational and rotational viscometer types (including some that measure kinematic viscosity – viscosity (η)/density (ρ)).

Ostwald type viscometers consist of a U tube, where on one arm there is a vertical section of precise narrow bore (the capillary). Above this is a bulb, and there is another bulb lower down on the other arm. In use, liquid is drawn into the upper bulb by suction, then allowed to flow down through the capillary into the lower bulb. Two marks (one above and one below the upper bulb) correspond to a known volume and the flow of sample between these marks is timed, the time being proportional to the sample's kinematic viscosity. Most commercial instruments are provided with a conversion factor, or can be calibrated by a fluid of known density and viscocity. In pilot scale studies associated with grain whisky production, U tube type viscometers have found application in the determination of the viscosity of in grain residue of alcoholic strength distillations, after adjustment of volume with water, centrifugation and filtration (Agu *et al.*, 2006).

The Newport Scientific Rapid Visco Analyzer™ is a cooking and stirring viscometer that has been optimized for testing the viscous properties of starch, grain, flour and foods. It has in built temperature control facilities and thus can be used to measure 'pasting curves' of cereal starches – variation of viscosity with a particular temperature ramping programme. It has found application in the determination of suitable wheat samples for grain whisky production (Broadhead *et al.*, 2004) and in the determination of performance of various barley types in relation to alcohol production (Agu *et al.*, 2008). This instrument can also be used to investigate the extent of modification (Section 2.6.2) of malted barley samples; poorly modified malt gelatinizes at a lower temperature than well modified malt and gives a higher viscosity mash (Broadhead *et al.*, 2004).

Foam is a very important property of most beers (Section 2.6.9), some ciders and sparkling wines. Foam stability is defined as the ability of the foam, once formed, to resist deterioration; it is considered as a function of the bulk liquid viscosity and surface viscosity, as well as the repulsion between electrical double layers of molecules and the Marangoni effect (the ability to repair broken film or bubble structures). Various aspects of foam stability can be measured (Section 2.6.9), the most commonly determined parameters being collapse rate (drainage or retention) and foam adhesion (cling or lacing) (Hughes and Baxter, 2001). One of the most widely used beer foam assessors is the Nibem Foam Stability Tester, which measures the foam collapse time over a distance of 30 mm. After filling the glass with highly reproducible foam made using special sampler and head devices, the glass is placed in the instrument and the foam collapse time is measured by decrease in conductivity.

Similarly, the Nibem Cling Meter calculates the glass area covered by foam by driving a conductivity scanning head down into a rotating beer glass. From the proportion of the area covered by beer foam and the total scanned area, the cling value is calculated and expressed in percentage foam coverage.

Bikerman's method is sometimes used to measure cider foam parameters (Blanco-Gomis *et al.*, 2007). The equipment consists of a glass column (60 cm $\times$ 1 cm) with a sintered glass disk (pore size 10 μm) at the bottom. Degassed cider (10 ml) at 20 °C is placed in the column and carbon dioxide is forced through the bottom at 30 ml/min. Maximum height and stable height can be recorded while the gas is flowing continuously, and foam collapse time can be determined once the flow of CO_2 is stopped.

Light Scattering and Refraction Methods

The extent of haze can be estimated using light scattering methods. Shallow light scattering instruments are better for hazes formed by larger particles, whereas wider angle instruments, measuring scattered light at 90° to the incident beam, are better for assessing hazes produced by smaller particles (say, 0.1–0.5 μm) (Bamforth, 2002).

In typical nephelometric turbidimeters, such as those of the Hach series, light from a tungsten filament lamp is passed through a sample cell containing the sample, where a 90° slit allows scattered light to reach the photomultiplier detector. The intensity measurement is compared with that of a turbidity standard, which has a predesignated turbidity expressed in nephelometric turbidity units (NTU). Common standards are formazin (a copolymer of hydrazine and hexamethylenetetramine) and polystyrene-divinylbenzene copolymer beads (AEPA-1).

With beers, there is a tendency for temporary or chill hazes, generally composed of smaller particles, to mature into permanent hazes (Section 2.6.9), composed of bigger covalently linked particles, upon storage. The haze stability of beers designed for a long shelf life is important and consequently is often assessed by light scattering devices, particularly in conjunction with accelerated ageing programmes. Here, the effect of a 24 h period of cold (0 °C) storage and 24 h of warm (37 °C) storage (reckoned to be equivalent to several weeks of normal storage) is used to predict the likelihood of permanent haze formation.

In winemaking, the 90° angle turbidometer (called a nephelometer) is the most widely used type, giving a result that describes the wine clarity in terms of nephelometric turbidity units (NTU). By observation, wines can be described as brilliant, clear, cloudy, dull or turbid. Brilliant corresponds to NTU values of $<$1.1, $<$1.4 and $<$2.0 for white, rosé and red wine, respectively, whereas turbid is characterized by NTU values $>$4.4, $>$5.8 and $>$8.0 for white, rosé and red wines, respectively (Ribéreau-Gayon *et al.*, 2000).

In brewing, light absorption can be used to assess the quality of barley for malting, particularly with regard to water take up by the starchy endosperm during steeping (Section 2.6.2). Shining light through pearled barley can distinguish between mealy and glassy endosperms, the former of which absorb water more easily during steeping. Pearled barley with glassy endosperms appears bright in the beam of light, whilst those with mealy endosperms appear dark, as a result of reflection and absorption, respectively.

The refractive index of sugar solutions and of ethanol-water solutions varies according to the concentration of sugar or alcohol. Consequently, refractive index measurement, using an Abbé or similar refractometer, can be used to assay sugar content of wine and cider musts or beer worts or the ethanol content of drinks, using a sodium lamp. Modern instruments have temperature control devices (correction must be made for temperatures other than 20.0 °C) and scales for both refractive index and sugar content, calculated as glucose or sucrose. The instrument may be calibrated with a proprietary standard, or by use of a series of standard solutions of sucrose in water or ethanol-water solutions, and refractive index can be related to concentration by use of tables in such reference texts as the *CRC Handbook of Chemistry and Physics*.

Thermal and Combustion Methods

The Kjeldahl method for the determination of total nitrogen content of foodstuffs is the time honored method, nowadays automated, but in recent years has been challenged by the more rapid and environmentally safer Dumas method. The Kjeldahl procedure involves heating (~370–410 °C) the accurately weighed sample in the presence of concentrated sulfuric acid with dissolved sulfate salts – usually K_2SO_4 and $CuSO_4{\cdot}5H_2O$, or a combination of Na_2SO_4, $CuSO_4{\cdot}5H_2O$ and $FeSO_4{\cdot}7H_2O$. Under these vigorous conditions, all the nitrogen in the sample is converted to ammonium sulfate. There are many commercial versions of varying sizes (macro and micro) and degree of automation (see, for example the Buchi AutoKjeldahl and Foss Tecator Kjeltec series), that differ in detail regarding the digestion, dilution, distillation and titration steps. Most Kjeldahl instruments use block digesters, with a fume removing device, such as a water or mechanical aspirator. The block digesters are operated by a controller that allows automatic timed temperature ramping and multiple temperature programmes. Distillation can be carried out (often automatically) by classical distillation or by more rapid steam distillation (3–8 min), in which case the procedure is often known as 'rapid Kjeldahl.' Determination of ammonia is carried out by titration (again often automated), as described earlier in Section 4.6.3 – see also Section 4.4.3.

The Dumas method (also automated, see for example www.gerhardt.de) is now often used to determine the protein content of powdered cereal grains and malted cereals, via determination of the total nitrogen content. An accurately weighed sample is combusted (at ~1000 °C) in excess oxygen in the presence of a catalyst, so that carbon dioxide, water vapor and oxides of nitrogen are formed from the carbon, hydrogen and nitrogen content of the sample. The gases are passed through a reduction furnace where oxides of nitrogen are converted to N_2 in the presence of copper. They are than passed over a Nafion® membrane, where most of the water is removed. The remaining water, along with the CO_2 is removed in self-regenerating adsorption traps. The elemental nitrogen is measured in a thermal conductivity detector, after calibration with a standard. EDTA (containing 9.56% N) is often used as a calibration standard. The results are reported as %N, which are then converted to percentage protein by use of a 6.25 conversion factor. The protein content is then usually expressed on a dry weight basis by taking into account the amount of moisture in the sample, which can be determined by drying a quantity of the flour at 105 °C for three hours. See Section 4.4.3 for colorimetric methods for the determination of protein and other forms of nitrogen in alcoholic beverages and their raw materials.

4.7
Sensory Analysis

Some readers may find certain expressions far-fetched. Cynics scorn the use of descriptions such as 'old straw, 'linoleum' or 'cheese rind' yet these are not fanciful: the physical and chemical compounds that produce the smell of linoleum, for example, can be present in wine.

—Michael Broadbent, 1991

4.7.1 Introduction

The best ingredients, combined with the most careful production methods and the most rigorous in line quality assurance may well give a consistently top notch alcoholic beverage, but whatever the history of the product, the final judgement regarding its quality, or at least its acceptability, will come from the drinker. Therefore, all alcoholic drinks manufacturers will include in their production process a program of sensory analysis, often at different stages along the production line. Sensory analysis, sometimes called organoleptic analysis, involves the assessment of the beverage by what is often loosely called 'tasting', but other than in its simplest form, sensory analysis is much more than this. It is an attempt to assess and describe the character of a drink in universally understandable terms using the natural senses of vision (for color, clarity), smell (for aroma/flavor), taste and touch (for texture and temperature).

All the natural senses, apart from sound, play an important part in sensory analysis. However, in this section, use of the senses of smell and taste will be emphasized, because they play a key role in assessing and describing the character of a drink. Description of color and reference to color scales (particularly for beers and wines) has been outlined in Sections 4.4.4, 2.6.2 and 2.6.13. Likewise, reference to clarity assessment is made in Section 4.6.3. The sense of touch is more or less limited to the impact of 'mouthfeel' (which includes astringency) and temperature of the drink in the upper digestive tract, along with the impact of its viscosity, relating to dissolved substances such as glycerol and sugars, and its homogeneity, relating to the presence or absence of suspended solids or bubbles of gas. Measurement of viscosity is outlined in Section 4.6.3.

The senses of smell and taste are sometimes known as the chemical senses, because of their reliance on the interaction between chemicals (aroma, flavor and taste chemicals) and the relevant sensory organs (chemoreception). The chemical sensory organs are especially well developed in most animals, where chemical signals play a most important role in their daily lives, including communication. In primates, humans and birds of

prey, sight and sound is more highly developed than smell and taste, but nevertheless, the latter senses are still of considerable importance.

Sensory reference literature regarding food aromas and flavors includes Burdock (2001), Civille and Lyon (1996), Ashurst (1999) and *Flavours and Fragrances* (2002). Also, for recommendations regarding experimental conditions, details of types of sensory tests and general information, see Table 4.7.1. Additionally, the reader is directed to a website on the science and art of flavor construction (with definitions) (Fischetti, 2002), an account on flavor chemistry (Cole and Noble, 2003) and a recent review on wine chemistry and flavor (Ebeler and Thorngate, 2009).

4.7.2 Olfaction and Taste

The olfactory system is located in the nasal cavity (Figure 4.7.1), where conchae (or turbinates) form a number of cavities and the superior conchae and olfactory clefts are lined with olfactory epithelium (or mucosa). The olfactory epithelium consists of receptor cells lodged between supporting (sustentacular) cells and basal cells, as well as olfactory (Bowman's) glands, which (along with the supporting cells) supply the mucous secretion that coats the epithelium. Receptor cells are developed from basal cells in about a month and perform their receptor function for a week or so before dying, breaking up and being replaced by new receptor cells.

The receptor cells may be thought of as specialized, primitive type bipolar neurons (Netter, 1991). Evidence suggests that there are many kinds of receptor cells, but that the signals from one type are led to a common area of the olfactory bulb. The receptor cells are elongated, with their nuclei situated at their upper ends and each possesses 10–15 olfactory hairs or cilia (of up to 0.3 mm in length) at their lower ends, which project from the epithelium surface into the covering mucus (Figure 4.7.2). The upper end of a receptor cell narrows and gives rise to an unmyelinated axon (0.2–0.3 μm in diameter). Large numbers of these axons are bundled together under the protection of a Schwann cell sheath, eventually passing through the cribiform

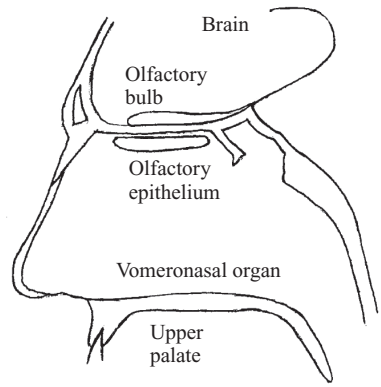

Figure 4.7.1 *Nasal cavity and location of olfactory system*

plate of ethmoid bone to the olfactory bulb, a flattened oval mass near the lateral margin of the cribiform plate (Figure 4.7.1). It is estimated that about 100 million olfactory axons enter the olfactory bulb.

The cilia have a fine structure made up of microtubules, which are essentially cylindrical lipid bilayer cell membranes. The membranes possess embedded receptor proteins, whose undulating structures (mostly α-helices) pass through the membrane at seven points, but with one terminal either side of the membrane, the inner terminus being linked to a G protein. It is thought that the odor binding sites are situated on three

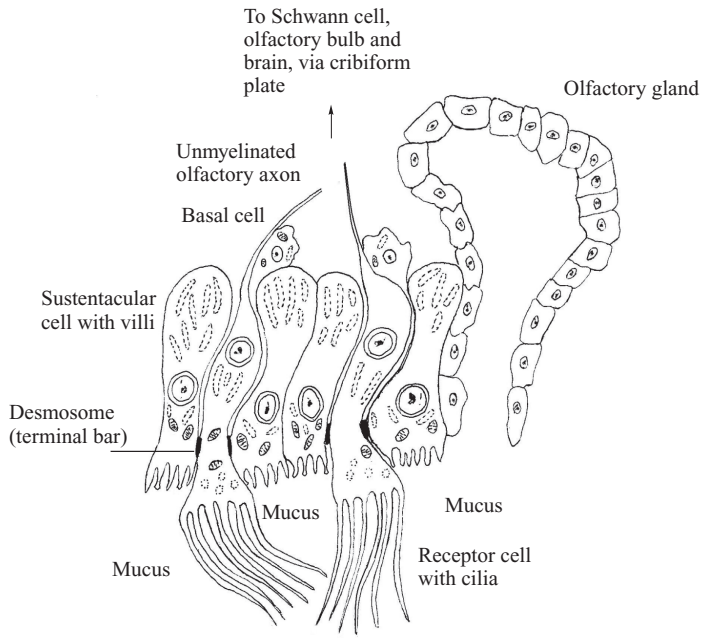

Figure 4.7.2 *Section of a small region of the olfactory epithelium*

neighboring protruding α-helical structures. The receptor proteins expressed by different receptor cells are similar except for the regions of hypervariability associated with the binding sites of the three α-helices. Also located in the membrane are numerous ion channels and the entire olfactory epithelium is covered in viscous mucus, which is has the important job of acting as a vehicle for odorant molecules, ions and a large number of secreted proteins.

For detailed discussions of the anatomy and functioning of the olfactory system, the reader is referred to Shepherd (1979), Netter (1991) and Matheis (1999).

Many theories of olfaction have been put forward over the years, most of them attempting to explain the interaction between the odorant molecules and receptors in the olfactory epithelium, the notion of receptors being universally accepted a long time ago. These theories include radiation, thermodynamic activity and membrane penetration as the mechanisms of olfaction, but nowadays the theories that are most highly regarded are those based on either recognition and/or vibration (Sell, 1997). Recognition theories strive to explain the olfaction mechanism in terms of some 'matching' mechanism that links the odorant to the receptor, rather like the 'lock and key' mechanism of enzyme action. The best known modern recognition theory is that of Amoore (1970), which regards primary odors as contributors to the broad spectrum of perceived odors, rather in the way that all colors are formed from the primary colors blue, red and yellow. He postulated that molecular shape or electrical charge was the key recognition factor between odorant molecule and receptor protein. Other recognition theories sought to explain odorant–receptor interaction in terms of intermolecular bonding, steric bulk and frontier orbital topography associated with the odorant molecule.

Vibration theories attempt to explain odorant molecule-receptor protein interactions in terms of a reaction (ultimately giving rise to an electrical signal) in the receptor caused by the sensing of specific vibration(s) in the odorant molecule. Turin (1996) proposed that electron tunneling provides the electric signal that results in the perception of a certain odor in the brain. The mechanism involves the receptor protein having two prosthetic groups, NADPH (as electron donor) and Zn^{2+} (as electron acceptor), but when there is no odor molecule specific to this particular protein present, electron transfer between the two sites is unable to occur, because the potential energy barrier is too high. When an odor molecule is bound between the two sites, an electron is able to tunnel through the energy barrier by using the odorant molecule's orbitals, thereby causing characteristic excited vibrational modes and creating a drop in electrical potential.

The many theories have tried to explain the mechanism of olfaction on the basis of empirical structure–activity relationships (SARs). Either some feature of structure or activity that is seemingly important in the observed SARs is postulated as being responsible for biological activity, or a biological mechanism is first postulated and then is linked to odorant structural features that would be in accord with the mechanism.

All these theories are deficient in that they are unable to account for all the known facts regarding olfaction and a great deal still needs to be learned. The problem is that there are many stages between the genesis of odor at the site of interaction and the perception of odor in the brain.

A modern picture of olfaction genesis is outlined in Figure 4.7.3. It involves the participation of odorant binding proteins (OBPs), of which there are many types. These probably have varying interactions with different odor molecules and receptor proteins, and their job is probably to chaperon the odor molecules to the relevant receptor protein where an interaction complex is formed, thus starting the process of events leading to odor perception. Formation of the interaction complex is thought to cause a change in conformation of the receptor protein, possibly by the formation of specific intermolecular attractions (such as hydrogen bonding) or by electron tunneling.

The change in conformation triggers a protein associated with the receptor protein (called a G protein) to activate the enzymes adenylyl cyclase or phospholipase C, which catalyze the formation of the second cell messengers cyclic adenosine monophosphate (cAMP) and inositol triphosphate (IP_3), respectively. These

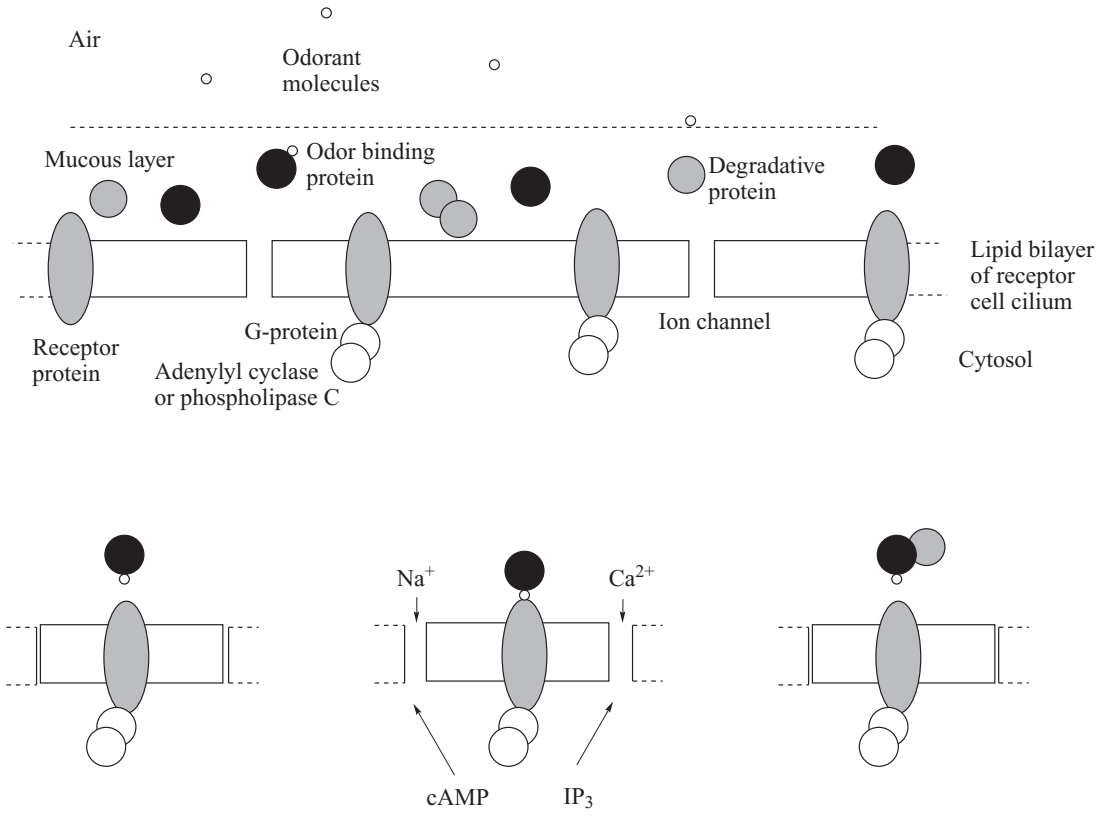

Figure 4.7.3 *Outline mechanism of initiation of olfactory response*

cause cAMP and IP_3 gated ion channels to open, allowing sodium and calcium ions to enter the cell resulting in a change in cell electrical potential (the cell becomes less negatively charged). If the stimulus persists, the potential change is propagated along the length of the neuron and is transmitted directly to the brain, where it is converted to an odor sensation.

There is a negative feedback mechanism associated with olfactory signaling, in that increase in calcium ion concentration within the cell decreases the sensitivity of the ion channels to cAMP, so that an action potential is maintained only by a strong odor stimulus.

The second messengers also trigger a process that deactivates the receptor protein by phosphorylation, which presumably dissociates the interaction complex, leaving the OBP and its odor molecule to be demolished by degradative proteins that are known to be present in the layer of mucous. Thus, signal generation ceases after removal of the odor source.

Most people can detect a very wide range of odors, associated with a large number of molecules. This is because most odorants are recognized by more than one type of receptor and most receptors can receive more than one odorant. This cross reactivity means that the few hundred types of receptors in humans work in concert to detect a wide spectrum of odors.

The odor of an alcoholic beverage, such as the bouquet of a wine or the hop aroma of a beer, is a very pleasurable experience. It depends on the persistent evaporation of aroma compounds from the surface of the beverage. Likewise, the drinking of an alcoholic beverage such as wine is accompanied by the perception

of a wide range of aromas and flavors, which changes as the drink is swallowed, suggesting that odorants are released from the drink at different rates and to different extents as a result of their different mass transfer characteristics between air and aqueous ethanol solution. Evaporation of volatile substances at the air–liquid interface has the effect of slightly warming the headspace above the liquid and slightly cooling the bulk liquid at the surface. In order to maintain a steady headspace concentration of volatile substances there must be continual movement of these substances in the bulk liquid to the interface. The Marangoni current is a major mechanism for doing this, the driving force being surface tension differences at the surface, which may in turn be caused by temperature or concentration changes. In water-ethanol solutions, ethanol preferentially accumulates at the interface, lowering the surface tension and thus increasing Marangoni convection, compared with purely aqueous solutions (Tsachaki *et al.*, 2008).

Dynamic headspace headspace studies on model wine solutions, designed to simulate the conditions when wine is sniffed, have indicated that the presence of ethanol (at 12% ABV) maintained the headspace concentrations of a number of odorants close to equilibrium values during gas phase dilution over 10 minutes (Tsachaki *et al.*, 2009). This was explained by an increase in mass transfer (additively to partition coefficient variation) due to the presence of ethanol, and this was supported by the observation of convection of odorants above model wine solutions (as opposed to aqueous solutions) using thermal imaging.

Real wine samples have been found not to maintain headspace concentration of odorants to the same extent. Results of dynamic headspace dilution experiments on model wine solutions spiked with proteins suggest that this is probably due to the presence of small quantitities of certain proteins (e.g. bovine serum albumin, β-casein and β-lactoglobulin) in real wine samples ((Tsachaki *et al.*, 2009). It appears that the proteins interfere with ethanol at the air–liquid interface. More mature wines will contain fewer proteins than young wines, because over the years the proteins will precipitate with tannins and tartrate salts as a deposit. This could partly explain why many wines gradually improve their quality and intensity of bouquet after spending many years in bottle and also why a very fine wine of great age will often release and maintain an intense perfume for a limited period of time before 'collapsing.'

GC-O and sensory analysis has shown that the nonvolatile matrix of wines exerts a marked effect on the perception of odor (Sáenz-Navajas *et al.*, 2010). For example, by adding red wine nonvolatile fractions to a white wine caused the suppression of white, yellow, citrus and tropical fruit notes, so that black, red and dried fruit notes became dominant. In particular, red wine nonvolatile matrices appeared to retain strongly the ester 3-mercaptohexyl acetate (an important odorant of Sauvignon Blanc wines), thus significantly reducing its odor impact. Also, Sáenz-Navajas *et al.* (2010) have shown that the wine nonvolatile matrix influences the release of aroma molecules, so that the headspaces above white wines are richer in fruity esters and volatile acids than those above red wines.

Another phenomenon that has interested aroma scientists is the observation that perception of certain aromas and flavors during the drinking of alcoholic beverages is sometimes time delayed, relying on the hydrolysis of flavorless conjugates to form aroma/flavor compounds after swallowing. For example, *S*-cysteine conjugates were found to be precursors of flavorful thiols, released from wines of Sauvignon Blanc some 20 seconds or so after swallowing (Tominaga *et al.*, 1998a; 1998b). Recently, Starkenmann *et al.* (2008) showed that similar cysteine *S*-conjugates in bell peppers are converted to odorous thiols by anaerobic bacteria (*Fusobacterium nucleatum*) in saliva, the mouth thus acting as a reactor producing odorants, but with the saliva moderating overall olfactory responses by trapping a proportion of the free thiols.

The odors and flavors of an alcoholic drink are notoriously difficult to describe in a universally acceptable way – using descriptions that are recognized unambiguously by all. Hence it is possible to devise nonequivalent, but broadly similar, flavor wheels or profiles for a particular drink, such as Scotch malt whisky (see Section 3.2.6, Figure 3.2.13; see also this chapter, Figure 4.7.7). However, these profiles, with their specific descriptors, work well in their own contexts, where tasters (panellists) have been trained with typical examples

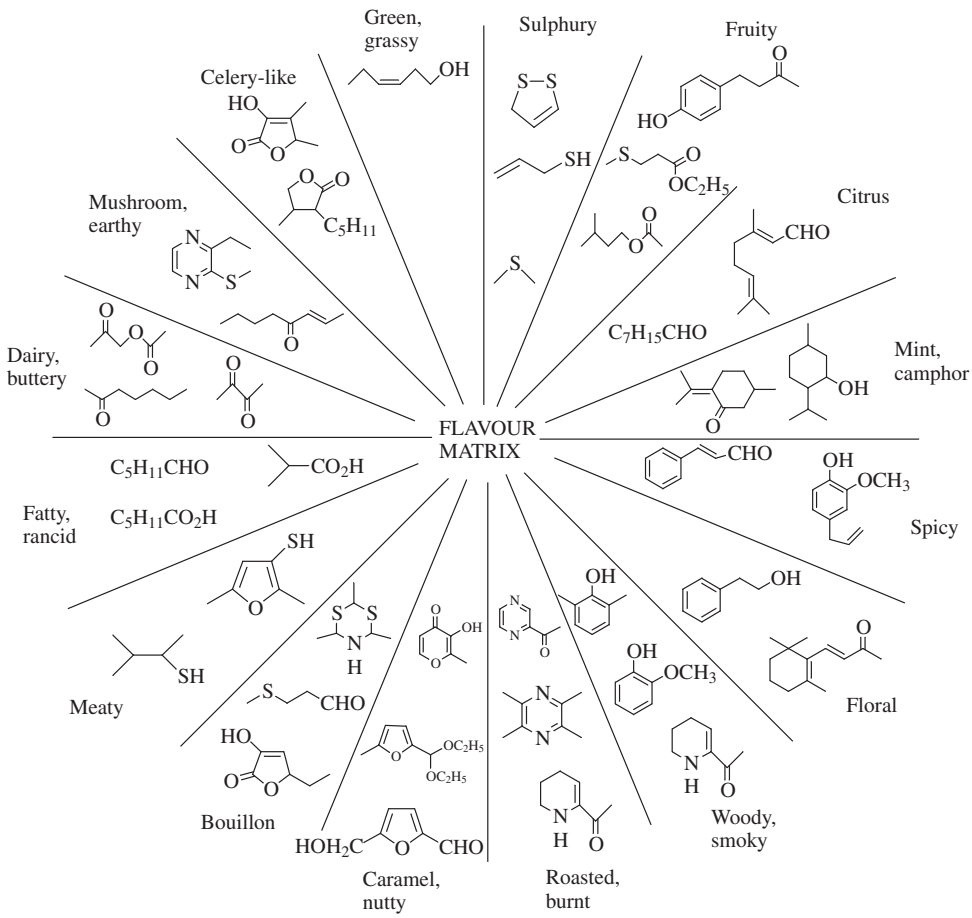

Figure 4.7.4 *Flavor matrix or wheel used for foodstuffs in general, illustrating a few representative flavor molecules*

of the flavor descriptors, sometimes with pure compounds that are associated with the flavors (Section 4.7.4). It is possible to construct general flavor wheels or matrices that account for the major flavor attributes of foodstuffs in general. Two such wheels are shown in Figures 4.7.4 and 4.7.5, where it can be seen that, while they are not equivalent, there is a broad similarity between the two. Figure 4.7.4 also includes some typical flavor molecules associated with each descriptor, whereas Figure 4.7.5 includes taste and mouthfeel as well as aroma/flavor and also illustrates how primary descriptors can be subdivided.

Although there is no universal agreement on a set of primary aromas and flavors, it has long been agreed that taste can be described by just four sensations; bitter, salty, sour and sweet. The sensations of taste originate from interaction between taste buds and taste molecules or ions. Taste buds are located all over the mouth, including the epiglottis, the top third of the esophagus, the larynx, the soft palate and the uvula (at the back of the mouth). However, the biggest concentration of taste buds is on the upper surface of the palatine section (front two thirds) of the tongue. Here, the taste buds are located in close packed short projections known as papillae, of which there are four types depending on their anatomy; filiform, foliate, fungiform and vallate.

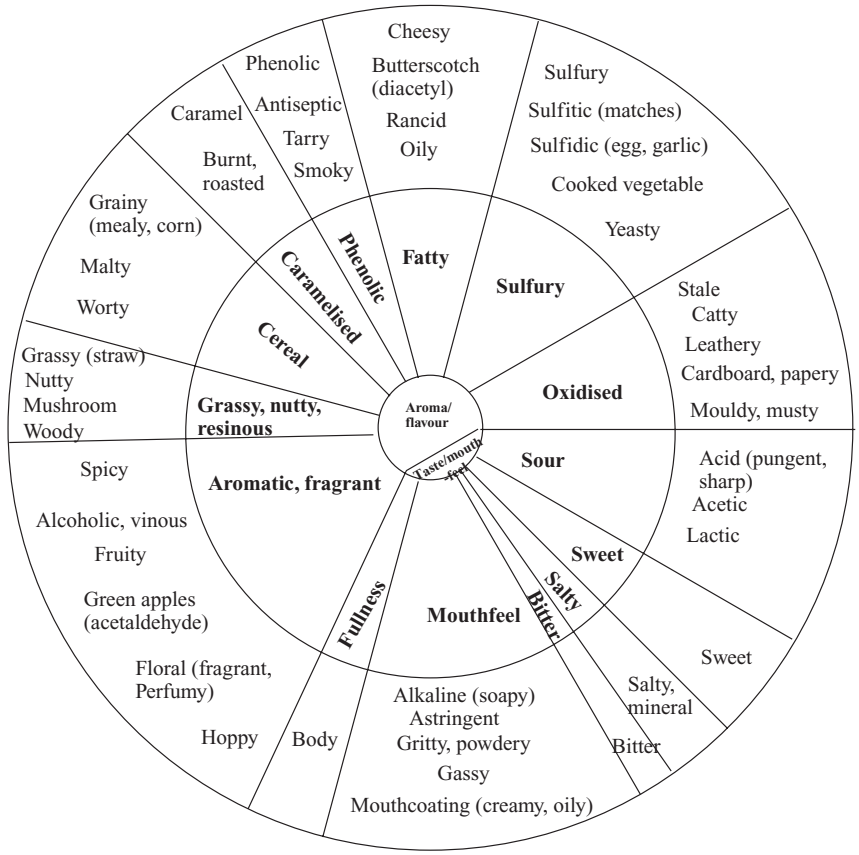

Figure 4.7.5 *Flavor, taste and mouthfeel wheel, showing subdivisions of major descriptors*

Figure 4.7.6 shows a simplified cross section of the central part of the tongue's upper surface, where it can it can be seen that the taste buds are embedded in the highly undulating epithelium, with apical pores on the outer surface and sensory nerve fibers leading off into the connective tissue. The nerve fibers are bundled into a succession of cranial nerves, which enter the brain via the brain stem and thence to the hypothalamus, the thalamus and sensory cortex areas of the brain.

The tongue is covered in mucous secreted by glands in the moat surrounding the vallate papillae and the salivary glands provide saliva with its various hydrolytic enzymes (such as amylases) and degradative enzymes (such as lysozymes).

The filiform or conical papillae are most numerous, but lacking taste buds, they are involved in trapping of taste substances. The flat topped fungiform papillae have taste buds giving both sweet and sour responses, whereas the the taste buds of the vallate and foliate papillae are associated with bitter (and sour) and salt (and sour) responses, respectively. The distribution of the different types of papillae on the tongue's surface reflects the dominant taste sensations in different parts of the tongue. Thus salt and sour taste sensations are strongest at the sides of the tongue, whereas sweet sensation is most pronounced at the tip and bitter taste sensation is prevalent toward the back of the tongue.

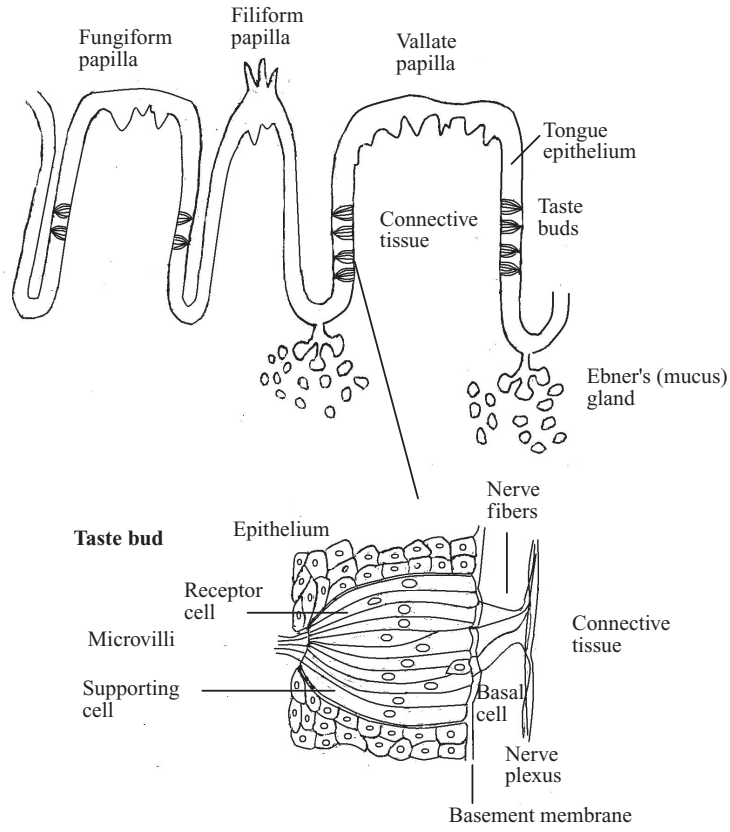

Figure 4.7.6 *Section through tongue papillae and section through taste bud*

The perception of astringency and bitterness are common in the consumption of many alcoholic drinks, such as beer, bitters, certain liqueurs, vermouth and wine (especially red wine). Bitterness is perceived by the taste receptors on the tongue, whereas astringency is regarded as a tactile (feeling or touch) sensation, characterized by a feeling of dryness and puckering of the mouth cavity. Interestingly, astringency is defined in a chemical way, as the ability to precipitate proteins, a property that probably gives rise to the characteristic mouthfeel. Both sensations are time dependent, taking time to establish maximum intensity and then gradually receding.

In wine, the major cause of bitterness and astringency is the presence of phenolic substances. Preleg *et al.* (1999) found that the flavan-3-ol monomers were more persistently and more intensely bitter than flavan-3-ol dimers and trimers formed from flavan-3-ols and (+)-dihydroquercetin. Astringency, on the other hand, was higher for the oligomers, but of the same duration as the monomers. Moreover, the bitterness and astringency depended on the type of linkage in the flavan-3-ol dimers. Thus, catechin-(4→6)-catechin (cat-(4→6)-cat) was more bitter than either cat-(4→8)-cat or cat-(4→8)-epicat, and cat-(4→8)-cat was more astringent than either cat-(4→6)-cat or cat-(4→8)-epicat.

The feeling of astringency in the mouth is thought to be a result of the formation of insoluble saliva protein (e.g. α-amylase)–polyphenol complexes – these, particularly if tannins are involved, reduce oral lubrication

and give rise to sensations of constriction, dryness and roughness (Haslam, 1981). Soares *et al.* (2009), using nephelometry (Section 4.6.3), dynamic light scattering and fluorescence quenching, have demonstrated how polysaccharides in tannic foods reduce astringency by forming either soluble protein/tannin/polysaccharide ternary complexes or soluble tannin/polysaccharide complexes, the polysaccharide competing successfully against saliva proteins. In the experiments, the tannins were procyanidins, the polysaccharides were cycoldextrin, gum Arabic and pectin, whereas the protein was porcine pancreas α-amylase, which is reckoned to be similar to the human enzyme.

In the case of wine and vermouth, the residence time in the mouth was found to have a strong influence on the perception of maximum astringency and on the rate of its decrease, which obeyed an exponential law (Valentová *et al.*, 2002). Furthermore, solutions of tannic acid and catechin were more astringent in water than in wine or orange juice, and added sugar decreased the astringency of red wine, illustrating the existence of masking effects. In the case of sugars, it is thought that their presence in alcoholic beverages increases saliva flow, so that either bitter or astringent substances are washed out of taste buds or sugar molecules interfere with the formation of complexes between salivary proteins and astringent components (Valentová *et al.*, 2002).

4.7.3 Odor Theshold, Odor Activity and Low Impact Odorants

Because of their profound effect upon the chemical senses, aroma compounds play a definitive role in the quality and character of alcoholic beverages. In the case of most drinks, aroma and flavor are influenced by the presence of hundreds of volatile and semivolatile compounds, which are normally determined by methods involving gas chromatography (Section 4.3.2). In total, however, aroma compounds normally comprise only a small fraction of the components present in the drink. For example, the concentration of total aroma compounds of wine is *ca.* 0.8–1.2 g/l; about 1% of the ethanol concentration (Rapp, 1998). Of these, higher alcohols ('fusel oils') make up about 50%, with the levels of the remaining odorants ranging from 10^{-4}–10^{-10} g/l (Rapp and Mandery, 1986).

The human olfactory system exhibits a rather sensitive and variable reaction to aroma compounds in alcoholic beverages. A measure of the contribution (or more crudely the 'strength') of a particular odorant is its odor threshold value (OTV, sometimes known as threshold odor concentration (TOC), or olfactory perception threshold), defined as the concentration of odorant at which the sensory difference from a control sample can be detected by 50% of panellists in a sensory test. Determination of OTV is thus an example sensory analysis, which requires testing to be carried out under conditions laid down in standard procedures provided by various statutory bodies and institutions related to the food and alcoholic beverage industries (Section 4.7.4).

As an example, consider the determination of the OTV of methyl-2-methyl-3-furyl disulfide (MMFDS) in whisky (Watts *et al.*, 2004). This was determined in 20% (v:v) ethanol following a common procedure used for sensory analysis of Scotch whiskies (Lee *et al.*, 2000). The MMFDS samples were prepared in a range of concentrations (100, 50, 10, 5 and 1 ng/l; i.e. 0.1–0.001 ppb) in 30 ml of 20% (v:v) ethanol in 130 ml clear nosing glasses. These samples were nosed by a sensory panel consisting of 13 members, who were required to say whether they could identify an aroma in each of the samples and whether they could describe that aroma. The test results were interpreted using specialist software (Section 4.7.3). The number of panellists detecting and recognizing (successfully describing) the aroma of MMFDS at each concentration was calculated. A probit regression was carried out on the data to determine detection and recognition thresholds. These were estimated at probit 0.5, the point at which 50% of the panel could detect or recognize the aroma. The recognition threshold and odor threshold (detection threshold) for MMFDS were found to be 18 ng/l and 15 ng/l respectively.

Although several aspects in the above procedure are specific to Scotch whisky (e.g. dilution of sample to 20% ABV, size of sample and glass, nosing only – no tasting; see Section 4.7.4) it can be regarded as being typical, and most importantly, the target odorant is sampled in the matrix most commonly used for sensory analysis of Scotch. It is important to determine OTVs of odorants dissolved in a relevant matrix or solution.

An alternative method of determining OTVs is illustrated for 1,3-dimethoxybenzene (*m*-DMB), a volatile component of Port wines (Rogerson *et al.*, 2002). Here, the method used was that of triangular tests according to forced choice ascending concentration series method of limits (ASTMS, 1991). A panel of seven tasters were given eight three-alternative forced choice (3-AFC) tests, which consisted of two blanks and an odd sample with added *m*-DMB to make up the triangle. The concentration of *m*-DMB in the eight odd samples differed by a factor of two, from 1.95 μg/l up to 250 μg/l. The tests were repeated until a correct answer (yes or no, with correct odor descriptors – hazelnut, medicinal, sweet) resulted for at least three in a row for each panellist.

The panel threshold was calculated as the geometric mean of the best estimate threshold for each panellist. OTVs of *m*-DMB were determined in two model wine systems (12% and 20% ABV; tartaric acid, 5.0 g/l, pH 3.5 to resemble Douro wine and Port, respectively): they were 21 μg/l and 47 μg/l, respectively.

Similar tests were also used to determine OTVs for abhexon (5-ethyl-3-hydroxy-4-methylfuran-2(5H)-one – a spicy flavor component of Sauternes) (Bailly *et al.*, 2009) and (*R/S*)-3-sulfanylhexan-1-ol, a flavor component of bell peppers and wines of Sauvignon Blanc (Starkenmann *et al.*, 2008). For abhexon OTV determination, the blanks were water:ethanol (88:12, v:v), and abhexon was spiked in this medium at 2.5–12.5 μg/l, whereas for (*R/S*)-3-sulfanylhexan-1-ol the blanks were water and the odorant was spiked in water at 4–500 ng/l.

OTVs vary widely, typically from 0.1 mg/l (10^{-4} g/l or ppm levels) to 0.1 ng/l (10^{-13} g/l or ppt levels) (Rapp, 1998), with many in the 1–0.01 μg/l (10^{-9}–10^{-11} g/l or ppb) level. It is widely held that if a component is present at concentrations much lower than its OTV, it will provide only a minor or background contribution to the overall aroma (but see later paragraphs of this section).

Odor activity values (OAVs) were constructed in order to give an estimate of the extent of contribution of an odorant, depending on its concentration and OTV (Equation 4.7.1) (Salo *et al.*, 1972).

$$\text{OAV} = \frac{\text{Concentration}}{\text{OTV}} \tag{4.7.1}$$

The OAV of an odorant is thus a dimensionless unit that indicates the likely extent of contribution of a particular odor compound to the overall smell of the drink; the larger the value the greater the contribution. On this basis, it has been proposed that only components with OAVs greater than 1 are likely to make a significant contribution (Guth, 1997)

Another way of measuring odor potency or impact (which can be compared with OAV), is gas chromatography olfactometry aroma extract dilution analysis (GC-O AEDA). For a review of the subject, the reader is referred to Delahunty *et al.* (2006) and Plutowska and Wardencki (2008) for general applications of GC-O. For more discussion on GC-O, see Sections 4.7.4 and 4.3.2. In GCO-AEDA, firstly, characteristic odor components of an alcoholic beverage are extracted (usually by liquid–liquid extraction) and determined by GC-O and identified (usually) by GC-MS. Then, GC-O is carried out on successively diluted samples of the extract until the odor can no longer be perceived for certain of the components, which are noted each time. Eventually, dilution will be so great that no odors are perceived by GC-O. The maximum dilution for each component is known as the flavor dilution (FD) factor and is a measure of the odor potency: the larger the FD, the greater the odor impact of that component. GC-O AEDA is thus an incremental GC-O technique. Another such method is charm analysis, which constructs an aromagram – a chromatogram with peak areas proportional to the odor activity (Acree *et al.*, 1984).

A more recent GC-O method involves sniffing of the eluent of a single GC experiment by 6–10 panellists simultaneously. The method is known as detection frequency analysis (DFA) and relies on the relative number of panellists detecting odors at particular retention times during a GC run being related to the relative importance of each aroma component (Falcão *et al.*, 2008). The nasal impact factor is defined by Equation 4.7.2.

$$\text{NIF} = \frac{N_t}{n} 100 \tag{4.7.2}$$

where N_t is the number of panellists recognising an odor at retention time t and n is the total number of panellists.

Such a technique was used to analyze Brazilian Cabernet Sauvignon wines, with the panellists recognizing aromas using 14 impact aroma descriptors. Furaneol was associated with a jam or caramel aroma and 2-methoxy-3-isobutylpyrazine (MIBP) was associated with vegetal or bell pepper aroma (Falcão *et al.*, 2008),

Recently, Poisson and Schieberle (2008a) used AEDA to determine 45 odor active components in Bourbon whisky with FD factors in the range 32–4096 (E)-β-damascenone and γ-nonalactone had the highest FD values (4096 and 2048 respectively), with and *cis* and *trans* whisky lactones also having high values (1024 and 512, respectively). The aroma compounds were extracted from diluted Bourbon whisky using diethyl ether and separated from nonvolatile components by solvent assisted flavor evaporation (SAFE) (Engel *et al.*, 1999). They were then separated into fractions containing components of increasing polarity by column chromatography. For AEDA, fractions were stepwise diluted with diethyl ether (1:1, 1:2, 1:4, 1:8 . . . , 1:256, . . . , 1:4096). Thirty one of the 45 most odor active components in Bourbon whisky were quantified by stable isotope dilution analysis (Poisson and Schieberle, 2008b) and their OAVs were calculated using this data and OTVs determined in water: ethanol (6:4 by volume). Twenty-six of these had OAVs greater than unity and when recombined they mimicked the overall aroma of the whisky.

As previously mentioned, GC-O and AEDA are the most frequently used methods to determine the most active odorants in an alcoholic or other beverage. Omission tests and reconstitution tests are often applied in conjunction with GC-O and AEDA data to judge the importance of one component or a group of components in a reconstituted mixture (see the example above). It is here that there is often a discrepancy between the overall odor of a reconstituted mixture of high impact odorants and that of the original beverage, even though the levels of major odorants are identical in both mixtures. This defect is sometimes known as 'reconstitutional discrepancy' and is believed to arise because the omission of low impact odorants in the reconstituted mixture (Bult *et al.*, 2001).

Low impact odorants (those with low OAVs) have been traditionally considered to be unimportant in the global aroma perception of a foodstuff or alcoholic beverage. However, there is a growing opinion that the presence of aroma components at sub- or peri-threshold levels may either modify olfactory perception of high impact odorants or act synergistically to influence the overall aroma profile (see for example Escudero *et al.*, 2004 and 2007; Ryan *et al.*, 2008; Sánchez-Palomo *et al.*, 2007; Caven-Quantrill and Buglass, 2008 and references therein). It should be noted that low impact odorants make up the big majority of aroma compounds in alcoholic and other beverages.

It seems that predictive mathematical models that reduce odor interactions to a set of simple rules are unreliable and at best can give a crude representation of a real odor (Ryan *et al.*, 2008). Instead, it appears that a combination of odor molecules interact with the olfactory system in a more complex way than in the proposals of simple addition/proportional odor representation and vector predictive models. For example, Atanasova *et al.* (2004; 2005) studied the qualitative interaction of binary mixtures of wine odorants with woody notes and fruity notes and found that a woody olfactory sensation dominated the odor of mixtures

where the perceived intensities of each unmixed compound were equal. Also, quantitative results at supra threshold levels indicated that perceptual interactions were not symmetrical and depended on concentrations.

There are many examples where inclusion of minor odorants (according to GC-O results), in a reconstitution mixture, at concentrations well below their OTVs, results in an overall aroma that is much closer to the real thing. It appears as if the minor components act in synergy to modify the olfactory perception of the major odorants. For example, when dearomatized wine was spiked with 2-methoxypyrazine (pepper notes) at levels found in wines, it was found that the odor perception was merely an indefinite earthy note (Escudero *et al.*, 2007). However, if 1-hexanol and (*Z*)-3-hexenol were also added (both at levels well below their OTVs), a peppery aroma was more easily discernable.

The importance of materially minor aroma components in overall odor perception can be illustrated in a different way – by the correlation between analytical and sensory data. The sulfury characters of 58 new make Scotch malt whiskies were determined by a highly trained and experienced panel of assessors and the scores were correlated with the levels of 36 known organosulfur congeners (obtained from headspace GC experiments) using partial least squares regression (PLSR) (Jack and Fotheringham, 2004). The correlation was 0.67. On the other hand, when the levels of another 20 (unidentified) sulfur components in the analytical data were included in the correlation analysis, correlation was improved to 0.79, indicating that these unknown components made a significant contribution to the global sulfury aroma perception of new make malt whiskies.

Because of repeated observations of the modification of high impact odorant perception by sub- and peri-threshold odorants, it has been suggested that the traditional GC-O AEDA and similar methods need to be extended to include neurological analysis (Ryan *et al.*, 2008). In particular, electroencephalography (EEG) and functional magnetic resonance imaging (fMRI) together could be linked with GCO/sensory analysis for a better understanding of odor perception.

4.7.4 Sensory Tests

Sensory evaluation is a valuable tool for both quality control and research in all areas of the alcoholic beverage industry. Standards and conditions for the various kinds of sensory analyses are in place in all countries, laid down by organizations or institutes dedicated to overseeing standardization and uniformity in many areas of commerce and industry. Many of these institutes are member bodies of the International Standards Organization (ISO), based in Switzerland (Table 4.7.1). Furthermore, individual institutes associated with the drinks industry have their own guidelines for sensory evaluation (e.g. The Institute of Brewing and Distilling). These standards are designed to maximize the quality and consistency of data generated from sensory tests and they refer to experimental procedure and conditions that are deemed to be necessary to achieve such data. They deal with all aspects of experimental set up from the type of room, including its sampling booths, temperature and lighting, to how the sample is presented, including volume, type of container and so on. Some of the standards also deal with the education and training of panellists.

However, for the sensory analysis of spirits, there are several aspects of sample handling and presentation that are not mentioned in the standards, as these are often nonspecific and apply to foodstuffs or alcoholic beverages in general. Consider the case of Scotch whisky sensory evaluation. Firstly, flavor sensory analysis is based entirely on aroma (known as 'nosing'), because of the detrimental effects of tasting or ingestion on the judgement and health of blenders or taste panellists, since they may need to judge a large number of samples during the course of a normal working day. Furthermore, Scotch whisky samples are diluted to 20% ABV prior to analysis for reasons of comfort (less pungency on the nose), and since they are not ingested, the same sample can be shared between a number of panellists. Hence, modifications of or additions to the general standard procedure need to be implemented in order to minimize variation in sample condition due to

Table 4.7.2 *Types of sensory analysis procedures and their uses*

Type of test	Examples	Applications
Descriptive	Free choice profiling method Flavor profiling method Quantitative descriptive analysis Trueness to type method	All these tests require a panel of experts or trained tasters. The aim is to describe the flavor of one or more samples using a specific vocabulary of sensory terms.
Difference	Duo-trio test Triangular test	Experts or trained panelists determine whether two or more samples are different or if they are identical.
Flavor scaling	Ranking test Estimation of magnitude test	Technical tasters determine intensities of one or more flavor descriptors in several samples.
Preference	Paired comparison tests	Consumer and trained tasters assess drink on the presence or absence of a flavor descriptor.
	Preference mapping tests	Tasters find relationships between different drinks.

Scotch whisky procedure mentioned above (Jack, 2003). The major guidelines suggested for Scotch whisky sensory evaluation included the following:

- Presentation of sample (30 ml) (20% ABV) in tulip glasses (130 ml) covered with watch glasses that are kept in place between evaluations
- Samples are all well equilibrated to room temperature, which is comfortable (e.g. 21 °C) and constant
- The length of time between sample preparation and evaluation should be minimized, as should the number of panellists, within practical limits
- In tests where samples are being compared, if a sample is spilled, all the samples are replaced.

In this way, sensory samples are presented to the panellists in optimum condition, allowing the achievement of high quality sensory data.

The many different kinds of sensory tests are summarized in Table 4.7.2, where it will be seen that the majority of them are conducted by either expert tasters or a panel of tasters who have undergone an extensive program of training in sensory assessment beforehand. Sensory panellists need regular training and assessment.

Descriptive tests and difference tests are probably the most frequently used sensory tests. Descriptive tests aim to provide an overall account of the aroma/flavor of an alcoholic drink using a vocabulary of flavor terms that has been agreed for that drink, whereas difference tests, on the other hand, aim to determine whether two or more samples are either identical or different.

Of paramount importance in descriptive tests is aroma/flavor terminology, the language of sensory analysis, which requires consistency in use and a common point of reference for meaningful communication (Simpson *et al.*, 2004). Ideally, a limited vocabulary of flavor descriptors should be available for a particular alcoholic beverage, and they should be and universally used by sensory analysis panels when assessing that kind of beverage. In practice, however, this has only been partially achieved. The most desirable attributes of a flavor vocabulary are (Simpson *et al.*, 2004):

- One-to-one correlation between flavor and descriptor
- A limited number of objective descriptors that are consistent with the beverage or sensory test
- Lack of subjective terms.

Vocabularies vary enormously in size from beverage to beverage, from 122 terms for beer (Meilgaard *et al.*, 1982) to 16 or so for certain spirits (Phelan *et al.*, 2004; Simpson *et al.*, 2004). As an example, in developing a vocabulary for gin, the experienced sensory panel was first given a number of samples of gin, gin concentrates and botanicals to assess and generate descriptors (Phelan *et al.*, 2004). The collection of terms was summarized and rendered down to a vocabulary of 16 descriptors: aniseed, buttery, citrus, floral, fruity, herbal, juniper, oily, pungent, soapy, solventy, sour, spicy, stale, sulfury and sweet (see Figure 4.7.7). The panel was then trained to understand and recognize each of the descriptors by use of training aids (including botanical distillates and raw botanicals) and practice sessions.

There are two basic approaches to developing a vocabulary, firstly by allowing the generation of personalized descriptors (free choice profiling) by trainee panellists and secondly by the imposition of descriptors on the trainee panellists in advance of the sensory assessment. The second approach is generally reckoned to be

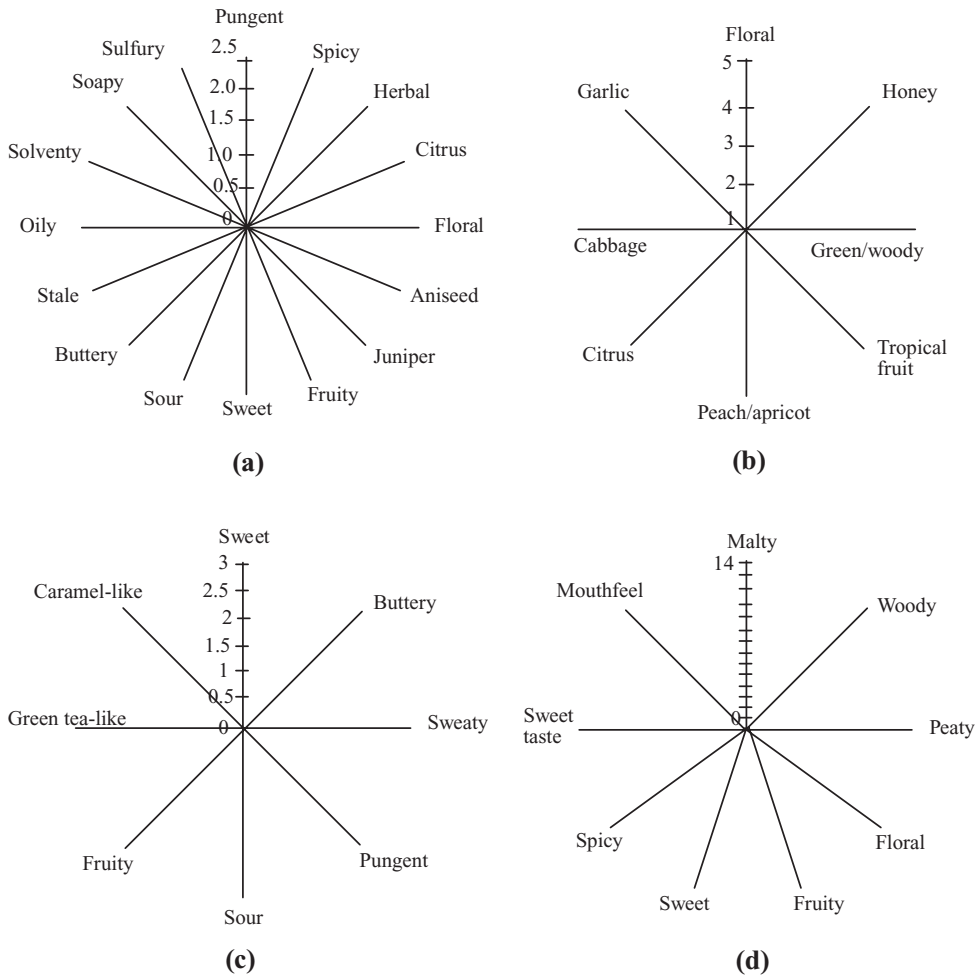

Figure 4.7.7 *Flavor profile templates for (a) gin and gin botanical distillates, (b) lychee, (c) strawberry juice and (d) Indian whisky. Scale used is shown only on one axis. Phelan* et al.*, 2004; Mahattanatawee* et al.*, 2007; Schieberle and Hofmann, 1997; Maitlin and Stephen, 2004*

rather more satisfactory, but sometimes a combination or hybridization of the two approaches is used. The choice of descriptors can be derived from authentic samples that have distinctive flavor attributes, such as botanical distillates for gin descriptors (see above), or peated malt whiskies for peat smoke descriptors, or Earl Grey tea for the bergamot descriptor used for wine made from Touriga Nacional and Port wine, for example. Alternatively, chemical reference standards can be used for training of panellists, where diluted pure flavor chemicals are added to model wine or neutral spirit, as has been proposed for whisky flavor training (Lee *et al.*, 2000).

Chemical flavor standards need to be of high purity food grade quality, but also need to be consistent from batch to batch. Most require very high dilution before they can be used as flavor standards and their solutions are not necessarily stable, often requiring fresh preparation. To overcome this problem, a series of microencapsulated flavor reference compounds are available for beer sensory analysis training and more recently for distilled spirits assessment (Simpson *et al.*, 2004). The flavor compound is released from a free flowing powder contained in a small capsule when added to a beer or spirits base. Each capsule contains a precise weight of flavor compound and the content of the capsule, unlike many diluted flavor references, is stable for years at room temperature. Spirits flavor standards include 2,3-butanedione (diacetyl, buttery), *o*-cresol (medicinal), dimethyl trisulfide (sulfury, onion), ethyl hexanoate (apple), ethyl maltol (sweet), eugenol (spicy), guaiacol (smoky), hexanal (grassy), isoamyl acetate (banana), isovaleric acid (cheesy), 2-phenylethanol (floral), vanillin (vanilla) and whisky lactone (coconut).

Sensory profiling is probably the most widely used kind of quantitative descriptive test (Stone *et al.*, 1974). Here, the already trained panellists are required to assess the samples, under standard sensory analysis conditions, according to the set of training descriptors. This is done using a scale for scoring each descriptor – the higher the score for a particular descriptor, the greater the presence of that descriptor in the global aroma or flavor. Mean scores are calculated for each descriptor and for each sample. The results can be visualized in a number of ways, but spider web diagrams are probably the most widely used representations of flavor profiles these days. Here, the mean scores for the flavor attributes are plotted on lines emanating from a central point at regular angles and the scores are then joined by straight lines, so the finished plot looks rather like a portion of a spider's web. Examples of spider web plots for gin (and gin botanicals), Indian whisky, lychee and strawberry juice can be seen in Figure 4.7.7. Examples of flavor profile templates used for sensory profiling of different kinds of Scotch malt whiskies can also be seen in 3.2.6 (Figure 3.2.13).

Special data collection software (such as those of Compusense) and standard spreadsheet, graphical and statistical software (such as Microsoft Excel or Unistat software) can be used to process the results in other ways than constructing spider web diagrams. Multiple comparison tests can be used to identify differences in the assessment of duplicate samples, thus ensuring that the panel is using the vocabulary reproducibly. Principal component analysis (PCA) can be used to classify groups of samples according to their sensory profile and also to determine the major descriptors that discriminate amongst samples. Analysis of variance (ANOVA) is frequently used to determine individual differences between panellists.

Descriptive sensory tests have been used to create flavor profiles for a wide range of alcoholic drinks and their precursors, only a few of which are quoted as examples here: gin (and gin botanicals) (Phelan *et al.*, 2004 – see Figure 4.7.7), lychees (Mahattanatawee *et al.*, 2007 – see Figure 4.7.7), strawberry juice (Schieberle and Hofmann, 1997 – see Figure 4.7.7), whiskies (Jack, 2003; Maitlin and Stephen, 2004 – see Figure 4.7.7; Poisson and Schieberle, 2008b) and wine (Carlucci and Monteleone, 2001; Genovese *et al.*, 2007; Guedes de Pinho *et al.*, 2007). Depending on the requirements of the test (e.g. for wine, aroma only or aroma, flavor, taste and mouthfeel), the samples and reference standards will be sniffed, or sniffed and tasted (sometimes swallowed). Likewise, whether the samples and standards will be sniffed, or sniffed and tasted depends on the nature of the sample and the accepted protocol for sensory analysis in that part of the alcoholic beverage industry. Beer, cider and wine, for example, can be sniffed and ingested, whereas Scotch whisky is sniffed ('nosed') only.

The design of a descriptive sensory test depends upon the specific goals of the analysis, but the major steps that are needed are summarized below:

- Selection of panellists and choice of descriptors to be used
- Training of panellists with samples and reference materials
- Testing, maybe in several sessions
- Receiving and processing the results by statistical methods
- Assessment and recommended adjustments for future tests.

All sensory sessions, and probably the basic experimental design, will be conducted according to protocols and guidelines laid down by the various standards or similar institutes (e.g. ISO or one of its member bodies, such as AFNOR).

Panellists will normally be experienced sensory assessors or they may have been chosen from preliminary aptitude tests. Choice of descriptors can be made from a consideration of sensory literature (e.g. see Mahattanatawee *et al.*, 2007), but is more likely to be made by preliminary sensory sessions with the panellists generating an initial set of descriptors, followed by deciding the most appropriate terms, usually 8–16 descriptors (e.g. Carlucci and Monteleone, 2001; Phelan *et al.*, 2004; Guedes de Pinho *et al.*, 2007). The descriptors can be entirely aroma/flavor related, as in the sensory analysis of lychee fruit (e.g. Mahattanatawee *et al.*, 2007) or can include taste and mouthfeel as in the assessment of young red wines (Carlucci and Monteleone, 2001).

Further panellist training sessions are then conducted in order to improve recognition and discrimination, using reference standards at various concentrations, as well as samples to be tested later. For example, 2-phenylethanol, cherry jam, aqueous quinine hydrochloride and aqueous tannic acid were used as reference materials for rose odor, cherry odor, bitter taste and astringent mouthfeel descriptors, respectively, generated by the panel for the description of young Aglianico wine (Carlucci and Monteleone, 2001). Similarly, bergamot oil or Earl Grey tea were used as reference standards for the bergamot odor descriptor of Touriga Nacional wines (Guedes de Pinho *et al.*, 2007).

Testing is usually carried out on a strictly limited number of samples per session, with the panellists testing the reference standards then assessing the intensity of each of the descriptor contributions in the samples. A 100 mm unstructured scale with anchor points at 'hardly perceptible' and 'intense' (or similar phrases) is often used for scoring, but point category scales are also used. The testing is usually performed in duplicate or triplicate.

Other sensory analysis tests that are often performed on alcoholic beverages include triangular tests (which can be used to establish OTV) and rank order tests. Triangular tests are designed to determine differences or similarities between samples. Trained panellists are subjected to three samples; a reference containing a component relating to a particular descriptor and two unknowns, one with and one without the same descriptor. In a study of the role of methional in the aroma of oxidized white wines, the samples were oxidized wine (reference) and ethanolic extracts or HPLC fractions of nonoxidized and oxidized wine of the same type (Escudero *et al.*, 2000). Panellists sniffed the reference first and then the first unknown and assessed the similarity of aroma using a 100 mm unstructured scale, anchored with 'identical to reference sample' on the left and 'different from reference sample' on the right. This was repeated for the second unkown sample. The results were treated in two ways: by the total and correct answers and by univariate analysis of variance of scale responses, in mm from the left anchor.

Rank order or preference tests are often used to determine acceptability of a certain product (e.g. a new product compared with current products of the same company) or to determine panellist preferences (e.g. amongst a new product and similar products of different companies). In these ways, new melon spirits and melon liqueurs, made in different ways (e.g. unmacerated spirit, spirit macerated with melon seeds and

placenta, etc.) were assessed for preference. Likewise, the most favored melon liqueur was assessed against well-known commercial liqueurs for acceptability (Hernández-Gómez, *et al.*, 2009).

The quality of an alcoholic beverage is partly a subjective matter and is difficult to either quantify or generalize, and just as difficult to predict from the beverage's chemical composition, despite many studies on the chemical origins of certain perceptions of quality, such as fruitiness, oak character and others. Recently, sensory analysis has been used, alongside GC-O to assess the quality of 25 premium Spanish red wines (Ferreira *et al.*, 2009). Panellists were given the coded wines to smell and taste, and to sort them into five categories, ranging from 5 (exceptional) to 1 (defective or rejectable). The quality index of each wine was obtained by averaging all the individual scores. The results were matched with partial least squares analysis of three analytical variables: defective odorants (mainly simple phenols), negative odorants and fruity-sweet odorants. It was found that quality, as decided by the panellists, was primarily related to the presence of defective or negative odorants, rather than to desirable fruity-sweet odorants.

Part 5
Nutritional and Health Aspects

Nigel J. Fuller, Suk Hean Lee and Alan J. Buglass

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

5.1
General Introduction

Evidence from prehistory indicates that alcohol may have been actively produced for human use in China and the Middle East as far back as perhaps 9000 BCE to 8000 BCE, but there are more certain archeological indications of wine production starting around 5000 BCE and beer from around 4000 BCE (Wolf *et al.*, 2008) (Section 1.2.1). Over subsequent millennia, its social effects and medicinal properties have continued to be highly valued with increasing and substantial quantities of alcoholic beverages being consumed as relatively safe and sterile sources of important nutrients, especially as communities began to grow. Bacterial contamination was essentially preventable during production of alcoholic beverages by the use of boiling, the presence of yeast in high concentrations and the relatively low pH, and the ethanol (alcohol) content per se also helped to prevent spoilage and preserve some of the nutritional value. From these early origins, the progression of knowledge and the craft of producing alcoholic beverages have resulted in their spread across the globe (Section 1.2.1). Essentially, alcoholic beverages with relatively low alcohol content are produced by the fermentation of grains, such as beers (Chapter 2.6), and fruits, such as ciders (Chapter 2.8) and wines (Chapter 2.9). Distillation of these primary products of fermentation yields beverages of relatively high alcohol content, such as spirits and liqueurs (liqueurs are often referred to as cordials, depending on location), enabling the more practical transport and storage of alcohol (Part 3). Generally, the fermentation and maturation processes are relatively short for beers and ciders to reach their optimum state for consumption, compared with wines and the distillation and aging of spirits (Parts 2 and 3).

The numbers and variations of alcoholic beverages based on these generic styles have increased substantially because of the many additional ingredients that may be used, frequently when concocting, for example, the numerous cocktails created from spirits or wines mixed with fruit juices. Therefore, manufacture of the vast numbers of multifarious alcoholic beverages is now possible by the use of a multitude of ingredients and many different processes, from small 'home brew' production through to the industrial scale of multinational concerns with their capacity for distribution throughout the world. In view of this, it is not surprising that there is substantial variation in the nutrient content of the vast array of alcoholic beverages currently available. Although these differences may be especially apparent between the main generic styles of alcoholic beverages, the typical nutrient content of which can be easily compared through general reference sources, such as Table 2.13 in *McCance and Widdowson's, The Composition of Foods* (Food Standards Agency, 2002), individual products within these styles also show considerable variation in nutritional value. Furthermore, as so many different alcoholic beverages are readily available from a substantial variety of sources, extremely variable quantities are also consumed according to individual preferences and patterns of drinking, with

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

significant implications for nutritional status and concomitant health consequences (see the general texts of Morgan and Ritson, 2003; Watson and Preedy, 2003). Unfortunately, because of the vast number and variety of styles, it is not possible in this chapter to research and cover the entire range of nutrients present in all of the conceivable alcoholic beverages. However, the content and potential nutritional value of the generic styles of alcoholic beverage, with specific examples of individual products wherever appropriate, will be considered, along with the evidence based metabolic sequelae, and possible health and social consequences of their consumption.

Although nutritional and health aspects are in reality inter-related, in this book, nutritional topics are emphasized in Chapters 5.2–5.5, whereas health topics are focused in Chapters 5.6–5.11. In view of this, Chapter 5.5 acts as a 'bridge' between the two, leading into Chapter 5.6, where it will be seen that many of the detrimental effects of extraneous alcohol consumption are, at least in part, a result of nutritional changes. Chapters 5.7 and 5.8 deal with health related topics concerning the carbohydrate content and antioxidant content (respectively) of alcoholic drinks. The later chapters, Chapters 5.9–5.11, focus on health aspects related to the toxic effects of minor beverage components, namely additives, residues and trace substances.

5.1.1 'Alcohol' in Perspective

In the context of alcoholic beverages the term 'alcohol' is usually applied when referring to ethanol (also known as ethyl alcohol), which is a primary alcohol with the formula CH_3-CH_2-OH, and, essentially, this generic use will be continued here. However, the definition of 'alcohols' includes a large number of related molecules with similar chemical and structural properties, many of which are toxic and some of which may occasionally appear as components of the diet. In very simple terms, alcohols are characterized by a hydroxyl group bound to a carbon atom of an alkyl group (alkyls take the form C_nH_{2n+1}; e.g. methyl CH_3 and ethyl C_2H_5), and they differ from each other by the number and position of carbon atoms present in the molecule. Alcohol (ethanol) is relatively toxic and so excessive exposure, especially through the very high levels that may be ingested on some occasions, is not to be recommended. However, alcohol may be considered to have some nutritional value that can be utilized by the human body because it provides energy, at 29 kJ/g alcohol, from its breakdown to the metabolic end products, carbon dioxide (CO_2) and water (H_2O); see 'Alcohol Catabolism' (Section 5.5.1). For general information, 1 kJ is equivalent to 0.239 kcal (i.e. 1 kcal = 4.184 kJ) so that 29 kJ/g alcohol is equivalent to 7 kcal/g alcohol, which is the alternative value seemingly most often quoted for the energy value of alcohol.

Certain alcohols, such as methanol, 1-propanol, 2-propanol and higher (secondary and tertiary) alcohols, which may be intentionally or accidentally ingested on occasions, are far more toxic and cannot be considered acceptable constituents of the diet, whereas others, such as sugar alcohols, are more readily accepted as dietary components. Glycerol, for example, is a sugar alcohol that may be a fairly major product of fermentation, or may be added to alcoholic beverages for character, but without the intoxicating properties of ethanol. Indeed, glycerol itself and certain other sugar alcohols are widely utilized as food additives, especially on a commercial basis by the food industry, because they do not cause intoxication, and significant levels of these alcohols may be present in many of the readily available and more highly processed foods found on supermarket shelves. Other alcohols that are produced during fermentation processes are known as fusel alcohols or fusel oils and are considered important to alcoholic beverages because certain of these more complex alcohols may add desirable character to some (e.g. see Section 3.7.2), but may impair the character of others if present at high levels (e.g. see Section 2.9.1). Levels of 1- and 2-propanols, butanol, furfural and amyl alcohol, for example, may be increased during fermentation under certain modifiable conditions (including higher temperature, lower pH and less than optimum yeast activity), and may be selectively included, or not, in distilled beverages as particular distillation processes are differentially applied according

to the resultant character desired (Chapters 2.2 and 3.1). Collectively, organic acids, esters and higher alcohols that may be distilled along with ethanol are known as congeners and the degree of difference amongst these many and varied substances may influence the amounts likely to be consumed of any particular beverage. Although detoxification of the relatively low amounts of methanol, and possibly other alcohols that may be ingested under usual circumstances of social drinking, provides small amounts of energy and carbon units that are disposed of through the usual metabolic pathways, such alcohols are not considered to be acceptable as nutrients because of the relatively high toxicity of these compounds and of their metabolites. For example, formaldehyde is an extremely toxic product of methanol catabolism (Section 5.5.2) that can lead to blindness and even death when methanol is ingested in sufficiently large quantities.

Relatively simple standardization of the alcohol content in different types of alcoholic beverage has been implemented in order to try to promote greater understanding of the implications of the large range of alcohol levels available from the different beverages, especially for health and legal reasons. Alcohol offered for sale in the UK (above 1.2%) must have its alcohol content clearly stated and displayed on the product itself or at the point of sale, usually as the amount of alcohol by volume (ABV) as percentage (e.g. 14% by volume, for a red wine). The 'unit' of alcohol in the UK is equivalent to 10 ml or 7.89 g of pure alcohol (the density of ethanol is 0.789 g/ml), which is the exact amount found in a 25 ml measure of 40% ABV spirits, and approximately that in a 125 ml glass of about 8% ABV wine or a half pint of 'session' beer (Section 5.6.1) of about 3.6% ABV. The current UK Government guidelines for healthy adults recommend no more than 3 to 4 UK units of alcohol per day for men and 2 to 3 UK units for women, with lower levels in pregnancy (less than 1 to 2 units on only a couple of occasions per week at most); see the website of the British Nutrition Foundation (http://www.nutrition.org.uk) for general information on dietary guidelines. The UK unit is not to be confused with a nominal and very variable 'standard' amount of alcohol applied to alcoholic beverages around the world, which are generally higher than the UK unit (see Section 5.6.1). In the USA, the standard amount is equivalent to 14 g or 17.75 ml (1.2 tablespoons or 0.6 fluid ounces), and in many other countries this amount is even greater; relatively high standard amounts are applied in Hungary (21.5 ml, 17 g) and Japan (25 ml, 19.75 g), for example. For a comprehensive review on the topic of standardization of alcohol and other important aspects of alcohol consumption and health, see Foster and Marriott (2006).

It is important to note that most wines and very many beers are currently being manufactured at much higher alcohol content than those produced previously, which is a source of some confusion to consumers as they may seriously underestimate their actual alcohol intake. Certain commonly consumed red wines now contain perhaps 14% ABV and those beers and lagers generally considered to be 'regular' may be at least 5% ABV; therefore, a traditional or standard serving is often equivalent to upwards of 1.5 UK units. Also, many measures, especially spirits and wines, and whether or not consumed at home or in retail outlets, are now served in greater quantities than traditional standard measures. For example, a 'glass' of wine is now often served as a 175 ml or 250 ml measure rather than the 125 ml standard measure. Another complication for the consumer is that alcoholic beverages may be offered for sale in variable and nonstandard volumes in retail outlets. For example, in contrast to the regular pint (568 ml) and half pint (284 ml) measures in UK public houses, beers and lagers may be available in cans of 330 ml or in bottles of 500 ml, making difficult the ready estimation of the number of 'units' available for consumption. Therefore, despite the generally open displays of alcohol levels at retail outlets and on the products themselves, it seems that a majority of consumers probably lack a full appreciation of their total alcohol intake when consuming a majority of alcoholic beverages, putting themselves at risk of acute and chronic harm due to relatively excessive consumption of alcohol to which they may be unaware and insensitive. For informative purposes, another representation of the alcoholic strength of a spirit is the alcoholic 'proof,' a value that approaches double (1.75×) that of the ABV (%) in the UK – so a 40% ABV spirit is actually equivalent to 70 degrees proof spirit.

5.1.2 The Extent and General Implications of Alcoholic Beverage Consumption

Estimates of alcohol intake and the associated costs to health and social implications vary somewhat according to the particular country and region of interest concerned (Prime Minister's Strategy Unit, 2004, www.cabinetoffice.gov.uk; Association of Public Health Observatories, 2007). Very generally, in the 'Western World' average yearly alcohol consumption for each adult approximates 10 l of pure alcohol from all of the multifarious alcoholic beverages. The proportion of people consuming alcohol in different communities also varies considerably (Sieri *et al.*, 2002), with some societies banning alcohol consumption altogether. Individual responses to alcohol and, indeed, the likelihood of individual susceptibility to alcoholism are determined by both genetic and environmental factors, and the extent of their interaction (Gurr, 1996). Multiple genes have been implicated in the heritability of dependence (Gurr, 1996), and demographic and social factors are also important in determining alcohol intake and its impact on health (Klipstein–Grobusch *et al.*, 2002; Rehm *et al.*, 2003), as are patterns of alcohol consumption (e.g. Puddey *et al.*, 1999; Rouillier *et al.*, 2004; Duffey and Popkin, 2007; Smith and Shevlin, 2008).

Alcoholic drinks may be consumed in addition to normal dietary requirements or may effectively replace other foodstuffs due to a number of possible changes in appetite and certain behavioral factors. Firstly, additional satiety influences (positive and negative) may be imposed on normal appetite control, such as those produced physically by increased volumes ingested and, also, through hormonal feedback mechanisms in response to digestion and assimilation of certain nutrients. Secondly, modifications in feeding behavior, such as changes to otherwise regular healthy eating patterns imposed by more frequent and extended drinking sessions, including missed meals, snacking to replace traditional meals and inappropriate food selection, alter intake of these nutrients compared to the usual diet. Lastly, patterns of food and nutrient consumption are also influenced according to acute or chronic use and low to moderate or excessive consumption at any particular time span (Forsander, 1998; Yeomans *et al.*, 2003; Yeomans, 2004; Caton *et al.*, 2007; Kokavec, 2008; see Section 5.5.3).

Although nutritional and health information is known to influence consumer perceptions, these perceptions are apparently not the most compelling determinants of drinking behavior and choice (Wright *et al.*, 2008). In Britain, about 90% of the adult population consumes or has consumed alcohol to some extent with about a quarter of consumers regularly drinking above recommended guidelines (Prime Minister's Strategy Unit, 2004; www.cabinetoffice.gov.uk). Most consume alcohol 'sensibly' but for many others consumption is excessive leading to possible dependence and harm, especially if this occurs over the long term. Dependence, both physical and psychological, is a major public health concern (Morgan and Ritson, 2003), even in the young (McArdle, 2008), and the vast extent of short- and long-term health and social issues has led to calls for nationwide strategies to tackle alcohol misuse, albeit with some consensus disunity (Babor, 2008).

However, although certain of the many factors associated with consumption of alcoholic beverages have the potential for serious harm, especially when alcohol is ingested in large quantities, other factors appear to confer some health benefits, even if only marginal. For some aspects of health the relative risk of alcohol consumption appears to follow a 'j' shaped curve in which low to moderate levels of intake are associated with lower risk to health than in abstainers or very occasional drinkers (Section 5.6.1) (Gurr, 1996). The apparent cardiovascular benefits observed on an epidemiological basis have led to deliberations concerning possible underlying protective mechanisms (e.g. Agarwal, 2002; Puddey *et al.*, 2003), including the effects of alcohol on blood platelets (Ruf, 2004), for example. However, the risk to cardiovascular health rises considerably as alcohol intake increases beyond that considered moderate, being highest in excessive drinkers and alcoholics (Gurr, 1996). Therefore, the possible nutritional and health consequences for individuals are extremely complex and potentially very serious indeed for high consumers, with major implications for population health (Table 5.1.1), now and extending further into the millenium (Foster and Marriot, 2006; for summary, see British Nutrition Foundation website, http://www.nutrition.org.uk). These effects of alcohol consumption

Table 5.1.1 *Potential health consequences of imbibing alcoholic beverages**

Accidents and injury	Unintentional and immediate physical lesions and even death due to intoxication related accidents, with possible short- and long-term consequences depending on severity, with violence and crime related intentional injuries associated with excessive alcohol intake.
Addiction	Possible long-term psychological and physical dependence.
Amnesia	Loss of memory for variable periods due to excessive alcohol intake.
Cardiovascular complications	Although there appear to be some cardiovascular health benefits especially at low levels of alcohol intake (e.g. reviewed by Puddey *et al*., 1999; Agarwal, 2002; Suter, 2004) and blood coagulability appears to be reduced by alcohol per se due to effects on platelet aggregation along with possible polyphenolic component effects (Puddey *et al*., 2003; Ruf, 2004), greater alcohol intake and concomitant metabolic challenges predispose to increased arrhythmias, cardiomyopathy, vascular hypertension and coronary heart disease (Morgan and Ritson, 2003).
Drug/alcohol interactions (pharmaceuticals and drug abuse)	Alcohol may reduce the capacity of the body to detoxify certain pharmaceuticals and xenobiotics, e.g. through various detrimental interactions with cytochrome P450 during catabolism of alcohol through the microsomal ethanol oxidizing system (MEOS; Leiber, 2000; Section 5.5.1).
Gastrointestinal problems	Gastritis, esophagitis and pancreatitis may develop over the short term with long-term exacerbations such as Mallory–Weiss syndrome (severe esophageal bleeding) as a result of the direct effects of alcohol per se on the gut with malabsorption of important nutrients potentially a major consequence.
Hepatic disease	Fatty liver, hepatitis and cirrhosis may be long-term consequences of excessive alcohol consumption due in major part to the metabolic challenges encountered during alcohol catabolism.
Hypersensitivity, allergy and autoimmune responses	Certain constituents of alcoholic beverages, other than alcohol, have been associated with specific hypersensitivity, allergic or autoimmune reactions, such as biogenic amines and polyamines in wines and beers causing allergic reactions (Kalac and Krizek, 2003; Vally and Thompson, 2003; Ancín-Azpilicueta *et al*., 2008) or the antigens gluten (wheat) and hordein (barley) exacerbating existing *celiac disease* (Ellis *et al*., 1990; Dostálek *et al*., 2006).
Hypoglycaemia	Changes in the flux of intermediary metabolites through usual metabolic pathways caused by high levels of alcohol intake may result in seriously low blood glucose concentrations.
Malignancies	Excessive long-term alcohol intake is associated with a number of malignancies, although alcohol per se may not be the agent specifically responsible.
Malnutrition	Inadequate nutritional status is associated with alcohol abuse either through reduced dietary intake of other nutrients or by the direct effects on nutrient absorption and metabolism.
Methanol toxicity	Methanol is a by-product of fermentation, which may be concentrated significantly particularly during illegal distillation, and its ingestion in sufficient quantities may lead to blindness and even death.
Myopathy	Occurs in skeletal muscle with a wide spectrum of symptoms and may be acute or chronic, with *rhabdomyolysis* a possible secondary complication of alcohol related disorders or its direct toxicity, with increased sodium permeability and consequent accumulation of calcium and associated hypophosphataemia reducing cellular ATP underlying the condition; tetany may also occur in alcoholics due to low levels of calcium and magnesium.

(*Continued*)

Table 5.1.1 (Continued)

Nervous system exacerbations	In addition to possible brain damage from cerebrovascular events (e.g. hemorrhagic stroke), alcoholic dementia, cerebellar degeneration, Wernicke–Korsakoff syndrome, Marchiafava–Bignami syndrome, peripheral neuropathy and neuropraxia, amongst other conditions, may also present, especially in chronic excessive alcohol abuse.
Osteoporosis	Alcohol appears to affect bone turnover leading to reduced bone mineral content and the occurrence of fracture may be more prevalent, although there are potential protective effects of silicon in beer against aluminium, the ingestion of which has implications for bone health (and aluminium is also associated with degenerative disorders of the nervous system).
Pneumonia	May occur due to aspiration of stomach contents during acute intoxication.
Poisoning	Acute excess quantities of alcohol may result in poisoning, with death occurring in half of all individuals when blood alcohol levels reach about 0.45%.
Psychological disorders and social consequence	Many psychological disturbances may occur with excessive and/or long-term alcohol consumption and its dependence that may lead to implications for acceptable social interactions with alcohol frequently implicated in suicides.
Sexual exacerbations, infertility and foetal disorders	Reproductive capacity can be significantly reduced in both susceptible men and women, with reduced fertility and increased risk of spontaneous abortion, and potentially serious risk to fetal health with fetal alcohol syndrome presenting in cases of serious alcohol misuse especially in the peri-conception period and early pregnancy, up to about 10 weeks, but throughout pregnancy there is an increased risk.
Skin disorders	Alcohol mediated skin lesions occur and increased risk of infective diseases is associated with alcohol abuse.
Withdrawal	Withdrawal from alcohol dependence is associated with sometimes severe physical and psychological reactions.

*Presented in alphabetical order, not in order of severity, and for general details of these health consequences, see Gurr (1996), Morgan and Ritson (2003), Paton and Touquet (2005), Smart (2007) and Watson and Preedy (2003).

on health are also well presented in a number of generally informative publications aimed at different levels of interest, background or requirements, including those of Gurr (1996), Morgan and Ritson (2003), Paton and Touquet (2005), Smart (2007) and Watson and Preedy (2003).

Although it is the amount of alcohol consumed that is of primary interest for health generally, there is also a lack of appreciation of the full implications of alcohol beverage intake on nutritional and health status. A vast majority of consequences of alcohol ingestion are clearly detrimental, as presented in Table 5.1.1. However, alcoholic beverage consumption is often associated with some purported health benefits. The nature of any particular type of alcoholic beverage and the specific circumstances surrounding its usage determines the volume likely to be consumed and, therefore, the total amounts of alcohol and nutrients (and potential toxins) likely to be ingested. Specific nutrient intakes are, for the most part, quite small in relation to dietary requirements for maintaining optimum nutritional status and health, although quantities of certain nutrients consumed in particular alcoholic beverages may be significant. Therefore, the intake of nutrients from alcoholic beverages may vary considerably in terms of their overall contribution to the diet and, of course, to fulfilling nutrient requirements (see Section 5.1.4). For example, a serving of 1 unit of lager may provide about 2% of purported daily requirement for thiamine but about 15–20% of that for folate (Section 5.4.1). When assessing the nutrient impact of alcoholic beverages, it is important to recognize that serving sizes differ considerably and that the overall nutrient load (i.e. the total amount ingested) is also variable

within and between individuals depending on consumer habits on a day to day basis. Such variability may be extreme as some consumers, possibly considered moderate drinkers on the basis of a weekly average, may be exposed to relatively low levels of alcohol intake almost every day, whereas others who are drinking equivalent amounts overall may be exposed to far higher intake levels during more intermittent sessions of 'binge' drinking, both modes of which may have implications for dietary intake and health (Puddey *et al.*, 1999).

5.1.3 Ingredients, Processing and the Nutrient Content of Alcoholic Beverages

Raw ingredients used in the production of alcoholic beverages are many and varied, some of which may contribute to the nutritional value of the final product, whereas others may not. In general terms, cereal grains are used for beers (Chapter 2.6) and fruits for wines (Chapters 2.9 and 2.11) and ciders (Chapter 2.8). Particular ingredients may be preferred for producing distilled beverages of specific character; whisky (Chapters 3.2 and 3.3) from fermented malt or cereal grains and brandy (Chapters 3.6, 3.7 and 3.8) from fermented fruit juices, for example. Other ingredients may be used for slightly less usual or speciality beverages, such as some root vegetables (e.g. for some vodka; see Section 3.4.3), molasses/sugar cane (cachaça and rum; see Sections 3.5.2 and 3.5.3), honey (mead; see Section 2.11.5), even flower petals for some wines, amongst many others. The relative availability of ingredients largely determines the styles of alcoholic beverages produced in a particular locality, with rice being the predominant staple grain in the East, corn (maize) in the USA and South America (the Incas, for example, were known to use corn for producing alcohol) and barley in the UK and Europe (Foster and Marriott, 2006). Almost any fruit may be used to produce wines locally, although grapes are the most abundant fruit used on a worldwide scale, and many fruits may also be used in producing fruit beers, such as in the UK and Belgium (Section 2.6.13).

Many beverages (alcoholic and nonalcoholic) are produced and consumed locally, even at the household level, such as some fermented milk products in Russia and parts of Africa, and many types of beers (e.g. pombe, shakporo, tella, and others made from various grains such as sorghum: see Section 2.7.2), wines and spirits, in particular geographical areas in different regions of Africa, for example. A fine description of how the wide variety of fermented beverages (including alcoholic wines, beers and spirits) are produced in Zimbabwe, as an example of an African Nation, at various levels from small household production through to large-scale manufacture, is provided by Gadaga *et al.* (1999). In South America, for example, beers were produced with manioc and peanuts as well as corn (Wolf *et al.*, 2008) (Section 2.7.2). Many of these household and local products are very crude in nature. However, because of the limited amount of processing involved, such products are usually perceived as having better nutritional qualities than the often clearer mass produced beverages. Homemade beers and wines are still quite a popular pastime in some countries such as in Europe, including the UK, although distillation is only permitted under license in the UK. Overall, however, homemade beverages are unlikely to have a major impact on nutritional status and health of the population in the more developed countries.

Supplementary ingredients, for instance fruit and herbs, and also the infused flavors of liqueurs, such as from chocolate, may be added to modify the product as processing progresses, as in the production of Vermouth (Section 2.12.2), apérifs (Section 2.12.3) and liqueurs (Chapter 3.9). Other ingredients, the additional flavoring hops added later in beer production for bitterness, or orange juice mixed with wine for making Sangria, for example, may be blended with particular beverages during and after the final production stages to modify the taste of the base product. Additives may modify the presentation or preservative properties, or simply produce a different type of beverage altogether, such as creating cocktails from a variety of mixers. Certain ingredients may be added during beer production in particular, in order to improve taste (e.g. some salts), or to provide body (e.g. maltodextrin) and smoothness (e.g. licorice sticks). Some waste products of fermentation,

such as spent ingredients and precipitates, may be allowed to remain in the beverage in greater or lesser quantities for particular character or may be removed completely during processing to produce a slightly different style of a particular beverage or simply to improve its presentation. Essential ingredients used in the initial stages of production, such as yeast, preservatives (e.g. sulfites) and finings (e.g. isinglass, egg white, bentonite, etc.) (Sections 5.9.2 and 5.9.3) may be partially or completely removed before the final product is ready. However, residual amounts of particular ingredients present in the finished beverage may have significance for health status (e.g. Vally and Thompson, 2003). For example, antigens such as gluten (wheat) and hordein (barley) present in some alcoholic beverages, specifically beer, may exacerbate existing celiac disease in susceptible individuals (Section 5.11.3) (Ellis *et al.*, 1990; Dostálek *et al.*, 2006); celiac disease is an autoimmune condition affecting the integrity of the small intestine leading to protein losing enteropathy and poor absorption of essential nutrients. Other constituents of finished alcoholic beverages, which are derived from the raw ingredients or produced during fermentation, may also have implications for health because of their potential biological activity in the chemical form as ingested or because they produce metabolically activated derivatives. These include the potentially beneficial phenolic antioxidants (Chapter 5.8) and phytoestrogens (e.g. Soleas *et al.*, 1997; Bravo, 1998; Eastwood, 1999; Puddey *et al.*, 2003; Aron and Kennedy, 2008) (Section 5.4.3) and the potentially detrimental biogenic amines (e.g. Ancin-Azpilicueta *et al.*, 2008; Kalac and Krizek, 2003 (Sections 5.3.4 and 5.11.3).

Distillation processes selectively concentrate alcohol at the expense of the other constituents, many of which are then not detectable at all or are only present in such small amounts that they could not make a significant contribution to the nutritional value of the diet or, indeed, to the possible detriment of health.

Reflecting this variability in ingredients and production methods, the nutrient content and, therefore, nutritional value to consumers of alcoholic beverages is also extremely variable. See Table 2.13 in *McCance and Widdowson's, The Composition of Foods* (Food Standards Agency, 2002) for comparison of nutrient concentrations in the generic classes of alcoholic beverage. Importantly, the contribution to nutritional status that might be expected from the constituent nutrients of alcoholic beverages under normal conditions may be significantly affected by alcohol induced alterations in nutrient bioavailability and disturbances of the usual metabolism of nutrients in the body during periods when alcohol consumption is sufficiently high (Lieber, 2000). Of further importance is that such alcohol induced alterations in nutrient bioavailability and metabolic disturbances may also adversely affect the absorption and metabolism of those nutrients normally available from other dietary sources ingested at or around the same time as high levels of alcohol are consumed (Lieber, 2000). Alcohol itself may interfere with normal healthy digestion and absorption processes and its metabolites may disturb certain intermediary metabolic pathways and cycles, blocking some reactions and redirecting the usual nutrient and energy fluxes into other pathways (see Section 5.5.4). In susceptible individuals, alcohol consumption does not necessarily need to be excessive by commonly accepted standards to influence nutritional status. Therefore, alcohol and its metabolites, formed during the breakdown of alcohol through intermediary metabolic pathways, may be of major detriment to health, but especially in high consumers and alcoholics. For more detailed information, please see Watson and Preedy (2003).

Alcoholic beverages may also contain a number of possible toxic contaminants derived from the raw ingredients per se or that may have originated during the production processes. Some congeners, for example, have been implicated in the toxic effects of alcoholic beverage consumption, especially at times of excess, perhaps exacerbating symptoms of a hangover, the effects of which are essentially transient in most consumers, although it is usually the light to moderate drinkers who incur most of the associated human 'costs' (Wiese *et al.*, 2000). However, severely debilitating conditions can result if high levels of the fermentation by-product methanol are consumed, especially as it may cause blindness. Potential toxins may arise from soil contaminants such as pesticides or heavy metals, depending on factors such as locality. Also, to reiterate, certain potential immunochemicals are also found in some alcoholic beverages. Gluten derived from grains, wheat in particular, or hordein in barley, which are the cause of celiac disease in genetically susceptible

individuals, may be present in finished beers. Although wines may be clarified with gluten instead of the usual animal proteins, it does not appear to be present in measurable amounts in the final products (Cattaneo *et al.*, 2003), and such immunochemicals are essentially absent from spirits due to distillation processes. However, some potential carcinogens, such as furans, may be introduced into spirits and wines that are matured in charred wood casks (Goldberg *et al.*, 1999). A number of other chemical constituents likely to be found in wines, beers and spirits, such as biogenic amines, have allergenic properties with health implications, especially for asthma sufferers (Vally and Thompson, 2003).

In contrast to potential toxicity, many of the constituents present in some alcoholic beverages, such as vitamins, minerals and some phytochemicals (compounds derived from plant metabolism; see Section 5.4.3), appear to be capable of positively promoting health in moderate consumers (e.g. Puddey *et al.*, 2003; Suter, 2004). Indeed, the ability of some plant derived antioxidants to scavenge and neutralize the free radicals or reactive oxygen and nitrogen species is believed to be particularly beneficial to health and, as a plethora of these phytochemicals are present in many wines, beers, ciders and certain spirits, alcoholic beverages are also considered to confer such health benefits (Section 5.8.5). However, with only a relatively small evidence base in terms of fundamental mechanisms and actual health outcomes, much of this belief is speculative and should be viewed with some caution (Soleas *et al.*, 1997). As most of the evidence is based on epidemiological studies, prospective and intervention trials are required for confirmation of the fundamental bases of purported health benefits of alcoholic beverages. One suggested rationale with some scientific credence is that the damage caused by free radicals may be prevented because plant derived antioxidants present in certain alcoholic beverages quench the oxidation potential of these free radicals before they can oxidize key structural and functional components of tissues and cells. Free radicals are produced during metabolic processes, including those involved in alcohol catabolism, and are purported to be detrimental to health because the oxidation of proteins and DNA, for example, by these free radicals is heavily implicated in some cancers and in exacerbating cardiovascular disease progression. The anomaly created by the apparent health benefits of consuming red wine, in particular, which supposedly helps to reduce the cardiovascular risk associated with high fat intake, especially saturated fat, and other inappropriate dietary and lifestyle practices is known as the 'French paradox,' albeit somewhat controversial (de Lorgeril *et al.*, 2002; Goldfinger, 2003; Ferrières, 2004). Such purported health benefits of wines (German and Walzem, 2000) have been extended to include beers (Denke, 2000; Baxter and Hughes, 2001; Kondo, 2004), and many spirits are known to contain antioxidants albeit representing a completely different spectrum of phytochemical components (e.g. Goldberg *et al.*, 1999). The reader is directed to Chapter 5.8 for more details on free radicals, antioxidants and health.

However, some of the health benefits usually attributed to other nutrients present in alcoholic beverages may in fact be due to some of the actions of alcohol per se; i.e. consumption of alcoholic beverages in low or moderate amounts may have health benefits independent of their direct nutritive value in that there are possible health gains through the relaxation aspects of moderate social drinking, associated lifestyle and nutritional practices, and other possible metabolic effects. Perhaps such factors may partially explain the j shaped curve of relative health risks. However, it should be noted that more than moderate consumption of alcohol, which is too often considered to fall within the bounds of reasonable 'social drinking,' has potentially serious consequences for health and acceptable social interactions (Morgan and Ritson, 2003) even though it is not outwardly perceived as being excessive.

5.1.4 Nutritional Considerations

In order to appreciate the full implications of the various levels of alcoholic beverage consumption in perspective of nutrient intake and concomitant nutritional and health status, it is important to understand the basic principles integral to the science of nutrition and dietetics. The amount of any particular nutrient that is

required to maintain health, that is the nutritional requirement, is very variable and depends on an individual's age, sex, physical activity levels, capability for absorption and metabolic utilization, and current health and disease status. Certain nutrients, such as the vitamins and some amino acids and fatty acids, are regarded as 'essential' in the sense that they cannot be produced endogenously, at all or in sufficient quantities, to support crucial metabolic processes, the lack of which will result in increased morbidity and mortality.

Dietary recommendations for the different population groups are defined by a series of dietary reference values (DRVs) which describe critical aspects of nutrient intake: DRVs include: (a) the lower reference nutrient intake (LRNI) below which nutrient intake is considered generally inadequate for individual members of any particular group, (b) the estimated average requirement (EAR) which is applied particularly to energy requirements in a population group and (c) the reference nutrient intake (RNI) which is applicable to micronutrients and protein, and is the value assigned to a population group in order to ensure that specific nutrient intake is sufficient for a vast majority of that group. The conceptual 'safe intake' may also be used which is a designated range of values between a higher limit, above which an increased health risk (potential toxicity) is considered significant, and a lower limit, below which there is no apparent risk of deficiency for any members of a particular group. Recommendations in the USA (dietary reference intakes; DRIs) may occasionally appear to differ from those of the UK; sometimes they are substantially different and, as such, these differences will be indicated where appropriate, but mostly any discrepancies are slight. More detailed descriptions of these principles and how they apply to the various classes of nutrients can be found on the websites of the British Nutrition Foundation (http://www.nutrition.org.uk), the Food Standards Agency (http://www.food.gov.uk/healthiereating) and the National Agricultural Library (NAL) at the United States Department of Agriculture (USDA - http://www.nal.usda.gov/).

During normal habitual consumption of food and drink in the absence of alcohol, dietary metabolic energy is differentially provided by the major food groups, fats (also known as lipids), carbohydrates and proteins, which are collectively known as the macronutrients (see Chapter 5.3). Essentially, recommended energy requirements for a diet considered generally healthy and balanced consist of about 35% from fats (lipids provide energy at 37 kJ/g – or 9 kcal/g), 50% from carbohydrates (at 16 kJ/g – often seen quoted at 4 kcal/g but, more precisely, 3.75 kcal/g) and 15% from proteins (at 17 kJ/g – or 4 kcal/g). For example, the energy intake recommended for an individual requiring a nominal 8368 kJ (2000 kcal) daily is, therefore, about 2929 kJ (700 kcal) or 78 g from fat, 4184 kJ (1000 kcal) or 250 g from carbohydrate and 1255 kJ (300 kcal) or 75 g from protein. This guidance for a healthy balanced 8368 kJ/day (2000 kcal/day) nominal intake from the various macronutrients quoted here is for illustrative purposes and is a very approximate average population value based on an intake of 6870 kJ (1632 kcal) for women and 9720 kJ (2313 kcal) for men (see British Nutrition Foundation website; http://www.nutrition.org.uk). The above values would need to be adjusted proportionally for application to an average dietary intake for individuals requiring different levels of energy intake, more or less according to whether they are more active or more sedentary. Of course there is great variation in energy requirements for individuals within the population according to body size and composition, as well as substantial differences in physical activity levels. Further details regarding dietary energy requirements are available in the Department of Health's COMA Report (Department of Health, 1991) and from the website of the British Nutrition Foundation (http://www.nutrition.org.uk).

Alcoholic beverages may, therefore, contribute significantly to overall energy intake because complete breakdown of alcohol to CO_2 and H_2O produces 29 kJ/g (7 kcal/g), a value that clearly falls in between those of the major food groups (16 kJ/g for carbohydrate; 17 kJ/g for protein; 37 kJ/g for fat). A single UK unit (10 ml; 7.89 g) of pure alcohol alone is equivalent to about 229 kJ; this is about 2.7% of the daily energy intake for an individual requiring 8368 kJ (2000 kcal) daily. However, in addition to the alcohol content, many alcoholic beverages also provide substantial amounts of energy from other food energy sources present, particularly carbohydrates. For example, a typical pint of beer or lager with moderate levels of alcohol (perhaps 3.6% ABV) that contains 837 kJ (200 kcal) of energy, in terms of alcohol plus carbohydrate content,

could provide 10% of the daily energy requirement of an individual for whom the daily requirement is 8368 kJ (2000 kcal). Some types of alcoholic beverage, for example premixed alcopops, are formulated for specific markets with possible large amounts of simple sugars and various chemical flavorings and colorings added to alcohol in various concentrations. Such concoctions are considered to be sources of calories only (so called 'empty calories'), with no additional nutrient value of any kind. However, some premixed concoctions do contain ingredients, such as fruit juices, with some potentially significant nutritional value.

Therefore, at times when alcohol is consumed in sizeable amounts, both the total amount of metabolic energy ingested and the balance of energy from the usual primary dietary sources may be altered significantly. Clearly, alcohol consumption without attendant reductions in energy intake from carbohydrates, fats and proteins, or certain other possible increases in behavior or changes in physiology, may lead to positive energy balance with concomitant weight gain; the extent of which is essentially dependent on the additional energy intake. Consider the potential implications of extra ingested alcohol being almost equivalent to fat in terms of metabolic energy (29 kcal/g – 7 kcal/g – energy from alcohol and 37 kJ/g – 9 kcal/g – from fat), rather than to carbohydrate or protein at only 4 kcal/g. However, not all consumers of alcoholic beverages gain weight as expected because of possible concomitant reductions in absolute levels of intake of the usual dietary energy sources, or changes in the relative balance of these energy sources, to compensate for the additional energy intake from alcohol. Indeed, many alcoholics exhibit characteristic weight loss, although this is often through associated malnutrition of different origins. Possible increases in physical activity may help to offset the additional caloric intake, most especially in some moderate consumers. In addition, production of energy in the form of heat through thermogenesis or futile cycles and its dissipation into the environment may increase depending on factors such as the predominant metabolic pathways (e.g. the microsomal ethanol oxidizing system – MEOS – see Section 5.5.1) which may be activated according to the amount of alcohol consumed and so may also contribute to weight maintenance, even though overall increased energy intake is apparent. However, the considerable intra- and interindividual variability in alcohol consumption imposes difficulties when assessing the relative contribution of alcohol to energy intakes and concomitant body weight control overall (Section 5.3.2) (Prentice, 1995). Although very low levels of alcohol or complete abstinence are generally recommended for optimum health, with few implications for energy balance, high or even moderate levels of alcohol intake can have major health sequelae beyond those of energy balance alone, especially as individuals have different abilities to detoxify alcohol with regard to genetic influences on the production of the specific enzymes needed for alcohol detoxification (Crabb *et al.*, 2004) (Section 5.5.1).

There are further implications for recommended dietary intakes because of differential habits of consumption of the various different types of alcoholic beverages and concoctions created from them. Firstly, current dietary recommendations in general are that sources of carbohydrates should be selected in order to avoid simple sugars (no more than 25% of dietary energy intake should be from simple sugars) in favor of the more complex forms of carbohydrate with their greater purported health benefits. A number of alcoholic beverages, however, are high in simple sugars, a large proportion of which may be added during processing. These include alcopops, certain liqueurs produced with sugar based infusions and cocktails made with mixers rich in simple free sugars. In other alcoholic beverages, especially some of the less refined fermentation products such as certain native beers (Chapter 2.7), the balance of carbohydrates present substantially favors those that are more complex in nature and may even make small contributions to the recommended daily intake of dietary fiber (essentially, dietary fiber is indigestible carbohydrate material derived from plant sources – see Sections 5.3.3 and 5.7.4). Secondly, high levels of saturated fats and cholesterol, predominantly from animal sources, and fats consisting mainly of *trans*-fatty acids are not recommended as part of a healthy diet (essentially, *trans*-fatty acids are used in the manufacturing of products containing fats for less expensive manufacturing options and with longer shelf life). Although alcoholic beverages rarely do contain any lipids whatsoever (negligible amounts are found in wines and beers, derived mainly from plant cell wall material), in those that do, their fat content has usually been added during the final stages of production, and includes

cream liqueurs (Section 3.9.5), for example, which could conceivably contain 5–6 g fat per 40 ml serving. Thirdly, the small amounts of protein in most alcoholic beverages are usually insignificant in terms of their contribution to recommended dietary requirements, although some products that are not treated by precipitation or filtration may contain plant proteins and particular beverages may have protein added as part of the final stages of production, e.g. from eggs or milk sources.

A healthy balanced diet overall should also have sufficiently varied foodstuffs to contain the recommended dietary requirements for vitamins and essential minerals or trace elements (collectively defined as micronutrients, Chapter 5.4), essential amino acids, and essential fatty acids, as well as other key nutrients such as the antioxidant phytochemicals. Certain alcoholic beverages may contain some or all of these essential nutrients in amounts that may be of some, if limited, benefit to health. However, significant intakes of alcohol and associated changes in behavior may also create imbalances in otherwise healthy dietary intakes, even in moderate consumers but, particularly, in heavy drinkers and alcoholics in whom such dietary anomalies may exacerbate the major health risks associated with ingestion of alcohol per se. For more easily accessible information on healthy eating and good nutrition, in general, see the websites of the British Nutrition Foundation (http://www.nutrition.org.uk) and the Food Standards Agency (http://www.food.gov.uk/healthiereating).

5.1.5 Summary

In conclusion, alcoholic beverages in their many forms and levels of consumption may have variable and extremely complex implications for nutritional status and health overall as they may influence levels of intake of specific nutrients to a greater or lesser extent, with both short- and longer-term consequences, many of which are detrimental, whilst others may be beneficial. Alcoholic beverages may be consumed on top of the usual diet or may replace more appropriate foods creating potentially harmful imbalances in otherwise healthy levels of nutrient intake. In contrast, certain types of alcoholic beverages are considered to contain significant levels of valuable nutrients; red wine, for example, is purported to be a significant source of antioxidants and beer is a source of B vitamins as well as antioxidants (Section 5.4.3 and Chapter 5.8). However, despite making available relatively greater amounts of such important nutrients, excessively high levels of alcohol intake, from wine and beer, as well as from stronger alcoholic beverages, may: (a) increase the bodily requirements for certain important nutrients, (b) interfere with the normal processing of macronutrients and micronutrients and (c) influence appetite in such a way that otherwise important sources of key nutrients are excluded from the diet. Indeed, these higher levels of alcohol consumption may compromise nutritional status to such an extent that medical intervention is required. It is also important to be aware that, although the nutrient content of certain alcoholic beverages may be beneficial to nutritional status and health if taken in moderation, a substantial number are providers of 'empty calories' only, in that the alcohol and free sugars contained in such drinks may contribute significant levels of energy, alone, with little or no additional nutrient value.

5.2

Factors Influencing the Nutrient Content of Alcoholic Beverages

The wide ranging nutrient content of the multifarious alcoholic beverages is governed by which of the numerous possible raw ingredients are used and in what combination, along with particular production techniques. Many of the original ingredients persist unchanged into the final product, some are lost, some are altered chemically and many others are produced during fermentation and ageing. Additional materials may be utilized for optimizing the fermentation process, zinc for example, or for preservative properties of the final product, such as the antioxidant glutathione (also present in the grape and produced by the action of yeast). Although the major types of alcoholic beverage are somewhat defined in character and, therefore, in alcohol and nutrient content, there is still much potential for variability regarding nutritional value between apparently similar individual products within each class. Fermentation processes (Chapters 2.2 and 2.3) modify the raw ingredients not only because yeast converts the fermentable sugars, mainly glucose and fructose, into alcohol, but also because yeast utilizes nutrients from these ingredients for its own growth and multiplication and, significantly, yeast produces certain key nutrients itself, most notably members of the B group of vitamins. Yeast may also be the major source of purines and pyrimidines in alcoholic beverages as these nucleotides are components of the nucleic acids, DNA and RNA, which are manufactured as the numbers of yeast cells increase during fermentation. Beers, in particular, have relatively high levels of purines, the catabolic products of which are associated with certain health issues, particularly gout, which exacerbates with increased levels of uric acid (Yamamoto *et al*., 2005) (Sections 5.3.4 and 5.5.5). Some of the more refined beverages, such as spirits that are produced through distillation of fermented products (Part 3), tend to have greater alcohol content and reduced nutritional value than the less refined products of simple fermentation, such as beers, ciders and wines. Importantly, because alcohol is concentrated by distillation, lower volumes of intake of spirits, liqueurs and fortified wines are needed to provide the same alcohol load as beverages with lower levels of alcohol.

Alcoholic beverages that are essentially finished may still be exposed to further dynamic chemical processes, resulting in some derivatives that may be detrimental to the taste and character of the alcoholic beverage or, indeed, other derivatives that are perceived to enhance its character, and it is often the balance of these processes that is critical (Parts 2 and 3). The effects of such 'ageing' of particular products are valued to such an extent that substantial resources are allocated to their manufacture and storage, the conditions of which may need to be very precise to reproduce the character and consistency required. However, the extent

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

to which these processes may be of tangible benefit or detriment to the nutritional value of such alcoholic beverages is not known with absolute certainty. The reactions occurring during ageing may produce, for example, derivatives of reducing sugars and amino acids, which have potential nutritional value, although the amounts involved are likely to be nutritionally insignificant because such compounds are not considered to be 'essential.' Essential nutrients are those that the body cannot produce endogenously and so their absence in sufficient quantities in the diet could lead to specific deficiency diseases. A number of derived compounds such as acetate and ethyl esters, furanic ethers, Maillard products and carbonyls contribute considerably to a wide variation of complex tastes and aromas, along with alterations in color (Section 2.6.2). These, and a multitude of other reactions, such as the oxidation of higher alcohols or lipids (derived from plant cell walls), hydrolysis of yeast derived esters and degradation of numerous compounds, may occur to a greater or lesser extent in many alcoholic beverages, depending on the length and conditions of ageing. For example, reactions such as degradation of hop bitter acids may occur in beers, especially in some speciality or seasonal beers that may be allowed to age for many months in casks before being tapped or, in some beers, perhaps undergoing secondary fermentation (e.g. Vanderhaegen *et al*., 2003; 2007) (Section 2.6.7). However, apart from increasing the alcohol content and decreasing the fermentable sugar content during secondary fermentation, the relatively significant changes in taste and character potentially created by reactions of this type are unlikely to be reflected in the overall nutritional value of the alcoholic beverage concerned. Such chemical reactions would only be of any real nutritional significance if the resultant products were essential nutrients. This is especially true if the contribution of the beverage to the classes of nutrients involved is relatively insignificant when compared to other dietary sources.

In contrast, certain changes that can occur during ageing may be nutritionally significant, which, again, can be either detrimental or beneficial, or perhaps both. Oxidation of many compounds can occur in alcoholic beverages stored in wooden casks, e.g. oak (see Section 2.9.5). Such casks allow some alcohol to escape and air, particularly oxygen, to be drawn in to replace it in a very gradual process, and so oxidation of some constituent compounds may occur. Once these beverages are bottled, oxidation reactions essentially cease or are very slow (see Section 2.6.12). Storage in wooden casks, especially charred casks, enables polyphenols, furans and other potentially beneficial compounds to be drawn out of the wood, which contributes to the character of the beverage, as well as being of possible nutritional value because many of these compounds have important bioactive properties. Some furans and other components may have antioxidant, anti-inflammatory and anticancer potential but, importantly, some may actually be carcinogenic (Goldberg *et al.*, 1999). Certain of the larger and more complex phenolic compounds, for example the tannins, may undergo precipitation, especially during long periods of storage. If any of these larger and higher capacity antioxidant bioactives are ingested they may cause precipitation of certain proteins affecting the bioavailability of ingested proteins and denaturing important digestive enzymes in the gastrointestinal tract to perhaps impair the digestion and assimilation of other key nutrients (Bravo, 1998).

Whatever the production method and style of the finished alcoholic beverage, an even greater range of styles may be created by the addition of mixers for cocktails. Fruit juices, milk and egg products are used to create cocktails that may add significant nutritional value to the basic beverage. For example, wines may have orange juice added to make Sangria and vodka may have tomato juice added to make a 'Bloody Mary.' Such mixers may contribute significant levels of vitamins, minerals and antioxidants that are otherwise absent from the foundation beverage itself or in concentrations that are too low to be of any nutritional value. In addition, the relative alcohol concentration is reduced according to the proportion of mixer added.

As actual production techniques of the multifarious alcoholic beverages are presented in the other Parts in this book, specific to each type and style of beverage, only appropriate details concerning processes that have particular influences on nutrient content are presented in the rest of this chapter.

5.2.1 Wines

Wine can be made from a multitude of different fruits and vegetables, but grapes are generally preferred especially for large-scale production and for which there is a long history (Soleas *et al.*, 1997). The variable nutrient content of wine types, and individual products within each type, is due to differences in the grape and other ingredients and manufacture within quite a broad spectrum of production processes (see Chapter 2.9). The harvesting of the grape is a process that can influence greatly the character, quality and nutritional content of the finished wine. Harvesting depends largely on the wine growing region. Some practices rely on the use of hand selection of the appropriate quality and pureness of grape, whereas other regions rely on mechanical harvesting machines that take all grapes on the vine (ripe, unripe and some possibly contaminated with mold and rot that can compromise the quality of the finished product) along with extraneous material, such as stems and leaves. Greater amounts of tannins, for example, may be available from the less selectively harvested sources of grape. In essence, alcohol in wines is produced by a period of primary fermentation of carbohydrates present in the juice, or must, of the fruit, which are predominantly fermentable simple sugars such as glucose and fructose, although additional extraneous glucose or sucrose (a dimer of fructose and glucose) may be added. Some sugars are allowed to remain for sweetness if desired in certain wines, but only very small amounts are present, if any, in finished dry wines and so the caloric value of dry wines is predominantly due to the alcohol content (29 kJ/g or 7 kcal/g). The sweeter wines, containing more free sugars than the dry wines, may contribute significantly to caloric intake (Section 5.3.3) due to significant levels of both sugars (16 kJ/g or 3.75 kcal/g) and alcohol (29 kJ/g or 7 kcal/g). The more lengthy secondary fermentation is the process whereby proteins are broken down and fine particles precipitate out to allow clear wine to be bottled and, therefore, negligible protein content usually remains in the finished product.

Certain key ingredients of grapes contribute to the nutrient value of the finished wine. Informative details of the typical nutrient content of grapes and other fruits may be found at the website of the National Agricultural Library (NAL) at the United States Department of Agriculture (USDA): http://www.nal.usda.gov/. Grapes may typically contain about 15 g/100 g of sugars (7 g glucose, 8 g fructose) that ferment into alcohol, usually the main source of the energy content of wines. Complex carbohydrates mainly found in the skins of grapes may be almost entirely removed during production, especially if just the juice is used, but some may remain in those wines that ferment the whole fruit. Many nutritionally valuable elements also remain in the final product (Soleas *et al.*, 1997), where some may be found in even higher concentrations than in the ingredients themselves. The concentration of potassium is relatively high in both grape juice and wine (typically 130 mg/100 ml and 190 mg/100 ml, respectively) compared to that of sodium (3 mg/100 ml and 4 mg/100 ml, respectively). However, some vitamins, such as vitamin C (about 10 mg/100 g grapes), may be largely destroyed during processing and storage, whereas others, the B vitamins, for example, are also produced by the action of yeast and may be present in significant quantities in the final product.

The typical nutrient content of wines generally may be compared to other alcoholic beverages in readily accessible sources such as such as Table 2.13 in the Food Standards Agency publication, *McCance and Widdowson's, The Composition of Foods* (Food Standards Agency, 2002) or at websites such as NutritionData, http://www.nutritiondata.com/. It is uncertain as to whether or not many of the micronutrients from wine can make a significant contribution to nutritional status and health, especially at higher levels of alcohol consumption because, although drinking wine potentially makes available greater amounts of such essential nutrients, relatively high levels of alcohol intake from wine, as for other alcoholic beverages, may increase nutrient requirements. This is because alcohol intake interferes with normal metabolic processes involving key nutrients (Leiber, 2000; Watson and Preedy, 2003) (Sections 5.5.4 and 5.5.5), and differentially affects appetite and behavior to alter intake of these nutrients from the usual diet, according to acute or chronic

use, and low to moderate or excessive consumption (Forsander, 1998; Yeomans *et al.*, 2003; Yeomans, 2004; Caton *et al.*, 2007; Kokavec, 2008) (Section 5.5.3).

Red wines (Section 2.9.2) are produced from the entire grape, with the juice providing the fermentable sugars from which the alcohol is derived; whereas the skins essentially impart the color, and the skins, seeds and stalks are the source of the phenolic compounds that are purported to have antioxidant properties and are, therefore, considered to be of tangible benefit to health. Phenolic compounds are the substances that produce the intensity of color in fruit and are found in especially large quantities in berry fruits (Hancock *et al.*, 2007), many of which are used in wine making. The more intense colors have, therefore, been implicated in the greater purported health benefits of red wines, which have about five times the level of these compounds compared to white wines (German and Walzem, 2000). Tannins, for example, add astringency to red wines but, with ageing, may form polymers that settle out. The alcohol content of most red wines is typically about 12–14% ABV.

White wines (Section 2.9.1), produced from the juice of the grape, tend to have slightly less alcohol content than red wine, but some may have more free carbohydrates as a result, although dry white wines and red wines are generally comparable in this respect. To reiterate, because whole grapes are not usually used in white wine production (or, if the whole grape is used, contact with the skin of the grape and its disruption is minimized) there are lower levels of phenolic compounds, perhaps only about one fifth on average of red wines (German and Walzem, 2000), and, therefore, the level of contribution of white wines to health overall is currently uncertain. In fermentation processes where the skin of the grape is allowed to remain, far greater levels of antioxidants may be observed in the finished wine (Fuhrman *et al.*, 2001).

Rosé wines (Section 2.9.2) are produced by three variations of the basic wine fermentation techniques in which: (a) the skins of the red grape may be left in contact with the juice for a short period only, (b) some of the red juice may be removed at an early stage and then fermented separately and (c) red wine may be blended with white wine. The nutrient content may be slightly modified accordingly, perhaps producing something that is between red and white wines in terms of alcohol content and also phenolic compounds, the levels of which bear a relationship to the intensity of color (Hancock *et al.*, 2007).

Traditional sparkling wines and champagnes (Section 2.9.3) are essentially produced from still wines with an additional fermentation process in the bottle that traps the carbon dioxide formed as alcohol is produced. In general, this process seems to have no real significance in terms of beneficial or detrimental changes in nutritional content and value compared to the original fermentation product.

Sweet or dessert wines may be produced by, essentially, one of four processes: the late harvesting of grapes to ensure greater residual sugar and sweetness, the addition of grape juice after fermentation, the freezing of grapes to concentrate the sugars and the deactivation of yeast before fermentation is complete. The nutrient content of sweet wines produced by these various processes may, therefore, be quite variable, with higher levels of free sugars potentially contributing significantly to their calorie content.

Fruit (and vegetable) wines (Chapter 2.11), of which grapes are a specific example, may be produced from almost all types of suitable fruit (and vegetables), with the nutrient content essentially depending on variations in the raw ingredients and production processes. For example, wines made with highly colored berries may have greater amounts of antioxidants than other fruit or vegetable wines; berries have been dubbed, rightly or wrongly, 'super fruits' and the color of the final product may be representative of the concentration of antioxidants present (Hancock *et al.*, 2007).

5.2.2 Beers

Beers are produced from cereals, most typically malted barley, although unmalted grains, corn and rice, are also used for brewing beers in many regions of the world. The complex carbohydrates contained in malted

barley, mainly starch and β-glucans, are broken down during mashing into simple fermentable sugars by the enzymes α-amylase and β-amylase that are produced during the initial process of malting (sprouting) of the grains (Section 2.6.2) (Hornsey, 1999). Proteins may be broken down into smaller peptides and amino acids by activated proteinases to help to make the beer clearer. However, some proteins are allowed to remain as these are necessary in order to hold the head of the beer. The relatively low levels of protein in beer do not seem to contribute greatly to the recommended levels of protein intake for optimum nutrition as the amount in one unit (half pint) might only be somewhere about 3% of the daily requirement for protein (Section 5.3.4.). At the stage when the separated wort is boiled with hops (Section 2.6.3), other ingredients such as herbs and fruits may be added for character and flavor, and these may also influence the nutrient content of the beer. Similarly to wines, the various ingredients and processes involved in beer production ensure a large variation in nutrient content, as well as alcohol levels, and these may also be modified by secondary fermentation phases. In general, beers these days are quite different from the crude, less processed, brews consumed earlier in history that may have contained more protein, vitamins and minerals, perhaps with a more cloudy appearance. However, certain local or specialized brews still retain such characteristics, sorghum beers produced in sub-Saharan Africa, for example (Section 2.7.2).

The source of water used in beer production is an extremely important factor as water is the largest component in the finished beer and is a determinant of the type of beer that is best brewed from a particular water supply (Section 2.6.2). Making an important contribution to flavor, the water supply is also the source of various elements and electrolytes that are essential for optimum nutrition, with significant amounts of minerals also present in other raw ingredients such as malt. Compared to soft water, some hard waters may contain very approximately 100 times the concentration of sulfate (typically perhaps 5 mg/l in soft water versus 500 mg/l in hard water), with far greater concentrations in hard than soft waters of calcium (10 mg/l versus 240 mg/l), magnesium (2 mg/l versus 50 mg/l), bicarbonate (15 mg/l versus 250 mg/l), nitrate (5 mg/l versus 240 mg/l) and chloride (5 mg/l versus 50 mg/l). As chloride may be added to supplies of drinking water, this may influence the character of beer produced in many regions. Water may be modified by the deliberate addition of salts in order to produce certain desirable characteristics that are intended to be reminiscent of beers produced from the characteristic water of other regions. Calcium sulfate is often added in a process known as 'Burtonization,' which is intended to mimic the water of the Burton-on-Trent area of the UK, a region in which the water is naturally high in sulfates (Section 2.6.2). Sulfates optimize production of the lighter beers, which have significantly greater concentrations of calcium and sulfates in the final product than darker beers. Calcium has potentially important affects on the nutritional content of beers because it precipitates phosphates, creating lower acidity and thus modifying enzyme activity, promoting protein and oxalate precipitation, and preventing uptake of certain silicates, tannins and polyphenols. If excessive bicarbonate is present, greater acidification may be achieved by the addition of sulfate, chloride, phosphate or lactate ions, all of which may affect electrolyte content of the final product. The concentrations of other elements and electrolytes vary considerably amongst the different finished beers, depending on raw ingredients and production processes. Most beers contain relatively greater amounts of potassium and lower amounts of sodium, with the purported health benefits associated with this balance favoring potassium, especially the supposed promotion of cardiovascular health through mechanisms that might help lower blood pressure, or at least not contribute to raised pressure. Any such health benefits may also depend on the relative amounts present of potassium, calcium and magnesium, as potassium appears to act effectively in synergism with these particular elements, as well as independently (Rylander, 2003). Other beneficial trace elements found in beers include magnesium, chromium, iron, silicon and copper and there are also very few potentially toxic trace elements usually present in the finished beer. However, alcohol consumption may influence the rate of loss of important nutrients through the kidneys (Rylander, 2003).

In addition to providing suitable amounts of fermentable carbohydrates, malt is a significant source of other, more complex, carbohydrates that have potential health benefits due to their relatively low rates

of digestion and assimilation in the body. Some of these complex molecules are only digestible by the bacteria of the large intestine that produce simple derivatives such as volatile fatty acids that can be absorbed and metabolized. Indeed, butyrate is an acknowledged source of metabolic energy for the cells of the gut wall (Cummings and Macfarlane, 1997). Some other complex carbohydrates found in beers are essentially indigestible contributors to the fiber content of the diet, passing unchanged from the body. In general, if processing is kept to a minimum and as the alcohol content of beers is increased, so the fiber content may also be raised (Section 5.7.4). A very strong beer approaching 11–12% ABV may contain up to about 6 g fiber/l, which could be about one third of the daily amount of fiber considered adequate for optimum health in the UK, which is currently 18 g/day (British Nutrition Foundation: http://www.nutrition.org.uk; Food Standards Agency:http://www.food.gov.uk/healthiereating).

The grains used for beer production contain many potentially valuable nutrients, including silicates that are under scrutiny at present regarding nutritional importance (Section 5.4.2), and the malting process produces a number of water soluble vitamins that contribute to the essential requirements of the human diet (British Nutrition Foundation: http://www.nutrition.org.uk; Food Standards Agency: http://www.food.gov.uk/healthiereating). The process of malting also influences antioxidant capacity (Lu *et al.*, 2007). The production of a number of beers, e.g. dark milds and stouts, is based on roasted barley which results in an altered composition of the roasted grain compared to the original grain and also leads to modified nutrient content of the final product, notably phenolic antioxidants and furans (Section 2.6.2).

Although hops are added during the production of beer in order to provide bitterness, aromas and preservative qualities, they contain a number of potentially significant functional nutrients that may be infused into the finished beer, but not all of the these particular phytochemicals are considered to be exclusively beneficial or desirable (Milligan *et al.*, 2000). Indeed, hops have been used in herbal remedies over the centuries, long before their use in beer production. Certain vitamins, such as vitamins A, thiamine (vitamin B1), riboflavin (B2), niacin (B3), cyanocobalamin (B12), folate and vitamin C, and elements, such as calcium, magnesium, manganese, potassium, selenium and zinc, are found in hops, but whether or not hops are nutritionally significant sources of these nutrients in beer is uncertain, as they may also be provided in considerable amounts by the other raw ingredients, especially malt, and by the action of yeast. In particular, the use of live yeast cells to produce alcohol also yields significant levels of vitamins, especially those members of the B group such as thiamine (although yeast also utilizes B1 for optimum fermentation), riboflavin, pyridoxine and folate (Sections 2.2.9 and 2.6.4). As the yeast culture grows and the cells divide, more DNA and RNA are formed, which contain the nucleotide purines and pyrimidines, of which the purines are associated with certain health problems such as gout (Yamamoto *et al.*, 2005). However, hops contain other potential health promoting constituents, including some phytoestrogens (plant derived compounds with estrogenic activity, some of which may not be entirely desirable; Milligan *et al.*, 2000) (Section 5.11.2), phenolics and α- and β-acids. Although similar compounds may be present in wines, a number of these potentially health promoting hop and grain derived phytochemicals are present only in beer, but whether or not they can make significant contribution to nutritional status is still somewhat speculative and uncertain. The phytochemicals in beer, derived from both the malt and hops, include a number of phenolic compounds, including monophenols (phenolic acids, alcohols and amines) at typical levels of 10–30 mg/l, monomeric polyphenols (flavanols and flavonols) at up to about 25 mg/l and condensed polyphenols (di- and polymeric catechin, proanthocyanidins and prodelphinidins) at about 20–140 mg/l (for more details see Section 5.4.3; the generally informative chapter by Baxter and Hughes, 2001, specifically page 109; Denke, 2000). Many of these are potentially beneficial bioactive compounds that have been shown to lower plasma lipids and raise plasma antioxidants (e.g. Gorinstein *et al.*, 2007).

Yeast requires certain key nutrients for growth and optimum fermentation potential, most of which are provided by the water, malt and hops. However, zinc is of particular importance to the brewing process as it is not generally present in sufficiently high quantities in the basic ingredients, especially malt, for the

optimum functioning of yeast (Vecseri-Hegyes *et al.*, 2005; 2006). Inadequate amounts of zinc may introduce complications, including unwanted side products of fermentation adversely affecting the character of the finished beer. Therefore, zinc is often added to overcome this limitation. However, much of this exogenous zinc may be taken up by the yeast and so does not appear in the final product because yeast is largely separated out as it may settle or be filtered.

Processing may also destroy or remove some vitamins, and some minerals and other nutrients may be removed by precipitation and so are not present in such large quantities in the final product. Vitamin C is highly susceptible to processing, with most being lost, but other members of the water soluble vitamins may be preserved at significant levels despite some losses.

5.2.3 Cider and Perry

Cider (from apples) and *perry* (pears) are produced by taking the juice from the pressed fruit and fermenting to near completion before racking into another vessel for a second fermentation. The second fermentation utilizes the sugars remaining from the first fermentation or may have supplementary sugars added from which additional alcohol is produced (Chapter 2.8). Apples and pears are relatively good sources of a number of important nutrients, including the B vitamins, elements and electrolytes, significant amounts of which may be found in the finished product, depending on the extent of processing. Traditional cider production is generally a relatively crude procedure involving little by way of simple separation of insoluble and spent ingredients by racking and filtering (Section 2.8.5). Therefore, the skins of the fruit are in contact with the fermentation medium for sufficient time to allow extraction of some of the antioxidants that are present in relatively large amounts in the skins, quercetin for example. As such, much of the original raw material may remain in the final product, depending on the character required with some finished ciders allowed to remain 'cloudy.' Therefore, significant amounts of the original nutritional value of the apple are retained along with production of other nutrients through fermentation. Other ciders are produced for appeal to the 'popular' market and further processing may be applied to increase clarity, for example, and, of course, such processes may alter nutritional content substantially. Therefore, although significant levels of certain water soluble vitamins and phenolic compounds may be present in many of these products, there is great variability as some of the more highly processed ciders have low concentrations of such compounds (e.g. Marks *et al.*, 2007). Alcohol levels in ciders vary considerably from about 3% ABV to about 8% ABV, typically, and possibly more in some specialist products.

5.2.4 Distilled Beverages

Distillation processes (Part 3) are intended to concentrate alcohol at the expense of water and to increase preservative and sterile properties, as well as to improve ease of storage and transport of the beverage. Distillation may be repeated one or more times depending on required alcoholic strength and desired character of the beverage. Distillation also removes some of the other nonvolatile components of the initial fermentation products such as some potential toxins (e.g. pesticide residues) and certain plant derived immunochemicals (e.g. gluten or hordein). Essentially, distillation is a three stage process in which the first part (the head or foreshot), containing compounds such as ethyl acetate and ethyl lactate, and the last part (the tail), containing compounds such as fusel oils, are mostly discarded, with small amounts of some of these compounds retained out of choice for particular character, taste and aroma. However, most of the potentially beneficial nutrients present in the fermentation product may also be lost during distillation, including carbohydrates, elements, electrolytes and vitamins. Distillation also causes the formation of certain aromatic compounds and the

breakdown of others that might change the character of the product, but these are unlikely to have any real nutritional significance because they are usually present in relatively low concentrations.

Following distillation, the ageing processes, which usually occur in wooden casks (e.g. oak, pine) and are intended to impart character to the beverage, may also add small amounts of potential nutrients and other compounds (Goldberg *et al.*, 1999; Madrera *et al.*, 2003), some of which may be carcinogenic. Interactions with the casks enable chemical modifications of the spirit to potentially produce any of about 300 or more compounds for improved taste and character; some of these are also purported to be functional trace nutrients, such as the vast array of phenolic compounds and furans, especially those produced in charred wooden casks (see for example Section 3.2.5). It is uncertain as to whether or not these particular nutrients, although having very strong specific antioxidant potential, are in sufficient quantities to be of any major nutritional value. Although the presence of methanol and some other by-products of the fermentation process may actively be discouraged to avoid undesired characteristics, certain levels of fusel oils are considered necessary for tastes and aromas that are characteristic of individual spirits and liqueurs, although they are not usually considered to be acceptable components of the diet. As any sugars remain in the still as alcohol is concentrated in the distilled beverage, the metabolic energy content of the final product of distillation predominantly depends on its alcohol content (29 kJ/g – 7 kcal/g) producing 229 kJ (55 kcal) per regular serving of 25 ml (10 ml or 7.89 g pure alcohol), unless sugars are infused at any stage in order to produce liqueurs, some of the sweeter versions of which may contain very high levels (Chapter 3.9). The final alcohol content of the distilled beverage may be denoted as alcoholic 'proof' which is a figure that is almost double (1.75×) that of the value of the ABV (%).

Spirits are produced by distillation of the fermentation products of grains, fruits and vegetables and, typically, they contain at least 35% (ABV) alcohol and have negligible sugar content. The first distillation may result in a product of about 25–30% ABV (Section 3.1.2). A second distillation stage is normally applied to purify the beverage by removal of toxic contaminants such as urethane (ethyl carbamate or EC – see Section 5.11.5) and many of the fusel oils (higher alcohols), the latter of which may be selectively distilled and allowed to remain, depending on the character required for the final product. Water may be added back to the product, which at this stage may be about 60–70% alcohol (ABV) (Section 3.1.2) in order to achieve a spirit of 40% ABV. The character and potential nutritional value of spirits is, therefore, reliant on the initial ingredients, such as the type of malt used for whisky, the type of still used, the source of water and the type of wood used for the barrel in which spirits may be aged. Spirits may be used as a base for formulating numerous cocktails (Section 5.2.7). As there are such vast numbers and varieties of other miscellaneous spirits consumed worldwide, and also because their nutritional value per se is fairly limited, only a few of the spirits more commonly consumed in the UK are considered further here.

Varieties of *whisky* (Scotch) (Chapter 3.2) and *whiskey* (Irish) (Section 3.3.2) and, indeed, those from other countries such as Bourbon from the USA (Section 3.3.4), may be produced from a number of grains, notably barley or malted barley, maize (corn), rye or wheat, and once distilled, the storage in oak casks for a minimum of three years allows for ageing and the natural infusion of small amounts of the potentially nutritionally functional phenolics and furans, although some such compounds may have toxic or carcinogenic potential (Goldberg *et al.*, 1999).

Brandy is the distilled product of grape fermentation (Chapter 3.6), with other fruit, and pomace (grape pulp), brandies usually being prefixed by the specific name of the fruit, e.g. cherry brandy (Chapter 3.8). The extent of ageing in wood determines the special character of brandy that distinguishes it from some clear fruit brandies which lack such ageing processes from which further key nutrients may be obtained. Certain 'old' brandies are aged for up to 10 years or more, which may significantly modify the character of the final product, as well as the micronutrient content, i.e. by allowing the further gradual uptake of polyphenols from the casks into the brandy.

Distilled from fermented molasses and the juice of sugar cane, *rum* (Section 3.5.2) is initially clear and then is infused with color and character by ageing in wooden casks and from which it may also gain small amounts of potentially functional nutrients and possibly some toxins. There are many variations in the production of rum in terms of the level of alcohol and the ageing processes that may result in differential nutrition values according to the specific product.

Vodka (Section 3.4.3) is a distilled beverage produced from any of a large number of fermented raw materials, but predominantly grains, potatoes and sugar beet are the generally accepted standard ingredients. The extended distillation and filtering processes with no period of ageing ensure that vodka is fairly pure mix of alcohol and water with only very small amounts present of impurities, with possible flavorings added during production, thereby limiting its nutritional value to the energy provided by its alcohol content alone. Flavorings or mixers added later may have some nutritional value – fruit juices, for example, may provide significant levels of water soluble vitamins, elements and electrolytes. Vodka produced illegally ('bathtub' or black market production) often contains higher levels of toxic compounds such as methanol that can lead to cirrhosis and blindness if ingested in sufficient quantities, and death can result in extreme circumstances (Section 5.5.2).

There are a number of types of *gin* (Section 3.4.2) that are available, depending on ingredients and processing. Juniper berries, the usual flavoring of gin, may be added both before and after distillation of the white grain spirit fermented base. Other fruits and herbs may also be used in addition to juniper berries or certain ingredients may be used instead; the addition of sloe berries, for example. The relatively high alcohol content in gin provides a significant amount of energy, otherwise any nutritional value is usually quite limited, but with some possible variation as nutrients essentially originate from the added fruit or herbs only.

Tequila (Section 3.5.5) is distilled from fermented blue agave and is aged in wooden casks for varying amounts of time to produce many different types. Taken neat in Mexico, it may be accompanied by sangrita, a mix of fruit juices and hot chilies or sauces to give possible added nutritive value. Elsewhere, Tequila may be taken with salt and lime, or other accompaniments, mainly for modifying effects and flavor, but which may also provide certain additional nutrients, but these are probably only of limited significance.

Liqueurs (or cordials) are distilled alcoholic beverages that have additional flavorings and also typically have relatively high sugar contents (Chapter 3.9). The potentially high levels of simple sugars along with the high levels of alcohol in liqueurs indicates that the majority are significant sources of empty calories, essentially, unless they are mixed with other beverages or ingredients that have some nutritional value, such as fruit juices or cream. For example, Irish Cream is a liqueur produced from whiskey, cream, coffee and other ingredients; a single serving of 40 ml Irish Cream provides about 544 kJ (130 kcal) metabolic energy from 5–6 g of alcohol (146–176 kJ or 35–42 kcal), 8 g of carbohydrates (134 kJ or 32 kcal), 5–6 g of fat (188–226 kJ or 45–54 kcal) and 1 g of protein (16 kJ or 4 kcal).

5.2.5 Fortified wines

Fortified wines (Chapter 2.10) are wines that have spirits added to increase the alcohol content above that made possible by yeast fermentation, because the activity of yeast is significantly reduced by high alcohol concentrations; at such levels the yeast cells themselves may actually be killed. Examples of fortified wines include *Sherry*, *Port, Madeira* and *vermouth*. *Sherries* (Section 2.10.2) are wines fortified with brandy after completion of fermentation and so are usually dry unless sweet flavorings are added to make the fairly popular sweet Sherry style. *Ports* (Section 2.10.7) are wines fortified with brandy during fermentation in

order to stop the process and leave some sugars unfermented, making Port wines relatively sweet. *Madeira* (Section 2.10.5) wines are fortified, but are also exposed to higher temperatures during storage to influence the character of the beverage, and may be exposed to the oxidizing actions of air to alter their character, but with little effect nutritionally. *Vermouths* (Section 2.12.2) are imparted with the flavors of aromatic herbs and spices and contain varying amounts of sugars according to sweetness required, creating extra dry, bianco and sweet red (colored with caramel), with an alcohol content of about 16%. Therefore, the nutritional value of fortified wines is variable, being clearly dependent on many factors. As an example, a 50 ml serving of sweet Sherry might contain about 285 kJ (68 kcal) metabolic energy, provided mainly by about 7–8 g (205–234 kJ or 49–56 kcal) alcohol and 3.5 g (59 kJ or 14 kcal) carbohydrate, with a very small contribution from protein.

5.2.6 Alcopops

Alcopops (Section 1.3.9) are a relatively new fashionable way of targetting alcoholic beverages at specific markets, especially the younger age groups of consumers. Usually of between about 4% and 7% ABV and typically sold in measures of about one third of a litre (330 ml in Europe and 12 fluid ounces in the USA), alcopops have slightly different origins in Europe and the USA. In Europe, alcopops are mostly produced from a spirit base, such as vodka or white rum, to which may be added simple sugars, flavorings and colorings. In the USA, alcopops are essentially flavored malt alcoholic beverages that have been concocted from a fermented base product which has had all of its fermented malt character artificially removed, followed by the addition of spirits to provide the increased alcohol content, along with simple sugars, flavors and colors. Other alcopops are produced from various wines, also with sugars, flavorings and colors added in various amounts. A slightly more recent trend is for the addition of stimulants, such as caffeine, which are usually of negligible nutritional value. In essence, alcopops have little, if any, nutrient value beyond their 'empty calorie' content derived from alcohol and simple sugars. However, although some of the mixers used to formulate alcopops for flavor and color also have negligible nutritive value, if any, others, such as fruit juices, potentially containing significant levels of vitamins and other trace nutrients, or milk products with some protein, lipids and trace nutrients, may make some small contribution towards nutritional requirements.

5.2.7 Cocktails

Cocktails are multifarious alcoholic beverages made usually from any of a large number of distilled beverages in combination with one or more flavored mixers. Accordingly, the nutritional content of cocktails depends on the amount and nature of both the distilled beverage base and the mixer. Obviously, although the alcohol concentration may be less than the constituent spirit or liqueur if the mixer has lower or zero alcohol concentration, consumption of the whole drink provides the same total amount of alcohol as the 'shot' of spirit (or standard amount added). Liqueurs may also provide a relatively greater amount of simple sugars. Alcohol and simple sugars provide energy, but nothing else of nutritional value. However, many mixers used in cocktails may make a significant nutritional contribution to the cocktail; others may not. Fruit juices, such as the popular orange juice mixer, may provide some important vitamins (especially vitamin C), elements and electrolytes; see *McCance and Widdowson's, The Composition of Foods* (Food Standards Agency, 2002); the website of the National Agricultural Library (NAL) at the United States Department of Agriculture (USDA): http://www.nal.usda.gov/. However, it should be recognized that fruit squashes (unless supplemented) may

provide fruit flavorings only. Cream may be added to create certain cocktails, which are then the source of some lipids and fat soluble vitamins, but these probably have little real nutritional impact. Protein may be added in the form of eggs or milk, for example (Section 3.9.5).

5.3

Macronutrient Content of Alcoholic Beverages

From the previous section, it can be seen that the various production methods involved may modify the nutrient content of any particular alcoholic beverage to be substantially different from the constituents of the original ingredients. Therefore, although nutrients contained in the ingredients may be known with some accuracy, chemical analysis of the final product is essential in order to ascertain the exact nutrient content of the various alcoholic beverages. Apart from alcohol concentration, which is required particularly for commercial and legal reasons, analyses of other constituents have been performed sporadically and often limited to specific nutrients according to the remit of the analyst involved, perhaps for commercial or research purposes. Therefore, although information regarding individual or groups of particular constituents in specific beverages may be obtainable from the literature, there is relatively little easily accessible reference information available for comparison of the entire nutrient content of alcoholic beverages, as determined by chemical analysis. A certain amount of relevant information has been collated by a relatively small number of authorities making accessible some summary information for the most commonly consumed styles of alcoholic beverage, for example in *McCance and Widdowson's The Composition of Foods* (Food Standards Agency, 2002), and other such sources include specialist websites (e.g. NutritionData, http://www.nutritiondata.com/). However, although generally applicable to other products within the same type, nutrient content may also vary considerably between alcoholic drinks that are otherwise very similar in style.

The potential nutrient intake or the nutrient load from alcoholic beverage consumption depends not only on the nutrient content, but also on the amounts likely to be consumed. Therefore, in order to avoid possible confusion, it is very important to recognize that nutritional information regarding individual products, styles or classes of alcoholic beverages may be presented as quantities present in different serving sizes (e.g. wine as 125 ml, 175 ml or 250 ml glass) and as concentrations (e.g. g/l or g/100g), or even as percentage of the daily recommended dietary intake per serving (e.g. 6%). Information on many nutrients is not consistently available. For example, values for individual free amino acids and free fatty acids are available for only a relatively few products, bearing in mind the vast numbers of beverages on the market, and often these simply represent typical values for generic classes of alcoholic beverages (see *McCance and Widdowson's The Composition of Foods* – Food Standards Agency, 2002; and NutritionData, http://www.nutritiondata.com/). Clearly, the vast range and complexity of alcoholic beverages precludes the presentation of the exact nutrient content of all possible styles and types. Table 5.3.1 provides typical values for water, alcohol and the macronutrient

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

Table 5.3.1 *Typical macronutrient content of the major generic classes of alcoholic beverage commonly consumed in the UK**

	Nutrient Content†‡					
	Wine		Beer		Spirit (40% ABV)§	
	/125 ml	/liter	/284 ml	/liter	/25 ml	/liter
Water (g)	100–114	810–910	260–270	920–950	17	680
Alcohol (g)	10–14	80–110	8–14	30–50	8	320
Carbohydrates**						
Total (g)	0.25–7.5	2.0–60	4–12	15–37	Trace	Trace
Free sugars (g)	0.25–7.5	2.0–60	Trace–8.5	Trace–30	Trace	Trace
Fiber (g)	Trace	Trace	Trace–2.8	Trace–10	Trace	Trace
Nitrogenous matter – proteins, amino acids, nucleotides etc. (g)	0.02–0.4	0.2–3.0	0.6–1.7	2.0–6.0	Trace–0.08	Trace–3.0
Lipid (g)††	Trace	Trace	Trace	Trace	Trace	Trace
Caloric value (kJ)	335–523	2678–4184	335–536	1172–1883	234	9373
(kcal)	(80–125)	(640–1000)	(80–128)	(280–450)	(56)	(2240)

*Typical guideline values are presented, drawn from a large number of sources considered to represent the range of each generic product most usually consumed in the UK (e.g. *McCance and Widdowson's The Composition of Foods* – Food Standards Agency, 2002). For comparative purposes, values are presented per serving of 125 ml wine, 284 ml (half pint) beer and 25 ml spirits, and also per liter. Although these volumes were originally considered to represent approximately one unit of alcohol, regular wines range in alcohol content from about 8% alcohol by volume (ABV) for some white wines, up to about 14% ABV, or more, for some red wines, and beers from about 3% ABV for some light beers and mild ales up to about 6% ABV, and more, for strong ales and barley wines.

†As well as the nutritionally significant micronutrient content, there are residual components of the production of alcoholic beverages that have no known nutritional value, and some may even be toxic but, in general, these compounds appear to make negligible contribution: e.g. during analysis of regular wines and beers less than 0.5g/serving may be specifically identified as 'ash' or nonspecific residues.

‡Wherever the value indicated is 'trace,' negligible or low amounts may be present that could influence the character of the beverage but that may be insignificant in nutritional terms.

§Spirits of 40% ABV (about 80% proof) are presented for comparison.

**Carbohydrate levels in alcoholic beverages may be very variable indeed, according to desired sweetness. Dessert wines, in particular, may have sweetness of character due to specific production techniques and liqueurs are, essentially, spirits that have sugar infusions according to taste required.

††Trace lipids in alcoholic beverages are derived from plant cell wall material.

(carbohydrates, proteins and lipids – or fats) content of the major classes of commonly consumed alcoholic beverage. However, it is important to be aware that the alcohol and nutrient content for individual products within each class and style of alcoholic beverage may occasionally extend far beyond the typical range presented. The macronutrients present in these major classes of beverage and their biological function are described individually in the following sections. The relative importance, in terms of absolute amounts likely to be provided of the various nutrients, that is the nutrient load, towards nutritional requirements, will also be appropriately considered. For information regarding key vitamins and minerals, see the micronutrient content of alcoholic beverages (Chapter 5.4).

Alcohol content is usually a significant determinant of how much of a particular alcoholic beverage will be consumed and, therefore, the contribution that its total intake is likely to have on dietary energy intake overall. Current recommendations are that alcohol should provide no more than about 5% of total dietary

energy intake, which should otherwise be provided by a balance of the macronutrient sources of dietary energy (carbohydrates, lipids, and proteins) during habitual consumption of food and drink (British Nutrition Foundation – http://www.nutrition.org.uk). Recommendations for a healthy balanced diet for an adult who does not consume alcohol would be expected to provide at least 50% of energy from carbohydrates (of which 11% would derive from free sugars, excluding those free sugars provided by milk), up to 35% from fat (of which 11% is provided by saturated fatty acids and 2% trans fatty acids) and 15% from protein. Therefore, for adults consuming alcohol at 5% of their daily energy intake these figures need to be adjusted slightly, with carbohydrates then representing 47% (10% free sugars excluding milk derived sugars) and fats contributing 33% (10% saturated fatty acids). Currently, the average UK diet generally conforms very closely to these recommendations with the *trans*-fatty acid levels being below recommendations, but saturated fats and nonmilk free sugars both above targets. For more details, see the British Nutrition Foundation website (http://www.nutrition.org.uk) and Department of Health's 'COMA' Report (Department of Health, 1991).

Fermentation products, such as wines, beers and ciders, usually comprise relatively small, but variable, amounts of carbohydrates, and nutritionally insignificant amounts of protein and fats (lipids). Spirits, being distilled products, essentially do not contain carbohydrates, proteins or fats. The addition of mixers to alcoholic beverages modifies the alcohol concentration and carbohydrate content, and may even add lipids or proteins to the beverage, according to content of the mixer; examples of mixers include fruit juices, which add primarily carbohydrates, with some vitamins and minerals (see Micronutrients, Chapter 5.4); cream, predominantly providing calories from lipid; and eggs, that contribute protein to the beverage. In addition to possible health consequences associated with ingestion of alcohol per se, preferential consumption of beverages of higher carbohydrate content may, therefore, have further implications for optimum health in terms of possible acutely raised blood glucose levels and chronic weight gain due to increased caloric intake, from carbohydrate (16 kJ/g or 3.75 kcal/g) as well as alcohol (29 kJ/g or 7 kcal/g).

The principle constituents of a vast majority of alcoholic beverages are water and alcohol and, essentially, these vary with each other inversely according to alcoholic strength; that is, as the proportion of alcohol increases, the proportion of water decreases. The alcohol content of beers, ciders and wines is essentially determined by the amount of fermentable sugars in the original mix and length of time of the fermentation processes, although some additional sugars may be added for a secondary fermentation, e.g. some sparkling wines and some bottled beers. Yeasts commonly used for producing most traditional alcoholic beverages are only capable of working in alcohol concentrations less than about 15% ABV and so alcohol levels do not exceed this value during fermentation. For spirits and liqueurs, the relative amounts of water and alcohol are determined by the extent of distillation, which concentrates the alcohol, with stronger distilled beverages being produced by additional distillation processes. With the exception of the occasionally significant, but very variable amounts of carbohydrates that might be present, other ingredients are usually too small in quantity to significantly affect the relative amounts of alcohol and water in a serving of these usual styles of alcoholic beverages. The addition of mixers, such as fruit juices, reduces the relative alcohol concentration proportionally as water is increased.

5.3.1 Water

Often overlooked in terms of its contribution to nutrition, water is usually the major constituent of any alcoholic beverage, including more than half the content of most spirits. There are multifarious sources of water used for aiding production of the raw ingredients or added during processing that contain a large variety of desirable and beneficial constituents, as well as some undesirable and possibly harmful constituents, many of which could be present in finished alcoholic beverages, depending on the particular processes adopted for

their production. For a comprehensive overview of water regulation in the USA, which is consistent with standards in the UK and Europe, see Tarver (2008). Along with raw ingredients, the source of water used in the production of alcoholic beverages is a determinant of the relative amounts of the various elements that are present in the final product of fermentation. However, further processing techniques, particularly distillation, eliminate much of the water and essentially all the minerals, leaving very small amounts of certain elements such as phosphorus, potassium and sodium, for example, in the final beverage, some of which may originate from elsewhere during continued processing, copper from distillation in copper stills (Sections 3.2.4 and 3.5.3) and as a result of aging, for instance (Section 5.10.3).

Alcoholic beverages may make a significant contribution to water intake, especially those with high water content such as beers. Indeed, to avoid ingesting contaminated water, beer has often been the beverage of choice over many centuries, especially as communities started to grow with people living in closer proximity to each other. During previous times in the UK, 'small beer' may have been consumed regularly by children for intake of water and other nutrients ('small' because of its low alcohol content compared with the stronger beers consumed by men and women, generally). However, despite being the major constituent of most alcoholic beverages, the potential hydration capability of water from these sources may be curtailed to a greater or lesser extent because of the diuretic effects of the alcohol (Kleiner, 1999), which are dependent on the relative amounts of alcohol present in the beverage combined with the quantities consumed. Therefore, additional intake of water may be beneficial at times of high alcohol consumption, especially to accompany spirits and liqueurs.

Essential to life itself and to optimum health and performance, water is a major functional component of the body, contributing very approximately 60% (42 kg) of body weight in a nominal 'reference adult man,' weighing 70 kg and in whom 15% of body weight consists of fat (or lipid), and contributes 55% (33 kg) body weight in a nominal 'reference adult woman,' weighing 60 kg, of which 25% body weight comprises body fat. It is essential that water lost from the body through the kidneys, lungs, skin and intestine is balanced by intake from food and drink to maintain a healthy equilibrium. Water output is extremely variable, and increases with such factors as high environmental temperature and intense physical activity. A typical daily water turnover for a sedentary/moderately active individual living in a fairly temperate region such as the UK may be around 2.5 l (perhaps 2.9 l for men and 2.2 l for women; Kleiner, 1999), which is *equivalent* to about eight (300 ml) glasses of water. However, it is important to understand that that the amount represented by these eight glasses is just that, an equivalent. A significant amount of water is obtained from all drinks, not just glasses of unadulterated water, and a very large proportion is also obtained from food, especially fruit and vegetables, making an average daily intake for the population of about 2.5 l in total. Over recent years the fact that this is equivalent to eight glasses of water has been mistakenly used by some health and fitness practitioners to indicate the need for a daily intake of eight glasses of water in addition to the other sources of water from both food and other drinks. This is essentially an ill considered myth, as is the often misinterpreted recommendation that beverages containing diuretic substances, such as coffee and alcoholic drinks, should not be counted towards water intake. Indeed, the effectiveness of hydration of water in a beverage is determined by the volume ingested in relation to the diuretic capacity of that beverage, i.e. although both may have the capacity for hydration, a cup of strong coffee might hydrate less than a cup of weak coffee.

Of the water required by a typical healthy, albeit sedentary, adult living in a temperate zone, about 1000 ml is provided as it exists in that molecular form (H_2O) from foods, with about another 250 ml provided by metabolic processes producing water as an end product of oxidation of mainly fats and carbohydrates (Kleiner, 1999). That is, although some foods (principally fruits and vegetables) contain relatively high amounts of water per se, other foods that contain sources of metabolic intermediary compounds, the fats and carbohydrates (and even alcohol), also contribute to water balance because they undergo catabolism to liberate water and CO_2 as end products of metabolism during energy production. Additional amounts of water are required at times of increased physical activity and in high environmental temperatures to replace that

utilized for temperature regulation. Under normal healthy conditions and sufficient fluid availability intrinsic mechanisms will ensure that the flux of water through the body is in equilibrium by a balance of hormones such as vasopressin, also known as antidiuretic hormone. Equally in health, excess intake is also balanced by increased output and, apart from being the result of certain underlying clinical conditions, excess intake in otherwise healthy individuals has seldom, if ever, been shown to be of major detriment. However, in certain disease states, such as alcoholic liver disease or kidney disease, positive water balance may exacerbate such serious health problems.

The amount of water present in the body is also known as the distribution volume into which water soluble alcohol may be distributed once it has been absorbed and before being broken down by the liver. Along with the capacity and location of the enzymes responsible for the breakdown of alcohol, it is this distribution volume that determines the effectiveness of the toxicity of alcohol and its intoxicating properties. This may be one of the reasons that women with lower total body water appear to be more susceptible to the effects of alcohol than men. An understanding of factors such as levels of body water is, therefore, important for consumers and practitioners, especially when treating the effects of alcohol per se in acute poisoning, for example, or the longer-term health consequences of chronic alcoholism, particularly alcoholic liver disease (cirrhosis). As well as its relative distribution into the total body water pool, the full intoxicating and metabolic potential of alcohol consumption is ameliorated by its rate of consumption, its concentration and the presence or absence of bubbles, the amount and type of food taken concurrently, and the effectiveness of the alcohol dehydrogenase enzymes present in the stomach, as well as in the liver (Crabb *et al.*, 2004).

The body mass index (BMI; kg body weight/height^2) is often, and frequently erroneously, used as indicative of the amount of alcohol that an individual may consume before reaching a level considered to increase health risk. However, BMI is dependent to a large extent on the relative amount of body fat, and it is also important to realize that the proportion of body weight accounted for by water is extremely variable due to the large variation in fat content between individuals (fat in its pure chemical form does not absorb alcohol). Body fat may represent perhaps only about 4% of body weight typically in body builders, but up to potentially 50% or more in morbidly obese individuals. Such considerations would result in proportions of water in the whole body of up to 70% (49 kg water in a 70 kg man of 4% fat) and down to 36% (26 kg water in a 70 kg man of 50% body fat). Therefore, because this level of variability in body fat is confounding, ineffective and uninformative for clinical use, the concept of dividing the composition of the whole body into its chemically distinct fat and fat free mass (FFM) compartments was applied for functionally standardizing body composition independently of the various levels of body fat. In body composition modelling (for example, Fuller *et al.*, 1992), all chemically extractable fat (all lipids) are assigned to the fat fraction of the body and FFM represents a conglomerate of every other chemical component of the body. The FFM is predominantly composed of water, protein and mineral in fairly consistent relationships with each other and it is considered to be the metabolically active body compartment.

$$\text{Body weight} = \text{fat} + \text{fat-free mass (FFM)}$$

$$\text{FFM} = \text{water} + \text{protein} + \text{mineral} (+ \text{ relatively smaller amounts of other components such as DNA, urea etc.})$$

This construct of body composition is modeled at the chemical level where all water is assigned to the FFM and is useful for many purposes of research and clinical practice, and so any alcohol absorbed by the body only appears in the FFM, not in the chemically distinct fat. This model is not to be confused with the conceptually valid and alternative tissue level model of body composition (Wang *et al.*, 1992) in which the various tissues, such as muscle and adipose tissue and organs, are composed of differential amounts of the body components according to structure and function. Water is distributed predominantly in tissues that have

relatively low fat content, such as muscle (consisting perhaps about 80% water), and less so in adipose tissue (about 20% water) that is designed for fat storage and metabolism. Therefore, ingested alcohol is distributed throughout the body tissues, but more so in muscle and organs and less so in adipose tissue.

This standardization of hydration fraction of FFM is of value to health practitioners in general because in a normal healthy adult there is a fairly constant hydration fraction of the FFM (mean, about 0.73 or 73%) that falls consistently within a very narrow range (perhaps about 70–75%). Importantly for practitioners involved in certain disease states, such as alcoholic liver disease (cirrhosis) and kidney disease, the fraction of water in FFM shows a much greater variability and may fall substantially outside the normal reference range. Cirrhosis patients, for example, may present with a hydration fraction outside either extreme with overhydration (edema and ascites) or underhydration, both of which are potentially very problematical (Morgan *et al.*, 2006). Total body water is distributed between the intra- and extracellular fluids, but in overhydration the main expansion occurs in the extracellular fluid. Aberrant body water may be of serious detriment to the normal physiological functionality of the body. The key functions of water are: (a) the efficient transport of nutrients, gases (O_2, CO_2), internal secretions (e.g. hormones) and waste products, both within and between the cells, helping to maintain the critical acid/base balance of the body for optimum organelle and enzyme performance, and (b) thermoregulation, particularly the elimination of excessive heat from the body, that may have been generated by metabolic processes or be the result of high environmental temperatures, and the dissipation of this heat into the surrounding environment through the skin (sweat) and lungs (water vapor). Although water insufficiency and imbalances may be responsible for some of the symptoms of the alcohol hangover (Wiese *et al.*, 2000), excessive alcohol intake can have far more serious health consequences than a transient hangover, due to its effects on water balance alone, with severe dehydration enhancing the toxic effects of alcohol and its intermediary metabolites, and exacerbating the effects of any xenobiotics that may be present. Also, dehydration significantly lessens the ability of the body to regulate its own temperature, which may lead to severe complications, even death, especially in extreme climatic conditions. However, it is also important to remember that excessive alcohol intake over the long term can lead to a number of serious health sequelae independently of issues of water balance, for which compensatory mechanisms are fairly effective overall.

5.3.2 Alcohol

After water, alcohol is predominantly the second major constituent in the usual styles of alcoholic beverages (Table 5.3.1), typically contributing about 3–4 g (or more)/100 ml (about 5% ABV or more) in beers and ciders, 6–11 g/100 ml (about 8–4% ABV) in wines and 15–30 (or more)/100 ml (20–40% ABV, or more) in fortified wines and spirits. The representation of alcohol levels as g/100 ml alcohol is an informative alternative to the UK 'unit' or other 'standard' amounts for comparative purposes depending on preference and required application (Section 5.1.1). However, the variability in alcohol content within each type of alcoholic beverage is substantial. For example, beers can be produced that are well below 3% ABV (2.4 g/100 g), with others up to about 12% ABV (9.5 g/100 g). Wines may be below 8% ABV (6.3 g/100 g), for some white wines usually, up to about 14% ABV (11 g/100 g) for some reds. The generally higher concentration of alcohol in spirits is also quite variable and spirits are often measured in proof as an alternative to ABV; a 40% ABV spirit is about 70 degrees of proof with a 25 ml serving containing 10 ml (or 7.9 g) alcohol. Alcohol content is a significant determinant of how much of a particular alcoholic beverage will be consumed according to taste and character of the beverage concerned as well as the capacity of the individual and, therefore, the contribution that its total intake is likely to have on dietary energy intake overall (see Chapter 5.5).

Alcohol may be considered as a nutrient in some respects as it provides a source of metabolic energy at 29 kJ/g (7 kcal/g). Otherwise, alcoholic beverages are generally perceived to be the source of so called 'empty

calories,' which essentially means provision of calories alone, from both alcohol and the simple sugars that are often present (carbohydrates provide 16 kJ/g or 3.75 kcal/g), with no further benefit as in many, but not all, alcoholic concoctions there are no other constituents with any significant nutritive benefit. Also, alcohol and its metabolites are essentially toxic to the human body, although it does provide a relatively sterile dietary environment for consumption of other nutrients, including water at times when alternative supplies of water may be contaminated. Alcohol may have health promoting benefits if taken in low to moderate amounts via any beverage style, as ethanol per se appears to lower cardiovascular risk, as suggested by certain fundamental and epidemiological studies (see Rimm *et al.*, 1996; Puddey *et al.*, 2003). Although there may be mixed influences on lipid metabolism depending on such factors as subject variability and amount consumed (Feinman and Lieber, 1999), moderate alcohol consumption may increase plasma high density lipoprotein (HDL) relative to low density lipoprotein (LDL) and promote cholesterol transport away from arterial walls, which appear to be beneficial, along with other clinically important effects such as promoting anticoagulant properties and direct effects on reducing platelet aggregation (Puddey *et al.*, 2003; Ruf, 2004). However, there are severe detrimental health effects of alcohol consumption possible in high consumers and alcoholics (Table 5.1.1 in Chapter 5.1; see also Chapter 5.5 and Sections 5.1.2 and 5.6.2).

Certain types of alcoholic beverage, especially those with relatively low alcohol concentration, are potential sources of important nutrients such as vitamins, minerals and antioxidants. In general, these sources include the less refined fermentation products of wines and beers, but not spirits, as distillation and concentration of alcohol tends to eliminate many of the less volatile compounds, including potential nutrients. However, the nutritive value of such beverages is uncertain because the amounts consumed may be too small to be effective, relative to dietary requirements, especially if the alcohol intake is low to moderate. Additionally, for those nutrients that might appear to be consumed in significant quantities from alcoholic beverages, there may be confounding effects of lower intakes from the otherwise usual dietary sources as, in high consumers and alcoholics especially, regular meal patterns, and food quantity and quality may be disrupted, reducing nutrient consumption overall. This may be because of either conscious or insensitive social changes or perhaps insensitive compensatory mechanisms to account for increased alcohol consumption. The alcohol ingested also interferes with absorption, assimilation and metabolism of a large number of important nutrients (Lieber, 2000), effectively increasing dietary requirements. High alcohol intake may also contribute towards significant imbalance of water in the body, as it is known to influence release of antidiuretic hormone, causing increased loss of water in the urine, potentially altering the flux of nutrients through key metabolic pathways.

5.3.3 Carbohydrates (Including Fiber)

Carbohydrates, also called saccharides, are simply composed of carbon, hydrogen and oxygen atoms (as is alcohol, incidentally; C_2H_5OH – the formula for ethanol), but exist in multiple and complex forms, with many important functions in the human body, and in plants, where they are integral to the provision, transport and storage of energy and constitute major structural elements. Monosaccharides (simple sugars such as fructose and glucose, amongst others) are the basic monomeric units of carbohydrates that may exist independently or may be used as the building blocks of disaccharides (two units), oligosaccharides (between two and nine units) and polysaccharides (10 or more units). Available, or glucogenic, carbohydrates are the free sugars (e.g. glucose, fructose and the oligosaccharides) and complex carbohydrates (glycogen, starch and dextrins) that collectively constitute the glycemic carbohydrates (see *McCance and Widdowson's, The Composition of Foods* – Food Standards Agency, 2002). Dietary carbohydrates are usually one of the major sources of total metabolic energy requirements providing 16 kJ/g (3.75 kcal/g) and representing typically 45–65% of energy requirements globally with the UK recommendation that carbohydrates should provide about 50% of energy

intake (see British Nutrition Foundation website – http://www.nutrition.org.uk). Based on a nominal daily energy intake of 8368 kJ (2000 kcal) for an 'average' individual in the population, the UK recommendation for daily carbohydrate intake would be about 250 g. Fats and protein, and any alcohol consumed, can also be broken down to provide intermediates for catabolism and energy production through acetyl coenzyme A and entry into the tricarboxylic acid cycle.

However, not all carbohydrates are utilized in the same way, with some of the more complex compounds (e.g. certain oligosaccharides, nonstarch polysaccharides and resistant starches, also known collectively as dietary fiber) being indigestible in the upper gastrointestinal tract and so pass into the lower gut where some may be utilized by gut flora and some perhaps eliminated essentially unchanged. Therefore, the oxidation of certain ingested carbohydrates may not be complete, indicating a difference between the potential fully combustible energy ingested, the digestible energy and the net metabolic energy that is actually realized (Elia and Cummings, 2007).

The ubiquitous carbohydrate, glucose, is central to intermediary metabolism and is especially important as the usual source of energy for the brain, which cannot utilize fats. In animals, glucose is stored as the polysaccharide glycogen molecule. In plants, glucose is stored as multiple units to form the polysaccharide molecule starch, which must be broken down to individual glucose units for utilization by yeast during fermentation. The malting and mashing processes used in beer production facilitate the enzymatic breakdown of the complex carbohydrates present in barley and other grains, predominantly the polymers starch and β-glucans, into simple sugars that are then more available for fermentation into alcohol (Sections 2.6.2 and 5.7.4). Dextrins are relatively low molecular weight carbohydrates that are produced by hydrolysis of starch, the higher linear and branched forms of which cannot be readily utilized by yeasts and so appear in varying amounts in some finished beers (Section 2.6.2). Fruits, particularly grapes, provide the simple sugars glucose and fructose that, as such, can be fermented to produce wines, in particular, without the need for further processing. A number of different carbohydrates are present in raw ingredients and find their way unchanged or modified into the final fermentation product in variable amounts, depending on the source of raw materials used and the type of alcoholic beverage produced. Analysis by various methods, such as HPLC, ion chromatography (Section 4.3.3) and gas chromatography (Section 4.3.2) and electrophoresis (Section 4.6.1), indicates the presence in beers of fairly sizeable amounts of the carbohydrate malto-oligosaccharides, consisting of maltose, maltotriose, maltotetraose and maltopentaose (maltohexose, maltoheptose and the higher malto-oligosaccharides are also found in amounts that decrease inversely according to molecular size), with slightly smaller amounts present of glucose, sucrose and fructose, as well as the sugar alcohol glycerol. Similar analyses for wines indicate varying, but often sizeable amounts of glycerol, glucose, fructose and tartrate, with lesser amounts of lactate, citrate, malate, succinate, acetate and others. It is difficult to be sure of exact quantities present in alcoholic beverages, as detection of individual carbohydrates and their respective levels are very much method dependent and, of course, actual levels vary considerably, being very much product dependent. Behind alcohol and CO_2, glycerol is usually the third largest product of yeast fermentation, but may be added artificially for smoothness, especially to some wines. In contrast to wines and beers, distillation processes ensure that spirits have effectively negligible carbohydrate content, unless perhaps a mixer might be added or sugars infused for producing liqueurs (Chapter 3.9).

Individually, the carbohydrates and alcohols other than ethanol are not thought to make important contributions to the nutritional value of beers and wines, as none of them are essential (i.e. carbohydrates can be produced within the body from breakdown of fats and proteins). However, collectively they may contribute significantly to metabolic energy at times of high alcoholic beverage consumption. Also, the contribution of carbohydrates (16 kJ/g or 3.75 kcal/g) to the energy content of many other types of alcoholic beverages could be considerably higher in, for example, sweet wines, liqueurs and fortified wines, and others that may have simple sugars added during the final stages of preparation, especially specific market orientated products such as 'alcopops.'

Beers and dry wines may provide relatively low amounts of carbohydrates in terms of dietary requirements, but which again vary greatly according to the particular product, and, to reiterate, these could be relatively significant at times of high consumption, providing energy at 16 kJ/g (3.75 kcal/g) of carbohydrate. A half pint of beer (284 ml) of about 3.6% ABV, although only about one unit of alcohol (7.89 g of alcohol at 29 kJ/g or 7 kcal/g, contributing 229 kJ or 55 kcal), may typically provide a total of 376 kJ (90 kcal), about 146 kJ (35 kcal) from carbohydrates. A serving of wine containing one unit of alcohol (125 ml of 8% ABV) may provide about 418 kJ or 100 kcal (about 188 kJ or 45 kcal from carbohydrates). In contrast, a serving of spirits containing one unit (25 ml of 40% alcohol) is not so product dependent and provides a consistent 229 kJ (55 kcal), as essentially all energy is provide by its alcohol content and no carbohydrates of metabolic utility are present. However, some beers, wines, fortified wines, dessert wines and infusions in liqueurs may be quite high in carbohydrates through the addition of flavoring and preference for sweetness (either by controlled fermentation or simply added in the final stages of manufacture). This extra carbohydrate content may significantly increase relative energy value even further. For example, a 38 ml serving of coffee liqueur (60–65% proof, about 30% ABV and 9 g alcohol) may provide 502 kJ or 120 kcal (264 kJ or 63 kcal from alcohol and 238 kJ or 57 kcal from carbohydrates) and a glass of sweet sherry (one 100 g serving of 15% alcohol) may provide up to about 711 kJ or 170 kcal (439 kJ or 105 kcal from alcohol and 272 kJ or 65 kcal from carbohydrates). The addition of mixers to alcoholic beverages effectively reduces their alcohol concentration (total alcohol quantity is the same) but, in part at least, any potential nutritional gains may be effectively diminished by added carbohydrates, again often in the form of free sugars. Examples of mixers include fruit juices, e.g. orange juice for sangria, which adds primarily water and carbohydrates (mainly as free sugars), with some vitamins and minerals (Sections 5.4.1 and 5.4.2). Certain concoctions may have carbohydrates added in conjunction with the addition of other ingredients such as cream, which predominantly provides calories from lipid (37 kJ/g or 9 kcal/g), and even eggs that contribute protein (17 kJ/g or 4 kcal/g) to the beverage. In view of all of these considerations, preferential consumption of such beverages of higher carbohydrate content may, therefore, have implications for optimum health in addition to those associated with the ingestion of alcohol per se.

Some of the less refined alcoholic beverages, especially certain beers and ciders rather than wines, also contain significant amounts of more complex carbohydrates, in contrast to the simple sugars, which may serve two functions with potentially significant health benefits. Those which are slowly digestible by the enzymes of the small intestine ensure that the absorption and concomitant rise in blood glucose is less rapid and with a lower peak concentration than that produced by the more simple monosaccharides and disaccharides. This means less demand on the pancreas for insulin production, along with its possible rebound effects, and lower blood glucose helps to avoid the possible damage inflicted on important functional proteins, including haemoglobin (Hb1Ac), and structural proteins in the vasculature, when glucose becomes attached to them (Ceriello *et al.*, 2008).

The second benefit of complex carbohydrates comes from those that are essentially indigestible in the upper human intestine, colloquially and collectively known as *dietary fiber*, which consists of insoluble and soluble plant derived nonstarch polysaccharides (e.g. cellulose), dextrins, β-glucans and many other molecules. Fiber is a key component of the diet because it is indigestible by enzymes in the upper intestinal tract, a property that is important in terms of potential health benefits, as it passes essentially unchanged into the large bowel. Some of the nonstarch polysaccharides, resistant starches and oligosaccharides that pass into the large intestine are utilized by the bacteria that reside there to produce other compounds of nutritional value, such as the volatile short-chain fatty acids, acetate, propionate and butyrate. Acetate and propionate are absorbable through the intestinal wall and are utilized for energy production within the usual pathways of intermediary metabolism, acetate being available to all cells, such as muscle, propionate usually being metabolized by the liver, and butyrate is a major source of energy for the colonic epithelium (Cummings and Macfarlane, 1997). The nutritional importance of complex carbohydrates is also due to the provision of

energy for bacterial growth. Any complex carbohydrates that remain unchanged or unused by the gut or the gut bacteria help to bulk the intestinal contents, along with greater levels of bacterial matter, reducing transit time and the potential gut contact time of any toxic compounds, which may be expelled from the gut with greater expedience.

As bacteria are provided with the energy to grow by such carbohydrates, they are also able to utilize certain potential toxins based on sulfur and nitrogen, which are detoxified by incorporation into bacterial proteins and excreted (Cummings and Macfarlane, 1997). Apart from a few alcoholic beverages that are relatively unrefined, e.g. some beers and ciders, or that may have ingredients added to the final product, fiber is not really present in any significant amounts due to clarifying and filtering processes etc. Fiber is absent from spirits due to distillation, negligible in wines and only present in small amounts in most of the more commonly consumed beers. However, some beers and ciders, especially those of higher strength alcohol and some specialist products, have significant amounts of fiber; perhaps 6 g/l in some strong UK beers, when considered in perspective of a daily intake of about 20–40 g fiber in a typical Western type diet and perhaps 50 g or more in less developed countries, or in regions in which cereals and fruits represent greater predominance in the diet. For example, some locally produced beers that are made from various grains, such as wheat or sorghum, may be consumed as the simple fermentation product without further processing to remove spent ingredients (Chapter 2.7). Certain cocktails and mixers may have added fiber in the form of fruit pieces, but again this is probably not of any major nutritional significance.

5.3.4 Nitrogenous Compounds: Proteins, Peptides, Amino Acids, Amines and Nucleotides

Proteins are large polymers made up of their constituent building blocks known as amino acids. RNIs for protein are 55.5 g/day and 45.0 g/day, respectively, for men and women of up to 50 years of age, with slightly adjusted values for those over 50 years (Department of Health's 'COMA' Report – Department of Health, 1991; British Nutrition Foundation website – http://www.nutrition.org.uk). These values are based on requirements of 0.75 g/kg body weight/day, slightly above the estimated average requirement of 0.6 g/kg body weight/day, in order to ensure inclusion of a majority of the population. However, people in the UK generally exceed guidelines for protein intake, with such levels constituting 10–35% of the total recommended daily energy requirements, with a target balance of 15% of total energy intake provided by protein (17 kJ/g or 4 kcal/g) – see website of the British Nutrition Foundation (http://www.nutrition.org.uk). With very few exceptions, the levels of protein in most alcoholic beverages are relatively insignificant in terms of their contribution to the diet. Beers may contain some proteins derived from the original ingredients, essentially malt (or fruits if used), and from residual yeasts, but many proteins are fully or at least partially hydrolyzed during production. Proteins are desirable in beers, as they make a predominant contribution towards maintaining the head of the beer. However, nutritionally significant amounts of protein may only be found in very few of the more commonly consumed beers in which levels of protein may reach about 1.7 g in half a pint (284 ml). This is equivalent to about 3–4% of the daily protein requirement in a 'reference' man weighing 70 kg and represents sufficient intake for up to 2–3 kg of the body weight. In the very early versions of beers and the less processed beers currently being produced there may be greater amounts of protein, but these styles are not as readily available as the more refined products of greater clarity demanded by market forces. Protease enzymes are responsible for the breakdown of many of the proteins in beer into peptides and amino acids. In wines, the more lengthy secondary fermentation breaks down proteins so that negligible protein content usually remains in the finished product. The levels of protein in spirits are also negligible, essentially because of elimination by distillation of any protein that is present in the fermentation product. However, there are certain residual proteins of significance to health that may be found in finished beers, especially those that are ethanol soluble storage proteins, or prolamins, of cereal grain origins and some of which may cause autoimmune reactions

in genetically susceptible individuals, a condition known as celiac disease (McGough and Cummings, 2005). Wheat and barley contain the glycoprotein, gluten (specifically constituted of gliadin and glutenin), and barley contains hordein, also a glycoprotein, of which significant amounts are quantifiable in certain beers (Ellis *et al.*, 1990) (Section 5.11.3). Although gluten may be used as a clarifying agent in wines, residual gluten, if any, may not be present in sufficient amounts to cause significant immunoreactive responses (Cattaneo *et al.*, 2003).

Peptides are smaller polymers of amino acid building blocks than proteins that may exist in relatively small amounts in beers and wines. Like proteins, ingested peptides are digested in the intestine releasing easily absorbable amino acids that may be used to construct functional proteins and peptides once assimilated into the body, such as structural elements, enzymes and hormones. One such tripeptide is glutathione (formed from the amino acids glycine, L-cysteine and L-glutamate), which occurs in grapes and is also produced by the action of yeast, and so is present in small amounts in finished wines and beers. Although ingested through wine and beer consumption, glutathione is unlikely to be absorbed as such into the body without first being degraded into its constituent amino acids and so, as it can be readily synthesized *de novo* by the body, it is not considered to be an essential nutrient. However, glutathione is a very important molecule in human biology because of its antioxidant properties that protect the cells directly against the effects of certain toxins, especially free radicals or highly reactive oxygen and nitrogen species (Wu *et al.*, 2004; Franco *et al.*, 2007) (see Chapter 5.8). There is a cellular equilibrium between the oxidized (GSSG) and reduced (GSH) forms of glutathione that is the key to its antioxidant potential since this balance greatly favors GSH, especially at times of oxidative stress due to increased levels of free radicals. Alcohol catabolism is itself responsible for production of certain highly reactive free radicals. It has been suggested that because wines and beers contain significant levels of multifarious antioxidants (Section 5.4.3) they may be of significant benefit in maintaining the important GSH/GSSG equilibrium by helping to keep glutathione in its reduced GSH form. Glutathione also appears to have an antioxidant role in the beers and wines themselves, by preventing chemical oxidation of vulnerable components and preserving the taste and character of such beverages, but glutathione derived from these sources is likely to be of limited nutritional value, making negligible contribution to daily requirements.

The building blocks of proteins and peptides are *amino acids* of which many, such as alanine, glutamic acid with glutamine, arginine, cysteine, methionine, asparagine, threonine, lysine and γ-aminobutyric acid, are present in variable amounts in wines, beers and ciders as free amino acids. Proline appears to be the most abundant, probably because it is not utilized by yeast, as are other amino acids. Because of the distillation processes, spirits contain negligible amounts of amino acids. Although some of the amino acids in beers and wines, e.g. methionine and lysine, are considered to be essential amino acids (those that cannot be synthesized within the body and so must be obtained from exogenous sources), alcoholic beverages are not considered to be nutritionally significant sources. For amino acid content of typical alcoholic beverages, see *McCance and Widdowson's, The Composition of Foods* (Food Standards Agency, 2002).

Biogenic *amines* and *polyamines* are present in fermented beverages at variable levels, depending on the original ingredients, including potential bacterial contamination, and processing techniques, and may be produced by decarboxylation of free amino acids in the beverage itself, beer for example (Kalac *et al.*, 2002; Kalac and Krizek, 2003). Different amines are produced in varying amounts according to the strain of yeast used for fermentation and are usually present in relatively small quantities in wines, beers, ciders and some spirits, perhaps just a few milligrams per liter up to about 130 mg/l (Ancín-Azpilicueta *et al.*, 2008). Essentially of negligible nutritional significance, some bioactive amines may be considered to be effective at the micronutrient level with concomitant health implications. Certain of these amines, including histamine, tyramine and phenylethylamine, are associated with some biological functionality, including potential toxicity and other health exacerbations such as allergenic and asthmatic reactions (Vally and Thompson, 2003), although the extent of these affects remains uncertain (Jansen *et al.*, 2003) (Section 5.11.3). Red wines appear

to contain far greater amounts than white wines, which may account for greater perceived occurrence of such reactions from red wine (Ancín-Azpilicueta *et al.*, 2008). Recently, there has been increasing interest in melatonin (*N*-acetyl-5-methoxytryptamine), which is an indoleamine synthesized from 5-hydroxytryptamine (serotonin) and is perceived to be of particular importance in many aspects of human biology, including key hormonal and antioxidant functions. For example, the cyclical nature of melatonin levels enables control of circadian rhythms, including the regulation of sleep (Danel and Touitou, 2004). Melatonin and its metabolites also have very powerful antioxidant properties as hydroxyl radical scavengers, perhaps five times greater than vitamin C, which is especially beneficial in maintaining the integrity of DNA (Coghill, 2007). As well as being synthesized by various tissues in the body, particularly the pineal gland, melatonin is also produced by plants, the products of which include alcoholic beverages. Of particular relevance, grapes (especially the skins of red grapes that contain melatonin in amounts that are variable depending on family of grape – Iriti *et al.*, 2006), apples and barley appear to be natural sources of melatonin (e.g. Badria, 2002; Iriti and Faoro, 2006). It is assumed, therefore, that melatonin and some of its bioactive metabolites might be present, probably in small and variable quantities, in the wines, ciders and beers produced from such sources, but relatively little definitive information on this subject is currently available. Alcohol itself is known to alter sleep patterns (Roehrs and Roth, 2001) and secretion of melatonin from the pineal gland, and this effect may be due to chronic exposure to alcohol or a shift in secretion patterns altering circadian synchronization (Danel and Touitou, 2006).

The nucleotides, purines, particularly guanine and adenine, and pyrimidines, particularly thymine, cytosine and uracil, are produced when yeast cells multiply during fermentation because these nucleotides are synthesized and incorporated into the nucleic acids DNA and RNA (thymine is usually found in DNA and uracil is exclusively found in RNA). As well as being integral to nucleic acids, phosphorylated purines (ATP, GTP) and phosphorylated pyrimidines (UTP, CTP) are important sources of energy generation for driving cellular reactions. Although humans do not need exogenous sources of these nucleotides because they can be synthesized *de novo* or salvaged and reutilized by the body, the ingestion of high levels of purines may impose increased health risks. The catabolism of both adenine and guanine proceeds via the common intermediary, xanthine, which is then converted into the end product uric acid and this relatively insoluble compound is then usually excreted in the urine. However, especially in conditions that produce unusually high levels, excess uric acid is implicated in some metabolic disease processes, such as gout, where it is deposited on joint surfaces and in other tissues. In addition to the potential effects of exogenous purines, ethanol per se is suggested to increase blood levels of uric acid, particularly as it promotes degradation of adenine coupled with increased production of lactate and concomitant hyperuricaemia, which may predispose to gout in the same way (Section 5.6.2). In contrast, the pyrimidines are reduced and cleaved to produce ammonia, CO_2 and β-amino acids, none of which are currently implicated in increased disease risk. Beers are more heavily implicated in increased risk of gout than wines because of their greater purine content. For a comprehensive review, see Yamamoto *et al.* (2005).

Generally, however, the amounts of proteins, peptides, amino acids and other nitrogenous compounds involved in alcoholic beverages in general probably make only small contributions to dietary requirements, unless added at the final stages of preparation, for example the addition of eggs, milk and tomato and orange juices for certain cocktails.

5.3.5 Lipids

Plant wall lipids from the raw ingredients used in the fermentation process may contribute to the character of an alcoholic beverage, but may be oxidized when exposed to certain prevailing conditions to cause undesirable changes in taste and character. Lipid levels are generally so low in wines, beers, ciders and especially spirits

that they are of negligible nutritional significance. However, they may be present as ingredients added at the final preparation stages of a particular beverage, e.g. cream liqueurs, and the addition of these sources may also contribute small quantities of fat soluble vitamins and minerals, as well as being a source of energy (lipids provide 37 kJ/g or 9 kcal/g).

5.4

Micronutrient Content of Alcoholic Beverages

The micronutrient content of an alcoholic beverage may be substantially different from that which might be expected based on the original ingredients and may also be extremely variable, even within each generic type of beverage, reflecting the similar situation encountered when considering macronutrients (Chapter 5.3). Therefore, chemical analysis of the final product is required to be certain of the micronutrient content and, therefore, potential micronutrient intake from the many alcoholic beverages currently available. Some summary information is readily available for the generic products (e.g. *McCance and Widdowson's, The Composition of Foods* – Food Standards Agency, 2002 and websites such as http://www.nutritiondata.com/). It is also important to be fully aware that micronutrient information may exist for various serving measures (e.g. wine as 125 ml, 175 ml or 250 ml glass), as concentrations in standard amounts (g/l or g/100 g, for example) or even as percentage of the RNI per serving, and so adjustments for actual serving sizes may be needed in order to provide a reasonable estimate of intake. The RNI is the dietary reference value normally assigned to micronutrients (as it is for proteins) and is the value applied to ensure that nutrient intake is sufficient for a vast majority of any population group of interest (see Nutritional fundamentals, Section 5.1.4, above, and the website of the British Nutrition Foundation – http://www.nutrition.org.uk).

Alcoholic beverages may contain sufficient amounts of many essential elements (also referred to colloquially as minerals and trace elements), electrolytes, vitamins and other compounds to make significant contributions to nutritional status, but these contributions could be quite variable. In nutritional terms, 'minerals' are considered to be those chemical elements other than carbon, oxygen, hydrogen and nitrogen, that are found to exist mainly in the form of ions and are essential for: (a) maintaining the electrolyte balance of the body, both as independent entities and in chemical combination with other elements, (b) utility in certain structural roles, such as calcium in bone, and (c) for acting as cofactors in some enzymatic reactions, copper in redox enzymes such as cytochrome oxidase, for example. Minerals are often classed as 'macrominerals' if they are required in relatively large amounts, such as calcium, which is integral to bone structure, or potassium for maintaining electrolyte balance. 'Microminerals,' that are required in relatively lesser amounts than the macrominerals, are also known as trace elements, and include copper, for example, which is integral to redox reactions of the oxidation and reduction pathways or electron transport chains, or iron, which is important for hemoglobin function, but required intake is relatively low on a daily basis. The simple ingredients, particularly the juice of the fruit for wines or malt and source water for beers, have variable, but significant, levels of

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

valuable elements and electrolytes that may survive processing and so persist into the finished product with potentially important nutritional benefits. Spirits, however, appear to contain very small amounts, if any, due to losses through the distillation processes. Alcoholic beverages generally contain relatively lower amounts of sodium compared to higher amounts of potassium than found in the usual diet, with potential health benefits, especially regarding cardiovascular function. For general information, see the website of the British Nutrition Foundation – http://www.nutrition.org.uk.

Other micronutrient constituents of alcoholic beverages, particularly the vitamins and phytochemicals, are also very variable. For example, certain of the water soluble vitamins and many of the different classes of plant derived antioxidants originating from either the raw ingredients or fermentation processes, or both, are found in variable yet potentially nutritionally significant quantities in wines, beers and ciders. However, although these particular compounds are essentially removed during the distillation of spirits, other potential micronutrients (and also some toxins) may be introduced at a later stage into distilled alcoholic beverages. In particular, for those beverages which are allowed to age in various types of wooden casks, certain phenolic compounds may become infused during storage and so present substantially altered nutrient profiles that may be specific to the individual product. Some such compounds appear to have potential health benefits, whereas others may be toxic or carcinogenic (Goldberg *et al.*, 1999). Dietary antioxidants, essentially consisting of vitamin E (tocopherols), vitamin C, vitamin A and β-carotene (the vitamin A precursor, provitamin A), with integral involvement of the mineral selenium and the vast array of polyphenols (Chapter 5.8), increasingly appear to have major significance for human nutrition and health status. Working independently or interacting in synergy, collectively these antioxidants help prevent oxidative damage by free radicals. Consisting mainly of reactive oxygen and nitrogen species, free radical damage of key molecules involved in cellular proliferation (e.g. DNA), transport (e.g. low density lipoproteins) and structure (e.g. cell wall membrane proteins) may be ameliorated through complex interactive reducing environments within tissues and cells provided by these dietary antioxidants (Eastwood, 1999). Alcoholic beverages may be an important, if variable, source of some of these antioxidants in their own right, but also if certain mixers, such as fruit juices, are added when making cocktails.

Due to the considerable variation in the types, composition and amounts consumed of the vast numbers of different alcoholic beverages, only the most common types will be considered here. However, the characteristics of any nutrients likely to be added to the basic beverage style will be presented in order to provide information on their nutritional value that is as comprehensive as possible. To reiterate, this is important because, although the intake of vitamins, minerals and other phytochemicals may be, on an individual basis, apparently too low in amount or concentration to be functionally effective, it has been suggested that certain members of these nutrient classes may act synergistically to provide significant nutrition and health value. However, there are particular confounding factors that may be encountered when trying to fully define the importance of specific nutrients, either individually or in combination, as they are usually consumed as part of the habitual diet along with a multitude of other bioactive compounds. The 'French paradox' phenomenon is particularly appropriate in this respect, as consumption of red wine has been implicated in reducing the apparent risk to cardiovascular health of the French population, despite relatively high intakes of animal fats in the diet. However, as such health benefits have been suggested mainly on the basis of associations evident from epidemiological studies, definition of any underlying mechanisms of individual nutrient effectiveness or synergistic activity must await more fundamental studies. Also, an important question remains as to whether or not it is the red wine per se that proffers some of these suggested health benefits; i.e. is it the effects of the alcohol content or some properties of phytochemicals in the red wine that confer cardiovascular protection (Rimm *et al.*, 1996), or simply perhaps that consumption of red wine is associated with some other health promoting practice? Although this is clearly a topic of some controversy, with many unanswered questions remaining, attempts have been made to view existing evidence in a balanced perspective (e.g. de Lorgeril *et al.*, 2002; Goldfinger, 2003; Ferrières, 2004). Furthermore, it is also important to consider the potentially

detrimental health implications of excessive alcohol ingestion on the intake, absorption, metabolism, excretion and, therefore, overall equilibrium, of a number of key micronutrients, including, for example, vitamin A, carotene, zinc, folic acid, iron and selenium (Lieber, 2000; and several chapters in Watson and Preedy, 2003).

5.4.1 Vitamins

Raw ingredients, such as fruit and malt, used in the production of alcoholic beverages are good sources of water soluble vitamins with the fermentation process potentially adding significant amounts due to the actions of yeast, some B vitamins such as riboflavin, for example. However, the vitamin content of the final product may vary considerably from expected levels because of further processing and storage conditions. For example, vitamin C is susceptible to the effects of heat and oxidation, and thiamine may be taken up and utilized by the yeast, so these vitamins may feature less significantly in finished beers or wines. Distillation processes ensure loss of essentially all water soluble vitamins. Fat soluble vitamins are not a significant nutritional consideration in any alcoholic beverage, unless a mixer such as cream is added to particular types of beverage for making specific cocktails. Typical concentration ranges of vitamins for generic styles of alcoholic beverages are presented in Table 5.4.1.

Table 5.4.1 *Typical water soluble vitamin content* of representative wines and beers† commonly consumed in the UK‡*

	Water soluble vitamin content§			
	Wine		Beer	
	/125 ml	/liter	/284 ml	/liter
Thiamine (B1; mg)	Trace–0.01	Trace–0.08	0.009–0.026	0.03–0.09
Riboflavin (B2; mg)	Trace–0.05	Trace–0.4	Trace–0.11	Trace–0.4
Niacin (B3; mg)	0.1–0.3	0.8–2.1	0.6–2.3	2.0–8.0
Pantothenate (B5; mg)	Trace–0.23	Trace–1.7	0.1–0.28	0.3–1.0
Pyridoxine (B6; mg)	Trace–0.1	Trace–0.8	0.03–0.26	0.1–0.9
Biotin (μg)	Trace–2.5	Trace–20	Trace–2.8	Trace–10
Folate (μg)	Trace–1.5	Trace–12	11–34	40–120
Cyanocobalamin B12; μg)	Trace–0.33	Trace–1.0	Trace–0.23	Trace–0.8
Vitamin C (ascorbic acid; mg)	Trace	Trace	Trace	Trace
Choline (mg)	6–8	48–64	22–35	77–123
Betaine (mg)	0.26–0.4	2.4–3.2	17–25	60–88

*Fat-soluble vitamins are usually only found in nutritionally insignificant or trace levels at best in alcoholic beverages and are, therefore, not presented.

†Spirits are essentially devoid of nutritionally significant vitamins due to distillation processes during production and, therefore, are not presented.

‡Typical guideline values are presented, drawn from a large number of sources considered to represent the range of each generic product most usually consumed in the UK (e.g. *McCance and Widdowson's The Composition of Foods* – Food Standards Agency, 2002). For comparative purposes, values are presented per serving of 125 ml wine and 284 ml (half pint) beer, and also per liter.

§Wherever the value indicated is 'trace,' negligible or low amounts may be present but which are insignificant in nutritional terms.

Water Soluble Vitamins

As individual nutrients, water soluble vitamins are essential for a number of roles in the human body. However, they are also thought to be able to act synergistically with other vitamins, minerals and phytochemicals for increased health benefits. The required levels of dietary intake for each vitamin is variable and depends on demands that are driven by the number and extent of the functions of the body in which the vitamin is involved, and these may be increased in times of physical activity, stress, trauma and injury. The water soluble vitamin content of alcoholic beverages in relation to the RNIs set in the UK to cover the body requirements for these vitamins is discussed here (see also Nutritional Considerations, Section 5.1.4). As well as being present in significant amounts in whole grains and lesser amounts in grapes and grape juice that are prepared and used for fermentation, B vitamins in particular are produced in significant amounts by yeast and may be present in nutritionally significant levels in the final products of fermentation. However, as with other less volatile compounds present in fermentation products, water soluble vitamins are essentially eliminated during distillation processes.

The important B vitamins, folate, pyridoxine, B12 and betaine (trimethylglycine), appear to be critical for the maintenance of cardiovascular health, primarily protecting against the exacerbating effects of homocysteine in recurrent cardiovascular events. Appropriate amounts and proportions of these particular B vitamins reduce blood levels of homocysteine, whereas deficiencies cause raised homocysteine levels. Homocysteine is a natural homolog of the amino acid cysteine that is formed from methionine and the intermediate *S*-adenosyl methionine in the body (i.e. it is not obtained from any dietary sources). It has a short period of existence before being recycled into methionine or irreversibly converted to cysteine. During its existence, homocysteine is highly reactive with the capability of detrimentally binding to structural and functional proteins, including those integral to the cardiovascular system increasing the risk to cardiovascular health. For a perspective on homocysteine and health, see de Bree *et al.* (2002), and for the major implications for both the health and treatment of high alcohol consumers, especially alcoholics, due to alcohol related nutritional disturbances exacerbating these effects, see Lieber (2000).

Thiamine (vitamin B1) is essential for healthy growth and development, the functioning of the nervous system and heart and it enables intermediary metabolism of carbohydrates to proceed effectively. Thiamine occurs in beer and wine products as it is present in the whole grains and fruit used in production, but due to losses occurring during processing (because it is both heat labile and is utilized by yeast), these levels are not necessarily nutritionally significant. The RNI for thiamine for adult males up to 50 years of age is 1.0 mg/day with 0.9 mg/day for those 50+ years, and 0.8 mg/day for all adult females (Department of Health's 'COMA' Report – Department of Health, 1991; British Nutrition Foundation – http://www.nutrition.org.uk), and so beer products especially could make a small contribution towards these recommendations. A 330 ml glass of regular lager may provide up to about 2% of the daily requirement of thiamine, with other types of beer potentially providing greater amounts of thiamine (perhaps certain beers that are less refined or those that have higher alcohol content). However, a glass of wine (any wine) appears to provide only about 0.01–0.02% of the daily recommendation. There is no measurable thiamine in distilled products. Thiamine deficiency leading to impairment of brain function may be particularly important in alcoholics, as thiamine intake may be very low and alcohol may interfere with thiamine absorption, but this has only been shown in animal models (Lieber, 2000).

Riboflavin (vitamin B2) is required for catabolism of carbohydrates, fat and protein in the production of energy, and also for iron metabolism and transport. The RNI of riboflavin is about 1.3mg/day for adult males and 1.1mg/day for adult females (Department of Health's 'COMA' Report – Department of Health, 1991; British Nutrition Foundation – http://www.nutrition.org.uk). Riboflavin is present in small amounts in grapes and grape juice, but is not present in finished wine in nutritionally significant levels, providing less than about 0.1% up to perhaps 3% at most of the RNI per individual serving. Beers, however, contain relatively greater

amounts of riboflavin; a can (330 ml) of regular beer might provide about 0.1 mg, with some less refined and stronger (ABV) beers providing greater amounts, perhaps up to about 10% or more of the RNI per serving. Distilled products usually contain no measurable riboflavin. However, alcoholic beverages that are made by the addition of milk or egg products (Section 3.9.5) may make a significant contribution to the required dietary intake of riboflavin as these particular products are recognized as good sources of this vitamin (British Nutrition Foundation – http://www.nutrition.org.uk).

Niacin (or nicotinic acid; vitamin B3) is present to a greater or lesser extent in most foods, but with very small amounts in grapes and grape juice, and is not found in any great quantities in wines, with a single serving providing up to about 0.3 mg (2% of the RNI). Beers, however, are richer sources of niacin with a 330 ml serving of regular beer or lager providing about 1.8 mg, which is slightly over 10% of the RNI. The RNI for niacin (nicotinic acid equivalents) is 17 mg/day for males and 13 mg/day for females, reducing to 16 mg/day and 12 mg/day, respectively at 50+ years. Distilled alcoholic beverages contain no measurable quantities of niacin. Certain mixers, such as milk, eggs and tomato juice, used to make alternative types of alcoholic beverages may contain small amounts of niacin, but their contribution to nutritional value overall is thought to be relatively insignificant when consumed in this form. Niacin is required for structural integrity in the skin and membranes, for functioning of the nervous system and for catabolism of nutrients to provide energy (for details see Department of Health's 'COMA' Report – Department of Health, 1991; British Nutrition Foundation – http://www.nutrition.org.uk).

Adult men and women require between about 3 and 7 mg/day of *pantothenic acid (vitamin B5)* which is considered the safe intake, but, because deficiency diseases are very rare, specific RNIs are not provided for this particular vitamin (Department of Health's 'COMA' Report – Department of Health, 1991). Pantothenic acid is used to synthesize coenzyme A, which enables cellular transport of carbon atoms that are important in respiration and the biosynthesis of fatty acids and cholesterol, amongst many other compounds, and coenzyme A initiates the all important tricarboxylic acid (TCA) cycle. Small quantities at least of pantothenic acid appear to be present in almost all foods. Relatively small amounts are present in grape and grape juices, and from negligible to relatively small concentrations in wines, perhaps only 0.1 mg (possibly about 1–3% of the safe intake) per serving. Similarly, levels found in beer are not particularly significant nutritionally, perhaps 0.1–0.23 mg per 330 ml serving of regular beer (about 1–8% of the safe intake), despite whole grains being a relatively good source of pantothenic acid. Distilled alcoholic beverages contain no measurable quantities of pantothenic acid. Therefore, generally, alcoholic beverages cannot be considered especially good or appropriate sources of pantothenic acid unless other ingredients, such as eggs, that are high in pantothenic acid are added, but, with one or two notable exceptions (Section 3.9.5), such beverages are not very common.

Vitamin B6 or pyridoxine (also pyridoxal) is a cofactor for a number of enzymatic reactions in protein and amino acid metabolism and in the breakdown of glycogen to produce glucose. Pyridoxine is also involved in iron transport and metabolism. The UK RNI for men is 1.4 mg/day and 1.2 mg/day for women (Department of Health's 'COMA' Report – Department of Health, 1991; British Nutrition Foundation – http://www.nutrition.org.uk). Good sources of pyridoxine are wheat germ and yeast, and there are potentially significant quantities that are retained in finished beers; for example, a 330 ml bottle of regular lager may contain 0.1–0.2 mg of pyridoxine which is about 8–15% of the RNI. Grapes contain small, but significant, amounts of B6 (perhaps about 7% RNI in 100 g of the fruit; National Agricultural Library (NAL) at the United States Department of Agriculture (USDA): http://www.nal.usda.gov/), with pyridoxine also present in finished wines, which may also contribute nutritionally significant quantities, as a standard glass of red or white wine can contain about 0.1 mg or about 8% of the RNI, although much less may be present, depending on the extent of processing of the wine. Distilled alcoholic beverages appear to contain no measurable quantities of pyridoxine.

Although *biotin (vitamin B7*) is present in high levels in brewer's yeasts and is relatively stable chemically, the levels in alcoholic beverages are relatively small. Adequate dietary levels, that are also considered to be within the safe intake limit, are somewhere between about 10 to 200 mcg per day and so the actual contribution of alcoholic beverages is difficult to ascertain, but may be nutritionally significant under certain circumstances. Biotin is a cofactor integral to a number of enzymatic reactions involved in growth, development and maintenance of cellular integrity of tissues such as nerves, skin and bone.

Folic acid (pteroyl glutamic acid; vitamin B9) is a product of yeast and is present in high levels in some fruits and vegetables, such as oranges and orange juice (National Agricultural Library (NAL) at the United States Department of Agriculture (USDA): http://www.nal.usda.gov/) that may be used in the production of certain alcoholic beverages. Folate is required for cellular reproduction and growth, and for forming blood cells and in the nervous system. There is some difference in dietary recommendations for folate intake between the UK and USA; the UK RNI for adult males and females is 200 μg/day, whereas the USA recommendation is considerably higher at 400 μg/day. Grapes and grape juice contain relatively little (about 1% or less of requirements per 100 g) and wines likewise (less than 1% of requirements per serving). However, sangria, which may have orange juice as a major ingredient and which has folate levels at perhaps 180–200 μg/l, may provide significant amounts of folate, depending on relative amounts of wine and juice in the mixture and quantities consumed, and whether or not folate absorption is compromised, perhaps during periods of excessive intake of alcohol. Beers contain relatively high levels of folates with 'can' sized servings (330 ml) of regular lager providing perhaps 20 μg (10% UK RNI). Whilst some beers may contain negligible folate (possibly due to conditions such as storage), others, especially stronger beers, may contain significantly more (Owens *et al.*, 2007). No measurable quantities of folate have been reported for distilled alcoholic beverages.

Cyanocobalamin (vitamin B12) is involved in normal cellular metabolic functioning and DNA synthesis and is particularly important for the nervous system and blood formation. The means by which the body obtains and utilizes vitamin B12 is complex. It is obtained from animal sources almost exclusively and requires a gastric intrinsic factor to be effectively absorbed. Essentially, B12 can only be formed from the activity of certain bacteria and, unless there is some sort of bacterial action, there is essentially no provision of B12 from the raw ingredients of alcoholic beverages or the fermentation processes. Therefore, under normal circumstances there is no measurable vitamin B12 in wines and distilled alcoholic beverages and only small amounts in beers; a 330 ml serving of regular lager may provide up to a possible 1 μg B12. The UK RNI is 1.5 μg/day for both men and women (the US DRI is considerably higher at 2.4 μg/day for adults). As vitamin B12 is present in dairy products and eggs, it may be found in significant levels in alcoholic beverages that are produced from these, such as fermented whole milk products or cocktails that have eggs added or emulsion liqueurs that are made with eggs (Section 3.9.5). However, alcoholic beverages made from the addition of cream, e.g. coffee cream liqueurs, appear to have negligible amounts of vitamin B12.

Now considered as an essential water-soluble B vitamin, *choline* is required for structural functions, neurotransmission and as a provider of methyl groups, through its *betaine* metabolite, a function that contributes along with other key B vitamins (folate, pyridoxine, vitamin B12) to the lowering of blood levels of homocysteine. As sufficient intake of choline is suggested to be around 425 mg to 550 mg per day, beer intake appears to be able to contribute significantly to this requirement (typically about 4–8% in a half pint), but wine intake is more marginal (possibly 1–2% from a 125 ml glass) and distilled products have negligible quantities, if any.

The UK RNI for *ascorbate (or ascorbic acid; vitamin C)* is 40 mg/day for both men and women (interestingly, the USA DRI is far higher at 75 mg/day for women and 90 mg/day for men). Ascorbate is required for connective tissue, blood vessels and the nervous system, being a key component in the synthesis of collagen in these tissues and in wound repair. It is present in varying quantities in the fruits and vegetables that may be used to produce alcoholic beverages. Some such fruits, especially those that are used for home beverage production, have substantial amounts of ascorbate (e.g. rose hip at 2000 mg/100 g of fruit), and others have

relatively high levels (e.g. blackcurrants at about 180 mg/100 g) when compared to daily requirements. Grapes are a significant source of ascorbate (about 10 mg/100 g). However, in the final products of fermentation and any subsequent distillation there is none or relatively little ascorbate because it is susceptible to degradation by heat (boiling alone is not totally effective) and exposure to air (oxygen), especially in combination. In those tested, most wines made from grapes, regular beers and spirits contain no measurable vitamin C. However, vitamin C may be added to some wines and some bottled beers (perhaps to 30 mg/l) in order to stabilize them against possible oxidation spoilage (e.g. oxidation of the trace lipids that originate from plant cell wall material) (Section 2.6.12). In alcoholic beverages that are mixed with fruit juices to produce certain cocktails or mixers, there are significantly higher levels of ascorbate. Fruit juices most usually added to alcoholic beverages include orange juice (typically 50 mg per fruit, and about 33 mg/100 g orange juice) and tomato juice (about 10 mg/100 g of fruit, and about 20 mg/100 g tomato juice) that may contribute significantly to daily requirements provided that any processing of the juice does not adversely affect the ascorbate levels.

Fat Soluble Vitamins

The several forms of the fat soluble *vitamin A* and the many members of the related family of *carotenoids (carotenes and xanthophylls)* are not considered to make any significant contribution towards the nutrient value of alcoholic beverages per se as they are present in low concentrations in both the raw materials and fermentation products (Section 5.11.2). However, vitamin A and its carotenoid precursors, pigments that confer colour to yellow and orange fruits (e.g. apricots) and vegetables (e.g. carrots) and egg yolk, may also be present in some of the ingredients, such as tomato, apricot and melon juices, cream and eggs, that could be added to certain alcoholic beverages to produce various cocktails. Vitamin A is essential for maintaining vision, immunity and bone health. Lycopene and lutein are carotenoids that have particular antioxidant properties protective of vision and against atherosclerosis. It is very unlikely that alcoholic beverages would make a major contribution towards dietary requirements, as the UK RNI for vitamin A is 700 μg/day (700 μg is equivalent to 2300 International Units – IU) for adult males and 600 μg/day for females. However, certain specialist alcoholic beverages may provide nutritionally significant quantities of vitamin A and carotenoids; a single serving of a coffee cream liqueur (Section 3.9.5) contains about 100 μg (300 IU) of vitamin A and related compounds. The key ingredient of these beverages for providing vitamin A is cream as, for example, coffee liqueurs made without cream (Section 3.9.4) contain negligible or no vitamin A. The other fat soluble vitamins (D, E and K) are not generally present in sufficient quantities in alcoholic beverages to warrant further consideration.

5.4.2 Electrolytes and Functional Elements (Minerals and Trace Elements)

There is some inconsistency with regard to the classification and terminology involved in nutritional aspects of the elements. From geology, the traditional understanding of 'mineral' is a naturally occurring, physically constant, highly ordered and structured substance or compound that is formed from geological processes, and is distinct from 'animal' and 'vegetable.' However, in nutritional terminology, minerals have become synonymous with inorganic elements that are essential for maintaining human life. Therefore, the nutritional contribution of those essential inorganic elements most likely to be found in the more commonly consumed styles of alcoholic beverage will be presented according to their predominant biological functionality; electrolytes and elements will be considered as discrete nutritional entities (see website of the National Agricultural Library (NAL) at the United States Department of Agriculture (USDA): http://www.nal.usda.gov/. Sodium (Na^+ ion), potassium (K^+ ion), chloride (Cl^- ion) and inorganic sulfate (i.e. sulfur in association with oxygen to form the SO_4^{2-} ion) are considered the essential electrolytes and are present in the body in

relatively large amounts. The remaining elements of nutritional importance may be considered to fall into two classes representing those required in large and small amounts, in macro (or bulk) and micro (or trace) levels, respectively. Elements required in relatively large amounts include calcium, phosphorus and magnesium. Certain trace elements, such as copper, may only be required in small quantities, but are essential for the proper functioning of particular enzymes, for example in the electron transport chain. Iron and selenium are of particular interest currently because deficiencies in specific vulnerable population groups are becoming a potential threat to optimum health (British Nutrition Foundation – http://www.nutrition.org.uk).

Inorganic elements and electrolytes in beers originate essentially from the malt with significant contributions likely from the source water and also from any salts that may be used to adapt the mineral content of this water for taste preferences and character. In wines, the mineral content is determined predominantly by the fruits and juices used as raw ingredients, but some salts may be added during processing, such as K^+ or Na^+ and SO_4^{2-} from oxidation of sulfites (Section 2.5.2). The various amounts and ratios of a number of inorganic elements and electrolytes are influential in the production of alcoholic beverages and on their nutritional content because of a number of possible factors: flavors and character may be affected directly; the performance of yeast is optimized by the presence of essential minerals such as magnesium, manganese, copper, zinc and sulfur; and, pH (measure of acidity) is dependent on certain ions, such as calcium, that help to precipitate some proteins and phosphates, producing an increase in hydrogen ion concentration (lower pH; greater acidity) and improving key enzyme activity as a result (Section 2.2.3). Additional zinc is often needed for promoting fermentation, as there may be insufficient zinc present in the raw ingredients for optimum yeast activity (Vecseri-Hegyes *et al.*, 2005; 2006). Much of the calcium naturally present in the source water, or perhaps added during processing, is precipitated before the product is finished. Distillation tends to eliminate a majority of minerals and trace elements so that spirits and liqueurs may have insignificant amounts, if any, of the key elements needed for optimum health. Therefore, distillation products will not be considered in great detail as sources of minerals, despite there being measurable quantities present of some elements, as these are generally negligible or too low to significantly affect daily nutritional requirements even if excessive amounts of such alcoholic beverages are consumed. Typical concentration ranges of electrolytes and elements for generic styles of alcoholic beverages are presented in Table 5.4.2. General information regarding recommended dietary requirements can be found at the British Nutrition Foundation website – http://www.nutrition.org.uk; and in the Department of Health's 'COMA' Report – Department of Health, 1991).

Electrolytes

Potassium is an essential electrolyte, which helps to optimize balance of fluid across the cell membranes to ensure proper cell functioning. Adult males and females require about 3.5 g of potassium per day (RNI), ideally provided by fruits and vegetables, which are relatively good sources. A single serving of wine may typically provide about 100–190 mg (3–5% RNI). Similarly, a regular beer (330 ml – can sized serving) provides only about 75–100 mg (2–3% RNI), and perhaps slightly more in some products. However, as it is the relative amounts of potassium to sodium that are important to health (potassium is thought to counteract the potential high blood pressure exacerbations of high sodium) and as sodium is relatively low in wines and beers, the consumption of wines and beers have been purported to have some nutritional benefits or, at least, may not be detrimental to health in this particular respect.

The RNI for *sodium* is 1.6 g/day for adults in the UK. The average Western diet contains a great excess of sodium partly due to the addition of salt to foods during processing and consumption. However, not all foods and drinks are high in sodium, and these include wines and beers. A serving of wine may contain only a negligible amount, about 5–7 mg or 0.3–0.4% daily RNI, a regular beer provides about twice this amount, but this is still nutritionally insignificant, and distilled beverages much less so (approximately10 times less).

Addition of mixers to spirit and liqueur bases can influence the relative amounts of sodium and potassium provided. Cream liqueurs, for example, may provide negligible potassium, but about 2% of the sodium RNI in

Table 5.4.2 *Typical nutritionally significant electrolyte and element content of representative wines and beers* commonly consumed in the UK*[†]

	Electrolyte and Elemental content[‡]			
	Wine		Beer	
	/125 ml	/liter	/284 ml	/liter
Electrolytes				
Sulfate[§]	Variable	Variable	Variable	Variable
Potassium (mg)	75–160	600–1280	85–140	300–500
Sodium (mg)	5–15	40–120	17–45	60–160
Chloride (mg)	4–14	30–110	60–100	170–350
Elements**				
Calcium (mg)	9–18	70–140	14–26	40–90
Copper (mg)	Trace–0.08	Trace–0.6	Trace–0.2	Trace–0.7
Iron (mg)	0.3–1.3	2.7–10	Trace–0.6	Trace–2.0
Magnesium (mg)	9–15	70–120	14–28	50–100
Manganese (mg)	0.05–0.17	0.4–1.3	Trace–0.09	Trace–0.3
Phosphorus (mg)	8–29	60–230	31–57	110–200
Selenium (μg)	Trace–0.3	Trace–2.4	Trace–3.4	Trace–12
Silicon (mg)	Trace	Trace	30–80	90–240
Zinc (mg)	Trace–0.17	Trace–1.4	Trace–0.9	Trace–3.0

*Spirits are essentially devoid of nutritionally significant elements due to distillation processes during production and, therefore, are not presented. However, some electrolytes may be present as water may be added back to the distillation product in order to achieve a certain alcohol concentration.

[†]Typical guideline values are presented, drawn from a large number of sources considered to represent the range of each generic product most usually consumed in the UK (e.g. *McCance and Widdowson's The Composition of Foods* – Food Standards Agency, 2002). For comparative purposes, values are presented per serving of 125 ml wine and 284 ml (half pint) beer, and also per liter.

[‡]Wherever the value indicated is 'trace,' negligible or low amounts may be present, but which are insignificant in nutritional terms.

[§]Sulfate content can be quite variable, but alcoholic beverages are not a necessary source of sulfate.

**See text for details of other potentially significant elements.

one serving. Although, in Mexico, Tequila (Section 3.5.5) is drunk neat (possibly accompanied by sangrita – see Section 5.2.4), elsewhere it may be consumed with large amounts of the crystalline mineral salt (table salt, NaCl) and lime, favoring sodium intake relative to potassium. In contrast, unprocessed fruit juices, such as grape, orange and tomato juices, added to alcoholic beverages provide additional potassium (maybe 3–5% of the RNI per serving, depending on mix), with negligible amounts of sodium.

The UK RNI for *chloride* is 2.5 g/day for adults. As nutritional entities, chloride and sodium are normally considered together since they are the constituents of common or table salt (NaCl, comprising about 60% by weight of chlorine). Therefore, because of its equivalence to sodium, wines and regular beers contain very little chloride (less than 10% RNI), the levels of which are relatively insignificant when considered in perspective of the usual intake of 'salt' in the diet (8.1 g/day for women and 11 g/day for men in the UK which are far higher than daily recommended levels of no more than 6 g/day). The very much lower amounts of chloride in spirits, predominantly due to distillation, are nutritionally negligible.

There are no recommendations for intake of inorganic *sulfate* because of the ready availability of sulfates from foods and water. Inorganic sulfates are complemented by organic sources of sulfur provided by the

catabolism of sulfur containing compounds, such as the amino acids methionine and cysteine. Nevertheless, wines and beers may be major sources of inorganic sulfates, especially those that have sulfur compounds added for modifying flavors or for imparting preservative properties during processing. Some beers are produced from water that contains naturally high levels of calcium sulfate, which has a particularly desirable property as it draws out hop oils to impart a characteristic firm bitterness. This property has been extended to beers from areas where the source water lacks calcium sulfate by introducing this, or perhaps magnesium sulfate, into the brewing procedure, a process known as 'Burtonization,' to mimic the source water from Burton-on-Trent in England, which is naturally rich in sulfates (Section 2.6.2). Since the times of the Greeks and Egyptians, and still in widespread use, sulfur based compounds have been added to wines, beers and ciders as preservatives. Collectively termed 'sulfites,' being based on sulfur dioxide (SO_2), there are a number of such preservatives (Sections 2.5.2 and 2.5.3) that are generally considered to be relatively safe when added to foods and drinks, as they can be readily detoxified by the liver, to produce the electrolyte sulfate for example.

Although sulfur compounds from alcoholic beverages are not of any major nutritional significance in terms of the amounts provided when compared to those needed for maintenance of optimum health, they may be important because of their potential effect on the balance of bacteria present in the anaerobic environment of the lower intestine (Gibson *et al*., 1993). Essentially, in the absence of sulfate in the diet, the bacteria of the lower intestine are predominantly those that produce methane; these are the methanogens. However, sulfate reducing bacteria predominate in the lower intestine when sufficient sulfurous compounds are made available and so sulfates and sulfites provided by alcoholic beverages, along with requisite hydrogen, may reach the lower gut and be utilized by these sulfate reducers under the prevailing anaerobic conditions to produce the extremely toxic compound hydrogen sulfide. Therefore, it is these sulfate reducing bacteria that have been implicated as potential causative agents in a number of disease states, especially certain conditions of the gut such as colon cancer and inflammatory bowel diseases, which may be exacerbated in susceptible individuals. However, further work is needed to ascertain which, if any, of the many sulfate reducing bacteria are specifically responsible for causing these diseases, or whether or not other gut bacteria may also be implicated. Indeed, there is also uncertainty as to whether or not sulfate reducers are causative of these conditions or merely opportunistic, inhabiting an already inflamed gut, or there may also be synergistic actions with other microbes and, of course, the balance of such microbes may also be important (Gibson *et al.*, 1993). Also, the absolute amounts of sulfate actually derived from alcoholic beverage ingestion and actually reaching the lower intestine and, therefore, the overall nutritional significance is largely unknown.

Functional Elements

Calcium is required by the body in relatively large amounts, as it is important in bone structure and function, for maintaining the acid base balance of body fluids and in blood clotting. RNIs set in the UK are about 700 mg/day for adult men and women although adequate intakes for optimum bone health are considered to be higher in the USA, at about 1000 mg/day for both men and women from age 18 to 50 years, rising to about 1200 mg for those of 50 years and above (Institute of Medicine of the National Academies – http://www.iom.edu/). Calcium is present in relatively small amounts in wines (perhaps 8–15 mg per serving) contributing only about 1% of the daily dietary requirement per serving. Similarly in beers, about 1% of the required daily calcium intake is present in a serving of 330 ml of regular beer or lager. Higher amounts of calcium are possible in beers made from water naturally rich in calcium sulfate or to which calcium sulfate has been added (known as 'Burtonization'), although much of this calcium may be precipitated out as insoluble calcium phosphates, for example, resulting in lower amounts in the final product. Calcium is absent from distilled beverages unless ingredients containing calcium are added from mixers, e.g. milk products added to coffee flavored liqueurs or fruit juices added to spirits. However, the amounts provided are very low, perhaps only about 1% of daily recommendations from a serving of cream liqueur or 1–2% of the RNI from a tomato

juice mixer depending on amount used. Orange juice that is supplemented with calcium may possibly be added as a mixer to some beverages to provide nutritionally significant amounts of calcium (perhaps 150 mg per 100 ml), although this is not such a common practice. Incidentally, the fat soluble vitamin D may also be used as a supplement in some orange juices; vitamin D and its metabolites aid in the efficient absorption and utilization of calcium to maintain the integrity of bone, for example. However, there is negligible vitamin D, if any, in a vast majority of alcoholic beverages compared to the amount of vitamin D usually obtained from the action of sunlight on vitamin D precursors in the skin that occurs mainly between the months of March and September in the UK.

Obtained from whole grains and seeds, *copper* is present in finished beers up to perhaps 0.07 mg in a half pint (6% of UK RNI; 1.2 mg/day for adults). Wines may contain relatively more, up to about 0.12 mg per regular serving (10% RNI). However, certain authorities have in the past recommended greater amounts, up to 3 mg/day for optimum health, in which case any copper present in wines and beers would, clearly, be far less significant nutritionally. Less refined products containing more of the original ingredients, such as some locally produced beers, may contain relatively greater amounts of copper, and the use of copper vessels for production may allow copper to infuse the beverage to a small extent. However, the question remains as to whether or not such levels reach nutritional significance. Indeed, it is also uncertain as to what extent copper may be biologically available in the forms present in alcoholic beverages (Section 5.10.3). Copper is required for the proper functioning of a number of enzymes, especially those involved in oxidation and reduction processes, i.e. the electron chain (Section 5.8.2).

Almost all of the *iron* contained in the body is found in the red blood cells, where it is an integral part of the haemoglobin molecule that binds oxygen for transport around the body. Requirements for adult women up until the menopause (RNI 14.8 mg/day) are far higher than for men or postmenopausal women, both of which require 8.7 mg/day. Therefore, the amounts of iron found in wines (0.4–0.7 mg; 3–8% RNI depending on requirement) and in most regular beers (0.1 mg, about 1%) are not considered to be of nutritional importance, especially as iron from such sources (nonheme iron) may not be as biologically available as iron obtained from animal sources (heme iron). Some beers, stouts for example, are claimed to have higher levels of iron but, again, their nutritional value is uncertain mainly for this reason. If nonheme iron is ingested with vitamin C then it is suggested that greater amounts of iron are potentially absorbed through this interaction. However, some iron may be bound to certain other dietary constituents, preventing absorption in this form and so may be passed from the body without being absorbed.

Magnesium is an important cofactor for many key enzymes in the pathways of the body involved in energy balance and also has important electrolyte functionality. Relatively large amounts of magnesium are required to fulfill these functions. Adult males require about 300 mg/day RNI and adult females 270 mg/day, depending on age. Therefore, the provision of 10–18 mg in a serving of wine provides about 3–7% of the RNI and 20–25 mg in a serving of regular beer contributes about 7–9% of the RNI.

Phosphorus is a key element with a number of biological roles, usually in the form of its phosphate moiety, for example: (a) as a major component of hydroxyapatite, phosphorus is an integral chemical component of the skeleton, (b) phosphorus is essential in the transport and storage of energy mainly because of the ability of phosphate to bind to adenosine to form the high energy compound adenosine triphosphate (ATP), which is used for quick release of utilizable energy in times of threat, stress and trauma, and (c) phosphates contribute to the structure of the nucleic acids, RNA and DNA. The RNI for phosphorus in adult males and females is 550 mg/day, so that a serving of wine providing 15–35 mg contributes about 3–6% RNI and a regular beer might provide about 50 mg (9% RNI); wines and beers may, therefore, be nutritionally significant sources of phosphorus. However, negligible amounts (perhaps 1–2 mg) have been measured in distilled beverages. Milk and egg products are considered to be good sources of phosphorus and so may provide significant amounts if used as mixers for some types of alcoholic beverages or as ingredients of emulsion liqueurs (Section 3.9.5).

The levels of *selenium* in food products are, generally, very much determined by the amount of selenium present in the soil from which the plant food sources are harvested, and any additional processing may influence these levels even further. Selenium supports antioxidant functionality through its integration with certain enzymes, thyroid and immune function. The RNI for adults for selenium is 75 μg/day for men and 60 μg/day for women. Therefore, the 0.2–0.3 μg in a serving of wine is negligible nutritionally and 1–2 μg in a serving of beer (1–3% RNI) has only marginal significance.

Although *silicon* is implicated in the maintenance of healthy bone, particularly in the prevention and treatment of osteoporosis in older people (especially postmenopausal women), connective tissue and wound healing, there are currently no definitive guidelines for dietary intake. Silicon may have an important protective role against the effects of aluminium, which possibly include dementia and bone exacerbations. Alcoholic beverages do not appear to contain aluminium, but beers and ciders, especially, may contain significant levels of silicon. Silicon is found in foods such as cereals, of which barley is of particular interest in brewing, whole grain products (especially beer), some vegetables, some fruits, notably apples, and hard water. It has been speculated that the amount of silicon required may be as low as 5 mg to 10 mg per day, provided it is in a form in which it may be readily absorbed e.g. silicic acid, whereas others suggest 20–50 mg daily because much silicon may be ingested in the form of insoluble silicates that are absorbed relatively poorly. Beers may contain silicon in levels between about 10 mg and 40 mg/l and so apparently may make a very significant contribution towards this requirement, especially as the silicates in beer seem to have relatively greater bioavailability. Wines do not appear to have nutritionally significant levels of silicon and levels in spirits are negligible.

Daily *zinc* RNIs are set at 11 mg for adult males and 8 mg for adult females. Therefore, the low levels of zinc found in a serving of wine (up to about 0.2 mg; 1–2% RNI) do not appear to make a nutritionally significant contribution to dietary intake. Although there is also some zinc in whole grains and zinc congeners may be added, further processing may reduce its levels in beers to virtually nothing, perhaps by binding to the phytates present and that are removed during processing. Spirits appear to have no measurable zinc present because of the distillation process, even though zinc may be added during production to modify the character of the beverage. However, small amounts of zinc may be present in some cocktails such as cream liqueurs, but again these are not thought to be nutritionally significant (perhaps about 1% RNI per serving).

Amid much debate regarding the need for fluoridation of water, as it is needed to prevent dental caries, fluoride does not otherwise appear to be an essential nutrient and it may be toxic in excess. Alcoholic beverages are not considered important sources of fluoride, although levels may be marginally significant if fluoridated water is used in their production, e.g. tap water or ice added to spirits.

5.4.3 Phytochemicals

Knowledge regarding the vast number and diversity of the phytochemicals, compounds derived from secondary plant metabolism, particularly the bioactive phytoestrogens and antioxidants, is ever increasing, with major interest focused on their purported nutritional and health benefits, including antibiotic and anti-inflammatory potential (Section 5.11.2) (Bravo, 1998; Eastwood, 1999; Aron and Kennedy, 2008). In addition to the antioxidant capacity of vitamins, other naturally occurring antioxidants, largely phenolic compounds, are present in relatively high levels in a great majority of wines, especially red wines, beers and ciders, which may have a tangible influence on the antioxidant status of consumers (Chapter 5.8) (Soleas *et al.*, 1997; Ghiselli *et al.*, 2000; Tsang *et al.*, 2005; Zern and Fernandez, 2005). There are also potentially significant amounts of antioxidants in some spirits, notably those spirits that are matured in oak casks (see for example, Sections 3.2.5, 3.3.4, 3.5.3 and 3.6.2). Much of the antioxidant character of spirits originates from the wood via infusion of antioxidants into the beverage over time (Goldberg *et al.*, 1999; Madrera *et al.*, 2003). Some

wines and beers may also undergo extended maturation processes in which the nature and amounts of plant derived bioactives, notably the antioxidants, may be modified. Within each category of alcoholic beverage there is substantial variability in the type and amount of each of the component antioxidant molecules, depending on factors such as source of ingredients and processing techniques that lead to antioxidant capacity being considerably product dependent (e.g. Landrault *et al.*, 2001). A large number of different casks are used in the aging of spirits that may be made from a variety of woods and with different levels of charring of these woods, and such factors mainly determine the amount and diversity of phenolic compounds present. Indeed, some furans may also be present in beers and spirits that have both carcinogenic and anticarcinogenic potential, as well as antioxidant and anti-inflammatory capacity (Goldberg *et al.*, 1999).

Generally, the color and the intensity of color of both the raw ingredients and the final product are potential indicators of the relative content of antioxidants (Hancock *et al.*, 2007). Average dietary intake of polyphenols from all foods is about 1 g per day and major sources include alcoholic beverages, mainly wines and beers, along with tea, coffee, fruit juices and other miscellaneous plant derived foodstuffs (Paganga *et al.*, 1999; Scalbert and Williamson, 2000).

In addition to their antioxidant capacity, certain phytochemicals are also considered to have other potential biological effects and health benefits, particularly in relation to maintaining cardiovascular and bone health and with anticarcinogenic activities. Although these benefits are due in large part, but not entirely, to their ability to quench free radicals or reactive oxygen and nitrogen species (Bravo, 1998), additional effects appear to include the estrogenic or antiestrogenic properties of phytoestrogens, characterized by chemical structures closely mimicking those of the naturally occurring sex hormones of the human body, which enables binding to key receptors and enzymes involved in metabolism of these hormones, especially at lower doses (Rosenblum *et al.*, 1993; Milligan *et al.*, 2000). Some of these effects are implicated in protective roles but others are not.

Although not ubiquitously considered essential to sustain human life, these multifarious compounds are of growing interest, as their consumption has been implicated in many and various benefits to health, especially in reducing cardiovascular health risks and in combating other degenerative diseases. The use of 'essential' in the nutritional sense implies that morbidity and mortality are inevitable without an exogenous source of such compounds in the diet – as would be the case with vitamin deficiencies, for example. In this particular sense, phenolic compounds and other phytochemicals are generally considered to be nonessential in nature and there is still some controversy surrounding the validity of claims that these compounds actually do have such an extensive range of health benefits. Indeed, in some quarters they are not considered to be nutrients on this basis and have even been labeled as 'antinutrients,' despite having recognized nutritional value in other ways (Bravo, 1998). According to dictionary definitions, nutrients are nourishment and as nourishment sustains 'proper condition,' perhaps beneficial phytochemicals should be considered as nutritionally significant, if not essential. In contrast, it is because of their ability to bind and precipitate proteins that some polyphenols, especially the larger molecular weight tannins, have been termed 'antinutrients,' as they appear to have potential adverse effects on digestion and absorption of proteins and may deactivate important functional proteins. For example, digestive enzymes may be impaired, which may interfere with digestion and absorption of other key dietary nutrients (Bravo, 1998). Polyphenols also have metal chelating capabilities (Section 5.8.7) (Bravo, 1998), which may be of detriment if such chelation interferes with the normal absorption and assimilation of valuable elements. In contrast, these binding capabilities may also extend to certain potential toxins, which may be of benefit if they can be eliminated from the body before being absorbed (Section 5.8.9).

Natural derivatives of the shikimate and acetate pathways in plant metabolism (Soleas *et al.*, 1997), there are a vast number of diverse and often complex phenolic phytochemicals that may be present in those plants consumed by humans (well in excess of 8000 presently described in the literature, of which greater that 5000 are flavonoids), considerable numbers of which may be found in alcoholic beverages. Each one of the phenolic compounds has in common at least one aromatic ring and at least one hydroxyl group, which are responsible for the antioxidant properties of these molecules. It is the molecular similarity to estrogen, particularly the

essential phenolic ring, which provides phenolic compounds with their estrogenic or antiestrogenic activities. More complex esterified, methylated and other derivatives may also be found naturally occurring and include phenol/coumaric acid and pyrocatechol/caffeic acid derived lignins, for example. Not all of these phenolic compounds find their way into alcoholic beverages and not all that are present in the final product have been measured as yet.

Polyphenols (consisting essentially of flavonoids and phenolic acids with smaller amounts of stilbenes and lignans, for example) (see Chapter 5.8) are the predominant sources, perhaps up to about 90%, of the antioxidant capacity present in the raw ingredients of alcoholic beverages, particularly the skins and seeds of grapes and also in malt and hops. Most polyphenols are extracted effectively during fermentation and may be quite well preserved in the final product, even if perhaps some are chemically altered or lost during later stages of production (Fantozzi *et al.*, 1998). Indeed, the production of some alcoholic beverages, notably certain red wines, may effectively concentrate these antioxidants to greater levels in the final product; the level in red wine could be up to four or five times the levels found in the ingredient grape juices. However, some potential antioxidants may be lost through precipitation. Once ingested, the bioavailability – absorption and metabolism – of polyphenols is determined by their particular chemical structures, molecular size, degree of polymerization and solubility, combined with levels of glycolyzation, acylation and conjugation, and possible synergism with other dietary components (Section 5.8.9). Indeed, in a specific example, anthocyanins were shown to be better absorbed when administered in grape juice than red wine, that led the authors to suggest a possible synergism with the glucose component of the grape juice (Bitsch *et al.*, 2004), although lower rates of absorption due to interactions with other components of the wine is possible. However, many polyphenols may not be ingested in an absorbable form and also may be indigestible by enzymes in the upper gastrointestinal tract, so pass into the colon where some of them may be metabolized by colonic bacteria (Section 5.8.9) (Bravo, 1998).

The nutritional importance to human health of phenolic compounds present in alcoholic beverages is uncertain for a number of reasons. As the antioxidant capacity of phenols and polyphenols is known to be variable between the different structural classes and the different compounds within these classes, the levels needed to have a significant effect on the human body is difficult to elucidate. The total antioxidant capacity may be a key factor; this is illustrated by the fact that red wine, with a mean concentration of total phenolic acids and polyphenols of about 1200 mg/l (typical range 900–2500 mg/l), has a greater purported potential health benefit than white wine, with a typical range of 190–290 mg/l. Interestingly, white wines that have been fermented with the skins of the grape apparently have greater antioxidant capacity than those that do not have the grape skin present so that the polyphenols cannot be extracted from it (Fuhrman *et al.*, 2001). However, even though certain classes or individual antioxidant compounds may be present in greater amounts in some alcoholic beverages than others, they may not have the same level of antioxidant capacity and be relatively less effective biologically, as well as having different levels of bioavailability (Soleas *et al.*, 1997; Bravo, 1998). Certain antioxidants in beers are purported to have as great or greater antioxidant capacity when compared to those present in wines, with greater potential for health benefits implied (for discussion see 'Beer and Health' in Hornsey, 1999 – Chapter 9). Also, although, in general, concentrations of antioxidants in beers may be lower than in wines, beer is usually consumed in greater quantities than wine so that the available antioxidant load may be at least comparable. The presence of alcohol may also be significant, as it appears to aid absorption of some compounds and may also cause chemical changes that increase antioxidant potential, or simply help to preserve it. The antioxidant potential of beer was suggested to be due, at least in part, to enhancement by ethanol per se (Ghiselli *et al.*, 2000). However, experiments comparing the antioxidant enhancing properties of ethanol consumption alone with alcoholic beverages containing antioxidant phytochemicals showed that there was little or no effect of ethanol per se and, as there was no apparent major effect of antioxidants from some nonalcoholic beverages, such evidence indicates that ethanol may act by simply aiding antioxidant absorption. In contrast, higher levels of absorbed anthocyanins were observed with grape juice ingestion compared to equivalent amounts taken in red wine, which the authors attributed to a synergistic effect of

glucose (Bitsch *et al.*, 2004). Interestingly, ferulic acid uptake if administered in beer is consistent with absorption from other sources in the diet, whole tomatoes for example (Bourne *et al.*, 2000).

The ability of the human body to digest, assimilate and effectively utilize the different phenolic antioxidants is also a little uncertain, as is the relative importance of their interactions with other nutrients. For example, polyphenols are known to be capable of binding with nonheme iron, a factor that could influence the digestion of both these important nutrients, potentially preventing proper absorption and thereby compromising both nutrition and health status. A number of polyphenols, especially some of the larger and more complex flavonoids (e.g. the tannins) are not readily digested and are, therefore, not readily absorbed in large amounts. However, many of the multifarious phenolics present in alcoholic beverages, provided that they are in certain forms, may be absorbed by the human intestine in quantities sufficient for health benefits; these include nonflavonoids, such as stilbenes and anthocyanins, and some flavanols are also capable of being absorbed. The active antioxidant group of polyphenols is the hydroxyl moiety which makes possible metabolic processing by the intestines as these compounds are being absorbed, and then by further metabolism in the liver and kidneys. By these processes, various conjugates may be formed, some of which retain and even enhance the original antioxidant capabilities of these phenolic compounds (Section 5.8.9). However, regular and continuous consumption of a sufficient amount and wide variety of phenolic compounds may be needed to maintain antioxidant potential for real and lasting benefit to health because of their rapid turnover, in terms of relatively high rates of absorption, assimilation and excretion.

As individual compounds, the antioxidant potential and other nutritional properties of polyphenols may not be sufficient to be nutritionally effective, but collectively there may be nutritional and health benefits (Eastwood, 1999). Indeed, the possible synergism of polyphenol actions may extend to include other antioxidants, such as some of the vitamins and minerals, to maintain a reducing environment. Glutathione is a very important molecule in this role because it has strong antioxidant properties when in the reduced form (GSH) that protects the cells against toxins, especially free radicals or highly reactive oxygen species (Wu *et al.*, 2004; Franco *et al.*, 2007). The equilibrium between the oxidized (GSSG) and reduced (GSH) forms of glutathione favors GSH when antioxidants are sufficient to maintain such a reducing environment. Alcohol catabolism is itself responsible for production of highly reactive free radicals. It has been suggested that because wines and beers contain significant levels of multifarious antioxidants they may be of significant benefit in maintaining this important balance by helping to keep GSH in its reduced form. Glutathione also appears to have an antioxidant role in the beers and wines themselves because its presence prevents chemical oxidation of vulnerable components and preserving the taste and character of such beverages, but glutathione ingested in this form is probably of limited nutritional value, as it is broken down in the intestine and so makes only a negligible contribution to daily protein requirements (see Section 5.3.4).

Plant derived bioactives extend to include many other classes of compounds. For example, certain members of the furan class of chemicals have antioxidant capacity and some have anticancer properties, although others may be toxic and carcinogenic (Goldberg *et al.*, 1999). Furans are derived from thermal decomposition of pentose based compounds (cellulose) and may be present in beers, wines and spirits, adding to the antioxidant capacities of vitamins and polyphenols also present.

Phytochemicals in Wines

Wines, especially red wines, are rich sources of bioactive phytochemicals (Soleas *et al.*, 1997; López-Vélez, *et al.*, 2003). There are well in excess of 2000 phenol based compounds found in wines, derived predominantly from the grape (van de Wiel *et al.*, 2001), the antioxidant properties of which are reputed to be responsible for the 'French paradox' because they confer cardioprotective effects through mechanisms opposing development of atherosclerosis, i.e. by helping to minimize oxidation of cholesterol (Puddey *et al.*, 2003). These phytochemicals come mainly from the seeds, skin and stems of the grape and there are generally greater levels in red wines than in white wines because such extraneous materials are allowed to remain in the

fermentation mixture for red wines, but which are usually removed for white wine fermentation (with some exceptions). The anaerobic environment of the fermentation process in wine manufacture not only produces alcohol but also modifies the phenolic content of the juice to alter antioxidant potential and enhance product stability. A comprehensive discussion and description of the numerous polyphenols found in red and white wines is presented by German and Walzem (2000; with an informative summary comparison presented by these authors in their Table 2, page 570). Furans may be present in wines that have been aged in wooden casks e.g. charred oak, due to leeching out.

Phytochemicals in Beers

The array of antioxidants originating from barley and malt has significance to both manufacturer and consumer, as they help to prevent the development of staleness in beer (e.g. Lu *et al.*, 2007), and many of them may be found in significant levels in finished beers. These and other plant bioactives, such as active phenolic derivatives or those originating from hops and added ingredients, may have importance because of their potential contribution to health and nutritional status of the moderate consumer through antioxidant (Ghiselli *et al.*, 2000) and estrogenic effects (Rosenblum *et al.*, 1993; Milligan *et al.*, 2000), some of which may be undesirable, especially in men. Potentially significant bioactive phytochemicals reported to be present in beer and mainly derived from hops include humulone (an α-acid), lupulone (a β-acid), phytoestrogens such as the relatively potent 8-prenyl-naringenin (hopein), daidzein and genistein, xanthohumol, a polyphenol of the chalcone group, flavonones, *iso*-xanthohumol, 6-isoprenylnaringenin (for discussion see 'Beer and Health' in Hornsey, 1999 – Chapter 9). The pooled concentration of polyphenols may decrease during the various stages of the brewing process, mainly because of precipitation of insoluble tannins and flavonoids (Fantozzi *et al.*, 1998). However, there are significant levels present in the final product, especially in the darker beers, and these are linked with alterations in metabolism leading to improved health, particularly lessening cardiovascular risk (Denke, 2000; Baxter and Hughes, 2001; Kondo, 2004; Gorinstein *et al.*, 2007).

Phytochemicals in Spirits (and Liqueurs)

Significant antioxidant capacity may be found in certain spirits and liqueurs, the levels of which depend on the particular production methods and aging processes involved during manufacture (e.g. Goldberg *et al.*, 1999; Madrera *et al.*, 2003). Some phenolic compounds derived from the original ingredients and those produced through the fermentation processes may possibly find their way into the products of distillation, but probably only in trace amounts at best. Other polyphenols and some furans, which are derived from thermal decomposition of cellulose based matter formed from charring of the wood, may be leeched out of casks used for maturing distilled beverages, producing significant antioxidant and estrogenic properties in some whiskeys, brandies and rums (e.g. Rosenblum *et al.*, 1993). Spirits produced without processes of aging in these wooden casks, such as vodka, gin, many fruit spirits and grappa, have been found to be largely devoid of antioxidant capacity, to such an extent that an effective negative oxidation capacity may be demonstrable (Goldberg *et al.*, 1999).

Alcohol Ingestion, Absorption and Catabolism: Metabolic and Nutritional Consequences

Consumed as a component of the diet or produced by the action of microorganisms present in the gut on the contents passing through the gut, alcohol, as a small water soluble molecule, may be absorbed into the blood along the whole length of the gastrointestinal tract. The rate of absorption is determined by a number of factors including: (a) alcohol concentration, (b) the type of alcoholic beverage consumed, (c) how quickly it is consumed, (d) the presence of any food and the amount and type of this food taken at and around the same time as the alcoholic drink, (e) the point of alcohol absorption in the gastrointestinal tract and (f) the extent to which any alcohol present has been broken down by the enzyme alcohol dehydrogenase (ADH) before it can be absorbed. Such factors are known to be interactive and variable and so contribute to differential rates of absorption both within and between individuals (Morgan and Ritson, 2003; Paton and Touquet, 2005; Crabb *et al*., 2004).

The rate of alcohol absorption is dependent on its concentration, being the highest from beverages containing about 20% to 30% alcohol, and on the speed of its consumption. Alcohol consumed in aerated beverages is more readily absorbed, as is alcohol taken on an empty stomach (Paton and Touquet, 2005). The amount and type of food taken at or around the same time as the alcoholic beverage contributes to the rate of alcohol absorption, predominantly because the rate of emptying of gastric contents into the small intestine is reduced by the presence of food. Spirits also reduce the rate of gastric emptying. Therefore, as the stomach absorbs alcohol relatively slowly compared to the faster rate of absorption from the small intestine, any alcohol that is retained in the stomach for longer periods effectively slows its rate of absorption. A number of drugs may act by either increasing or decreasing the rate of gastric emptying. Additionally, although a large proportion of alcohol in the stomach may be metabolized by very active ADH enzymes in certain individuals with such capacity before being absorbed into the blood (Crabb *et al.*, 2004), other individuals may not have this capability. In such susceptible individuals, a relatively greater proportion of the alcohol ingested may be absorbed, with the potential for greater intoxication and harm, although the amount ingested overall may be lessened as a result.

Once it is absorbed, alcohol passes via the portal vein to the liver where it is metabolized, the extent of which depends on the capacity of the enzyme systems that it encounters relative to the amount of alcohol

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

present. Any alcohol that passes through the liver without being metabolized distributes within the water compartments of the various body tissues through the systemic circulation.

The human body has no capacity for the storage of alcohol per se and so, as it is also highly toxic, alcohol needs to be eliminated from the body or detoxified with expedience. The largest part, by far, of any alcohol ingested by the body or, indeed, any that is produced by microorganisms in the intestinal tract, is metabolized by the liver, with much lower levels metabolized in other tissues, and perhaps only about 2–5% being eliminated unchanged in urine, breath and sweat. However, the liver has a limited capacity for alcohol breakdown resulting in increasing blood alcohol levels during periods where ingestion exceeds this capacity, with concomitant increased risk of organ and tissue damage. Typical alcohol metabolism is about 6 g/h, but the actual rate for individuals varies considerably. Blood alcohol concentrations after consumption of alcoholic beverages in the absence of food reach their maximum quite quickly, perhaps within 30 min for a single drink with a much higher peak occurring later as consumption increases (Wilkinson *et al.*, 1977), with maximum levels and the times of achieving these peaks depending on quantity ingested and prevailing conditions of absorption and assimilation. Following cessation of alcohol consumption, blood levels gradually decrease with alcohol breakdown in the liver and other routes of elimination as the blood circulates the body, with the extent of alcohol exposure varying with total amount and rate consumed. It is important, especially for moderate and 'sensible' drinkers, to be fully aware that blood alcohol levels reach a lower maximum peak and remain lower if an equivalent quantity of alcohol is consumed over a longer time period.

Alcohol consumption and catabolism has potentially serious implications for health, especially in terms of liver disease (Section 5.6.2), by generating oxidative stress, particularly through the cytochrome P450 CYP 2E1. In addition, alcohol intake may effectively displace the intake of other nutrients and alcohol and its metabolites may interfere with certain metabolic pathways of a number of key nutrients, even if dietary intake of these nutrients may be apparently adequate (supposedly meeting those levels of nutrients required for optimum health in the absence of alcohol). As CYP 2E1 also converts other xenobiotics into highly toxic intermediates, alcohol may also act synergistically on CYP 2E1 with such xenobiotics (e.g. paracetamol), and especially in the fasted state, to deplete glutathione (GSH) levels (Section 5.3.4) and significantly contribute further to oxidative stress. Provision of the amino acid cysteine may be used to replenish GSH therapeutically.

5.5.1 Alcohol Catabolism

The pathways of alcohol metabolism result in certain intermediary compounds that may be more or less toxic than alcohol itself and which, along with other nutrients ingested at the same time or perhaps as integral parts of alcoholic beverages themselves, impact in various ways on nutrition and health, either detrimentally or beneficially. The first biochemical reaction of alcohol breakdown, or catabolism, is catalyzed by the enzyme ADH, which is a zinc metalloenzyme that exists in multiple forms, or isoenzymes. The presence of some of these isoenzyme polymorphisms, although they may have the potential to oxidize alcohol at different rates, does not appear to have a major effect *in vivo* under normal circumstances in most populations. However, in certain populations, relatively inefficient or nonfunctional ADH polymorphisms may limit the ability to tolerate even low levels of alcohol. An isoenzyme of ADH, along with cytochrome P450, with potential for oxidizing alcohol is present within the gastric mucosa, but, although it has been suggested that up to about 20% of that ingested may be oxidized in the stomach by this route, the exact structure and role of this particular isoenzyme in alcohol metabolism overall is relatively unknown.

In order to prevent or minimize any possible damage caused by ingested alcohol reaching susceptible cells in key organs and tissue systems supplied by the systemic circulation, it is important to understand the potential extent of action of the ADH enzymes essentially present in the stomach and liver. Therefore, the concept of 'first pass metabolism' (FPM, or presystemic metabolism) has been applied. The FPM is the amount of alcohol broken down by ADH enzyme action in the stomach and liver (the predominant organ

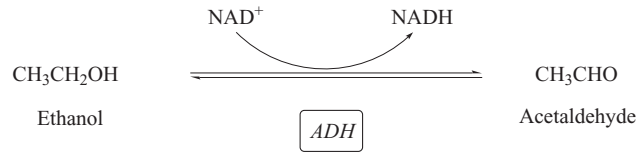

Figure 5.5.1 *The conversion of ethanol ('alcohol') to acetaldehyde. ADH is alcohol dehydrogenase; NAD is nicotinamide adenine dinucleotide*

for alcohol detoxification) to attenuate the potential systemic effects of alcohol. The extent of FPM may be determined practically by administration of ethanol either orally or intravenously followed by a sequence of blood alcohol level measurements which are used to: (a) construct a graph of alcohol concentration against time for each route of administration, (b) obtain by integration the areas under the curves for each of these routes and (c) calculate the difference between these areas under the curves to provide a measure of FPM. It is interesting that large numbers of individuals in certain populations do not have active gastric ADH enzymes; in particular, about 30% of some Asian populations lack active ADH and women generally have lower ADH levels than men (e.g. Frezza *et al.*, 1990). A particularly good descriptive account of the implications of different expressions of ADH polymorphisms (and acetaldehyde dehydrogenase) is that given by Crabb *et al.* (2004).

Alcohol takes precedence in the hierarchy of macronutrients to be oxidized, followed sequentially by carbohydrates, proteins and fats, with the oxidation of these other macronutrients, particularly fats, being suppressed temporarily during the disposal of alcohol, which occurs to a greater or lesser extent, depending on the amount of alcohol present. There is also some controversy regarding the efficiency of utilization of the energy provided by alcohol oxidation (Prentice, 1995). The products of alcohol catabolism are variously utilized by the usual pathways and cycles of intermediary metabolism, potentially creating an imbalance in the normal metabolic flux through such pathways, especially in times of excessive alcohol consumption (see Section 5.5.4).

In healthy individuals with a moderate alcohol intake, the first stage in the catabolism and detoxification of alcohol, predominantly in the liver, involves the cytosolic enzyme ADH and chemical reduction of the oxidized form of the cofactor nicotinamide adenine dinucleotide (NAD^+) to NADH (Figure 5.5.1); this reaction catalyzes the conversion of alcohol to acetaldehyde, an intermediary product that is more toxic than alcohol, but which is rapidly converted to acetate and then to other harmless products.

In consumers of higher levels of alcohol and in alcoholics, there is the alternative mixed function oxidase pathway of the smooth endoplasmic reticulum, a cellular organelle, that also produces acetaldehyde from alcohol. The microsomal ethanol oxidizing system (MEOS) of the cytochrome CYP 2E1 isoform of P450 catabolizes alcohol in conjunction with the reduced form of the cofactor nicotinamide adenine dinucleotide phosphate (NADPH), hydrogen ions and oxygen to form acetaldehyde, the cofactor $NADP^+$ in its oxidized state and hydrogen peroxide (Figure 5.5.2). The potential activity of this enzyme may be increased

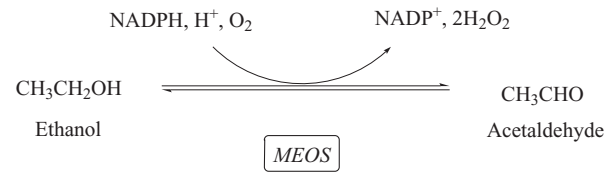

Figure 5.5.2 *The conversion of ethanol to acetaldehyde. MEOS is microsomal ethanol oxidizing system; NADP is nicotinamide adenine dinucleotide phosphate*

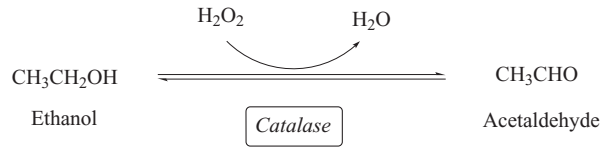

Figure 5.5.3 *The conversion of ethanol to acetaldehyde using the enzyme catalase*

significantly as a result of chronic use or abuse of alcohol. The MEOS system uncouples oxidative phosphorylation to release some of the energy contained in alcohol for dissipation as heat rather than storage. Oxidative phosphorylation would normally be the pathway involved in converting metabolic energy released through alcohol catabolism to formation of high energy phosphate bonds in ATP. Such uncoupling and energy release may be partially responsible for limiting the potential weight gain from excess alcohol intake (Prentice, 1995).

The ADH pathway is dominant at low levels of alcohol because the reaction constant or K_m for this enzyme reaction (the K_m of a reaction is a constant that indicates the potential rate of the reaction) is much lower than that for the MEOS pathway, which may become more significant at higher alcohol levels, and this rate may be increased up to about 10-fold. Alcohol may also be oxidized by the enzyme catalase, which is located in the peroxisomes (Figure 5.5.3). However, this particular pathway is not believed to make a significant contribution to alcohol catabolism under normal physiological conditions (Morgan and Ritson, 2003). Whichever pathway has been involved in the first stage of breakdown of alcohol, it is essential that the acetaldehyde produced is further metabolized to limit its toxicity, as it has the potential to damage both functional and structural components of cells by forming adducts with a number of important molecules such as DNA, RNA and proteins.

Acetaldehyde is converted to acetate by two isoenzymes of acetaldehyde dehydrogenase, located in the cytosol and in mitochondria, and involves the integral conversion of the cofactor NAD^+ to NADH (Figure 5.5.4). Polymorphisms of acetaldehyde dehydrogenase are known to exist which are associated with interindividual differences in the efficiency of alcohol breakdown and this may be, in part at least, the basis of differences between the sexes in dealing with the after effects of intake of alcoholic beverages. It is believed that individuals lacking sufficient acetaldehyde dehydrogenase activity may show the characteristic signs of reddening in the face due to build up of acetaldehyde.

Alcohol catabolism has, at this point, produced the nontoxic derivative, acetate; this acetate is now condensed with coenzyme A in a reaction in the cytosol that also involves ATP to form acetyl coenzyme A (acetyl Co-A), with the production of the side products pyrophosphate (PPi) and AMP (Figure 5.5.5). Acetyl Co-A can now enter the tricarboxylic acid (TCA) cycle (also known as the citric acid cycle or Kreb's cycle), the enzymes of which are situated in the mitochondrion, where acetyl Co-A is used in aerobic respiration, to be eventually broken down to produce CO_2, water and energy. The TCA cycle is more normally instigated

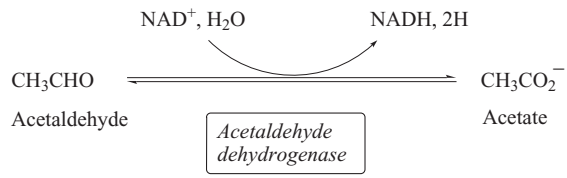

Figure 5.5.4 *The conversion of acetaldehyde to acetate. NAD is nicotinamide adenine dinucleotide*

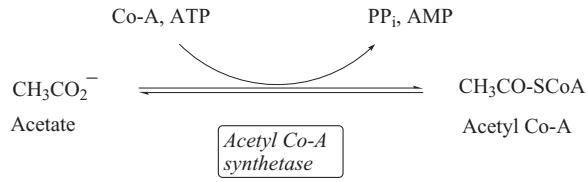

Figure 5.5.5 *The conversion of acetate to acetyl Co-A. Co-A is coenzyme A; ATP is adenosine tri-phosphate; PP_i is inorganic phosphate; AMP is adenosine mono-phosphate*

by acetyl Co-A derived from pyruvate and its interaction with the pyruvate dehydrogenase complex. Alternatively, in some circumstances, such as those that might occur after alcohol consumption, acetyl CoA can also be used as a substrate for lipogenesis, the synthesis of molecules of fatty acids that can be stored in the adipose tissue of the body.

It is evident that alcohol ingestion may have a number of metabolic sequelae that could have major implications for health, as described in Chapter 5.6.

5.5.2 Methanol Catabolism

Methanol is another primary alcohol found in alcoholic beverages in varying amounts according to type of beverage, with the highest concentrations, up to about 2% by volume, being present in dark wines and spirits, such as red wines, brandies and whiskies. The metabolism of methanol follows a similar pathway to that of ethanol (Figure 5.5.6), but is reported to be much slower, by about 10-fold. The catabolism of methanol by ADH produces formaldehyde, which is very toxic indeed.

Formaldehyde is converted to another highly toxic intermediary, formate (formic acid), using enzymes with aldehyde dehydrogenase activity (Figure 5.5.7); formaldehyde dehydrogenase and acetaldehyde dehydrogenase with this capability both appear to be active in this process in the liver, but some evidence suggests that formaldehyde dehydrogenase and alcohol dehydrogenase are so similar that they may essentially be the same enzyme.

Formate is a metabolic intermediate of one carbon compounds, with its carbon atom appearing in methyl groups for transmethylation, eventually being oxidized to carbon dioxide, although some formate may be excreted unchanged in the urine.

5.5.3 Effects of Alcohol on Intake of Foods and Energy

Amounts and patterns of food intake are differentially influenced by alcohol consumption, the extent of which depends on acute or chronic use or whether it is low to moderate or excessive consumption during particular

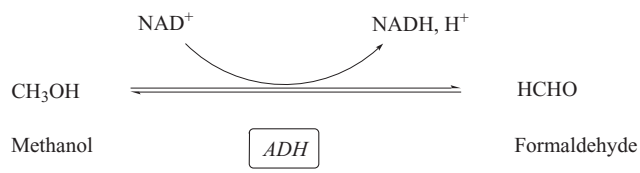

Figure 5.5.6 *The conversion of methanol to formaldehyde. ADH is alcohol dehydrogenase; NAD is nicotinamide adenine dinucleotide*

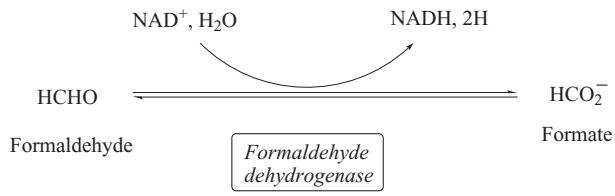

Figure 5.5.7 *The conversion of formaldehyde to formate. NAD is nicotinamide adenine dinucleotide*

time frames (Forsander, 1998; Yeomans *et al.*, 2003; Yeomans, 2004; Caton *et al.*, 2007; Kokavec, 2008). It appears that alcohol consumed on a single occasion has a short term stimulatory influence on appetite, the 'aperitif effect,' which may increase food intake in the short term, provided that any food is taken within one hour, otherwise such stimulatory effects may not be maintained. Food intake in the mid- to longer-term may then be reduced as a compensatory response. Increases in orosensory mechanisms and/or impaired satiety mechanisms have been implicated in these appetite stimulatory effects of alcohol, or the disinhibition of restrained eating (Yeomans, 2004). Primarily, alcohol acts centrally by stimulating γ-aminobutyric acid receptors, as well as having other pharmacological effects implicated in appetite acting through, for example, leptin, serotonin, glucagon-like peptide-1, neuropeptide Y and endogenous opioids. There may also be the effects of expectation. The timing of alcohol intake is also important, as its pharmaceutical actions occur sooner than its nutritive effects. However, any energy consumed in the form of alcohol (7.1 kcal/g) is considered per se to be an additional passive intake in excess of energy requirements as, from a limited body of evidence in humans, there is no compensatory response to any additional intake of energy from alcohol. In animals it appears that any additional energy intake obtained from alcohol is compensated for by a reduction in food intake, primarily in the form of carbohydrates if all macronutrients are made freely available. Therefore, regular consumption of alcohol in moderation may effectively increase habitual energy intake because of the additional provision of calories from the alcohol and the induced increase in food intake, which is not subject to compensation due to the continued alcohol intake.

Alcohol intake in humans and animals is influenced by relative consumption of the macronutrients; in experimental conditions high protein and low carbohydrate diets tend to lower alcohol consumption, whereas high carbohydrate and low protein tends to increase intake. Such factors may be less influential in high consumers and alcoholics as satiety mechanisms may be outweighed by other more compelling factors. The overall effects of these factors on energy balance and maintenance of body weight is uncertain and varies considerably between individuals because of additional factors such as possible compensatory metabolic mechanisms and changes in physical activity. These issues are reviewed by Prentice (1995) and Yeomans (2004).

5.5.4 Consequences for Intermediary Metabolism of Alcohol Catabolism

The products of complete alcohol detoxification are now indistinguishable from regular intermediary substrates and cofactors universally involved in various reactions within the normal metabolic processes. However, such substrates and cofactors may be produced in disproportionate amounts to those normally encountered in intermediary metabolism and their excess may adversely influence the normal functioning of key enzyme processes in certain pathways and cycles. This leads to changes in the normal flux of intermediary substrates, diverting them into alternative pathways, which may then lead to further metabolic exacerbations.

Alcohol catabolism may result in metabolic imbalances because of the increased reduction of NAD^+ to NADH through reactions catalyzed by the enzymes alcohol dehydrogenase and acetaldehyde dehydrogenase. The generation of reducing equivalents may exceed capacity for redox homoeostasis, leading to these metabolic disturbances. In the cytosol, the rate of conversion of glucose to pyruvate during glycolysis may be impaired because of the decreased availability of NAD^+ for the step that converts glyceraldehyde-3-phosphate to 1-3-biphosphoglycerate within the 'pay off' phase of glycolysis. The pay off phase is so called because of the net gain of ATP and NADH from this phase, as opposed to the 'preparatory' or 'investment' phase of glycolysis, which initially consumes energy for the pathway to generate appropriate substrates for this pay off phase. Therefore, lower levels of energy rich products will result in conditions that favor the reduced state of the cofactor, i.e. the NADH form.

Although NADH is also a normal product of glycolysis, it is essential that adversely high levels, perhaps derived from alcohol catabolism, are oxidized back to NAD^+ to prevent metabolic complications, such as acidosis. In the cytosol, effectively facilitating this oxidation can occur through, primarily, the malate–aspartate shuttle or, of secondary importance, the glycerol–phosphate shuttle, both of which shunt these reducing equivalents to the mitochondria where electrons are eventually coupled to the high energy containing molecule adenosine triphosphate (ATP), which is produced through the process of oxidative phosphorylation. These shuttles are essentially dependent on substrate concentration. However, the extent to which the whole process can occur is reliant on the rate of functioning of the TCA cycle within the mitochondria, as this may be constrained by build up of cellular energy levels and NADH. Increased levels of cellular energy and NADH, derived from the mitochondrial conversion of acetaldehyde to acetate by acetaldehyde dehydrogenase during alcohol catabolism, may limit the rate of further mitochondrial conversion of NAD^+ to NADH, thus slowing flux of substrates through the malate–aspartate and glycerol–phosphate shuttles. Reactions within the TCA cycle that involve the NAD^+/NADH cofactor and, therefore, those that are potentially constrained by increases in the ratio of NADH:NAD^+ are: isocitrate to oxalosuccinate, α-ketoglutarate to succinyl-CoA and malate to oxaloacetate. Thus, three molecules of NADH are generated from NAD^+ for every acetyl group entering the TCA cycle.

Increased amounts of NADH may also impact on the process of gluconeogenesis. The normal metabolic fate of the substrate pyruvate is the production of glucose. Pyruvate is derived from usual metabolic processes such as transamination of amino acids. NADH affects the rate of interconversion of pyruvate and lactate by favoring lactate production through its influence on the reversible reaction involving the enzyme lactate dehydrogenase, so effectively reducing gluconeogenesis from pyruvate, as this pathway is inhibited by low concentrations of pyruvate. The consequent lactate build up generates acidosis and potential hypoglycaemia occurs with the lower rate of glucose synthesis. Lactate also interferes with the ability of the kidney to excrete uric acid, and uric acid build up by this route may contribute towards hyperuricaemia leading to gout. This may also occur through ketosis and acetate production induced by excess alcohol combined with ATP catabolism or through purine production. Of all factors that contribute to hyperuricaemia, the influence of alcohol on metabolism of the purine bases hypoxanthine, xanthine and uric acid is one of the most significant (Yamamoto *et al.*, 2005 and Section 5.3.4).

Alcohol induced lipid synthesis may occur through two metabolic pathways that produce glycerol and fatty acids, with the result that heavy drinkers and alcoholics may gain body weight initially through increased fat deposition. The electron transport chain may be an alternative beneficiary of NADH, synthesizing ATP as a ready source of energy, a reaction that inhibits the normal oxidation of fats in the fatty acid spiral and TCA cycle and allowing fats or acetyl Co-A to accumulate with the concomitant production of ketone bodies. Additionally, positive lipid balance may also be enhanced as the rate of fatty acid oxidation may be reduced through its reliance on sufficient concentrations of the oxidized form of the cofactor, NAD^+. Although ethanol stimulates hepatic lipogenesis to raise plasma triglycerides, it also increases metabolism of triglyceride rich

lipoproteins in the periphery, because of induced lipoprotein lipase activity, and increases apolipoprotein synthesis (ApoA1 and ApoA11) in hepatic cells with the net effect of increasing the plasma high density lipoprotein (HDL) fraction; raised levels of HDL are considered to be a negative risk factor for coronary heart disease. For general discussion of cardiovascular implications of alcoholic beverages, see Puddey *et al.* (2003).

It is the toxicity of alcohol and its intermediates in conjunction with its effects on metabolic imbalance that contribute to the health risks and, indeed, hangover associated with consumption of alcoholic beverages (Wiese *et al.*, 2000), especially excessive consumption. For example, the aldehydes are toxic because they are capable of forming adducts with proteins and nucleic acids, as well as interfering with other key biochemical compounds and reactions.

It is argued that the suppression of fat oxidation, in particular, by alcohol consumption, on top of the caloric intake of the normal diet, should lead to weight gain mainly through increased storage of fat. However, other changes in metabolism (e.g. futile cycles that essentially 'waste' energy through the dissipation of heat), dietary intake and physical activity levels may help to balance energy intake and expenditure, and so maintain consistent body weight in moderate consumers of alcoholic beverages. This seems to be an important factor resulting from induction of the MEOS pathway for alcohol catabolism in individuals consuming high levels of alcohol, especially alcoholics. So far, experimental and epidemiological evidence is inconclusive and the debate is ongoing as to whether or not calories from alcohol count significantly towards energy balance and obesity (Prentice, 1995; Foster and Marriott, 2006).

5.5.5 Effects of Alcohol and its Metabolites on Absorption, Metabolism and Utilization of Key Nutrients

Alcohol and its toxic metabolites have major effects on absorption, metabolism and activation of a number of other important nutrients (Lieber, 2000; and various chapters in Watson and Preedy, 2003). Although the nutrient intake of low or moderate consumers of alcohol may not be significantly affected, in high alcohol consumers and alcoholics nutrient supply may be limited to the detriment of nutritional status with major clinical exacerbations. This may occur not only because of relatively low intake of nutrient rich foods, either by inadequate amounts of food consumed in total or by poor selection of available foods, but also because of major interference with the normal digestion, assimilation and metabolism of nutrients. In heavy consumers and alcoholics especially, alcohol ingestion may be associated with bouts of diarrhea, possibly because of changes in gut motility in which the impeding waves of the jejunum are decreased and the propulsive waves of the duodenum are increased with exposure to alcohol. Alcohol may also exacerbate any existing lactase deficit. However, even in low and moderate consumers, alcohol may have detrimental effects on the digestion and absorption of other nutrients, which usually occur at the subclinical level in most healthy individuals, but there may be a significant health risk to the more susceptible. Alcohol interferes with digestion of macronutrients (fat, protein, carbohydrate), especially by acting to decrease the secretion of digestive enzymes released from the pancreas. Even if food is digested, absorption of all nutrients may also be impaired due to damage to the cells of the stomach and intestines. In those alcoholics with apparent concurrent nutrient deficiencies, nutrient absorption may be impaired to an even greater extent. For example, alcohol has been implicated in impairing absorption of folate because it inhibits expression of a folate carrier; folate deficiency variously created by this and other factors, such as low folate intake and increased renal excretion of folate may reduce further the effectiveness of the folate transport proteins. Furthermore, folate deficiency also appears to compromise nutritional status by reducing absorption of thiamine.

Even if nutritionally significant amounts of nutrients are absorbed, alcohol and its metabolites may interfere with utilization and storage of important nutrients. The effect of alcohol may be through a direct influence on the nutrient concerned, or through modifying enzyme actions or actual enzyme damage in the enzymes of pathways involving that particular nutrient. For example, in erythrocytes the rate of degradation of pyridoxal-5′-phosphate (vitamin B6) is greater in the presence of acetaldehyde; this may occur through its displacement from protein and subsequent hydrolysis by phosphatases. Alcohol exposure also inhibits hepatic folate uptake and increases renal excretion of folate, creating changes in methionine metabolism in the liver, while also exacerbating oxidative hepatic damage with further implications for carcinogenesis. Vitamin B12 status is also reduced with exposure to alcohol. Therefore, inadequate levels of folate and vitamin B12 occurring independently or concurrently could be significant in metabolism of one carbon compounds with potential procarcinogenic effects due to loss of maintenance of integrity of DNA, potentially through such factors as aberrant base incorporation, and its possible increased strand break vulnerability, impaired DNA methylation and reduced DNA repair mechanisms. Loss of such capabilities is especially important in view of the additional risk to the integrity of DNA (and RNA and protein) by increased levels of free radicals created by catabolism of alcohol and its metabolic consequences. Alcohol also interferes with protein and nitrogen metabolism. Even the transient effects of isolated exposure of alcohol interferes with hepatic uptake of amino acids, elevating their blood levels and impairing synthesis of key proteins and their secretion e.g. albumin, fibrinogen and some key lipoproteins. As discussed above, alcohol also influences metabolism of the purine bases leading to hyperuricaemia and gout (Yamamoto *et al.*, 2005; and Section 5.3.4).

Such detrimental effects of alcohol and its metabolites may not be immediately evident in low to moderate consumers, but may be exacerbated considerably in high consumers and alcoholics, leading to conditions recognized as symptomatic of deficiency diseases and other seriously debilitating conditions associated with compromised metabolism, and these are described in greater detail in the following chapter, which considers the health implications of alcoholic beverage consumption (see particularly Section 5.6.2).

5.6

Health Consequences of Alcohol Intake

Even in your pleasures you should be wise.

—Voltaire

5.6.1 Overview: Alcoholic Beverages and Society

In addition to complementing the intake of water and nutrients provided by essential nonalcoholic drinks (Wolf *et al*., 2008), alcoholic beverages have the biphasic effects of stimulation and sedation, the relative sensitivities of which are determined subjectively by the concurrent blood alcohol levels and may be perceived as desirable outcomes of alcohol consumption (Addicott *et al*., 2007; Morean and Corbin, 2010). Alongside taste, these factors help to explain why consumption of alcoholic beverages such as wines, beers and spirits has long been integral to various cultures throughout the world, although alcohol use may be prohibited on religious grounds in many others. The extent of both the significant health consequences and potential benefits associated with alcoholic beverage intake is determined predominantly by the amount of alcohol consumed, possibly tempered by other factors such as the time period over which drinking occurs, concurrent ingestion of food, relative concentration of alcohol and the presence or absence of enzymes that break down alcohol and its toxic by-products into nontoxic end products. It is not surprising therefore, that major societal, cultural and environmental dynamics may influence the fine balance between health maintenance and detriment. For the essentials of health implications associated with alcohol intake see the general texts of Morgan and Ritson (2003), Paton and Touquet (2005) and Smart (2007).

In order to better understand the multifarious health consequences and possible benefits of ethanol intake in cultural perspective, a sketch is provided here of the major influences on alcoholic beverage consumption. There are a number of reasons why alcoholic beverages are consumed, including:

- As sources of safe uncontaminated water; drinks containing low or moderate levels of alcohol were much safer than local water in many places throughout the world, especially as more heavily populated communities started to develop, which is still the case in some parts, and, for example, low alcohol beers were often provided for manual workers, such as in the steel industry.

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

- As significant sources of food; the cloudy maize and sorghum based drinks of South America and Africa, in particular, are considered significant sources of nutrition.
- As accompaniments to meals, including aperitifs, drinks with the meal and digestifs; these practices are common throughout the world and somehow or other involve most of the beverages described in this book.
- As adjuncts integral to formal and informal meetings, ceremonies of some religions, such as baptisms, funerals and weddings, parties and other celebrations and social gatherings and events.

In societies in which alcohol is tolerated, moderate consumption is associated with most of these practices or occasions and so is considered quite acceptable on a social level. However, excess intake is a ubiquitous social problem, which exacerbates at different levels within communities that are otherwise accepting of alcoholic beverages, and may be part of the reason that some other communities prohibit the use of alcohol. Differential levels of consumption are determined by a number of factors, with young people particularly vulnerable to the temptations of drink, and those in certain social groups more so, through the influence of advertising, role models and peer pressures. The lure of alcohol may be at its strongest when there are also established legislative or social restrictions, sometimes taking this to excess as seen with weekend binge drinking, for example. It is quite clear that alcohol and some of its catabolic products are extremely toxic, particularly in the young and other vulnerable groups, causing many acute and chronic conditions to exacerbate, especially if alcohol is ingested to excess, whereby the substantial increases in morbidity and mortality then become major public health concerns. For public health perspectives on alcohol intake in the UK, see the websites of the Department of Health (http://www.dh.gov.uk/) and the Faculty of Public Health (http://www.fph.org.uk/). The extent of damage caused at different levels of alcohol intake is differentially determined by individual characteristics, such as the capacity of enzymes in the stomach and liver to break down alcohol and the capability of the body to neutralize or deactivate highly reactive intermediary compounds that may be formed during catalysis of alcohol.

Alcohol intake is completely forbidden on religious grounds for millions of people and many populations across the world. Within many societies, particularly those of Anglo Saxon, Celtic or Nordic origin, where alcohol is not necessarily illicit, temperance movements have variously existed over the years that seek to limit the drinking of alcoholic beverages by legislative (political) means or social pressures. Although prohibition, as experienced by Canada and the USA (~1919–1933) and Scandinavia (except Denmark), for example, is an extreme measure taken to try prevent any alcohol consumption at all, it has quite often had the opposite effect by fostering the illegal private and 'commercial' production and smuggling of alcoholic beverages, leading to expanding crime and excessive drinking in certain sections of society. Perhaps the great jazz cornetist Bix Beiderbecke might not have died in 1931, at the age of just 29, if prohibition had not been in force in the USA at that time. Most temperance movements are based on religious beliefs and have had (at least temporary) influences on alcohol consumption in many countries over many years, usually by legislation that restricts availability in some way. Still today, on the one hand there are those who would say, 'I hope the day is near at hand, When strong drink will be banished from our land.' (William McGonagall). But on the other hand, there are many who are skeptical of extreme measures. 'Prohibition has made our president a dictator, executing an unpopular law by force of arms. It has made our congressmen cowards and hypocrites, passing more and more oppressive laws, while themselves carrying whisky flasks in their hip pockets. Prohibition has divided our people into factions almost as bitterly hostile to each other as the factions that existed before the Civil War' – the opinion of William R. Hearst in the 1930s.

Governments have imposed various restrictions on alcohol, especially in times of war, quite often with the aid of influential abstemious individuals or groups. During World War I the British Government introduced legislation to limit consumption of alcoholic beverages, part of which was the setting up of restricted opening hours for licensed premises (public houses, inns and hotel public bars). In Germany and Austria, certain

quantities of barley for brewing were redirected into the making of bread, and the French Government requisitioned the cider orchards of Brittany and Normandy for the production of industrial spirit and banned the production and sale of absinthe in 1915. In the UK, in 1916, the government requisitioned (nationalized) the breweries and licensed premises of several breweries around the important munitions factories in the Carlisle, Gretna and Annan areas. By strictly overseeing the production and drinking of beer in that area, the government sought to control the perceived heavy drinking of munitions workers (Hornsey, 2003).

The relationship between alcohol consumption and health is complex (Mukamal and Rimm, 2008; Rehm *et al.*, 2010), being detrimental with high intake, but apparently beneficial at low to moderate intake at the population level (Grønbaek, 2009), but with no definitive consensus as to whether or not to drink in moderation or to abstain for maximum health benefits for individuals (Mukamal *et al.*, 2006; Kloner and Rezkalla, 2007). When relative morbidity and mortality rates are plotted against increasing levels of alcohol intake, the result is a j shaped curve (Figure 5.6.1). This appears to be due mainly to the effects of low to moderate alcohol consumption reducing the incidence of coronary heart disease to slightly below that of abstinence, but then the risks associated with increasing alcohol intake rise significantly in a largely dose related manner (Gurr, 1996). Generally, there is little or no advantage of alcohol per se on public health overall. The dividing lines between possible health benefits and causing no harm, minimal harm and significant harm are diffuse for populations because of considerable variability in response to alcohol between people, but for any individual this divide may be quite well defined. This is confounded by the fact that some modern societies have seen the rise of binge drinking or excessive consumption of alcohol over relatively short periods of time, interspersed with periods of low level intake or abstention. Binge drinking is a particularly worrying trend in some societies (e.g. Britton and McKee, 2000), even more so in young people (Plant *et al.*, 2009) and especially children (e.g. Stolle *et al.*, 2009). Furthermore, although health problems generally become more pronounced with increased ethanol intake per se (i.e. dose related), they may be compounded by other concurrent factors, such as poor diet, smoking, pharmaceuticals (prescription and so called 'leisure' drugs) and lack of exercise. Therefore, for the individual, these factors help to explain why there is no strict definition of low, moderate and excessive intake when applied to alcohol consumption. Even intakes consisting of less than a 'moderate' weekly intake of alcohol may be far more detrimental than beneficial for some individuals, depending on

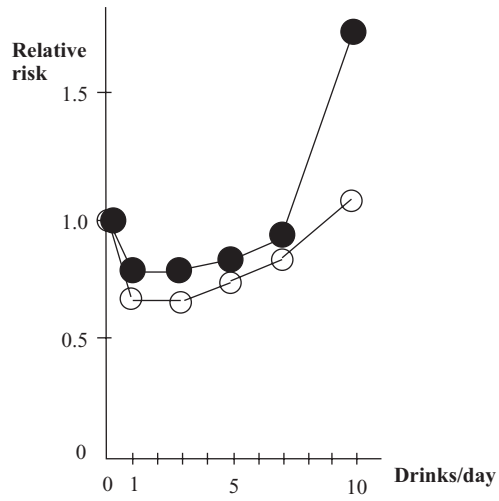

Figure 5.6.1 *Relationship between alcohol consumption, all cause mortality (●) and cardivascular disease mortality (◯)*

distribution of intake over the week. Indeed, binge drinking may be worse for health than exactly the same amount of alcohol consumed over longer periods, but in moderation. Again, general texts (Gurr, 1996; Morgan and Ritson, 2003; Paton and Touquet, 2005; Smart, 2007) provide further insights into alcohol and health, with a comprehensive review of moderate drinking provided by Gunzerath *et al.* (2004), and the more complex nutrition and health issues are considered in greater detail in Watson and Preedy (2003).

Epidemiological evidence and some mechanistic studies suggest that low to moderate alcohol intake imparts specific health benefits to certain populations in general (e.g. in the Mediterranean – Athyros *et al.*, 2007/8) and particularly to individuals at risk from metabolic syndrome (Alkerwi *et al.*, 2009), cardiovascular disease (with the possible exception of stroke), diabetes (Koppes *et al.*, 2005; Baliunas *et al.*, 2009) and neurological disorders (Collins *et al.*, 2009). The reductions in risk may or may not be due entirely to alcohol per se, since there are many other substances in alcoholic beverages that have been implicated in health benefits, such as polyphenols (especially in red wine; see Chapter 5.8) and β-glucans (especially less refined beers). There could also be a possible synergism between alcohol and other entities, which also gives rise to some apparent health benefits. For example, there may be some protection against stomach infection by *Helicobacter pylori* (which has been linked with dyspepsia and ulcer formation) by both alcohol and the antioxidants found in some alcoholic beverages (Lin *et al.*, 2005), although there is some doubt about this (see below). Alcohol consumption has also been linked anecdotally with some protection against the formation of kidney and gall bladder stones and as a measure of protection against osteoporosis. However, whether or not some or all of these purported multifarious effects of moderate alcoholic beverage consumption are actually beneficial is still largely speculative. However, there is also some question as to the health value overall and strong alcohol per se may be a direct cause of many inflammatory conditions.

The exact effects of alcohol experienced by an individual depends on body size, the relative amounts of metabolically active tissues, sex, heritability, ethnicity and some concurrent factors, such as general health, fatigue and state of mind. Clearly, there is, for even the average individual, a certain minimum risk associated with low to moderate consumption, which is considered to be up to about three drinks daily. Exactly what is meant by 'a drink' (i.e. reflecting the amount of alcohol actually consumed) has been the subject of much debate, giving rise to the concept of a standardized unit of alcohol. The fact that the definition of a unit of alcohol varies from country to country indicates (Table 5.6.1) general uncertainty amongst health researchers, health practitioners and policy makers. Nonetheless, broad policy guidelines for recommended maximum

Table 5.6.1 *Units of alcohol from around the world*

Country	Unit of alcohol or standard drink (g ethanol)	Official recommendations for daily maximum drinks for men (M) and women (F) (units/day)*
Australia	10	2 (M), 2 (F)
Austria	6	4 (M), 2.67 (F)
Canada	13.6	2 (M), 2 (F)
Denmark	12	3 (M), 2 (F)
Japan	19.75	1-2
New Zealand	10	3 (M), 2 (F)
UK	8	4 (M), 3 (F)
USA	14	2 (M), 1 (F)

*Where daily limits are the same for men and women (e.g. Canada), the weekly limits often allow more drinks for men (e.g. in Canada, maximum weekly intake for men is $2 \times 14 = 28$ units, whereas for women it is $2 \times 9 = 18$).

daily intakes have been laid down (e.g. Department of Health website – http://www.dh.gov.uk/), even if they do differ in policy and approach (Crombie *et al.*, 2007).

The factors that cause certain individuals to cross the dividing line between low or moderate and excessive drinking are not fully understood and whether or not a moderate drinker will progress to a state of alcohol abuse is not possible to predict with any certainty from current knowledge (Lucas *et al.*, 2005). For these and other reasons, the American Heart Association advises people who have medical conditions that may supposedly benefit from low alcohol intake, not to take up drinking alcohol if they do not already do so (O'Keefe *et al.*, 2007).

Acute health problems due to excess alcohol include increased risk of accidents and injury, transient gastrointestinal problems, cardiovascular effects, toxicity and behavioral changes, along with the risk of death from vomit inhalation in the extreme (Vonghia *et al.*, 2008). Accidents occur as balance and judgments of distance and speed are generally impaired after consumption of more than about three or four drinks and large excesses may cause further impairment due to transient hypoglycemia. Chronic problems include addiction, cardiovascular disease, damage to the central nervous system and other neuropathies, liver disease, cancers, osteoporosis, arthritis and psychological disorders. Malnutrition, presenting either as undernutrition or overweight and obesity, is a possible outcome of long term alcohol misuse with various disease exacerbations that this may cause due to the added burden of poor diet and poor nutritional status. Of course there are possible consequences for every member of the community of another person's excessive alcohol consumption, acute or chronic, e.g. accident or intrafamily issues (Greenfield *et al.*, 2009).

Based on the differential implications of alcohol consumption, whether for benefit or harm and at the individual or population health levels, various methodologies are used to assess the effects of alcohol intake by measuring physiological responses in individuals through to the prevalence of alcohol related diseases in populations. In order to establish the true effects of alcohol, it is essential to design statistically sound research studies that are based on techniques appropriate to the research in question and, therefore, avoid obtaining erroneous or misinterpreted data. The dissemination of misleading information obtained through poorly planned and executed research may impact significantly on recommendations for public health promotion strategies, etc. There are a number of ways of classifying research study designs according to the question being asked and resources available, but they essentially fall into two main categories, experimental and observational.

Experimental studies, including powerful randomized controlled trials, are statistically powerful designs that may be prospective and longitudinal and measure the differential effects of interventions in a treatment group against a control group, similarly examined, but without the intervention or administered with a placebo instead. These studies are likely to provide the most convincing data on causation of alcohol related disease. However, it would be unethical and expensive, amongst other things, to subject a group of healthy individuals to years of excessive alcohol intake, or indeed any of its toxic metabolites, to see if their occurrence of disease was worse than in a control group of abstainers (e.g. Ren and Wold, 2008). In contrast, if the short term differential effects of intervention using a specific nutrient in alcohol, say a particular polyphenol in wine, are intended, then this is less of an ethical issue. It is important for study validity that the intervention and control groups are matched as consistently as possible in all other factors, diet for example, so that any difference between them is as certain as possible to be due to the intervention of alcohol itself and not to confounders, such as differential levels of smoking between the groups.

Observational studies can largely be divided into prospective and retrospective subcategories, each of which can be further subdivided into longitudinal and cross sectional designs. Of particular importance to evaluating the effects of alcohol on population health is the science of epidemiology, the use of statistical methods specialized for making inferences that reflect experimental study design as far as possible, but cannot be used to replace interventions or to draw the same conclusions regarding disease etiology. Observational studies can only infer that associations exist between cause and effect or outcome, they cannot conclusively

prove causation like the more powerful experimental studies. However, the use of case control studies is particularly valuable in assessing the possible effects of alcohol in later disease onset and again essentially uses two groups retrospectively, or even prospectively, one with exposure to alcohol and one without (the control group), and examines the difference between them in terms of outcome, thereby enabling stronger inferences of association to be drawn. However, there are potential difficulties with such studies, including the reliability of recall and the presence of uncontrolled confounding factors (diet, exercise, smoking etc.).

For more information regarding study design in general, see Altman (1991) and Nelson *et al.* (2004).

Of course laboratory studies are also important, particularly for determining the mechanisms of how alcohol affects health, and may be performed either *in vivo* in individuals, or groups of subjects, or *in vitro* on cell lines and organelles, and on isolated biochemicals; they have the advantage that some of the short-term direct effects of alcohol can be studied in controlled conditions with little risk of lasting harm. Human studies include analyses of biological fluids, such as plasma and urine, and physiological measurements, such as heart rate, blood pressure and cognition. Studies using animals have the advantage of including whole tissue analyses, but they may not be acceptable, as the findings may not be appropriate to physiological responses in humans.

5.6.2 Harmful Effects of Excessive Alcohol Intake

Although a low to moderate intake of alcohol may perhaps be of some health benefit, levels above about three to four standard UK units lead to significantly increased risk of mortality from circulatory disease, and several other conditions, as well as to increases in morbidity generally, especially liver, gastrointestinal and neurological diseases. Such risks are essentially dose dependent, with women more susceptible than men to alcohol overall (e.g. Nolen-Hoeksema and Hilt, 2006; Lang *et al.*, 2007; Ferreira and Willoughby, 2008; Taylor *et al.*, 2009). Athletic performance is variously, mostly adversely, affected by alcohol consumption (El-Sayed *et al.*, 2005; Shirreffs and Maughan, 2006). A summary of significant conditions generally associated with alcohol intake is given in Table 5.1.1 of Chapter 5.1. The development and progression of certain alcohol related conditions, especially those promoting some cancers, are known to be modified by individual genetic make up and epigenetic effects (Shukla *et al.*, 2008), but this complex area of investigation is still largely in its infancy (Druesne-Pecollo *et al.*, 2009; and see 'Hepatic (Liver) Disease' section). As the following section covers the most important or defined health implications, which is not exhaustive, useful perspectives may be found in texts by Paton and Touquet (2005), Morgan and Ritson (2003) and Smart (2007), and more specific nutrition related issues are presented in more depth in Watson and Preedy (2003). Also, there is such a vast amount of information currently available on alcohol and health that only certain references have been selected as the most interesting and/or appropriate for either providing direct factual matter or as a means to sourcing further details, i.e. through the use of comprehensive reviews (e.g. Gunzerath *et al.*, 2004).

Accidents and Injury

Both acute and chronic misuse of alcohol increase the risks of accidental injuries and death, such as from mishaps in the home or at an otherwise secure event, road traffic accidents, industrial accidents, fires (very often associated with smoking) and even drowning. Indeed, the relative risks of morbidity and mortality directly associated with accidents and injuries influenced by alcohol intake are higher than other alcohol related sequelae (Morgan and Ritson, 2003) and, as for other consequences of excess intake, the risk is dose dependent (Taylor *et al.*, 2010).

As well as increasing the risk of injury, excessive alcohol consumption also increases the risk of morbidity and mortality following trauma or surgery, and recovery time is greater, because wound healing, including

collagen production, epithelial restoration and blood vessel repair is impaired by exposure to alcohol consumed before sustaining injury (Radek *et al.*, 2009).

Alcohol Addiction (Alcoholism, Alcohol Abuse or Alcohol Dependence)

This addictive syndrome is characterized by compulsive alcohol abuse leading to possible long term psychological and physical dependence, with significant deteriorations in health and social consequences. As well as excessive abuse of alcohol, the alcoholic: (a) may be unable to control its use, which is usually persistent despite recurrent health and social implications, (b) may neglect other activities and social interactions whilst concurrently fostering alcohol related behaviors or succumbing to their sequelae, (c) may develop increasing levels of tolerance and (d) may suffer serious physical and psychological symptoms upon withdrawal (McKeon *et al.*, 2008). Its causation and pathophysiology remain largely unclear, but are known to be multifactorial (Moussas *et al.*, 2009). Alcohol addiction may be at least partially under the influence of genetic (Stacey *et al.*, 2009) and environmental interactions with alcohol consumption (van der Zwaluw and Engels, 2009) and may involve a number of neurotransmitters (Heinz *et al.*, 2009).

Chronic alcohol abuse may also have indirect implications for health. For example, there is evidence of increased alcohol mediated incidence of acute respiratory distress syndrome and severity of multiple organ dysfunctions in critically ill patients (Moss and Burnham, 2003; Boé *et al.*, 2009).

The individual physical and psychiatric consequences associated with alcohol dependence syndrome are described in the appropriate sections within this chapter.

Cardiovascular Complications

The association between alcohol and cardiovascular health detriment or benefit is particularly complex and may depend on the balance between antioxidant and prooxidant status and its relative contribution to the development of atherosclerosis (Puddey *et al.*, 2003). Although low to moderate levels of alcohol consumption appear to be of some cardiovascular benefit, there is little to question that excessive amounts have truly detrimental effects, the severity of which worsen with increasing alcohol intake in an essentially dose-related manner (Gurr, 1996). However, there is even debate as to whether or not alcoholic beverages do actually provide any true cardioprotective effects at all (e.g. Fuchs and Chambless, 2007) as there are methodological issues that may confound the validity of many of these studies. Evidence that low to moderate alcohol consumption is relatively cardioprotective and that, above a certain point, increased levels of alcoholic beverage consumption significantly raise the risk of cardiovascular morbidity and mortality, is predominantly taken from epidemiological studies, some of which present quite strong associative evidence, but are not conclusive of causation, as the relationship of alcohol and health is so complex (e.g. Mukamal, 2007). Clearly alcohol should never be recommended as a substitute to lifestyle and other therapeutic agents (Vogel, 2002) based on epidemiological evidence alone. Ideally randomized controlled trials are needed to confirm whether or not alcohol is actually the predominant causative agent per se, or if alternative etiological factors are central to cardiovascular health detriment or benefit, such as the by-products of alcohol catabolism, the other constituents of alcoholic beverages or the pattern of consumption (O'Keefe *et al.*, 2007). As such studies may be extremely difficult and unethical to undertake in humans as serious harm may be inevitable, animal models are often used to suggest both causation and possible mechanisms of action (e.g. Zhang *et al.*, 2004), but findings in animal models may not be entirely appropriate to the human condition. Therefore, in order to build a complete picture of how alcohol impacts on human health, a number of different, but integrated, approaches are needed (Lucas *et al.*, 2005). Possible benefits of alcohol per se on cardiovascular health and other components of alcoholic beverages are discussed in the next section (Section 5.6.3).

Metabolic challenges created by both greater acute and chronic alcohol intake clearly predispose to cardiovascular exacerbations (Kawano, 2010), including cardiac arrhythmias, cardiomyopathy, vascular hypertension and coronary heart disease, with the particular disease presentation determined by the relative amount and pattern of alcohol consumption and length of time of exposure (see general text of Morgan and Ritson, 2003). The heart itself is acutely affected by excessive alcohol intake which causes reduced physiological function through diverse origins involving alcohol and many of the metabolic products of alcohol catabolism, particularly acetaldehyde (Ren and Wold, 2008). Chronic alcohol use may cause cardiac myopathy characterized by feelings of fatigue and breathlessness in the first instance, which may alleviate on abstinence, otherwise it may exacerbate as arrhythmias, cardiomegaly, dysfunction of cardiac myofibrillar architecture and contractility, and also as hemorrhagic stroke, noncoronary artery disease related heart failure, edema and increased venous pressures, and other symptoms of heart failure with continued alcohol abuse (Klatsky, 2009; 2010).

Increases in systolic and diastolic blood pressure, or hypertension, are associated with alcohol intake, again in a dose related manner and dependent on individual (e.g. male versus female) and population (e.g. Asian men) characteristics (Taylor *et al.*, 2009), although definitive mechanisms have not yet been fully identified (Klatsky and Gunderson, 2008). Hypertension may be caused, at least in part, by vascular endothelial dysfunction mediated through alcohol induced oxidative stress, insulin resistance and increased lipoproteins (Bau *et al.*, 2007). Chronic heavy drinking apparently leads to a higher risk of hemorrhagic stroke, but not of ischemic stroke generally (Klatsky, 2007), although again this is complicated because a number of factors have been implicated with risk of stroke and there are disparate outcomes in terms of the different subdivisions of ischaemic and hemorrhagic stroke that may present due to differential amounts and patterns of alcohol consumption (Klatsky, 2005). Although high density lipoprotein cholesterol (HDL-C) levels are increased by alcohol intake, this purported cardiovascular risk benefit observed in many other situations is offset by raised low density lipoprotein cholesterol (LDL-C) levels and particularly by increased concentrations of serum triglycerides (Böhm *et al.*, 2004; McBride, 2008). Also, platelet aggregation, which may be decreased by low intakes (Ruf, 2004) is increased by chronic alcohol consumption (Böhm *et al.*, 2004).

Drug/Alcohol Interactions (Pharmaceuticals and Drug Abuse)

There are multifarious interactions of drugs and alcohol that may have differential implications for drug efficacy and health sequelae according to whether or not alcohol intake is concurrent and is acutely excessive or chronically abused (Weathermon and Crabb, 1999). For a very informative but general perspective, see Morgan and Ritson (2003, pages 48–50). Older adults may be particularly vulnerable to such interactions as there is increased usage of drugs and there may be complications with compliance (Adams, 1995; Moore *et al.*, 2007).

In the first instance, drug ingestion may be limited because of poor compliance, anorexia or vomiting and the presence of alcohol in the gut may interfere with absorption of drugs, physically limiting or even enhancing the amounts available to target tissues (e.g. Lennernäs, 2009).

Alcohol and its products may reduce the capacity of the body to detoxify certain pharmaceuticals and xenobiotics, e.g. through various detrimental interactions with cytochrome P450 (CYP2E1) during catabolism of alcohol through the microsomal ethanol oxidizing system (MEOS; Leiber, 2000). Efficacy of prescription drugs may be also inhibited by alcohol through competition at the site of action and other actions such as compromising lipid membranes and the enzymes of some biochemical pathways.

The interactions of alcohol and drugs may be additive or each may potentiate the effects of the other. For example, alcohol taken in addition to particular drugs, such as sedatives and some analgesics, may cause drowsiness and so there may be increased risk in the operation of machinery and driving etc. The toxic effects of some drugs may be exacerbated by alcohol, causing local lesions in the gut and liver, for example.

Alternatively, some drugs may inhibit the enzymes responsible for alcohol catabolism leading to significant build up of the toxic product, acetaldehyde.

As well as alcohol itself, alcoholic beverages also contain additional components that are likely to interact with drugs, potentially modifying their efficacy, including antioxidants (possible actions on CYP2E1 and the redox system), tyramine (acts on monoamine oxidase inhibitors producing hypertension) and other constituents of red wines and beers, such as congeners (e.g. Jang and Harris, 2007).

Gastrointestinal Disorders

Excessive alcohol intake has many acute and chronic effects throughout the gastrointestinal tract, impairing its ability to digest and absorb nutrients which may initiate a cyclical progression of further damage to the functional reserve and regenerative capacity of the gastrointestinal tract, which exacerbates malnutrition even further (Rajendram and Preedy, 2005). Alcohol related mucosal damage may also predispose to malignancy, especially if associated with smoking (Pelucchi *et al.*, 2006; Seitz and Cho, 2009). Although alcohol is not carcinogenic, or at least has very low carcinogenicity, its toxic metabolite, acetaldehyde, is a purported carcinogen, as it forms adducts with DNA potentially causing cancers, such as those of the gastrointestinal tract (Seitz and Meier, 2007; and see 'Malignancies,' below).

Chronic alcohol abuse may lead to alcoholic liver disease, often in association with other liver lesions and hepatitis C (Wakim-Fleming and Mullen, 2005), with the resultant increase in portal pressures eventually leading to esophageal varices, a life threatening condition requiring immediate and effective management (Garcia-Pagan *et al.*, 2008).

Alcohol stimulates gastric acid secretions and impairs sphincter pressures and esophageal peristalsis causing gastroesophageal reflux with consequent esophageal mucosal damage, including esophagitis, mucosal ulceration and Barrett's Syndrome (an epithelial metaplasia). Such changes are partly due to the alcohol itself and occur irrespective of the type or amount of beverage involved (Bujanda, 2000), in large part because of the acid and gastrin present in the reflux. Animal models suggest that alcohol sensitizes the esophageal mucosa to damage via changes in epithelial transport, intercellular junction disorder and weakening of the mucosal barrier, all of which permit hydrogen ion penetration of the mucosal barrier (Bor *et al.*, 1999). However, although animal models provide important information and pointers, they do not necessarily represent how human gastrointestinal systems respond to alcohol (Siegmund *et al.*, 2005). In extreme cases, severe vomiting can cause tearing of the distal part of the esophagus, known as Mallory–Weiss syndrome, which presents in a majority of alcoholic patients who have consumed excessive quantities of ethanol in the hours preceding examination (Bujanda, 2000).

Even in less extreme cases, there may be increased secretion of gastrin and gastric acid, which is partially associated with the nature of beverage consumed. Fermented drinks (beer, cider, wine, etc.) appear to stimulate gastric acid and gastrin release, whereas distilled beverages apparently do not (Teyssen *et al.*, 1997). It has been suggested that small acidic and carbohydrate molecules, such as succinic and maleic acids, may be more potent gastric stimulants than ethanol (Teyssen *et al.*, 1999). Such molecules are found in far greater amounts in fermented than in distilled beverages.

Gastric emptying is also affected by intake of alcoholic beverages, although differentially according to amount and type consumed. Low alcohol concentrations facilitate gastric emptying, whereas it is delayed by high alcohol concentrations, and fermented beverages accelerate gastric emptying (see Bujanda, 2000). Acute and chronic gastritis, in large part a result of increased acid secretion in the stomach, are common amongst heavy drinkers, especially alcoholics, and gastric and duodenal lesions caused by alcohol appear to be dose related (Knoll *et al*., 1998). Although consumption of alcohol itself has been implicated in gastric ulcer, this link is considered tenuous, and there now appears to be no association between excessive alcoholic beverage consumption and the incidence of gastric ulcers (Bujanda, 2000).

Acute and chronic alcohol consumption affects bowel motility, prolonging overall transit time, because it impairs contractile protein, vagal nerve and neuroendocrine functions, with orocecal transit time very much higher (156 min) in alcoholics compared to social drinkers (94 min) and abstainers (86 mins). Greater exposure to toxins is thought to be a factor in the development of malignancies in the lower bowel, and associated with lower levels in alcoholics of the protective agent *S*-adenosylmethionione, although the causes are multifactorial and complex (Bujanda, 2000). The lower bowel is also prone to hemorrhoids and colon varicosities due to cirrhosis and increased portal tension.

Other intestinal disorders observed in heavy drinkers (especially alcoholics) include diarrhea and malabsorption of nutrients, caused by alcohol induced changes in the digestion and absorption of food. Excessive alcohol intake probably decreases the activity of mucosal disaccharides and increases mucosal permeability, facilitating the output of water and saline solutes, giving rise to diarrhea. Malabsorption occurs in heavy drinkers, even those on an otherwise healthy diet, because impaired intestinal absorption processes cause lower uptake of many nutrients, including amino acids, mineral such as calcium, iron and zinc, and vitamins B_{12} and thiamine, for example. The comprehensive review by Bujanda (2000) provides greater details in perspective of the effects of alcoholic beverage consumption on gastrointestinal health and secondary malnutrition.

Hepatic (Liver) Disease

Excessive consumption of alcohol can lead to various lesions in the liver (Adachi and Brenner, 2005) and it is one of the leading causes of liver disease and liver disease mortality worldwide, already well established in developed countries and with increasing incidence in the developing world (Albano, 2008). Men whose intake is, on average, more than 7 or 8 units (about 60 g) of alcohol daily (a unit is 8 g or 10 ml of pure alcohol) and women drinking more than 5 units (40 g) a day are more likely to develop alcoholic liver disease than low to moderate drinkers. Clinical presentations of alcohol related hepatitis include jaundice, enlarged liver and fluid retention. Men, in particular, with mild to moderate disease may recover fully upon abstinence from alcohol. Severe alcoholic hepatitis is likely to progress to cirrhosis, more especially in women, with the development of hepatocellular failure and portal hypertension with a number of associated conditions, especially some blood coagulation and vascular disorders and hepatic encephalopathy (dysfunction of the brain – confusion, low levels of consciousness, etc.). Alcoholic liver disease is also implicated in the dysfunction of other systems, the innate and adaptive immune responses (Nath and Szabo, 2009), for example. Of those who develop cirrhosis, some will go on to acquire carcinoma of the liver (McKillop and Schrum, 2009). Overall, with continued use and abuse of alcohol, the prognosis for those with alcoholic liver disease, especially hepatocellular carcinoma, is poor. The progression of alcoholic liver disease and clinical signs of the various stages of its exacerbation are well summarized by Morgan and Ritson (2003) and are described in more detail by Lucey *et al.* (2009).

There are a number of key factors that contribute to alcoholic liver disease pathogenesis which is complex at the biochemical, cellular and organ levels and its etiology extends beyond simple malnutrition (Lieber, 2004; Albano, 2008). For example, alcohol readily induces oxidative stress through a number of pathways, particularly involving CYP2E1, threatening liver function (Cederbaum *et al.*, 2009). Alcohol is toxic to the liver predominantly because of its conversion to the primary catabolic product, acetaldehyde, which is a known carcinogen. Degradation processes involving alcohol dehydrogenase (oxidation of alcohol to acetaldehyde) generate NADH, the reduced form of NAD, which promotes fatty acid synthesis leading to steatosis, the abnormal build up of lipids in liver cells, and collagen synthesis through the increased production of lactate from pyruvate, amongst other factors. Alternatively, if activity of the cytochrome CYP2E1 (MEOS) is induced, there is build up of highly reactive oxygen species or free radicals that cause peroxidation of lipids

and cell membrane lesions, amongst other significant examples of the potential damage of oxidative stress created by excessive alcohol intake (Lieber, 2004; Albano, 2006; Cederbaum *et al.*, 2009). Oxidative stress is also evident in the mitochondria because the key reducing agent, reduced glutathione, is also oxidized through binding to acetaldehyde (Lieber, 2004). These events, alongside other proinflammatory events, lead to the inflammation, necrosis and fibrosis that are associated with alcoholic liver disease progression and may result in cirrhosis for a significant proportion of affected individuals.

Alcohol impairs the metabolism of methionine at various points, most critically methionine synthase which is a key in homocysteine remethylation. Excessive use of alcohol appears to reduce levels of *S*-adenosylmethionine and increase levels of *S*-adenosylhomocysteine and homocysteine, which are toxic, potentially causing severe impairment of liver function (Kharbanda, 2009). Significant health implications of this include increased fat deposition, apoptosis, damage to key hepatic proteins and oxidative stress, which progressively lead to such impairment.

Alternative pathways also exist for the detrimental effects of alcohol on liver function, some of which contribute to activation of hepatic stellate cells which is a central element in the development of fibrosis (Cubero *et al.*, 2009). This mechanism is thought to involve the liver–gut axis because elevated plasma endotoxins, derived due to reduced gut patency, cause inflammatory and innate immune responses in Kupffer cells via Toll-like receptors, among a number of other purported pathways (Nagata *et al.*, 2007; Szabo and Bala, 2010). Hepatic protein dynamics are also known to be modified by alcohol, with two mechanisms of trafficking identified (Shepard *et al.*, 2010a), and liver proteins are susceptible to hyperacetylation (Shepard *et al.*, 2010b). Other complex biomolecular pathways contributing to alcoholic liver disease have been suggested (e.g. Purohit *et al.*, 2009).

Hepatocellular carcinoma is associated with progressive liver disease (McKillop and Schrum, 2009) and synergisms that exist between alcoholic liver disease and hepatitis C are considered to increase the risk of hepatocellular carcinoma pathogenesis and mortality rates (Morgan and Ritson, 2003, page 18; Mueller *et al.*, 2009).

There are similarities in the etiology of other alcohol related conditions, such as cardiovascular diseases or cancers, in that the pathogenesis and extent of alcoholic liver disease and its possible progression to hepatocellular carcinoma may also be modified by differential responses to alcohol and its metabolites, due to variable genetic and epigenetic origins (Juran and Lazaridis, 2006; Wilfred de Alwis and Day, 2007). Polymorphisms in alcohol dehydrogenase, aldehyde dehydrogenase and CYP2E1, involved in alcohol catabolism itself, and enzymes involved in the metabolism of folate have been implicated (Druesne-Pecollo *et al.*, 2009). As well genetic predisposition to hepatic carcinoma, epigenetic alterations in DNA, including methylation, also occur, causing malignant changes, but these are less well understood (e.g. Herath *et al.*, 2006; Nishida, 2010).

Hypersensitivity, Allergy and Autoimmune Responses

Certain alcoholic beverages may have constituents implicated in some specific and nonspecific hypersensitivity, allergic or autoimmune reactions, including alcohol per se. Biogenic amines and polyamines in wines and beers may cause allergic reactions including asthma (Kalac and Krizek, 2003; Vally and Thompson, 2003; Ancín-Azpilicueta *et al.*, 2008), although some controversy exists as to their purported role in intolerance (Jansen *et al.*, 2003). The antigens gluten (wheat) and hordein (barley) that are in some alcoholic beverages, particularly beers, may exacerbate existing celiac disease (Ellis *et al.*, 1990; Dostálek *et al.*, 2006). Alcoholic beverages may induce the symptoms of irritable bowel syndrome (MacDermott, 2007), urticaria and anaphyloid reactions due to alcohol itself and many other, nonspecified, constituents (Ehlers *et al.*, 2002; Gonzalez-Quintela *et al.*, 2004).

Hyperuricaemia

Gout, the most common form of inflammatory arthritis in men, has long been at least anecdotally associated with chronic heavy alcohol consumption; hence, the stereotypical image of the aged, port drinking, retired colonel in a wheelchair with one foot heavily bandaged. Epidemiological studies have implicated alcohol consumption in hyperuricaemia (Choi *et al.*, 2004), possibly in a dose related manner, which in certain conditions leads to the painful condition known as gout. Integral to nucleic acids, the purines, guanine and adenine, are produced when the yeast culture grows during fermentation. Also, purines in their phosphorylated form (ATP, GTP) are important sources of energy generation for driving cellular reactions. Ingestion of high levels of exogenous purines perhaps from particular alcoholic beverages is implicated in hyperuricaemia because the catabolism of adenine and guanine proceeds, via xanthine, producing uric acid. Under certain conditions, hyperuricaemia may lead to gout, where uric acid crystals are deposited on joint surfaces and in other tissues. Alcohol per se is also purported to increase blood levels of uric acid, by promoting increased degradation of adenine and increased production of lactate (Yamamoto *et al.*, 2005). Beers are more heavily implicated in increased risk of gout than wines, partly because of their greater purine content, but spirits with negligible purine contents also raise urate (wine is considered to be a possible protective factor in some quarters).

Hypoglycaemia

Changes in intermediary metabolism caused by excess alcohol intake may result in lowered blood glucose concentrations, or hypoglycaemia. Both gluconeogenosis and glycogenolysis are inhibited by alcohol, which has particular implications if alcohol is consumed without food and in conditions in which glycogen levels are low, for example after very heavy exercise programs or sports. Alcohol is also known to increase insulin sensitivity, possibly lowering blood glucose even further. Potentially, there are significantly greater implications of excessive alcohol intake for people with diabetes (van de Wiel, 2004).

Malignancies

Excessive chronic alcohol consumption has been linked to a number of cancers, including those of the upper digestive tract and airways, although the relative risks and mechanisms may vary considerably, depending on location; the strongest associations appear to be between level of alcohol intake and cancers of mouth, pharynx, larynx and esophagus, with lower, but still significant, risks for stomach, colorectal, liver, breast and ovarian cancers (Bagnardi *et al.*, 2001; Pöschl and Seitz, 2004; Boffetta and Hashibe, 2006; Seitz and Becker, 2007; Seitz and Stickel, 2007). Alcohol (ethanol) per se does not appear to be directly carcinogenic, although it predisposes to malignancy, particularly in association with smoking (Pöschl *et al.*, 2004; Salaspuro and Salaspuro, 2004; Pelucchi *et al.*, 2006; Seitz and Cho, 2009). However, alcohol does have carcinogenic potential, as it can inhibit normal DNA methylation and modulate retinoid metabolism (Morgan *et al.*, 2004; Seizt and Stickel, 2007). In concentrations greater than about 20%, alcohol per se may cause local injuries to mucous membranes, leading to accelerated cell division and regeneration (hyperproliferation) that may ultimately lead to replication errors during DNA synthesis resulting in genetic changes, such as dysplasia and leukoplacia and carcinogenesis, which may be particularly significant in the pathogenesis of mouth (Ogden, 2005) and throat cancers (Riedel *et al.*, 2005) and esophageal and gastroesophageal cancers (Franke *et al.*, 2005), with gastric reflux also implicated (Pera *et al.*, 2005).

However, the primary catabolic product of alcohol, acetaldehyde, has been heavily implicated in carcinogenesis and mutagenesis, as have CYP2E1 derived reactive oxygen species through alcohol catabolism (Pöschl *et al.*, 2004), and acetaldehyde poses an independent risk as it is a natural constituent of many alcoholic

beverages (Lachenmeier *et al.*, 2009), notably hot Calvados as an interesting example (Linderborg *et al.*, 2008), and may be a direct carcinogen in some particularly vulnerable tissues and organs, according to cumulative exposures from environment and individual genetic and behavioral traits (Salaspuro, 2009). Acetaldehyde is usually broken down to acetic acid by acetaldehyde dehydrogenase. However, in many individuals the relative rate of this conversion may be limited, either because of reduced levels of the enzyme or reduced enzymatic capacity due to altered structure resulting from different genetic polymorphisms. Acetaldehyde may then accumulate, increasing carcinogenic potential. Mitochondrial type II alcohol dehydrogenase (ALDH2) is responsible for most acetaldehyde oxidation, but some Asian populations, including about 50% of Japanese, possess a hereditary deficiency in this enzyme. Although the symptoms of high levels of acetaldehyde are extremely unpleasant and may deter people from excessive alcohol consumption, a number of people with some such polymorphisms may become alcoholics. Indeed, epidemiological studies have shown that amongst Asian heavy drinkers, the risk of alcohol related cancers of the aerodigestive tract may be much increased in those with ALDH2 deficiency (Salaspuro, 2007; Asakage *et al.*, 2007).

The relative risks of developing cancer for chronic heavy alcohol consumers may be further increased for a variety of independent reasons with some possible overlap between them. Firstly, high consumption of particular alcoholic beverages may increase the likelihood of exposure to certain carcinogens, such as the possible presence in the finished beverage of congeners, mycotoxins (see Section 5.11.4), additives (Chapter 5.9), uncontrolled pesticide residues (Section 5.10.2) etc. Secondly, smoking and poor oral hygiene is often associated with alcohol abuse leading to increased exposure to acetaldehyde (Salaspuro, 2009). Thirdly, malnutrition may occur in excessive drinkers because of poor dietary practices and/or alcohol induced changes in digestion, absorption, assimilation and metabolism of key nutrients. Dietary deficiencies have been implicated in the pathogenesis of malignant diseases because DNA damage is not then preventable (e.g. Ames and Wakimoto, 2002). Some of these key nutrients, particularly those with antioxidant potential, such as certain vitamins, minerals and polyphenols, may be protective against the pathogenesis of cancer because they modulate the carcinogenicity of highly reactive free radicals, such as superoxide, peroxide and hydroxyl (see section 5.8.1), many of which may be derived from catabolism of alcohol via CYP2E1, from smoking or directly as constituents of the particular beverage concerned.

Long-term high daily levels of alcohol consumption increase the risk of hepatocellular carcinoma, with exposure to alcohol of greater than 10 years and in excess of 80 g daily leading to a fivefold increase in risk (Morgan *et al.*, 2004; McKillop and Schrum, 2009). However, alcohol consumption is only one factor contributing to the different potential mechanisms in the pathogenesis of liver carcinoma (Herath *et al.*, 2006).

Organs of the upper aerodigestive tract are particularly vulnerable to cancers due to cumulative environmental and individual behavioral exposures to acetaldehyde, as well as alcoholic beverage consumption, such as poor oral hygiene, smoking and its presence in a number of food sources (Salaspuro and Salaspuro, 2004; Salaspuro, 2009). Although relatively lower for lung cancer than other cancers, there is some suggestion that the alcohol related risk of lung cancer is differentially associated with the type of alcoholic beverage and amount consumed, but the link is not certain and is confounded substantially by smoking, and modest wine consumption may actually be protective in some way (Chao, 2007; Chao *et al.*, 2008).

Meta-analysis points to a relatively small positive association between alcohol intake and incidence of breast cancer (Collaborative Group on Hormonal Factors in Breast Cancer, 2002) with a possible modulation of risk attributable to estrogen (Seitz and Maurer, 2007).

Malnutrition

Optimum nutritional status is an important mediator of the risk to health posed by excessive alcohol intake. Certain key nutrients (e.g. vitamins, minerals, polyphenols) are considered to be required as protective agents

against the detrimental effects of the toxic (e.g pesticides, methanol), carcinogenic (e.g. acetaldehyde) and highly reactive oxidation catabolic products (e.g. peroxides, superoxides, hydroxyl) that are due to alcohol consumption. However, excessive long-term alcohol consumption may result in malnutrition either through reduced dietary intake of essential nutrients or by the direct effects of alcohol and its by-products on nutrient absorption and metabolism. Detailed information on alcohol consumption and its effects nutrition can be found throughout the rest of this chapter with relevant references.

Metabolic Syndrome

Although it is not a discrete disease as such, the metabolic syndrome is a multifactorial condition associated with the development of serious noncommunicable chronic diseases, such as type 2 diabetes and cardiovascular disease. Metabolic syndrome is generally characterized by central obesity with various presentations of dyslipidaemia (increased blood triglyceride levels and reduced HDL-C levels), hypertension, raised fasting blood glucose levels and possible microalbuminuria. The underlying mechanisms are uncertain, but insulin resistance is heavily implicated. Although low to moderate alcohol intake may lower insulin resistance and the prevalence of metabolic syndrome (Alkerwi *et al.*, 2009), consumption in excess of recommendations may contribute to some of the specific components of the metabolic syndrome and its disease exacerbations, with suggestions that genetic–environmental interactions with alcohol (Corella, 2007) and pattern of drinking (Athyros *et al.*, 2007/8; Fan *et al.*, 2008) may have significant impact either way.

Methanol and Higher Alcohol Toxicity

Methanol, which is found in most alcoholic beverages in varying, but relatively low amounts, is not usually a major threat to health, as such, although the consequences may be acutely debilitating, perhaps causing headache and vomiting etc. However, it is extremely toxic and is catabolized to formaldehyde which is particularly toxic, and formaldehyde is then converted to another highly toxic intermediary, formic acid, which eventually is further broken down to nontoxic products or excreted. These toxic intermediary metabolites lead to high anion gap metabolic acidosis, increased osmolality, cellular and organ dysfunction, particularly neurologic, cardiopulmonary and renal (Jammalamadaka and Raissi, 2010). Methanol and higher alcohols may be concentrated during illegal distillation, and its ingestion may lead to blindness and even death. Along with certain higher alcohols and other toxic constituents, methanol may also be present in surrogate alcohols used by alcoholics and the risk of ingestion may be higher in communities where use of illegally produced alcohol is in more common practice, in some parts of Russia for example (Lachenmeier *et al.*, 2007).

Muscle

Alcohol consumption has major implications for both cardiac and skeletal muscle (Preedy *et al.*, 1999; Urbano-Márquez and Fernandez-Solá, 2004). Cardiac muscle may be susceptible to cardiomyopathy, characterized by progressive left ventricular dysfunction and arrythmias, arising from both acute and chronic alcohol excesses, increasing the spectrum of cardiovascular complications (Urbano-Márquez and Fernandez-Solá, 2004; and see 'Cardiovascular' section above). Likewise, skeletal muscle is susceptible to structural and functional myopathy due to acute and chronic alcohol abuse, with the extent of damage being dose dependent and the pathogenesis multifactorial, involving impaired myofibrillar protein synthesis, with perturbations of gene expression being heavily implicated, oxidative stresses, induced apoptosis and aberrant biomembranes (Adachi *et al.*, 2003; Urbano-Márquez and Fernandez-Solá, 2004; Fernandez-Solá *et al.*, 2007). Acetaldehyde has also been implicated in alcoholic myopathy (Preedy *et al.*, 2007).

Binge drinking may cause acute episodes of pain (myalgia), swelling and weakness in muscles, and more severe acute binge drinking may lead to rhabdomyolysis, with the associated myoglobinuria possibly causing renal tubular necrosis and kidney failure. Chronic myopathy is a muscle wasting condition caused by long-term excessive alcohol consumption, with progressive muscle weakness (see Morgan and Ritson, 2003).

Nervous System and Psychological Disorders

The variable neurological responses to acute alcohol intoxication are determined by a number of factors, including how quickly blood glucose levels rise and the extent of tolerance that might be developed. As intoxication builds, at relatively low levels there may be differential responses due to associated social interactions possibly causing relaxation, elation and effusive behavior in congenial surroundings, but depression and feelings of isolation, and the beginnings of aggressive and violent behavior in more hostile settings. As higher levels of intoxication develop, control of physical processes is gradually lost with reduction of stability, speech is slurred, there is increased risk taking as reasoning is prejudiced, drowsiness occurs and, depending on the individual, various responses may follow from jocularity to aggression, violence and paranoia (see Morgan and Ritson, 2003, pages 43–44). At least partial loss of memory of specific events during acute intoxication appears to be quite common.

Acute alcohol intoxication may have particular problems in adolescents, as the young may be less tolerant of its psychological and physiological effects. Alcohol consumption in adolescence may have greater significance as the brain and nervous system are still developing and, therefore, are more vulnerable to the toxic effects of alcohol, and some chronic nervous system dysfunctions and behavioral impairments may exacerbate more readily with alcohol consumption in this age-group (Guerri and Pascual, 2010).

Chronic excessive alcohol intake has long been associated with a number of disorders of the central nervous system (Charness, 1993; Greenberg and Lee, 2001), including alcoholic dementia, cerebellar degeneration, Wernicke–Korsakoff syndrome, Marchiafava–Bignami syndrome and central pontine myelinolysis, as well as possible brain damage from cerebrovascular events (e.g. accidents and hemorrhagic stroke), and peripheral neuropathy. Hepatic encephalopathy (dysfunction of the brain – confusion, impaired consciousness) is at least partially the result of alcoholic liver disease (see above). Contrary to common belief, excessive alcohol consumers and alcoholics with no overt clinical signs of neuropathology or hepatopathology may have some regional brain and cognitive impairment (Harper and Matsumoto, 2005; Oscar-Berman and Marinković, 2007; Harper, 2009).

Alcoholic dementia may occur in long-term excessive alcohol intake and is characterized by cognitive impairment with the possibility of slightly marred intellect, but the exact mechanism and level of impairment for the diagnosis is still uncertain (Hulse *et al.*, 2005). It is associated with heavy drinking (Letenneur, 2004) and may present with physical signs of cortical and cerebral white matter atrophy. However, there is some suggestion that alcohol may not have an associated increased risk of dementia (Anstey *et al.*, 2009) and may even have some protective value at low levels of intake (Letenneur, 2004; Peters *et al.*, 2008; Pinder, 2009) (see also Section 5.6.3).

Cerebellar dysfunction due to chronic alcohol consumption is characterized by reduced motor control (movement and balance) and a wide spectrum of neuropsychological impairments (Fitzpatrick *et al.*, 2008) with a number of possible causative mechanisms implicated (Jaatinen and Rintala, 2008), including thiamine deficiency (Mulholland, 2006). Thiamine deficiency associated with chronic alcohol abuse is also heavily implicated in Wernicke–Korsakoff syndrome, although the origins of Wernicke–Korsakoff syndrome may be multifactorial, and which is characterized by Wernicke's encephalopathy, consisting of confusion, eye indications and ataxia, and Korsakoff's psychosis; amnesia with severely impaired retrograde and anterograde memory (Morgan and Ritson, 2003, pages 20–21). Central pontine myelinolysis and Marchiafava–Bignami syndrome are quite rare (see Morgan and Ritson, 2003, page 21).

There are significant psychological symptoms associated with the alcohol withdrawal syndrome (see below).

Osteoporosis and Trauma: Bone Fracture Risk

Bone fractures are associated with acute excess alcohol intake due to both accidents and violent intentional injury. Although moderate alcohol consumption is associated with lower risk of hip fracture, chronic alcohol usage may lead to low bone density, osteopenia and osteoporosis, which increase the risk of bone fracture (Mukamal *et al.*, 2007; Berg *et al.*, 2008) and delays in fracture repair (Chakkalakal, 2005). Alcohol has a toxic dose dependent effect on osteoblast activity, suppressing differentiation and promoting adipogenesis, reducing the rate of bone remodeling, and in fracture, alcohol prevents synthesis of an ossifiable matrix slowing repair (Chakkalakal, 2005). The catabolism of alcohol produces highly reactive oxygen species which have been implicated in skeletal pathologies, including impaired bone remodeling (Banfi *et al.*, 2008).

Pancreatic Disease

Causative mechanisms leading to the development of alcohol related pancreatitis remain obscure (Schneider and Singer, 2005) partly because the susceptibility of individuals varies enormously with some low to moderate drinkers developing this condition, although there is evidence of a dose related risk of alcohol consumption on pancreatitis (Irving *et al.*, 2009). Also, particular constituents found in certain alcoholic beverages may have differential health benefits and detriments (Feick *et al.*, 2007). Acute inflammation episodes are characterized by pancreatic endocrine and exocrine insufficiencies, which may lead to malabsorption of key nutrients, jaundice and diabetes, and other severe metabolic disturbances and circulatory failure (Morgan and Ritson, 2003, page 18).

Poisoning

Acute ingestion of alcohol may result in intoxication when blood levels reach 1.8 g/l (0.18%, 180 mg/dl) and stupor and coma at 3.5 g/l (0.35%, 350 mg/dl), with death occurring from alcohol poisoning at when concentrations reach 4.5 g/l (0.45%, 450 mg/dl) in about half of all individuals so affected. This potentially fatal concentration is equivalent to 5–8 g/kg body weight in adults and 3 g/kg body weight in children, depending on fatness, at least in part. Extreme intoxication leads to severe hypoglycaemia, hypokalaemia, convulsions, metabolic acidosis, respiratory depression, possible cardiac arrythmias and then death; see the website of Southend NHS (http://www.southend.nhs.uk) for concise summary information.

Psychological Disorders and Social Consequences

Psychological disturbances occurring with excessive long term alcohol consumption may include depression, anxiety and psychosis, amongst others, and these may have social implications for interpersonal relationships and work attendance and performance, and they may often result in antisocial and criminal behavior, depending on the interplay of a number of factors (Morgan and Ritson, 2003, pages 30–32).

Excessive drinking and psychological disorders can have a significant bearing on family inter-relationships, and, conversely, family matters can affect the level of alcohol use and abuse, with serious implications for the development and wellbeing of children (Leonard and Elden, 2007).

Respiratory System

Pneumonia may develop through aspiration during acute intoxication. Excessive alcohol exposure has been associated with airway function pathobiology (Boé *et al.*, 2009), but its significance is not completely certain (Sisson, 2007) and there are potential health benefits and detriments from the nonalcohol constituents of alcoholic beverages (e.g. Kamholz, 2006).

Sexual Exacerbations, Infertility and Fetal Disorders

Reproductive capacity can be significantly reduced by acute and chronic alcohol intake. In men, alcohol has adverse effects on the hypothalamus, anterior pituitary gland and Leydig cells of the testes (Emanuele and Emanuele, 1998). In women, alcohol may reduce fertility, increase the risk of spontaneous abortion, produce menstrual perturbations and increase the risk of fetal harm (Bradley *et al.*, 1998). Even with moderate alcohol consumption there are differential effects on levels of various hormones (Gill, 2000). Indeed, excessive beer consumption appears to have a particular reproductive impact in both men and women, possibly due to certain estrogenic constituents of hops (e.g. Milligan *et al.*, 2000), and in lactating women beer drinking appears to impair milk production and motor functions of infants (Mennella, 2001; Rayburn, 2000).

Although there is still uncertainty as to whether or not moderate prenatal alcohol consumption has adverse outcomes in pregnancy (Henderson *et al.*, 2007), the evidence is strong that excessive intake, including binge drinking that extends into very early unrecognized pregnancy, may be detrimental to fetal development with concomitant life long impairments of physical and mental function (Jones *et al.*, 2006; Guerrini *et al.*, 2009). Throughout pregnancy, but particularly at 4-10 weeks, alcohol has serious implications for the developing fetus, with fetal alcohol spectrum disorder and the more serious fetal alcohol syndrome presenting at various levels of intake (Mukherjee *et al.*, 2006; Guerrini *et al.*, 2009). However, there is still some uncertainty concerning the exact amounts and patterns of intake required to produce specific symptoms, but, importantly, certain pregnancies appear to be more vulnerable to alcohol toxicity with serious fetal symptoms possibly developing even with low to moderate intakes (Guerrini *et al.*, 2009). Fetal alcohol spectrum disorder essentially presents with neurobehavioral deficits and the worsening impairments of fetal alcohol syndrome include growth retardation, central nervous system disorders, congenital abnormalities and craniofacial abnormalities (Autti-Rämö, 2002). However, alcohol is also implicated in other disorders such as those of the kidney, liver and gastrointestinal tract (Hofer and Burd, 2009).

In many countries, although it is mandatory to include on the label of an alcoholic beverage a warning on the dangers of alcohol consumption specifically during pregnancy, there is a general lack of awareness, especially in the UK, of the serious harm that alcohol can do to the fetus (Mukherjee *et al.*, 2006; Guerrini *et al.*, 2009).

Skin Disorders

Alcohol abuse, even at its early stages, may manifest as many diverse skin lesions or may exacerbate others (see Morgan and Ritson, 2003, page 22), and some are associated with the development and progression of liver disease (Ghosn and Kibbi, 2008); alcohol related skin lesions include spider naevi, linear telangiectasia, discoid eczema, acne rosacea, psoriasis and seborrhoeic dermatitis, with increased risk of infective skin diseases (Higgins and du Vivier, 1994; Smith and Fenske, 2000; Kostović and Lipozencić, 2004).

Withdrawal

The presentation of psychological and physical symptoms associated with the alcohol withdrawal syndrome is uncertain and may be anything from mild to severe, with variable outcomes from insomnia through to seizures and delirium tremens (McKeon *et al.*, 2008). Pharmacologic treatments are generally symptom based and are cross tolerant with alcohol, and such patients also need personalized, psychological and environmental support (Anonymous, 2007).

5.6.3 Possible Benefits of Low to Moderate Consumption of Alcoholic Beverages

So, evidently, consumption of alcoholic beverages has the potential for exacerbating a wide range of deleterious effects on health from transient minor injuries and lesions to very serious chronic harm and even death when consumed to excess (Table 5.1.1 of Section 5.1.2 and Section 5.6.2). However, alcoholic beverages do appear to have some health benefits as, for example, in the past and in some communities today, such beverages provide a relatively safe source of nutrients and especially water at times when alternative sources may be contaminated. Other particular health benefits appear to be associated with low to moderate alcohol consumption as shown by the 'j' or 'u' shaped pattern of relative risk with increasing intake, which shows that low to moderate intake levels present lower risk than either complete abstinence or higher intakes, especially those amounts ingested by excessive drinkers and alcoholics, in which morbidity and mortality rates are significantly increased (Gurr, 1996). Such epidemiological evidence is associative and, therefore, not conclusive of causation and so prospective and intervention trials, and mechanistic studies are required to confirm that there are tangible health benefits of low to moderate alcoholic beverage consumption (Freiberg and Samet, 2005; Collins *et al.*, 2009; Di Castelnuovo *et al.*, 2010). For example, it would be of value to identify mechanisms involved in neutralizing the detrimental effects of alcohol ingestion and its toxic catabolic intermediates, perhaps by the multitude of antioxidant constituents of particular beverages (e.g. Soleas *et al.*, 1997). However, the epidemiological evidence can still be considered a relatively strong foundation on which to base and test the premise that regular low to moderate alcohol consumption is causally linked to reduced risk of cardiovascular diseases; this is because the purported protective effect has been shown in several independent studies on different population groups (e.g. Yusuf *et al.*, 2004; Mukamal *et al.*, 2006; Beulens *et al.*, 2007; Djoussé and Gaziano, 2007), including type 2 diabetics (e.g. Koppes *et al.*, 2006).

Some of the health benefits of alcoholic beverage consumption may be due to the actions of alcohol per se, possibly as much through the psychological and social aspects of low to moderate drinking as any direct biochemical or physiological effect. However, regular low to moderate alcoholic beverage consumption may be associated with other more healthy lifestyles and dietary practices (Grønbaek, 2006) and, very often, the actual act of drinking may be conducted within a relaxing environment and convivial company. Alternatively, moderate alcohol consumption has been shown to increase plasma high density lipoprotein cholesterol levels relative to low density lipoprotein cholesterol, thereby essentially on balance preventing cholesterol deposition and plaque formation at arterial walls, and also to promote anticoagulant properties through direct effects on reducing platelet aggregation (Puddey *et al.*, 2003; Ruf, 2004). For example, a particular intervention of moderate wine consumption (Hansen *et al.*, 2005) showed an increase (11–16%) in fasting plasma high density lipoprotein cholesterol, with concurrent decrease (8–15%) in fasting fibrinogen, compared with water and red grape extract, although other indices of cardiovascular health did not change significantly, possibly because of a relatively short time frame (four weeks).

Although it appears that low to moderate alcohol consumption provides cardiovascular protection through a number of suggested mechanisms (Agarwal, 2002), including enhanced insulin sensitivity along with increase in blood high density lipoprotein cholesterol levels and improvements in atherosclerotic inflammatory

processes, conclusive characterization of cause and mechanisms is yet to be found (e.g. Freiberg and Samet, 2005). Low to moderate alcohol intake is associated with a decreased risk of developing type 2 diabetes (Koppes *et al.*, 2005; Djoussé *et al.*, 2007). Furthermore, moderate alcohol consumption (taken with food) has been shown to increase insulin sensitivity in established type 2 diabetics (Greenfield *et al.*, 2005) and in nondiabetics (van de Wiel, 2004). The mechanism of increased insulin sensitivity caused by moderate alcohol intake is not fully understood, but may involve a number of factors (Greenfield *et al.*, 2005). The anti-inflammatory effects of low to moderate alcohol consumption have been demonstrated (e.g. Collins *et al.*, 2009).

There is also some evidence from population based cohort and case control studies, conducted in several parts of the world and across genders and racial groups, that the moderate regular consumption of alcohol, particularly wine, is associated with a lower risk of developing dementia (Alzheimer's disease and vascular dementia) (Pinder, 2009).

It has been found that age related cognitive decline is lower in regular light drinkers and older drinkers with mild cognitive impairment (MCI) are less likely to progress to Alzheimer's disease than abstainers of similar age. Mechanisms for these possible neuroprotective effects are unknown at present, but the antioxidant and related properties of wine may be involved, although light consumption of wine appears to modify the neuropathology of Alzheimer's disease, especially with regard to the deposition of amyloid plaque.

The relative nutritional significance of different nutrients found in the multifarious alcoholic beverages available, and their possible beneficial synergisms, have been considered previously in the appropriate sections of this chapter. Although the effects of some of these nutrients are sufficient to be implicated in protective roles, others are not, and actual definitive biological effects have yet to be demonstrated (van de Wiel and de Lange, 2008). Many of the constituents of alcoholic beverages with antioxidant potential, such as some vitamins, minerals and phytochemicals (derivatives of plant metabolism; see Section 5.4.3, Chapter 5.8 and Section 5.11.2), may promote health in moderate consumers because they appear to collectively scavenge and neutralize the harmful highly reactive oxygen and nitrogen species, or free radicals (Puddey *et al.*, 2003; Suter, 2004). Although such free radicals occur endogenously during metabolic processes and exogenously with ingestion and assimilation of foods, they are also produced as the result of detoxification of alcohol itself (see Chapter 5.5). Free radicals damage key structural and functional components of tissues and cells, such as proteins and DNA, unless they can be effectively neutralized by sufficient antioxidant capacity. The 'French paradox,' of relatively good cardiovascular health, even in the face of less healthy dietary and lifestyle practices, has been generally attributed to consumption of red wine, as it contains relatively large amounts of antioxidants (German and Walzem, 2000; de Lorgeril *et al.*, 2002; Ferrières, 2004). However, white wines (Lamuela-Raventós and de la Torre-Boronat, 1999), beers (Denke, 2000; Kondo, 2004) and some spirits (Goldberg *et al.*, 1999) have also been implicated in such health benefits as they too may contain significant levels of phytochemical antioxidants, albeit of different origins and amounts to those of red wines. Nevertheless, there may be differential effects according to the particular beverage concerned and its relative constituents, perhaps with wine consumption associated with more favorable levels in serum of high density lipoprotein cholesterol and fibrinogen, and lower systolic blood pressure, than consumption of either beer or spirits (Ambler *et al.*, 2003). In contrast, the effects of low to moderate alcohol consumption on health may be independent of the type of alcoholic beverage, with equal reduced risks of myocardial infarction being ascribed to beer, spirits and wine (Cleophas, 1999; Schröder *et al.*, 2007), and reduced incidence of type 2 diabetes (Djoussé *et al.*, 2007). It may be that the apparently greater benefits of red wine are more attributable to other factors such as healthier lifestyles (Grønbaek, 2006).

Laboratory studies have been used to try to elucidate the purported mechanisms of protection offered by various components of alcoholic beverages. In one illustrative example, the extent of DNA damage was measured in human lymphocytes exposed to either oxidative stress, with hydrogen peroxide, or to γ-radiation in the presence of individual beverage components and in constituent mixtures typically found in alcoholic

beverages, and compared to controls. Interestingly, the greatest protection against both of these stress agents was afforded by a mixture typical of wine, with ethanol and phytochemicals (e.g. catechin and caffeic acid) in a possible synergistic combination that exceeded the protective effects expected by the sum of the individual constituents (Greenrod and Fenech, 2003).

5.6.4 Conclusion

It is clear that excessive alcohol consumption, whether acute or chronic, may have severe deleterious effects on every cell, tissue and organ of the body, with the extent of damage being essentially dose dependent, but such effects may be quite variable between individuals and communities because of genetic and phenotypic differences in susceptibility. Conversely, there is now quite a substantial body of speculation and scientific opinion, mainly from epidemiological evidence, suggesting that low to moderate consumption of alcoholic beverages on a regular basis, rather than less frequent binge drinking, may actually reduce the risks of all cause mortality, particularly from coronary heart disease, and there may be other health benefits potentially attributable to alcohol per se and to certain other constituents of alcoholic beverages. However, there is little indisputable evidence of alcohol beverage consumption being *directly* causal of health benefits. There is much lively debate in the literature concerning these issues; for a recent example, see Stockley (2009), and for a comprehensive review of moderate drinking, see Gunzerath *et al.* (2004).

5.7

Carbohydrates in Alcoholic Beverages and Health

The first part of this chapter is focused on the calorific value of certain alcoholic beverages (particularly beers) in the context of relative ethanol and metabolizable carbohydrate content, how this relates to health and how these drinks are perceived by the general public. For a more general account of carbohydrate nutritional value of alcoholic beverages, the reader is referred to Section 5.3.3. The next sections describe the production of low and high carbohydrate beers, and the final part is dedicated to a discussion of health values of nonmetabolizable carbohydrates (again, particularly with reference to beers), such as β-glucans and other fibrous oligomers and polymers.

5.7.1 Metabolizable Carbohydrate

Metabolizable carbohydrates, such as starch (polymers), sucrose, glucose and other sugars, are those that are utilized in cell metabolic processes as a source of energy. In most countries, for most people, they are the biggest providers of dietary energy. Many people in western countries are classed as overweight, as defined by their body mass indexes (BMI = mass (kg)/height^2 (m^2)) being over 25. Additionally, a significant number of these can be classed as obese, with BMI 30. This situation has become more acute since the 1950s, with increased richness of diet and increased use of machinery, leading to a general lack of physical exercise. Overweight in general, and obesity in particular, have been linked to higher risk of disease and to shorter lifespan. Of particular interest here are links with increased risk of cardiovascular disease, cancer and diabetes. Although genetic factors may contribute to some people's high BMI values, it is probable that the greatest contributor to this situation is a greater input of energy (calories) over output of energy – that is, overeating, overdrinking and underexercising. Increased awareness of this situation, especially over the last three decades, has led to considerable interest in special diets, exercise regimes (especially 'working out' and jogging) and in special beverages, both alcoholic and nonalcoholic, and both high and low carbohydrate types. Much of this interest is focused on intake of carbohydrates, the cheapest form of food energy or calories.

A calorie (cal) is defined as the amount of heat energy needed to raise the temperature of 1 g of water by 1 °C. The energy value of foods is commonly expressed in units of kilocalories (kcal = 1000 cal = 1 Cal), and it is generally agreed that, apart from very young children and the elderly, most people need an input of 2500–5000 kcal per day, depending on (amongst other factors) the amount of daily exercise.

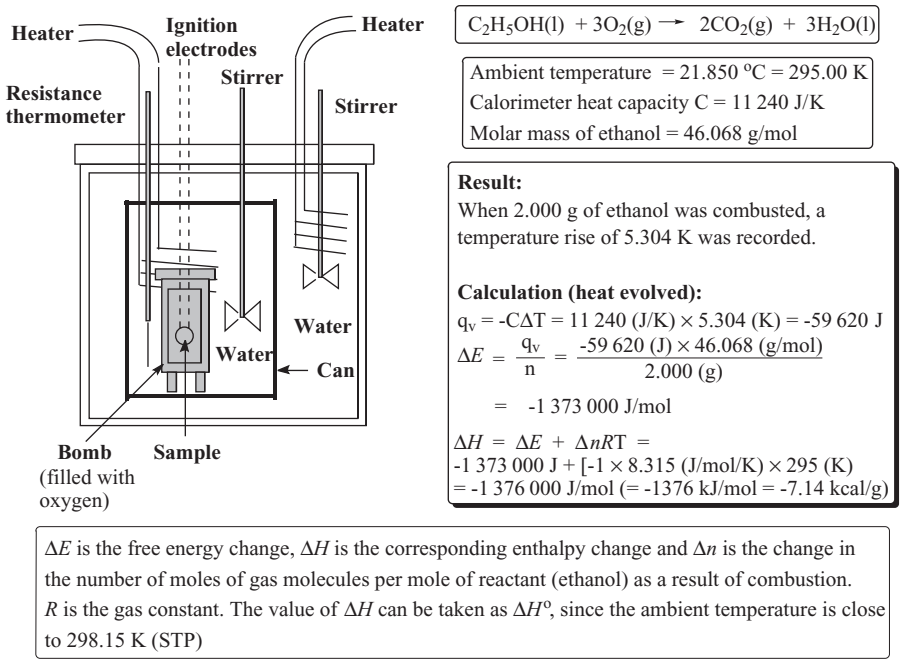

Figure 5.7.1 *Schematic diagram of a bomb calorimeter used to determine calorific value of substances and foodstuffs, via free energy and enthalpy (heat) of combustion. The calorimeter heat capacity is deduced by measuring the rise in temperature of the water as a result of applying a known voltage to the heater coil (of known resistance) for a specif ic time*

The total potential energy of foodstuffs (the 'calorific value') can be estimated by combusting the food in a steel bomb calorimeter (Siska, 2006) (Figure 5.7.1). Combustion releases heat, which is measured by the temperature rise of the bomb calorimeter, or more specifically of the water in which it is immersed. The heat released can be calculated as shown in Figure 5.7.1 and is expressed as kcal/mol or more usually as kcal/g, since most foods are complex mixtures of substances.

Although the measured calorific value of a particular substance (e.g. glucose or maltose) differs from those of other chemically related substances (e.g. fructose or sucrose) and will be higher than the *in vivo* calorific value of the substance (because of incomplete metabolic oxidation), useful rules of thumb for calorific values can be devised for estimating energy input on consumption of foodstuffs. These are (in kcal/g) 3.8 for carbohydrates, 4.0 for proteins and 9.0 for fats. To this, for alcoholic beverages, we can add 7.1 kcal/g for ethanol. Since most alcoholic beverages contain no fat and little protein (with the general exception of beer and other cereal based beverages), their calorific values can be related to ethanol and carbohydrate contents, with the former contributing about twice (w:w) as much as the latter.

The calorific value of an alcoholic drink can be estimated from Equation 5.7.1.

$$\text{Calorific value (CV)} = 7.1\text{E} + 3.8\text{C} + 4.0\text{P} \tag{5.7.1}$$

Here, CV is expressed as kcal/100 ml, and E, C and P are ethanol, carbohydrate and protein content, respectively, in g/100 ml. In many cases, the last term of Equation 5.7.1 will make a negligible contribution

to CV. An alternative calculation of CV is given by Equation 5.7.2.

$$CV = 6.9E + 4.0(RE - A) \tag{5.7.2}$$

This time, CV is expressed in kcal/100 g, and E, RE and A are ethanol, real extract (see Section 2.6.4) and ash, respectively, in % (w:w). Apart from Equations 5.7.1 and 5.7.2, CVs are often given as 'kcal per serving' in books and web pages giving dietary information for health conscious people. A serving is a typical portion of foodstuff (in mass or volume) that would be consumed as a unit, typically ~360 ml (~12 US fluid ounces) for beer, ~120 ml (4 US fluid ounces) for wine and ~45 ml (~1.5 US fluid ounces) for spirits and liqueurs. Typical calorific values, ethanol contents and carbohydrate contents are given for various alcoholic beverages in Table 5.7.1. Also shown here are CVs and carbohydrate contents for some nonalcoholic drinks, for comparison. Although the values in Table 5.7.1 are only typical or representative values, it can readily be seen that the drinks with the higher CVs are generally those with higher ethanol contents, and the drinks with the highest CVs of all are sweet, highly alcoholic drinks. It is also apparent from Table 5.7.1 that, contrary to widespread public belief, spirits and wine generally have higher CVs than beer or cider. If one takes the view that unburnt calorie intake equals fat, then wine is more fattening than beer.

Legislation exists, or is underway, in many countries to impose mandatory requirements on alcoholic beverage producers to include nutritional information with their products, along with health warnings and information on additives. This information is usually on a subsidiary label under the main label, or on the back of the bottle or can. In many countries, this is in line with general foodstuff labeling, especially of processed foods. The general public has long been aware that the only really sensible way to avoid weight

Table 5.7.1 *Calorific values, ethanol content and carbohydrate content of some alcoholic beverages*

Beverage	Typical carbohydrate content/% w:w	Typical ethanol content/% v:v	Calorific value/kcal per g
Barley wine	6.8	9.6	0.79
Lager	2.9	5.0	0.40
Pale Ale	3.4	5.6	0.56
Porter	4.6	5.7	0.56
Stout (sweet)	6.6	4.5	0.54
Stout (bitter)	2.8	4.0	0.35
Light beer	1.8	4.2	0.31
Low carb beer	0.7	4.2	0.26
Low alcohol beer	1.6	0.4	0.27
Cider	3.0	6.0	0.36
Sweet cider	5.0	6.0	0.56
Dry wine	0.03	12.0	0.80
Sweet wine	13.3	12.0	1.6
Spirits	–		2.3
Liqueurs	47		3.8
Cola drink	7.5	–	0.28
Diet cola drink	–	–	–

gain or to lose weight is to strike the right balance between calorie intake and calorie usage (i.e. between eating and exercise). This, and recent labeling legislation, increasing amounts of information on the Internet and the growth of the health food industry has prompted many consumers to focus on the calorie content of their alcoholic beverages (see Section 1.3.10). Unfortunately, alcoholic drinks, and beer in particular, have suffered from being classed as 'high carb' by many influential diet regimes (Bamforth, 2005). Pressure is such that many breweries produce beers specifically labeled as 'low carb,' 'low C,' 'diet,' 'diät,' 'light' or 'lite,' thereby implying that normal beers are 'high carb.' Table 5.7.1 shows that beers in general have lower carbohydrate contents than many beverages (alcoholic or otherwise) and its average calorific value is lower than that for many beverages. Furthermore, the carbohydrate contents and CVs of all but the strongest and sweetest of alcoholic beverages compare reasonably with those for many nonalcoholic drinks (Bamforth, 2005). Finally, intake of carbohydrates per serving of alcoholic drinks compares favorably with intake per serving of nonalcoholic drinks and solid foodstuffs, such as bread, other cereal or cereal products, fruit and vegetables (Bamforth, 2005). For example, a 360 ml glass of pale ale contains around 12 g of carbohydrate, compared with 26 g in a serving of noodles or 29 g in a serving of grapes.

5.7.2 Low Carbohydrate Beers

Although it has been shown in the previous section (see Table 5.7.1) that ethanol, rather than carbohydrate, contributes most to the energy value of alcoholic beverages, there is still a significant demand for low carbohydrate beers. This is partly because of the continued general public misconception that carbohydrates are 'bad' and partly because of the need for alcoholic drinks with low sugar content for people with metabolic disorders, such as diabetes. Additionally, since low carbohydrate beers have about half the energy value of standard beers (Table 5.7.1), they are often heavily promoted by large brewing companies in order to attract more health conscious (usually younger) beer drinkers. As a compromise, some breweries produce a light or 'lite' beer, usually with an energy value somewhere between a regular beer and a low carbohydrate beer.

The production of low carbohydrate beers does not present the brewer with such a severe problem as low alcohol beers (Chapter 2.13). The secret is to provide the wort with enzymes that can cleave the branches from amylopectin (or branched α-glucans) to give linear starch (amylose) and linear oligosaccharides (Section 2.6.2). These can then be hydrolyzed by α- and β-amylases to lower sugars (predominantly maltose), giving a highly fermentable wort (i.e. one with low levels of branched α-glucans or dextrins, that are not fermented by normal brewing yeasts). There are several methods by which this can be achieved, as outlined in Figure 5.7.2.

Limit dextrinase (LD) is the barley enzyme that is able to hydrolyze α-glucan branches. However, in a normal mash, unlike α- and β-amylases, LD remains mostly bound to proteins (known as inhibitors) and hence its activity is rather low. Furthermore, LD activity in wort is strongly influenced by pH and the presence of reducing agents, and it seems that the enzyme is highly temperature sensitive, being essentially denatured at temperatures much above 60 °C. It appears that the presence of reducing agents stimulates cysteine dependent proteinases into cleaving the LD inhibitor protein linkages, thereby releasing free LD into the wort (Jones and Budde, 2003; Heisner and Bamforth, 2008). Furthermore, it has been demonstrated that a 3 h incubation period at pH 4 leads to a threefold increase in extraction of free (active) LD from malted barley at 24 °C, compared with extraction at the more usual mashing pH of 5 (Heisner and Bamforth, 2008). It should therefore be possible to produce highly attenuated beers by dint of pH adjusted, ramped temperature mashing. An initial low pH, low temperature period should produce enough LD activity to cleave many of the branches of amylopectin to give mainly linear starch and linear α-glucan molecules. Increase of pH and ramping of temperature to a rest at 60–65 °C should then allow α-amylase and β-amylase to hydrolyze these molecules to maltose (mostly), maltotriose and glucose.

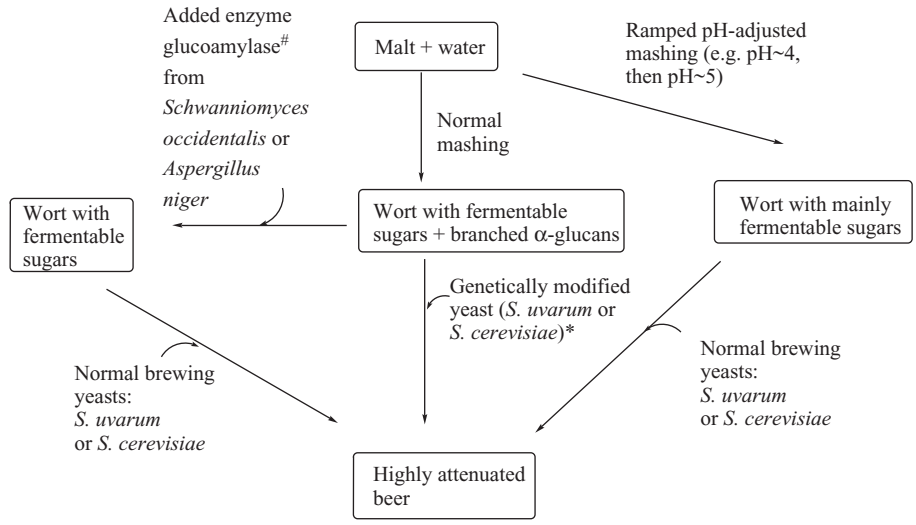

Figure 5.7.2 *Methods for the production of low carbohydrate beers. *With genes that express the α-glucoamylase of* Aspergillus niger *or* Schwanniomyces occidentalis. Saccharomyces diastaticus *will give a compromise result; its glucoamylase will degrade α-glucans, but not at the branches. #Pullulanase or limit dextrinase (LD)*

At the present time, most low carbohydrate beers are produced either by use of exogenous glucoamylase enzymes (usually from *Aspergillus niger* or *Schwanniomyces occidentalis*) in the mash or by fermenting conventional worts with genetically modified yeasts (Figure 5.7.2). Recombinant DNA techniques allow the incorporation of the glucoamylose genes from *Aspergillus niger* or *Schwanniomyces occidentalis* into the *S. uvarum* or *S. cerevisiae* brewing strain genomes. The resultant yeasts are usually genetically stable and exhibit normal fermentation patterns. An example (Hornsey, 1999) comes from the Brewing Research Foundation Institute (Nutfield, UK), who were pioneers in this field. Here, a lager yeast (NCYC 1342) with incorporated glucoamylase genes from *A. niger* was able to attenuate a 1044 °OG wort (80% malt; 20% maltose syrup) at 998° in 12 days, producing a beer with 6.2% ethanol (v:v) (diluted to 5.0% ABV prior to packaging). High attenuation brewing is also of interest to distillers of whisky (and whiskey), because of increased efficiency of distillation (Chapter 3.2).

Most of the large brewing companies produce at least one low carbohydrate beer, usually described as ‘light’ or ‘lite’ (‘low carb’ or ‘low C’ are other names), which refer to the low carbohydrate content rather than the color, although all the well known brands are pale, like Pilsner beers. Indeed, they are bottom fermented, but there the analogy with true Pilsner beers ends; low carbohydrate beers generally do not have the balance of flavor and delicacy associated with the better Pilsners.

5.7.3 High Carbohydrate Beers

The brewing of high carbohydrate beers, by the very nature of the brewing process, leads to a low alcohol product (called malt beer, Malzbier, malt beverage, etc.). The types and styles are discussed in Section 2.6.13. Because of their low ethanol (usually <2% ABV and often below 1% ABV) contents and high carbohydrate contents, high carbohydrate beers are of high nutritional value and as such have been prescribed for convalescent patients in the past. Similarly, some of the better known versions were originally brewed by seaport

breweries (or those close to the sea), in the nineteenth century, for sailors about to embark on a long voyage. Nowadays, the selling point of high carbohydrate beers is still nutritional value, but the target consumers are athletes, pregnant women and active, health conscious people in general. The high carbohydrate content is suitable for supplying energy for both short bursts of vigorous activity or more protracted, milder activity associated with athletic events or exercise, like working out or jogging. Sufficient exercise ensures that the carbohydrates are nearly all combusted, with little, if any being stored as glycogen or fat. Likewise, sufficient exercise will ensure that the low ethanol content consumed is not converted to fat. Also, exercise will help to maintain low blood serum low density lipoprotein cholesterol (LDL-C) levels, high high density lipoprotein cholesterol (HDL-C) levels, low cholesterol levels and low triglyceride ester levels, which are commensurate with low risk of cardiovascular disease (Sections 5.6.2 and 5.6.3). Furthermore, the very low amount of ethanol consumed in a normal serving will be in the beneficial category (Section 5.6.3), thus enhancing to some extent the benefit of exercise.

High carbohydrate beers can be brewed from worts that have been mashed at high enough temperatures to disable β-amylase (Section 2.6.3). This means that the worts contain relatively little maltose, maltotriose and glucose, the carbohydrates being mostly partially fermentable or unfermentable branched α-glucans. Some German high carbohydrate beers (Malzbier) are brewed from a standard, dark, low hopped wort of about 12 °Plato, but cooled to just above freezing point before the yeast is pitched. It then undergoes a very limited, slow fermentation, ultimately giving a beer with 0.5% ABV or less, thus qualifying it in German law as an alcohol free beer.

5.7.4 Nonmetabolizable Carbohydrate

The numerous enzymes and other substances of the human digestive system are unable to cleave covalent β-links in oligomeric and polymeric carbohydrates (see Section 2.6.2, Figure 2.6.5). Carbohydrates (typically cellulose or β-glucans), as well as other fibrous constituents of cereals, fruits and vegetables, such as lignins, polyphenols and proteins, that are not directly metabolized by the human digestive system are well known to be essential items of human diet, despite their lack of direct nutritional qualities. One main benefit of these fibrous materials is in the binding of waste in the gastrointestinal tract and its rapid passage through the large intestine. Another benefit is the stimulation of the immune system, particularly phagocytes such as macrophage cells. Linked with this is the fact that gut lactic acid bacteria thrive in the presence of fiber; they are able to metabolize some of these fibrous substrates, producing chemicals that may stimulate the immune system. Diets high in fiber are known to decrease the risk of several diseases, notably colon cancer, heart disease and diabetes. Refinement of food (e.g. dehusking of cereals and filtration or clarification of beverages) leads to products with lower fiber content. A combination of low fiber content, high refined carbohydrate content, high meat content and high refined sugar content in the diet, which is typical of many western countries, is thought to account, at least in part, to the higher incidences of colon cancer, heart disease and diabetes amongst westerners, as opposed to Asian or African peoples.

It is probable that polyphenols, which are naturally bound to fibrous carbohydrates and proteins, make a significant contribution to the health benefits associated with dietary fiber, since they are known to be readily fermented by gut microflora in the large intestine to simpler phenols that can be absorbed through the gut wall (Section 5.8.9). Indeed, the polyphenol content of the insoluble fibrous material of various beverages has been found to be in the range 1.4–50.7% (dry weight) and in the range 2.9–62.8% (dry weight) for soluble fiber (Goñi *et al.*, 2009).

The large intestine or lower gut is the largest of the immunological organs in humans: a well functioning intestine therefore protects the whole body against a wide range of external pathogens (bacteria, cancerous cells, dead cells or debris, foreign cells, etc.). The intestinal natural immune defence system is composed

mostly of phagocytes: macrophages, T- and B-lymphocytes, and dendritic cells. It appears that the presence of dietary fiber in the gut changes the relative quantities of phagocytes, influences signaling of T-cells and increases the activity, potency and recognition ability of macrophages, without normally overactivating them (Muscat *et al.*, 2007). These events are probably mediated by gut lactic acid bacteria (or their fermentation products of the fiber), which grow well after the consumption of fiber.

Intraperitoneal injection of yeast derived β-glucans were shown to increase leukocyte and lymphocyte cell numbers and the same time they increased the level of natural killer (NK) and lymphokine activated killer (LAK) activities of these cells in mice exposed to whole body X-ray irradiation (Gu *et al.*, 2005). Injected mice showed much greater resistance to tumor growth and secondary infections associated with irradiation.

Cereal derived β-glucans (from oats) in the diet have been shown to offset the risk of upper respiratory infection with exercise stress in mice (Davis *et al.*, 2004) and (from barley) to decrease total and non-HDL cholesterol in hypercholestemic Syrian golden hamsters (Wilson *et al.*, 2004). The latter effects were observed with both lower molecular weight and high molecular weight β-glucans, suggesting that β-glucans in general possess cholesterol lowering and antiatherogenic activities. These results from intervention experiments on animals are in broad agreement with epidemiological or meta-analytical observations on the incidence of disease related to dietary fiber intake in human populations. Human diet intervention studies on well controlled type 2 diabetes patients have revealed further beneficial effects of cereal derived β-glucans. A diet including β-glucans (from oats) and nonsucrose sweeteners led to even greater metabolic and anthropometric improvements than a successful diet based on the American Diabetes Association's nutrition recommendations (Reyna *et al.*, 2003).

The cell walls of cereals used in brewing contain arabinoxylans (pentosans) and β-glucans, mostly as medium to high molecular weight polymers. During malting to produce well modified barley malt, many of these polymers are degraded (hydrolyzed) by β-glucanase enzymes (Section 2.6.2) to give lower polymers and oligomers. These are still classed as β-glucans (or pentosans) since they still possess (mainly 1→4) β–linkages between monosaccharide units, which makes them indigestible to humans, and they are known more generally as soluble dietary fiber. Further degradation of these molecules occurs during low temperature mash in (Section 2.6.3).

In the production of more highly refined beers (the majority), particularly those where filtration is involved, it is in the brewer's interest to minimize the amount of high molecular weight β-glucans and pentosans. High concentrations of these polymers (especially arabinoxylans) in the beer increase its viscosity and decrease its filterability through membrane filters (Sadosky and Schwarz, 2002). However, despite these precautions, dimeric and trimeric β-glucans (cellobiose and cellotriose, respectively) as well as low molecular weight oligomers (e.g. cellohexose) and arabinoxylans of similar molecular weights survive in these beers (∼0.5–3 g/l) (Gromes *et al.*, 2000; Hughes and Baxter, 2001), thus giving even the more refined beers a valuable, if low fiber content. In the USA, the FDA daily recommended intake of dietary fiber is 25 g, which means that a liter of processed beer a day could supply around 10% of this requirement, thereby classifying the beer as a good nutrient source, according to this Authority.

At the other extreme, unfiltered and unrefined cereal based alcoholic drinks of Africa (bouza, burukuta, pombe, shakporo and others), Asia (makkoli and others) and South America (Section 2.7.2) must be relatively rich in both 1,4-β-glucans and arabinoxylans from cereal, and 1,3- and 1-6-β-glucans from yeast, including laminaribiose, laminaritriose, higher oligomers and polymers. These drinks are usually served 'green' (still fermenting) and as thin or thick porridges, depending on the style of the brewer or tradition of the area. Either way, the solids contents of the thinnest unfiltered drinks are probably around 5–10% and so must provide a significant measure of nutrition with respect to both digestible carbohydrates (α-glucans) and nondigestible (dietary fiber) carbohydrates (β-glucans and arabinoxylans). In addition, these drinks supply proteins, amino acids, minerals, vitamins and antioxidants, including polyphenols.

In between these two extremes, the unfiltered cask-conditioned beers and bottle-conditioned beers (both minority products) of Australasia, Europe and USA can contain up to ∼10 g/l of dietary fiber (Hughes and Baxter, 2001). Additionally, suspended yeast cells will supply a small quantity of 1,3- and 1,6-β-glucans. Interestingly, an earlier study of 15 commercial beers revealed arabinoxylans to be much more abundant than β-glucans, with concentrations ranging from ∼0.5 g/l for an American light beer to ∼4.2 g/l for a German wheat beer (Schwarz and Han, 1995).

5.8
Antioxidant Value of Alcoholic Beverages

5.8.1 Overview

The following sections give a brief description of aerobic metabolism, oxygen in metabolic processes and reactive oxygen species, followed by an account of the nature and effectiveness of natural antioxidants and free radical scavenging substances in alcoholic beverages and their raw materials and precursors. The emphasis is on polyphenols, since the major part of the huge amount of dietary antioxidant research has been directed towards them and they are well known to be potent *in vitro* antioxidants and are widespread in alcoholic beverages and some of their raw materials and precursors.

It is now generally believed that oxygen was absent from the atmosphere at the time of the Earth's formation, about 4.8 billion years ago; the atmosphere was basically a reductive atmosphere. The first organisms were anaerobic, but photosynthetic organisms (such as cyanobacteria) began to evolve around 2 billion years ago. These produced oxygen as a photosynthetic product and it was another half billion years before the first aerobic organisms emerged. The photosynthetic organisms thrived and evolved further, and as the concentration of oxygen in the atmosphere increased, the aerobic species did likewise. Many anaerobic species did not adapt to the increasingly oxidative atmosphere and died out, as oxygen is toxic to anaerobic species. However, many anaerobic species survive today by inhabiting oxygen free environments, such as soil, but the fact is that these organisms thrive in the absence of oxygen, but die in its presence. So, it appears that there is some fundamental cellular toxicity associated with use of oxygen in respiration and that aerobic organisms have some in built defence mechanisms acting against this toxicity, which anaerobic species do not possess.

It is also known that the many aerobic organisms that exist today sometimes suffer from incomplete or faulty protection against oxygen toxicity and are subject to 'oxidative stress.' The stress is caused by the presence of reactive oxygen species (ROS) or reactive nitrogen species (RNS), many of which are free radicals. ROS are necessarily formed at the end of the respiratory electron transfer chain, which is itself linked to aerobic cell metabolism, especially the tricarboxylic acid cycle. ROS are also produced by biotransformation enzymes (e.g. cyclooxygenases (COX) and cytochrome P450 isoenzymes) during the elimination of exogenous substances (e.g. foreign cell debris, drugs, toxins) and endogenous compounds (e.g. unwanted steroid hormones).

Biotransformation enzymes are active during immunoresponse processes, such as the destruction of pathogens (e.g. bacteria, defective or cancerous cells) by macrophages. They are also involved in the degradation of cell debris following necrosis (unprogrammed cell death caused by infection, injury or lack of oxygen). Each of the above processes is characterized by local tissue inflammation, which sets off a number

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

of biochemical responses, modulated by cell signaling molecules such as leukotrienes and prostaglandins. The biochemical responses (e.g. upgraded synthesis of C-reactive protein in the liver), along with high cytochrome activity, elevated concentrations of oxidized lipids due to ROS action, and other factors can be used as markers for inflammatory diseases, such as atherosclerosis. Reactive oxygen molecules that escape the defensive mechanisms cause cell damage in many ways, by oxidation and by the setting up of complex free radical chain mechanisms.

There is good evidence to suggest prolonged damage of this kind can lead to or contribute to the onset of a number of diseases, particularly cardiovascular disease and cancer. More generally, it is thought that chronic oxidative stress results in accelerated ageing and progressive breakdown of cellular function. Along with good lifestyle, which includes sufficient exercise, good diet (including especially fresh fruit, vegetables and certain beverages, including alcoholic varieties, but only in moderation) is thought to offer some protection against ROS, possibly through the presence of natural antioxidant molecules in the foodstuffs. The observed lower incidences of cardiovascular disease and certain cancers in populations who follow the above-mentioned lifestyles, is thought by many to be (at least in part) the result of the presence of relatively high levels of antioxidants in the diet, including those found in red wine and other alcoholic drinks.

5.8.2 Summary of Aerobic Cell Metabolic Processes

In the aerobic cell metabolism, food molecules like carbohydrates are oxidized essentially by the removal of hydrogen and electrons, which are ultimately combined with oxygen to form water: $2H^+ + 1/2O_2 + 2e^- \rightarrow H_2O$ ($\Delta G^\circ = -158.1$ kJ/mol).

This actually occurs via a series of complex interconnected redox reactions, often called the electron or hydrogen transfer chain, and leads to the ultimate reaction of combining four protons and four electrons with one oxygen molecule to produce two water molecules. This occurs right at the end of the chain and involves the redox protein complex known as cytochrome a, a_3 or cytochrome c oxidase. In between, there is a host of reactions, the overall effect of which is to transfer protons and electrons from the original food molecules to oxygen molecules. Thus, the electron chain process is intimately linked to the redox reactions of the oxidative degradation of food molecules, as illustrated by glycolysis (see Figure 2.2.2 in Chapter 2.2) and the tricarboxylic acid (TCA) cycle (Krebs or citric acid cycle) as outlined in Figure 5.8.1. Also intimately linked to all of this is the regeneration of ATP from ADP and P_i (inorganic phosphate). Many enzymes and other proteins play crucial parts in this entire set of events.

The TCA cycle contains several redox processes, as well as other reactions. The redox reactions involve dehydrogenase enzymes, where hydrogen transfer is performed by either NAD^+/NADH (mostly) or FAD/$FADH_2$ coenzyme systems. The reduced forms of these coenzymes are converted back to the oxidized forms by a series of interconnected redox processes involving dehydrogenases, ubiquinones, ferrodoxins and cytochromes. The last named occur at the very end of the redox process and catalyze the combination of oxygen and protons to produce water. Cytochromes contain iron ($Fe^{2+} \leftrightarrows Fe^{3+}$) in heme units and the cytochrome a, a_3 complex also contains copper. The entire redox chain is called the electron (or hydrogen) transport chain and occurs, along with the TCA cycle and ATP synthesis, in cell mitochondria. The important events that occur in the inner mitochondrial membrane are outlined in Figure 5.8.2.

5.8.3 Short Review of Oxygen in Cell Metabolic Processes

The redox agents that follow the ubiquinone redox system in the electron transport chain are the cytochrome proteins, whose family name is derived from the color changes that accompany their oxidation-reduction. They

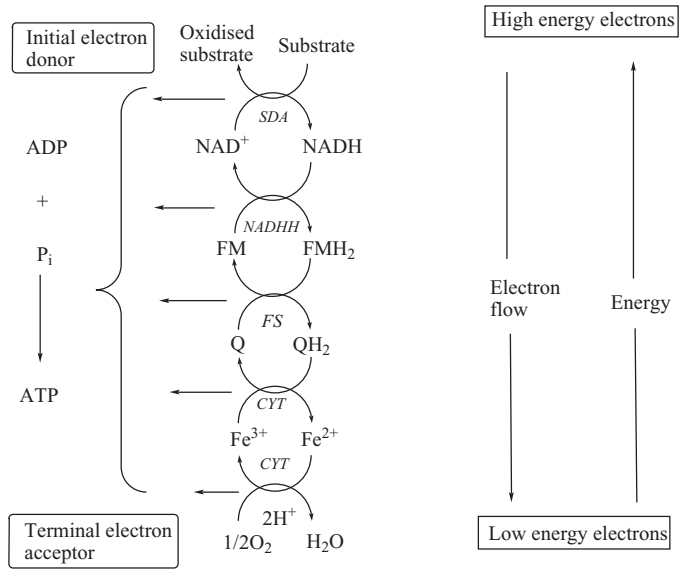

Figure 5.8.1 *The electron chain process. Simplified, showing principal redox cofactors. NAD+/NADH = nicotinamide adenine dinucleotide; FMN/FMNH2 = flavine mononucleotide; Q/QH2 = ubiquinone. The species in italics are enzymes: SDA = substrate dehydrogenase; NADHH = NAD dehydrogenase; FS = ferrodoxins; CYT = cytochromes*

are arranged in the order (after ubiquinone): cytochrome b, cytochrome c_1, cytochrome c and cytochrome a,a_3. It is the last protein (or rather, protein complex) that is responsible for transfer of electrons to molecular oxygen; it is the terminal electron donor of the electron transport chain. Cytochrome a,a_3 is often called cytochrome c oxidase. The redox centers of all the cytochromes are heme prosthetic groups (as in hemoglobin) and the redox reactions all inlvolve the interconversion $Fe^{II} \leftrightarrows Fe^{III}$. Hence, the cytochromes belong to the big family of heme proteins, which can be classified according to the structure of the heme group: heme a, as in

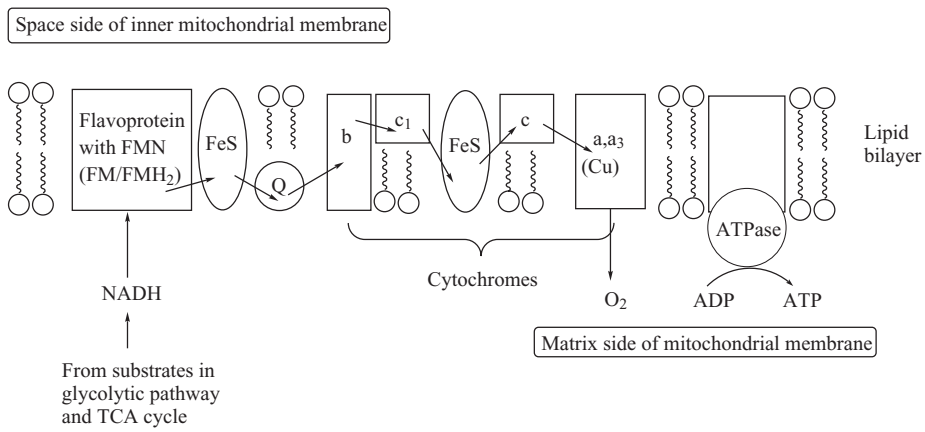

Figure 5.8.2 *Electron transport in inner mitochondrial membrane. Straight arrows represent electron flow. FeS = ferrodoxin (not all of them are shown)*

cytochrome a,a_3, heme b, as in cytochrome b, heme c as in cytochromes c, heme d, as in some catalases, etc. (see http://metallo.scripps.edu/PROMISE/). Other examples of heme proteins are myoglobin, hemoglobin, catalases and some peroxidases.

Cytochrome a,a_3 is the electron donor to oxygen molecules. It contains two heme redox centers (hence its name) and two $Cu^{I} \leftrightarrows Cu^{II}$ redox centers (one of which is a binuclear site) (see www.life.uiuc.edu/crofts/bioph354/cyt_ox.html for more details). At the binding site, heme a_3 and Cu_B act in conjunction to reduce O_2 to H_2O (Figure 5.8.2), coupled to the generation of a proton electrochemical gradient across the membranes in which protein is embedded: 4cyt c(red) + $8H^+$(in) → 4cyt c(ox) + $4H^+$(out) + $2H_2O$.

Cyt c (red) and cyt c (ox) represent the reduced and oxidized forms of the electron donor; H^+(in) and H^+(out) represent protons, which are pumped from the inner (matrix) side of the membrane toward the outer side.

5.8.4 Incomplete Reduction of Oxygen, the Formation of Reactive Oxygen Species and Cell Damage

The oxygen molecule itself, in its stable ground state, is not toxic. However, because of its biradical (triplet state) structure, it can act as an electron acceptor only in a specific fashion. In particular, it is probable that the four electrons donated to each O_2 molecule at the end of the electron transport chain are transferred in a stepwise manner, rather than simultaneously, as shown in Figure 5.8.3 (www.life.uiuc.edu/crofts/bioph354/cyt_ox.html).

All of the named species in Figure 5.8.3 are potent oxidizing agents that arise from the partial reduction of O_2 and all contain oxygen, hence they are known as reactive oxygen species (ROS). Moreover, hydrogen peroxide is produced during oxidations catalyzed by certain oxidase enzymes, such as monoamine oxidase and xanthine oxidase. Hydrogen peroxide, toxic in itself, can produce hydroxyl radicals via reactions of the type: $H_2O_2 + O_2^{-\bullet} \rightarrow OH^- + OH^{\bullet}$.

The hydroxyl radical is one of the strongest of all oxidizing agents and from a consideration of all the above factors, it can be seen that ROS pose a powerful threat to living cells because of the damage they can cause to biomolecules, especially to proteins and the lipid molecules of cell membranes, through oxidation and establishment of radical chain reactions (Figure 5.8.4).

The natural mechanisms that are available to cells for the removal of toxic reactive oxygen species fall into two categories: nonenzymic detoxification and enzymic detoxification. In nonenzymic detoxification, small molecules, such as glutathione, ascorbic acid (vitamin C), tocopherols (vitamins E), carotenes (and vitamin A), lycopenes and others are thought to scavenge ROS before they can cause damage to cellular tissues. The *in vivo* modes of action of most of these molecules are not known for certain, but some may react preferentially with one or more of the reactive oxygen species, whereas others (such as tocopherols) terminate

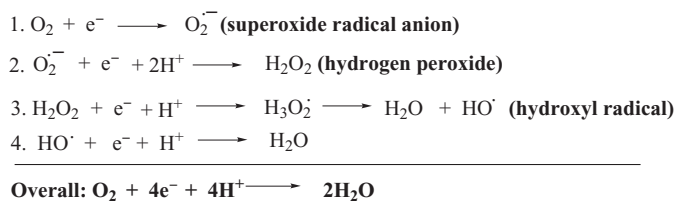

Figure 5.8.3 *Stepwise production of ROS from dioxygen, electrons and protons*

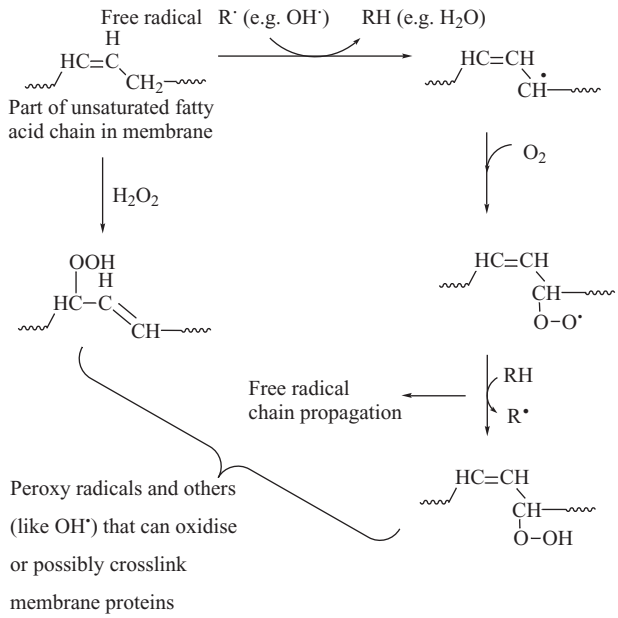

Figure 5.8.4 *Scheme for membrane lipid damage by ROS*

oxidative free radical chain reactions (as in lipid oxidation) or reconvert oxidized cellular constituents back to their naturally reduced forms. It has long been realized that a diet rich in fruit and vegetables can provide sufficient levels of certain of these antioxidants (especially vitamins A, C and E) and hence it is feasible that they help maximize the protection of cells from oxidative damage. Additionally, a host of other antioxidants exist in foods – again, especially in cereals, fruit and vegetables or foods derived from these, such as beers, juices, wines and extracts (e.g. tea). Many of these foodstuffs contain phenolic compounds and this aspect is considered in Section 5.8.6.

Cells possess a number of enzymes for removing ROS. For example, hydrogen peroxide can be reduced by catalase and peroxidase enzymes (Figure 5.8.5). DH_2 is a reduced organic compound, of which there are

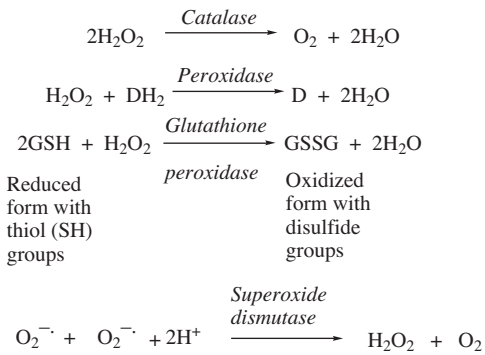

Figure 5.8.5 *Some cellular enzymic mechanisms for removal of ROS*

many, that behaves as a hydrogen donor. Glutathione is an example of such a compound and the enzyme glutathione peroxidase catalyzes the reaction shown in Figure 5.8.5. Superoxide, on the other hand, is disposed of by an enzyme known as superoxide dismutase (SOD). This catalyzes dismutation of $O_2^{-\bullet}$ (a dismutation is a reaction in which identical molecules have different fates) (Figure 5.8.5). The hydrogen peroxide product can then be reduced by enzymes or antioxidants, as described previously. Catalases, peroxidases and the cytochromes all belong to the heme family of proteins. Catalases, for example possess heme type b or d units (http://metallo.scripps.edu/PROMISE/), and are thought to catalyze the decomposition of hydrogen peroxide in the manner shown in Figure 5.8.5. Peroxidases also possess heme b units, although the Fe species is coordinated to a histidine residue (like heme a_3 of cytochrome a,a_3), rather than a tyrosine residue, as in catalases. The action of peroxidases is thought to be similar to that of catalases, except that the former also use an organic compound (e.g. glutathione – see Figure 5.8.5) for oxidation, in order to reduce H_2O_2.

Superoxide dismutase does not belong to the heme family of proteins; instead it is a more complex protein containing copper and zinc units, which are presumably used in the redox mechanism.

5.8.5 Natural Antioxidants in Food

Strictly, antioxidants are substances that interrupt the free radical chain mechanism promoting the oxidation of lipids (see Figure 5.8.4). Nowadays, upwardly spiraling interest in biological antioxidants has resulted in a much broader meaning for the term 'antioxidant.' It can be taken that any molecule that somehow works towards the minimization of oxidative cell damage is a biological antioxidant. This broader definition will be used in this section.

It has long been known from epidemiological studies that the inclusion of reasonable amounts of cereals, fish, fresh fruit and vegetables (or beverages derived from these) in the diet has a tendency to reduce the risk of certain diseases, particularly cardiovascular diseases (CVD) and a limited number of cancers. Likewise, epidemiological studies have demonstrated recently that intake of reasonable amounts of tea and wine, especially red wine, can have similar benefits, particularly with references to CVD. Since there is good evidence to suppose that cardiovascular diseases and cancer may be sponsored by oxidative cell damage in general and by oxidation of specific molecules, the beneficial effects from moderate intake of these foodstuffs have been linked, at least in part, to the presence of natural antioxidants (Table 5.8.1).

Whilst there is little doubt that the phenolic molecules listed in Table 5.8.1 are potent *in vitro* antioxidants (in the broadest sense), there is little firm evidence for their value as direct *in vivo* antioxidants. Indeed, particular health benefits attributed to certain diets may result from a combination of factors that depends on several components of the diet. Furthermore, diet molecules, such as wine polyphenols, may contribute to observed health benefits in several ways, most of which may not involve the molecule as a direct antioxidant at all (see Section 5.8.7).

At the present time, there is intense research activity in many aspects of this field, although there are still huge gaps and many uncertainties in our knowledge. Still relatively little is known about the bioavailablity, absorption and metabolism of antioxidants and even less is known about *in vivo* mechanisms of protection and mode of disease prevention. Also, there are differences in antioxidant assessment results between animal and human intervention studies and yet again between *in vitro* and *in vivo* studies. Additionally, *in vitro* testing methods have often employed phenol concentrations that are far in excess of those likely to be found *in vivo* (e.g. $\sim$1 μM in plasma) (see references in Cren-Olivé *et al.*, 2003; Halliwell, 2006).

Another problem is that certain antioxidants (such as ascorbic acid), in the presence of oxygen and Fe^{2+}, can actually behave as pro-oxidants and are able to generate hydrogen peroxide, which can promote numerous reactions, including hydroxylation of phenylalanine residues in proteins. Moreover, polyphenols have also been shown to generate hydrogen peroxide and other cytotoxic substances on contact with cell culture media

Table 5.8.1 *Some components of foodstuffs displaying* in vitro *antioxidant activity*

Antioxidant	Main dietary sources	Comments
Carotenes and vitamin A	Vegetables: carrots, broccoli and other green vegetables. Vitamin A from animal sources	Polyunsaturated lipid species: β-carotene is a precursor of vitamin A
Lycopenes	Tomatoes	Polyunsaturated lipid species
α-Tocopherol (vitamin E)	Green vegetables, seeds and cereals	A lipid phenolic compound with a long saturated side chain
Lecithin	Vegetables and animal sources	A phosphatidylcholine lipid found in cell membranes
Vitamin C (ascorbic acid)	Vegetables and fruits, especially capsicums (sweet peppers), tomatoes, brassicas, blackcurrants, kiwi fruit and citrus fruits	Water soluble and easily destroyed, especially in the presence of metal ions, like Fe^{2+}
Nonanthocyanin phenolic compounds	Vegetables and fruits, also tea and wine	Many different structures, from simple phenols and cinnamic acids to flavonoids and 3-flavanols – see Figures 5.8.6 and 5.8.7
Anthocyanins	Dark fruits, such as black grapes, mulberries, blueberries, also red wine	

(Long *et al.*, 2000), thereby putting the interpretations of several *in vitro* cell culture studies in considerable doubt; cancer cells possibly being killed by H_2O_2 rather than directly by polyphenols (Halliwell, 2006).

In general, it is much more difficult to assess the value of nonessential antioxidant components of diet (like polyphenols – see Section 5.4.3) than essential components (like vitamins). Their value should be considered as beneficial only with reference to defined circumstances. For example, polyphenols in red wine can be described as inhibitors of cardiovascular disease in healthy individuals on well balanced diets that include the moderate daily intake of red wine. This does not guarantee that the same polyphenols per se taken as intensive supplements will give the same benefits or will offset the effects of a less healthy diet or lifestyle, such as one with high fat and/or high alcohol intake. Furthermore, human intervention studies involving purified antioxidant chemical components of diet, as opposed to the whole source, have failed to give consistent results with respect to protection against heart disease and cancer (Stanner *et al.*, 2004; Frankel and German, 2006). Frankel and German (2006) have advised that such studies should be redesigned to resolve conflicting results of earlier intervention studies. In particular, using separate biomarkers to distinguish healthy from diseased individuals may be of help (Astley, 2003). Frankel and German (2006), and Halliwell (2006) have given very useful summaries on the antioxidant values of phenols and other substances.

5.8.6 Phenolic Substances in Alcoholic Beverages

Phenols are found in all higher plants; in leaves, stems, roots, flowers, seeds, skins, husks and fruit. They have great diversity of structure, but they must have at least one phenolic hydroxyl group (i.e. with OH covalently bonded to an aromatic carbon atom, usually a benzene ring carbon). Most possess several phenolic OH groups and consequently are often known as polyphenols. Many natural phenolic compounds exist as monomers

(composed of just one molecular unit), whereas others exist as oligomers or polymers, containing from two to a large number of repeating or similar molecular units. The latter are often known as tannins, although this term is sometimes used to describe plant phenols in general.

As a result of fermentation and other processes involved in the manufacture of alcoholic beverages, some phenols are inevitably present in the finished drink, although their levels vary enormously, according to the type of processing and aims of the processor. Thus, red wine is rich in phenols, rosé wine less so, cider, perry and white wine less still, with beer generally having the lowest phenolic content.

Phenolic compounds in alcoholic drinks are derived from three main sources:

- From materials used to craft the beverage (e.g. malt, hops, fruit, stalks, pips)
- From metabolic and other reactions that occur during processing, especially during alcoholic fermentation (yeast metabolism) and malolactic fermentation (bacterial metabolism)
- From additives (e.g. from contact with oak or chestnut casks or chips, or from added spices, herbs or pine resin).

The major classes of monomeric phenolic compounds found in alcoholic beverages are shown in Figure 5.8.6. Although flavonoid phenols tend to receive the greatest attention in the literature (especially with regard to antioxidant activity), the nonflavonoid phenols are probably just as widely distributed in alcoholic beverages. Certain classes of phenols, such as isoflavones, coumarins and chromones are not included in Figure 5.8.6 mainly because of their more limited occurrence in alcoholic drinks.

Figure 5.8.7 shows the major classes of polymeric phenols (tannins) found in alcoholic drinks. Of these, the procyanidins (such as B_2, B_3, and larger oligomers) are the most widespread, being found in beer, cider, perry and wine (including fruit wines). Table 5.8.2 lists typical or major phenolic types found in the most common fermented beverages, although it is worth remembering that many alcoholic beverages contain a large number of phenolic compounds, often at low levels.

Monomeric phenols are found in beverages as glycoside or ester derivatives (as well as underivatized forms – aglycones – in the case of flavan-3-ols), whereas procyanidin type polymers are present as aglycone forms. Glycosides include monosaccharides D-arabinose, D-glucose, L-rhamnose and D-xylose and disaccharides such as rutinose (see Section 2.8.1, Figure 2.8.2, Section 2.11.2, Figure 2.11.1 and Section 2.11.3, Figure 2.11.5), which are sometimes esterified (e.g. as acetyl, coumaroyl or galloyl derivatives; see Section 2.10.7, Figure 2.10.13). In the source materials, some phenols are bound to proteins, pectins, β-glucans or arabinoxylans of cell walls; this is especially the case for hydroxycinnamic acid type phenols (such as *p*-coumaric acid and ferulic acid) in barley and malted barley (Dvořáková *et al.*, 2008), and for procyanidins in cloudy apple juice (Barth *et al.*, 2007).

Polyphenols and lignins constitute an important part of dietary fiber, along with digestion resistant carbohydrates and proteins, the polyphenolic content sometimes exceeding 50% (dry weight) of insoluble dietary fiber and exceeding 60% of soluble dietary fiber in some beverages (Goñi *et al.*, 2009). The percentages of phenolic substances in the fiber in beer, cider and red wine were in the middle to higher part of the above ranges. It is believed that fermentation of some of these polyphenols in the large intestine by bacterial microflora contributes a significant amount to the health benefits associated with dietary fiber.

5.8.7 Some Chemical Characteristics of Phenolic Compounds

It is of interest to give a brief survey of selected *in vitro* reactions of phenols, as this may help in understanding their many *in vivo* reactions. The fact that many phenolic substances are relatively easily oxidized means that they are potent *in vitro* antioxidants, often being preferentially oxidized when in mixtures containing

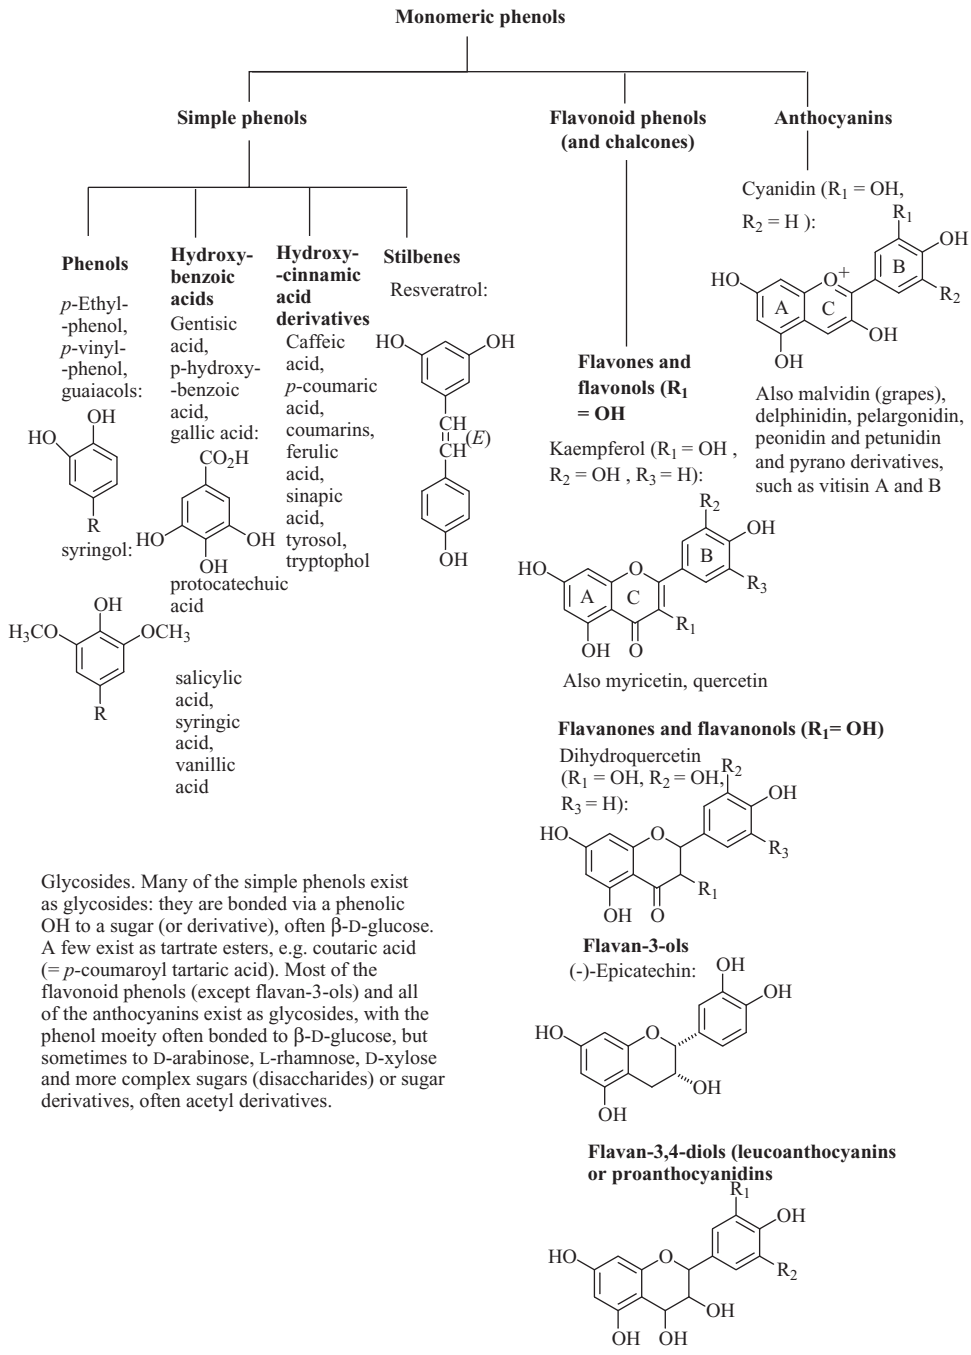

Figure 5.8.6 *Monomeric phenols in alcoholic beverages*

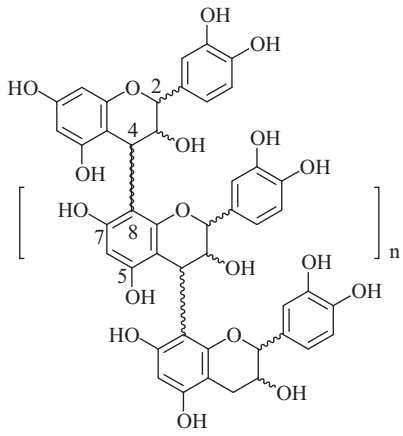
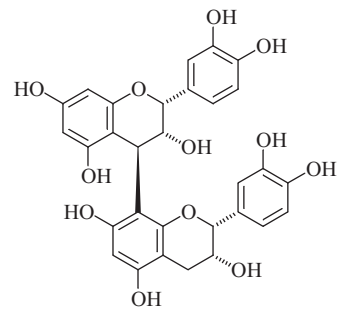


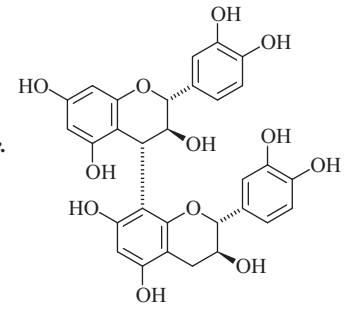
Procyanidin general structure, with type B (4-8) interflavan bonds

These are condensed catechic tannins, made from flavan-3-ol monomers. They are found in most fermented beverages, derived from the source.

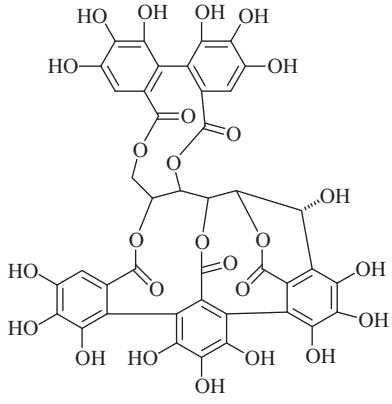
Type B procyanidins have just one interflavan bond between monomers, either C(4)-C(8) or C(4)-C(6) (not shown here).
Type A procyanidins have an ether bond between C(5) or C(7) on the lower unit and C(2) on the upper unit, as well as either a C(4)-C(8) or C(4)-C(6) bond.



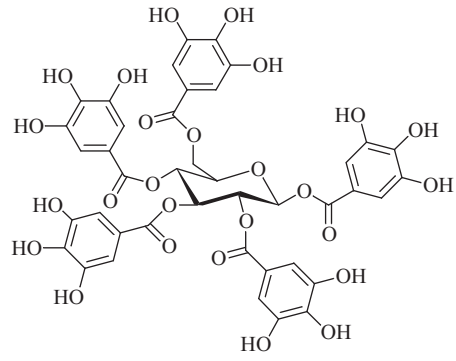
Procyanidin B2, based on (-)-epicatechin



Procyanidin B3, based on (+)-catechin



Castalagin, an ellagitannin from oak or chestnut.



Pentagalloylglucose

These are hydrolyzable tannins, based on sugar derivatives of phenolic acids, gallic acid, ellagic acid (hexahydroxydiphenic acid) nonahydroxytriphenic acid and others. They are derived mostly from woody materials.

Figure 5.8.7 *Some major polymeric phenols found in alcoholic beverages*

Table 5.8.2 *Major types of phenolic substances in alcoholic beverages*

Beverage	Representative monomeric phenol types	Polyphenol and tannin types	Typical total phenolic content (TPC)/g/l gallic acid equivalents (GAE)	Comments
Beer and other cereal based drinks	Cat, cin, fol, sp	Pro	<< 0.1	The brewing processes remove most phenols
Cider	Cat, cin, fol, sp	Pro	≤ 0.5	See Figures 2.8.2 and 2.8.8; Tables 2.8.3 and 2.8.4 in Section 2.8.2
Perry	Cat, cin, fdl, fol, sp	Pro	≤ 0.5*	See Table 2.8.2, Section 2.8.2
White wine (including fruit wine)	Ba, cat, cin, sp, fdl, fol	Pro	~0.3	Some phenols of type ba, sp may arise from wood ageing
Red and rosé wines (including fruit wines)	An, ba, cat, cin, fol, sp	Pro, ell†	≤ 3	See Figure 2.10.13, 2.10.7, Figure 2.11.5, 2.11.3. Some phenols of type ba, sp may arise from wood ageing

An = anthocyanin and nonpolymeric derivatives, such as vitisin A and B, ba = benzoic acid derivatives, cat = flavan-3-ols, cin = hydroxycinnamic acid derivatives, ell = ellagitannins, fdl = flavan-3,4-diols (leucoanthocyanins), fol = flavonols, sp = simple phenols, pro = proanthocyanidins and polymers based on flavonoid monomers. *for bittersweets; †in strawberry – see Figure 2.11.5, Section 2.11.3

other oxidizable substances. Simple phenols are oxidized by mild oxidizing agents (Figure 5.8.8), whilst 1,2- and 1,4-dihydric phenols are even more easily oxidized to 1,2- (or *o*-) and 1,4-(or *p*-)-benzoquinones (respectively). Many natural phenols possess catechol (1,2- or *o*-dihydroxy units) that can be chemically or enzymically oxidized to *o*-benzoquinone groups, as shown for (+)-catechin, a common component of alcoholic beverages (de Gaulejac *et al.*, 2001) (Figure 5.8.9). It is understood that *o*-benzoquinone groups can bind covalently to proteins, one of the factors that contribute to permanent hazes in maturing beer (Section 2.6.9). It will be emphasized later that a common general feature of polyphenols and tannins is their ability to bind proteins.

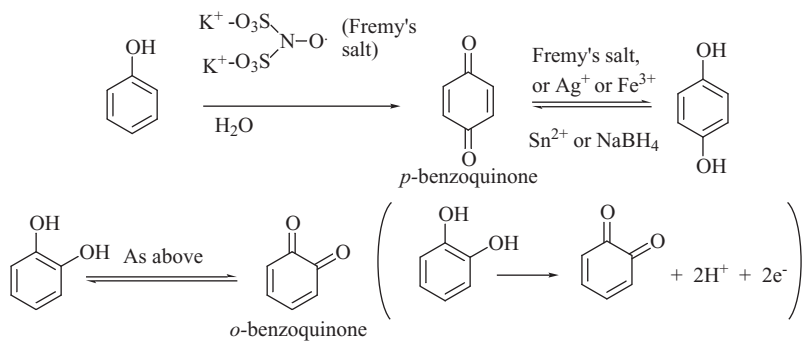


Figure 5.8.8 *Oxidation of phenols* in vitro

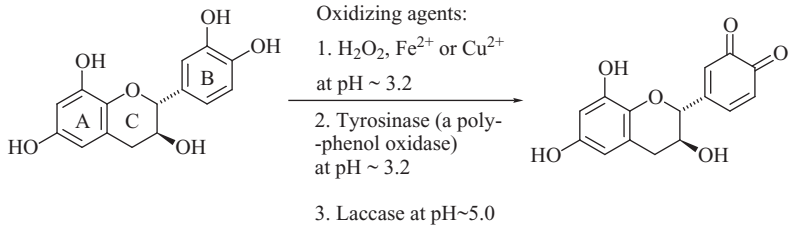

Figure 5.8.9 *Oxidation of B ring catechol unit of (+)-catechin*

It is believed that the first step in the oxidation of polyphenols is the formation of resonance stabilized phenoxyl radicals. Simple phenols, and especially conjugated phenols are able to form relatively stable phenoxyl radicals by hydroxyl hydrogen abstraction and are thus capable of disrupting free radical propagation in chain mechanisms such as those observed in the peroxidation of lipids (Figure 5.8.4). This phenomenon, shown by many conjugated and aromatic molecules, is known as radical scavenging. Phenoxyl radicals are resonance stabilized (a form of thermodynamic stabilization), but some with flanking bulky groups are also sterically (kinetically) stabilized. In a study of the antioxidant values of citrus flavanones, Di Majo *et al.* (2005) showed antioxidant power, as measured by scavenging competition for peroxy radicals with crocin, is dependent on both methylation at the catechol unit in ring B and on the nature of glycosation at position 7 in ring A. For the aglycones, the presence of C(4)-OCH_3 enhanced antioxidant activity somewhat, whereas with the 7-rutinosides, antioxidant ability was greater with an unmethylated catechol ring B unit. This catechol unit (methylated or not) appears to be important, but not essential for radical scavenging activity, since narengin, with only one ring B OH group, also shows antioxidant properties.

Phenolic substances, tannins in particular, are noted for their binding to proteins – indeed this quality is important in the tanning of leather materials, and contributes to influences on overall nutrition (Section 5.4.3). Hydrolyzable tannins especially contain large numbers of phenolic OH groups that can act as either hydrogen bond acceptors or hydrogen bond donors with proteins, besides having carbonyl oxygen and other oxygen atoms that may act as hydrogen bond acceptors. Castalagin (Figure 5.8.7) for example has 16 phenolic OH groups and 10 other oxygen atoms that could conceivably participate in hydrogen bonding. Given the right conditions, say a local mildly alkaline environment, phenols may be able to form ionic bonds with arginine and lysine residues of proteins. Additionally, lipophilic attractions between the phenol aromatic rings and the side chains of phenylalanine, tyrosine and other aromatic amino acid residues may also be possible.

Polyphenols should also be capable of hydrogen-bonded attractions with carbohydrate and nucleic acid molecules. Given the extent of the many weak bonding capabilities of phenols, it is likely that polyphenol–carbohydrate or polyphenol–protein interactions (e.g. at receptor sites) are important in some of the *in vivo* processes that result in the known health benefits that can occur when phenol containing alcoholic beverages are consumed in moderation.

The fact that polyphenols are generally good metal chelators is of interest because many oxidations are catalyzed by transition metal ions (Fe^{2+}, Fe^{3+}, Cu^{2+}, Mn^{2+}, etc.), since these ions can readily exchange electrons, thus enabling them to initiate free radical chain reactions. Polyphenols, especially those with catechol units, by forming chelate complexes with metal ions such as Fe^{2+} and Fe^{3+} can render these ions less able to participate in the generation of free radicals, as initiators (Bujanda, 2000). This may be one of the mechanisms by which inhibition of the oxidation of membrane or lipoprotein lipids may occur in the presence of phenols.

Polyphenols and other antioxidants exhibit a wide range of nonantioxidant *in vitro* activities, some of which could contribute to *in vivo* disease protection by the presence of such constituents in the diet. For

example, some flavonoids and other phenols are inhibitors of oxidative or degradative enzymes, such as cyclooxygenases, matrix metalloproteinases, lipoxygenase and xanthine oxidase. *In vivo*, these effects may limit unsaturated fatty acid oxidation and protect against atherosclerosis, or limit the invasive properties of cancer cells and metatstasis. Some polyphenols (e.g. flavan-3-ols) block folate metabolism, thus possibly inhibiting cell proliferation. Likewise, catechins inhibit telomerase, a nucleoprotein whose activity has been linked to the 'immortality' of cancer cells. Several polyphenols are known to downregulate transcription factors such as NF-κ-B, or are active receptor binders or are known to be inhibitors of angiogenesis. Carotenes and selenium are known to stimulate immune response or to upregulate the production of protective enzymes (Halliwell and Gutteridge, 2006).

5.8.8 Health Benefits and Antioxidant Potency of Alcoholic Beverages, their Phenolic Extracts and their Individual Phenolic Components

The association of certain components of diet, commonly known as antioxidants, with reduced risk of certain diseases and pathological conditions (notably cardiovascular diseases, diabetes and certain cancers) is well known. Amongst those components, and sometimes prominent, are phenolic compounds. Red and rosé wines, including fruit wines, generally possess the highest phenolic contents, with white wine, beer and spirits being relatively poor sources, unless phenols have been added, as additive components, such as in liqueurs, bitters, cocktails, aperitives, vermouths and retsina.

The primary evidence comes from whole beverage and whole food epidemiological studies, which have been critically summarized (Bujanda, 2000; Stanner *et al.*, 2004; Meyskens and Szabo, 2005 and many references therein). As discussed in Section 5.6.3, low to moderate consumption of alcoholic beverages in general is associated with reduced risk of cardiovascular disease (in particular) and certain cancers, such as some of those of the gastrointestinal tract. Ethanol itself plays a role in reducing the risk of cardiovascular disease, but the consensus of opinion is that phenols also play an important part and that the two may be most effective together. It is possible that other components (e.g. β-glucans (Section 5.7.4), pentacyclic triterpenoids, Maillard reaction products and degraded chlorophylls (Section 5.8.10) play some part too.

Given such evidence, many animal intervention and human intervention studies (*in vivo*), as well as *in vitro* studies have been undertaken in recent years using either whole beverage samples, phenolic extracts or single/mixed specific phenolic components. Intervention studies are usually carried out by observing changes in risk factors or changes in the levels of disease biomarkers in a group of subjects that are randomized into subgroups ('arms') to take (injested or injected) beverages or placebo. In the case of humans, the risk factors can be physical ones such as heart rhythm or blood pressure, or concentrations in biological fluids of specific chemicals (say for cardiovascular disease), such as blood HDL-C, LDL-C, trigycerides and fibrinogen levels. Biomarkers (usually measured in plasma, serum or urine) can be specific ones for particular conditions (say atherosclerosis) such as homocysteine, C-reactive protein, interleukin-6, intercellular adhesion molecule-1, etc., or more general markers for oxidative stress, such as F_2-isoprostanes and 19- or 20-hydroxyeicosatetraenoic acid (19- or 20-HETE) (Section 5.8.9). The same argument applies to animal intervention studies, with the addition that there is the opportunity to study biomarkers in whole tissue, as well as biological fluids.

Human intervention studies have tended to show that moderate intake of alcoholic drinks (especially red wine) favorably alters the levels of certain cardiovascular disease risk factors in healthy individuals (Hansen *et al.*, 2005; Natella *et al.*, 2002; Vásquez-Agell *et al.*, 2007). Similar benefits were found on moderate red wine intake by subjects with type 2 diabetes mellitus (Marfella *et al.*, 2006) and by mildly hypocholesteremic subjects (Naissides *et al.*, 2006).

Intervention studies on rats have demonstrated that those fed with red wine had lower lipid peroxidation, greater reduced glutathione levels and higher antioxidant enzyme activity compared with alcohol-fed rats (Assunção *et al.*, 2007). Also, red wine was found to attenuate alcohol induced rise in blood pressure in Sprague–Dawley rats, although the effect was not mediated by the inhibition of cytochrome catalyzed hydroxylation of arachidonic acid (Section 5.8.9) (Cowpland *et al.*, 2006).

Thus, intervention studies tend to corroborate the association between moderate red wine consumption and lesser risk of cardiovascular disease. Moreover, individual polyphenols (catechin and quercetin) were found to improve F1-labeled blood clot lysis on injection into ApoE knockout mice (atherosclerosis model) to the extent that lysis was at the same level as in 'wild type' control mice (Booyse *et al.*, 2007). Furthermore, polymeric proanthocyanidins from grape pips were found to increase antioxidant defences in rat plasma (Koga *et al.*, 1999), whilst a combination of gallic acid, total catechins and total resveratrols showed similar effects in rabbits, whereas total anthocyanins contributed more to vasodilatory effects than to antioxidant effects (Burns *et al.*, 2000).

Thus, there is a body of *in vivo* evidence for the involvement of phenolic compounds, as such, in protection against cardiovascular disease, thought not necessarily via direct antioxidant pathways. This is discussed further in Section 5.8.9.

There is less clear direct *in vivo* evidence of protective effects of beverage polyphenols, as such, against gastrointestinal and other cancers; beneficial effects appear to depend on dose, biological redox status and biological environment (Bujanda, 2000). Recently, cloudy apple juice was found to be more effective than clear juice or phenolic extracts in the modulation of 1,2-dimethylhydrazine-induced colon cancers in rats (Barth *et al.*, 2007). This implies that the colloidal suspension of proteins, fatty acids, cell wall polysaccharides, pectins, polyphenols and a host of other compounds, has a greater protective effect than polyphenols alone. This has been interpreted as a synergistic action between pectins and procyanidin type polyphenols in particular, which is discussed in Section 5.8.9.

More recently, Zhang *et al.* (2009) have shown that dietary grape extract, taken as 5% of the diet and corresponding to daily consumption of 7 μg of resveratrol, significantly reduced the incidence and multiplicity of tumors in the small intestine of male Fischer rats. The tumors were induced by azoxy methane in the diet. Extrapolation of animal data suggested that a 100 ml glass of red wine per day might provide protection against small intestinal cancer development in humans. Interestingly, it was also shown that resveratrol (although at much higher levels than in the animal study) inhibited the *in vitro* growth of human colonic adenocarcinoma (Caco-2) cells, mainly by inhibition of cell proliferation, rather than by cell viability.

The *in vitro* antioxidant value (often known as total antioxidant activity or TAA) of juices, alcoholic beverages and extracts can be estimated by a number of chemical/spectroscopic methods. These methods are discussed in more detail in Section 4.4.3, but include the crocin bleaching method, the 2,2-diphenyl-1-picrylhydrazyl ($DPPH^{\bullet}$) method, the ferric reducing ability of plasma (FRAP) assay, the ferricyanide reducing method, the oxygen radical absorbance capacity (ORAC) method and the trolox equivalent antioxidant capacity (TEAC) assay.

In general, there is a positive correlation between TAA and total phenolic content (TPC). Thus, red wines tend to have higher TAA values than white wines (Stasko *et al.*, 2002). The best correlation between TAA and phenolic concentration in red wine was for proanthocyanidin (polymer) fractions (Sánchez-Moreno *et al.*, 2003), partly explaining why older wines (with higher polymeric phenol contents) usually have higher TAA values than young wines (Larrauri *et al.*, 1999; Burns *et al.*, 2001). Radical scavenging power (often measured by the $DPPH^{\bullet}$ method) was likewise in the order red wine $>$ rosé wine $>$ white wine, and in white wines, hydroxycinnamic acid derivatives and flavonols were found to be largely responsible for radical scavenging ability, whereas flavan-3-ols were the main antioxidants (Psarra *et al.*, 2002). For red wines, reasonable correlations (R^2 up to 0.55) were found between TAA and catechin, gallic acid, myricetin and peonidin 3-glucoside concentrations (Di Majo *et al.*, 2008).

In nongrape based alcoholic beverages, high TAA values have been measured (by the Fe^{2+}/Fe^{3+}-thiocyanate method, Section 4.4.3) for Chinese yellow wine (or its concentrate), made from glutinous rice and wheat (Section 2.7.1) (Que *et al.*, 2006). The total antioxidant activity of 14 unmalted barley varieties has been determined by several methods, showing that total phenolic content of the barleys was well correlated with reducing power and radical scavenging power (by both ORAC and $DPPH^{\cdot}$ assays) (Zhao *et al.*, 2008).

Wines from black fruits, such as blueberry, have been shown to have similar TAA values to red wines (Sánchez-Moreno *et al.*, 2003). Similarly, dark fruits that are the basis of red fruit or country wines (e.g. blackberry, blackberry × raspberry hybrids and black cherry) were found to have similar TAA values to those of black wine grapes by the FRAP method (Pantelidis *et al.*, 2007). Likewise, North American huckleberries had high TAA values (ORAC assay), with *Vaccinium ovatum* being superior to *V. membranaceum* in this respect. The former were also higher in TPC and total anthocyanin content (Lee *et al.*, 2004).

There are a great many *in vitro* studies in the literature that were designed to test the polyphenol antioxidant hypothesis and to shed light on antioxidant and other mechanisms of interaction between polyphenols and biological systems. Much of this work involves the observation of physiological and biochemical changes in cells in response to contact with whole beverages, phenolic extracts or individual phenols. The main potential problem with results from these types of studies is the extrapolation to *in vivo* situations; cell responses *in vitro* may be quite different to *in vivo* responses. Also, the concentrations of phenolic compounds exposed to *in vitro* cells were often far greater than those ever experienced *in vivo* (Frankel and German, 2006). Furthermore, in experiments involving exposure of cancer cells to individual phenols or even phenol rich beverages, cell death (or other effects) may sometimes be attributed to the production of H_2O_2 from reactions of polyphenols with cell media (Long *et al.*, 2000).

Finally, although *in vitro* results generally support the antioxidant hypothesis, there is sometimes seemingly contradiction in detail (such as which class of phenols, like anthocyanins, flavonoids or proanthocyanidins, are most effective), which might be a result of differences in experimental conditions.

Earlier studies suggested that wine (especially red wine) and phenolic extracts were able to inhibit the (often Cu^{2+} catalyzed) *in vitro* oxidation of LDL and that the activity was collective and not due to a single phenolic component, although the best correlation between concentration and extent of inhibition of oxidation was for catechin (Frankel *et al.*, 1995; Teissedre *et al.*, 1995). Other studies under similar conditions using phenolic fractions from juice, wine and grape pips pointed to the greater antioxidant activity of procyanidin oligomers, flavan-3-ols and myricetin (Teissedre *et al.*, 1996). Wines made from mixtures of blackcurrants and crowberries or bilberries were effective in the inhibition of methyl linoleate peroxidation (Heinonen *et al.*, 1998). Wines were more effective than liquors, but there was no correlation between effectiveness of peroxidation inhibition and total phenolic content. In a study of the *in vitro* LDL oxidation in blood platelets, a red wine anthocyanin fraction, rather than whole wine, dealcoholized wine or phenolic acid/flavonol fractions was most effective at inhibiting LDL oxidation and platelet aggregation, two major events in the pathogenesis of atherosclerosis (Ghiselli *et al.*, 1998).

On the other hand, a study of *in vitro* inhibition of oxidative damage to catalase inactive human erythrocytes using red wine anthocyanin fractions demonstrated the polymeric subfraction to be the most effective (Tedesco *et al.*, 2001). Likewise, wine phenolic oligomers/polymers have been shown to be the best radical scavengers (de Gaulejac *et al.*, 1999; Rigo *et al.*, 2000). More recently, a blueberry extract of vinylpyranoanthocyanin-catechin oligomers (portisins, see Section 2.10.7, Figure 2.10.13) proved to be more effective than other phenolic extracts in reducing 2,2′-azobis(2-methylpropanamide).2HCl induced peroxidation of liposomal membrane lipids (Faria *et al.*, 2005). Also recently, both anthocyanin and procyanidin extracts of blackcurrant and boysenberry were able to protect human HL-60 promyelocytic cells and neuroblastoma cells against oxidative damage by hydrogen peroxide (Ghosh *et al.*, 2006).

Resveratrol from black grapes or red wine was shown to effectively counter apoptosis of human peripheral blood mononuclear cells caused by the oxidative activities of added 2-deoxy-D-ribose. However, inhibition of fatal damage was highly dependent on resveratrol concentration, maximum activity occurring at the 20 μM level (Losa *et al.*, 2001). Higher concentrations of this phenol actually showed pro-oxidative behavior, something that could apply to doses of polyphenols in general, though it should be borne in mind that there is little evidence that *in vivo* cells experience even 20 μM concentrations of phenolic substances. Thus, most *in vitro* evidence suggests that phenolic oligomers and polymers are generally more effective lipid oxidation inhibitors than other (monomeric) polyphenols, but there is *in vitro* evidence that all the important phenols found in alcoholic beverages have some effect against oxidative damage. Also, most data suggest that red wines are rather more effective *in vitro* inhibitors of oxidative cell damage than white wines, cider, perry or beer.

However, experiments have shown that white wine made with just 18 h skin contact (most white wine receives virtually no skin contact time) had a similar *in vitro* inhibition of LDL oxidation as a red wine, despite the fact that the total phenolic content of the white wine was still only 23% that of the red wine. This suggested that white grape skin substances (phenols and other compounds) are pro rata more powerful antioxidants than black grape/red wine compounds (Fuhrmann *et al.*, 2001).

Other *in vitro* studies on oxidative damage related to cardiovascular disease have taken rather different approaches. Extracellular addition of Chinese yellow wine to cultured rat vascular smooth muscle cells reduced homocysteine induced matrix metalloproteinase-2 (MMP-2) (Guo *et al.*, 2007). MMP-2 has been implicated in atherosclerotic plaque growth and instability (Section 5.8.9). In experiments inducing oxidative stress in myotube cultures by hypotonic shock, it was found that the presence of catechin and quercetin lowered the level of ROS and osmolyte release (of leukotrienes and taurine in particular), as well as inhibiting the oxidation of 2′,7′-dichlorodihydrofluorescein (Young *et al.*, 2004). However, trolox (Section 4.4.3) or α-tocopherol did not significantly influence leokotriene and taurine efflux, thus suggesting that the myotube culture responses to the presence of flavonoid phenols may not be confined to redox activity. Oxidative damage to DNA of *in vitro* cell cultures has been the focus of attention of some studies. Thus, monomeric and polymeric phenolic fractions from red wine were observed to inhibit chemically induced oxidative damage to herring sperm DNA (Lodovici *et al.*, 2001), whereas caffeic acid and catechin were shown to offer protection to human lymphocyte DNA against oxidative damage caused by either H_2O_2 or γ-rays (Greenrod and Fenech, 2003).

As a result of the observation from epidemiological studies that polyphenol rich diets (including low to moderate intake of some alcoholic beverages, especially red wine) may reduce the risk of certain cancers, there has been much research activity centered on the *in vitro* effect of polyphenols on cancer cells. Some earlier work in this area is summarized in Bujanda (2000) and in the references that follow.

Recent research has shown that whole berry black fruit extracts (Seeram *et al.*, 2006) and individual phenols (Ma *et al.*, 2007) have some marked effects on certain human cancer cell lines. Berry extracts at concentrations of 25–200 μg/ml were evaluated to inhibit the proliferation of human breast (MCF-7), colon (HT-29 and HCT 116), oral (KB and CAL-27) and prostrate (LNCaP) cancer cell lines (Seeram *et al.*, 2006). All the extracts exhibited inhibition of cell proliferation in all the cell lines, especially at the higher concentrations. Furthermore, black raspberry and strawberry extracts in particular exhibited high pro-apoptotic activity (∼threefold over untreated controls) against human HT-29 colon cancer cells. Earlier work has also shown berry extracts to have *in vitro* pro-apoptotic effects on human cancer cells (Ramos *et al*., 2005; Heo and Lee, 2005). Additionally, phenolic fractions or individual polyphenols have demonstrated inhibitory effects against various human cancer cell lines, such as red wine phenolic fractions against melanoma cell colonies on agar (Gómez-Cordovés *et al.*, 2001) and isorhamnetin (a flavonone glycoside) against esophageal squamous carcinoma cell line Eca-109 (Ma *et al.*, 2007).

5.8.9 Mechanisms of *In Vivo* Health Benefits of Dietary Phenols: Antioxidants or Otherwise?

The possible roles of phenols in food, wines and other beverages as *in vivo* antioxidants have been reviewed (de Beer *et al.*, 2002, de Lange and van de Wiel, 2004; Manach *et al.*, 2004; Tripoli *et al.*, 2007; Serrano *et al.*, 2009). Although there is substantial evidence that phenolic substances in alcoholic beverages, upon moderate consumption, contribute to health benefits, and polyphenols are well known to be potent *in vitro* antioxidants, there is little firm evidence that they act as direct antioxidants *in vivo*. Indeed, there is seemingly conflicting evidence in the literature regarding *in vivo* mechanisms – see for example Cowpland *et al.* (2006) and Ghiselli *et al.* (1999). More specifically, there is *in vivo* evidence that conflicts with *in vitro* evidence (Section 5.8.8) for the inhibition of lipid oxidation mechanism of phenolic antioxidant activity in, for example, preventing or delaying atherosclerosis (Hodgson and Puddey, 2005; Cowpland *et al.*, 2006). Part of the problem lies in the design of and interpretation of results of intervention (i.e. *in vivo*) studies and corresponding *in vitro* studies, as already discussed in Section 5.8.8 (Frankel and German, 2006). Another problem is the extreme complexity of the *in vivo* processes; relatively little is known about the bioavailability and metabolism of phenolic compounds. Also, there is a wide choice of biomarker molecules (in plasma, serum or urine) with which to correlate general protection from diseases (e.g. cardiovascular disease) or with particular aspects of a disease, such as the growth and instability of plaque in atherosclerosis.

As far as antioxidant activity is concerned, quite a few biomarkers of *in vivo* lipid oxidation or general oxidative stress have been used, including eicosanoids (such as isoprostanes), isofurans, isoketals (isolevuglandins), malondialdehyde and neuroprostanes. In recent years, much work has focused on isoprostanes in blood or urine as products of *in vivo* free radical (nonenzymic) peroxidation of lipids (especially arachidonic acid) (Montuchi *et al.*, 2004). The most studied isoprostanes are of the $F_{2\alpha}$ group of stereoisomers: they are isomeric with cylcooxygenase-1 (COX-1) derived prostaglandin $PGF_{2\alpha}$ (Smith, 2008) (Figure 5.8.10). Of these, probably the best known and most common stereoisomer is 8-isoprostaglandin- $F_{2\alpha}$ (8-*iso*-PG $F_{2\alpha}$

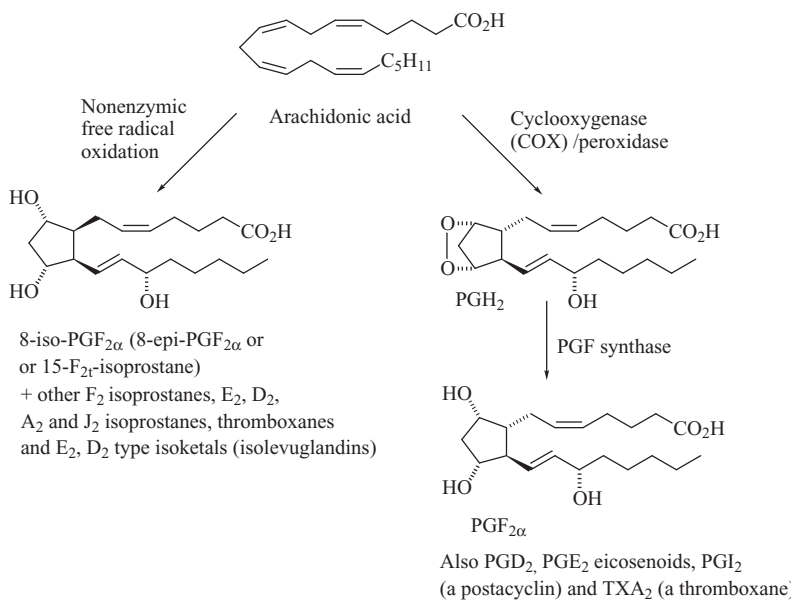

Figure 5.8.10 *Isoprostanes and prostaglandin $F_{2\alpha}$ from oxidation of arachidonic acid*

or 8-*epi*-PG $F_{2\alpha}$), sometimes known as 15-F_{2t}-isoprostane (Figure 5.8.10). Many other products of free radical oxidation of arachidonic acid are produced via the isoprostane pathway, including some with 3-hydroxycylopentanone rings (E_2- and D_2-isoP), cyclopent-2-enone rings (A_2- and J_2-isoP), γ-ketaldehydes (isoketals or isolevuglandins: iso-LGs, or E_2- and D_2-isoK) and thromboxanes (isoTxA_2 and isoTxB_2). The latter are also produced from arachidonic acid by COX enzymes (Smith, 2008).

Other cell membrane unsaturated fatty acids (e.g. α-linoleic acid, γ-linolenic acid and eicosapentaenoic acid, as well as docosahexaenic acid in the central nervous system) can also be oxidized by ROS via free radical chain mechanisms to give isoprostane type molecules. Hence there is theoretically an enormous number of isomeric and nonisomeric oxidation products of lipid oxidation. It is believed that the F2-isoprostanes are at first formed as phospholipid esters in membranes and are then hydrolyzed to free forms by phospholipases.

Apart from free-radical oxidations promoted by ROS, enzymes such as the COX isoenzymes (COX-1, COX-2 and COX-3) and cytochrome P450 isoenzymes are able to oxidize lipids to a range of products, such as prostaglandin $PGF_{2\alpha}$, thromboxanes and 20-hydroxyeicosatetraenoic acid (20-HETE). COX isoenzymes are widely distributed in body tissues. Additionally, myeloperoxidase (MPO), was observed to be excreted by phagocytes in wild type mice upon stimulation by pathogens. MPO is able to synthesize isolevuglandins (isoLGE_2 and iso[4]LGE_2) via the isoprostane pathway, beginning with the peroxidation of arachidonic acid. These isolevuglandins are able to form stable plasma protein adducts, which may be useful as a sensor of *in vivo* oxidative stress (Poliakov *et al.*, 2003).

It is now widely held that the observation of elevated concentrations of F_2-isoprostanes in biological fluids is a good (maybe the best, but not perfect) indicator of the extent of general oxidative stress. Furthermore, increases in F_2-isoprostane levels have been noted as early events in many pathological conditions, including asthma, cardiovascular disease, hepatic cirrhosis and Alzheimer's disease. Although not proven in every case, this suggests a causative role for oxidative stress in at least some of these diseases, especially cardiovascular disease (Voutilainen *et al.*, 1999; Montuschi *et al.*, 2004; Stocker and Keaney, 2004; Gross *et al.*, 2005).

In some human intervention studies with phenol rich beverages (red wine, dealcoholized red wine, grape juice and tea) reduced levels of oxidative damage biomarkers (such as F_2-isoprostanes) have been observed (Halliwell *et al.*, 2005). In other experiments, however, red wine polyphenols or other phenol rich beverages showed beneficial effects against atherosclerosis (by analysis of other risk factors), but did not influence lipid peroxidation (i.e. there was no significant effect on serum or urine F_2-isoprostane levels) (Halliwell *et al.*, 2005; Hodgson and Puddey, 2005; Hodgson *et al.*, 2002). It thus appears that phenolic substances in beverages may act against a variety of cardiovascular pathological conditions via a number of different mechanisms. The mechanisms and extent of beneficial health effects appear to depend on the type and range of phenolic substances present, and also on the medium in which the phenols are ingested. Additionally, there may be synergistic effects between phenolic substances and ethanol (Saucier and Waterhouse, 1999) and other beverage substances such as pectins (Barth *et al.*, 2007).

Two main general modes of *in vivo* action of beverage phenolic compounds, depending upon their fate in the gastrointestinal tract, need to be considered:

- *Postabsorption action*. Phenols are absorbed somewhere in the digestive system where some metabolic changes occur and the metabolites pass into the blood stream into tissues where health benefits occur before excretion.
- *Preabsorption action.* Phenols perform their beneficial reactions prior to absorption and excretion. This mode of action is thought to be most likely in the large intestine, where levels of phenolic substances can be comparatively high.

In the first mode of action, phenol metabolites have been found in human plasma, but usually in concentrations lower than 1 μM (Halliwell, 2006). For example, conjugated flavonoids, methylated gallic acid

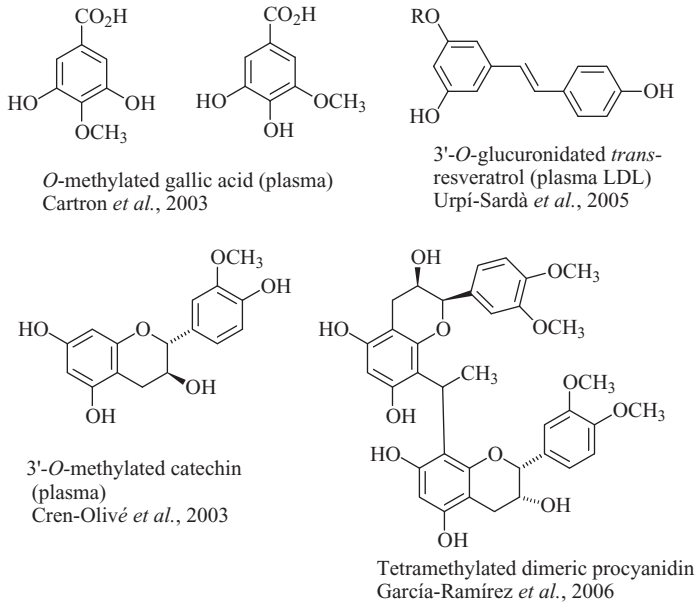

Figure 5.8.11 *Some polyphenol* in vivo *metabolites*

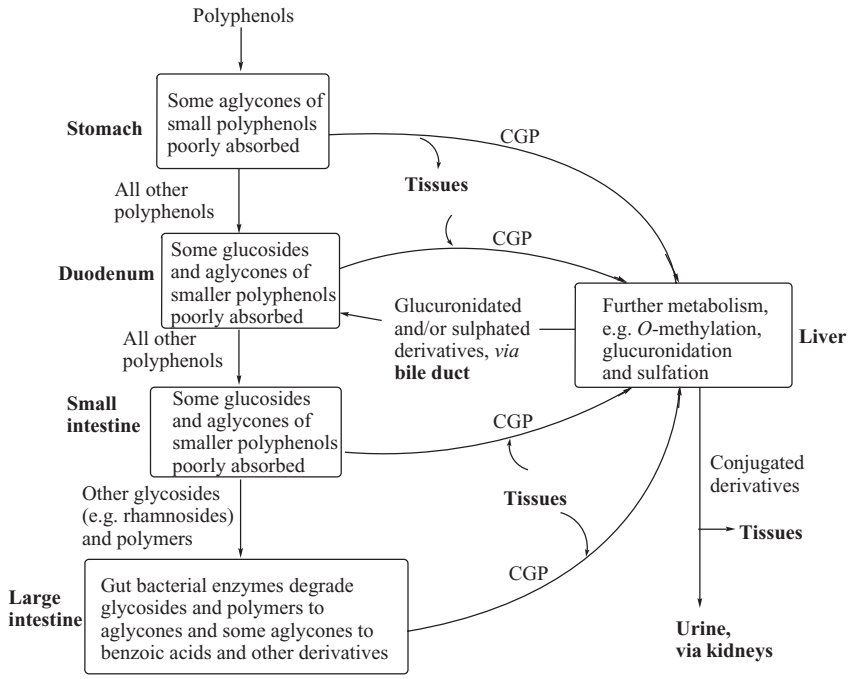
and various catechin metabolites (Figure 5.8.11) have been detected in blood. Catechin metabolites in the bloodstream may be of sufficient concentration to offer protection against LDL oxidation (Donovan *et al.*, 1999), giving some support to the LDL oxidation theory of atherosclerosis (Donovan *et al.*, 1999; Cren-Olivé *et al.*, 2003). However, many of these metabolites have been shown to be poor *in vitro* antioxidants compared with the aglycones or original beverage phenols, possibly because *O*-methylation (a common metabolic transformation) lowers radical scavenging ability. Phenolic compounds in general are not well absorbed, their bioavailability being dependent on dietary source (Manach *et al.*, 2005). Some scientists believe that the presence of ethanol enhances the bioavailability of phenols, which may explain why red wines (and red fruit wines) have often been found to offer somewhat greater health benefits than phenolic extracts or dealcoholized wine alone.

Figure 5.8.12 sketches the metabolic fate of dietary phenols. In general, polyphenols are poorly absorbed: for example, plasma concentrations of quercetin metabolites are no more than 0.1 μM following consumption of red wine samples containing 35 mg of quercetin each (Henning *et al.*, 2005; Manach *et al.*, 2005). The least well absorbed of all polyphenols are anthocyanins and proanthocyanadin polymers. Flavan-3-ols and flavonols are rather better absorbed, whilst the most effectively absorbed flavonoids are isoflavones, which are minor polyphenols in most alcoholic beverages. It seems that very little absorption of polyphenols occurs in the stomach and most are not degraded by the highly acidic conditions in the stomach, hence they pass on to the rest of the digestive system more or less intact.

Some absorption of flavonoid aglycones and glucosides, as well as free benzoic acid and hydroxycinnamic acid polyphenols occurs in the duodenum and small intestine. Glucosides are hydrolyzed in enterocytes by cytosolic β-glucosidases or by extracellular enzymes of the brush border membrane of the small intestine. At the same time, most of the resulting aglycones are glucuronidated by membrane bound glucuronosyl transferases and/or *O*-methylated by catechol *O*-methyl transferase. *In vitro* studies (Yi *et al.*, 2006) showed that anthocyanins can be transported through Caco-2 intestinal cell monolayers with a general efficiency of ~ 3–4% (1% for delphinium glucoside).



CGP = circulatory (plasma) conjugated polyphenol metabolites, usually *O*-glucuronides and *O*-methylated derivatives bound to albumin mostly, but also to other proteins, such as LDL

Figure 5.8.12 *Summary of metabolic fate of dietary polyphenols*

In general, the best absorbed here were glucosides and anthocyanidin rings with fewer OH groups. Cyanidin 3-glucoside of black raspberry (this is a common anthocyanin of black fruit wines) is absorbed through the human small intestine mostly as the intact glucoside, which appears as such in the plasma and urine, along with a small amount of *O*-methylated metabolite (Ichiyanagi *et al.*, 2007). Other cyanidin 3-glycosides (the 3-rutinoside and 3-xylosylrutinoside), like most polyphenols, are present in urine as metabolites, in this case as *O*-methylated derivatives at the 3′ position for the rutinoside and at both 3′ and 4′ positions for the xylosylrutinoside (Tian *et al.*, 2006). More recently, 18 phenolic acid metabilites acids were detected in the urine of human subjects 2–6 h after being fed bilberry-lingonberry purée, which contains anthocyanins and phenolic acids (Nurmi *et al.*, 2009). Several of these, including homovanillic, vanillic acids and hydroxylated phenylpropanoic acids, were judged to be metabolites of methylated anthocyanins, but their low concentrations in urine indicated that still a large part the metabolic products remained unknown.

Other flavonoid glycosides (e.g. arabinosides, rhamnosides and xylosides), carbohydrate bound hydroxycinnamic acid derivatives and proanthocyanidins, along with other unabsorbed polyphenols, must pass to the large intestine, where enzymes of the gut flora hydrolyze glycosides to aglycones and some flavonoid aglycones to hydroxyphenylalkanoic acids, hydroxybenzoic acids and phenols (Figure 5.8.13). These microbial metabolites are absorbed, whence they appear in the bloodstream as glucuronidated, *O*-methylated derivatives or as glycine-conjugated derivatives (Manach *et al.*, 2004). Recent studies have shown that plasma and urine levels of these metabolites are higher than those of tissular metabolites, suggesting that they may contribute significantly to the reduction of atherosclerosis risk factors and other health benefits associated with moderate wine consumption. Indeed, this may be the major mode of action regarding proanthocyanidins (some of the most abundant beverage polyphenols), since only the B_2 dimer has been found in human plasma

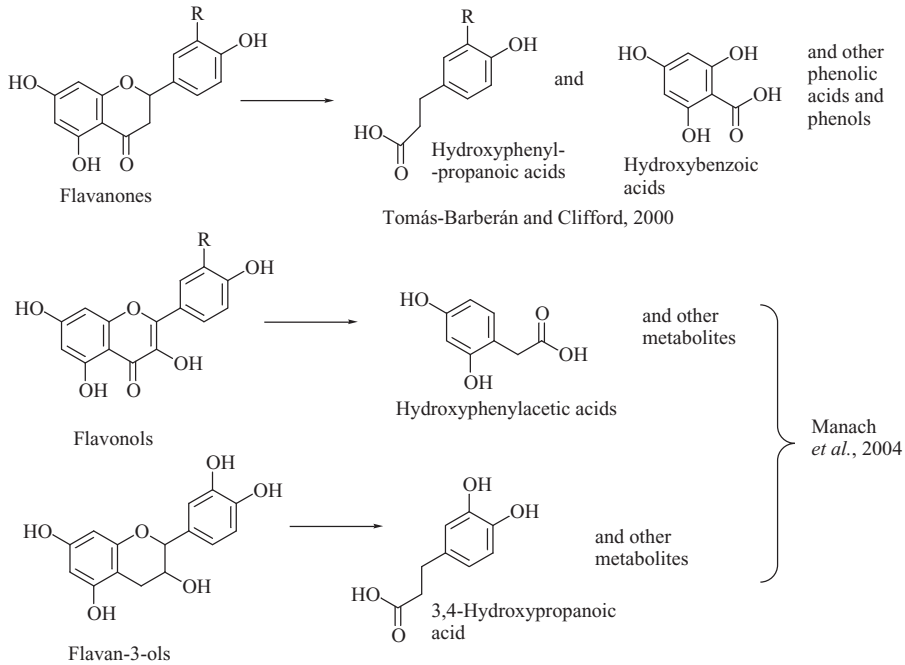


Figure 5.8.13 *Summary of metabolic fate of dietary polyphenols*

and even then, only at 0.04 μM concentration. There is also evidence that raspberry anthocyanins per se are only poorly absorbed before reaching the small intestine and substantial amounts pass to the large intestine, where degradation by microflora occurs (Borges *et al.*, 2007). Gut bacteria also hydrolyze large carbohydrate bound polyphenols, thus releasing the aglycones for further metabolism in the colon. This could explain why cloudy apple juice (and the same could apply to cloudy cider) was more effective than clear juice in modulating chemically induced colon cancers in rats (Barth *et al.*, 2006).

Polyphenol concentrations in the colon can reach several hundred μM, and even if the majority are neither metabolized nor absorbed, they may still play an important local role in the transformation of potential toxins and carcinogens, quite possibly acting as extracellular antioxidants. After all, the colon is particularly exposed to oxidizing agents, and most other dietary antioxidants, such as vitamins C and E are mostly absorbed before they reach the middle and lower colon.

Circulatory polyphenols (Figure 5.8.11) exist mostly as conjugated metabolites (*O*-methylated, *O*-glucuronidated and sulfated derivatives) that are extensively bound to plasma proteins, notably albumin, although red wine *trans*-resveratrol and the 3-*O*-glucoronides (Figure 5.8.11) of *cis*- and *trans*-resveratrol were found in human LDL particles after moderate red wine consumption (Urpí-Sardà *et al.*, 2005). This is consistent with the hypotheses that early events in atherosclerosis involve LDL lipid oxidation and that polyphenols behave as antioxidants in the prevention or delay of this condition. Recently, *trans*-resveratrol itself has been shown to bind strongly to bovine serum albumin (BSA, which has a high homology and a similarity in sequence and conformation with human serum albumin) in aqueous solution (i.e. *in vitro*) (Cao *et al.*, 2009). Fluorescence and IR spectroscopic results indicated the guest–host binding distance was less than 7 nm, suggesting that energy transfer from BSA to *trans*-resveratrol may occur via the formation of electrostatic attractions.

O-Methylation and *O*-glucuronidation can occur in a wide range of tissues, including enterocyte cells of the intestines, but sulfation occurs in the liver. Once in the blood stream, polyphenol metabolites are known

from radioactive labeling studies to be widely distributed in tissues, including those of the gastrointestinal tract, the brain, the liver and the endothelium (inner lining of blood vessels). The last named is probably one of the major target sites for flavonoid uptake, with concentrations of metabolites ranging from 0.03 to 3.0 μg of aglycone equivalents per g of tissue. There are relatively few reports of polyphenol metabolites in tissues, probably because of the difficulty in extraction of sufficient quantities of metabolites for analysis. However, a tetramethylated metabolite of a synthetic dimeric procyanidin, consisting of (–)-epicatechin units linked by an ethyl bridge (Figure 5.8.11), was isolated from the livers (as well as plasma) of Wistar rats after 2 h of feeding (García-Ramírez *et al.*, 2006). The procyanidin feeding rate was 200 mg/kg body weight, which led to a maximum of 15 μg of metabolite per gram of liver tissue. Conversely, there was no evidence of the presence of metabolites of higher synthetic procyanidin oligomers (trimers etc.) in either plasma or liver tissue. This suggested that natural procyanidin dimers (but not higher oligomers) are probably rapidly absorbed and metabolized and hence may be good agents of beneficial biological activity.

Some ingested *trans*-resveratrol is metabolized *in vivo* by hydroxylation (probably by various cytochrome P450 isoenzymes, such as CYPB1 or 1A2) at the 4′ position, giving piceatannol (Potter *et al.*, 2002, Piver *et al.*, 2004), a stilbene that shows even greater general *in vitro* antioxidant value than the resveratrols. This is of particular interest, because as already mentioned, polyphenol metabolites frequently exhibit reduced *in vitro* antioxidant activity compared with the original.

However, data is still scarce and the nature of the tissue metabolites may be different from that of plasma metabolites, due to specific uptake or specific intracellular metabolism. Nevertheless, it is possible that certain polyphenol metabolites (say, those of flavonoids) may be present in certain tissues (say, endothelial cells) in sufficient concentration to afford direct antioxidant protection (say, against atherosclerosis). As already discussed, there is little direct conclusive evidence of this, although there are many other ways that *in vivo* phenol metabolites may be of health benefit; these are discussed in the closing paragraphs of this section.

Very little is known of the kinetics of uptake and elimination of polyphenols in body tissues, but the major excretion route are known to be via bile or urine. It seems that larger more highly conjugated polyphenols are preferentially excreted in bile to the duodenum, where further metabolism and absorption can occur in the intestines, recirculating the metabolites via the liver. In this way, it is possible that metabolites of certain polyphenols could remain in the body for some considerable time ($>$7 h). Smaller, less conjugated polyphenols are preferentially excreted via urine. Recovery of polyphenol metabolites in urine tends to be moderate ($\sim$30% for epicatechin in cocoa), to low ($<$10% for wine catechin and anthocyanins), although the lowest experimental recoveries may be due to analytical difficulties or lack of knowledge of metabolites.

Again, there are few precise data regarding half lives of polyphenol metabolites in human plasma, but common phenols of alcoholic beverages, such as anthocyanins and flavan-3-ols generally have half lives of the order of 2–3 h, whereas isoflavones (less common in alcoholic beverages) and flavonols (such as quercetin) have half lives of about 4–8 h and 11–28 h, respectively. Since the major polyphenols in alcoholic drinks are anthocyanins, flavan-3-ols and proanthocyanidins, it seems unlikely that significant accumulation of plasma metabolites will occur in the body, except perhaps after rapidly repeated intake (binge drinking?), which will have negative health effects (Section 5.6.2). Thus it is likely that polyphenol metabolite concentrations fluctuate between repeated the distant intake of alcoholic beverages associated with regular moderate drinking.

There is growing evidence that polyphenols exert at least part (and possibly a major part) of their health benefits by influencing cell signaling pathways, (Williams *et al.*, 2004). Cells respond to stresses by increasing or decreasing the availability of certain proteins, by altering the expression of specific genes, using signal transduction pathways. These pathways regulate many cell processes, such as apoptosis (programmed cell death), growth and proliferation. Kinase enzymes are crucial for signal transduction pathways: they catalyze the phosphorylation (or dephosphorylation) of signal transduction proteins and eventually influence the activity of transcription factors (proteins that bind to specific response elements on DNA, promoting or inhibiting specific gene transcriptions).

There is good evidence to suggest that flavonoids such as catechin or quercetin (as well as ethanol) in alcoholic beverages reduce the risk of cardiovascular disease by increasing the expression of endothelium fibrinolytic proteins, such as t-PA (Booyse *et al.*, 2007). This increases the fibrinolysis or lysis of atherosclerotic fibrin clots, thus preventing build up and rupture of plaque that leads to thrombosis or stroke. In particular, it has been proposed that polyphenols (and ethanol) increase the expression of t-PA by activation of p38 MAPK signaling. Transcription of t-PA is up regulated via specific polyphenol and ethanol transcription factor binding sites in the t-PA promoter protein.

There is also evidence that certain polyphenols are able to inhibit directly the action of certain metabolic enzymes. For example, it is possible that this kind of action demonstrated by procyanidins may occur earlier in the sequence of events that can eventually lead to atherosclerosis and stroke; a sequence that is linked to obesity in many individuals. It is known that a diet high in procyanidins can minimize weight gain and prevent obesity, although on the negative side, this may be accompanied by less efficient digestion and a drop in nutrient uptake (Section 5.4.3). Simultaneous ingestion of apple polyphenol extract (rich in oligomeric procyanidins) and triglycerides fats significantly inhibited an increase in plasma triglyceride levels in both mice and humans (Sugiyama *et al.*, 2007). Likewise, the same group showed that procyanidins, especially the higher oligomers, inhibited the *in vitro* action of pancreatic lipase on 4-methylumbelliferyl oleate, thus suggesting apple polyphenol extract procyanidins inhibited triglyceride absorption by inhibiting the activity of pancreatic lipase in mice and humans.

In general, polyphenols may inhibit a variety of chronic diseases by selective inhibition of kinases (Williams *et al.*, 2004). For example, cell growth and proliferation are regulated by growth factor proteins that start signal transduction cascades by binding to specific receptors in cell membranes. Polyphenols may alter growth factor signal transduction by either blocking receptor growth factor binding or by inhibiting receptor phosphorylation (that is, blocking the action of certain kinases). Thus polyphenols may help prevent cancer by inhibiting proliferation, inducing apoptosis and preserving cell cycle regulation, by a number of specific cell signaling mechanisms. Additionally, some polyphenols are known to inhibit angiogenesis (development of new blood vessels) and matrix metalloproteinase (MMP) expression. New blood vessels are essential for the supply of oxygen and nutrients to growing tumors, and MMPs, overexpressed and excreted by tumor cells, break down extracellular tissues (collagen, gelatin and other fibers), allowing invasion of surrounding tissue by tumor cells. Hence polyphenols may prevent cancer by inhibiting the growth of cancerous masses and the spreading of cancer cells.

It was previously mentioned that *trans*-resveratrol is partially metabolized to piceatannol in humans. Density function theory (DFT) calculations suggest greater reactivity of piceatannol over *trans*-resveratrol towards hydroxyl and peroxyl radicals (Rossi *et al*., 2008), in agreement with observation of the greater *in vitro* antioxidant power of the metabolite. Similarly, molecular modeling showed that piceatannol is more able than *trans*-resveratrol to form a complex with tetrameric transthyretin (TTR), a cerebrospinal fluid protein that is thought to offer protection against Alzheimer's disease by binding to Aβ peptides and preventing them forming amyloid fibrils (Costa *et al.*, 2008). The stilbene polyphenols are known to bind (*in vivo*) to specific plasma membrane binding sites, which could increase the expression of protective TTR and they also bind to Aβ peptides *in vitro*, thus preventing fibril formation, although the molecular mechanisms of these interactions are unknown.

Polyphenols may prevent CVD by decreasing cell adhesion molecule expression, thus discouraging the incorporation of inflammatory monocytes from blood into the endothelium (Choi *et al*., 2004; Ludwig *et al.*, 2004; Stocker and Keaney, 2004), which is thought to be important in the early stages of CVD. They are also known to increase endothelial nitric oxide synthase (eNOS) activity (Anter *et al.*, 2004). Nitric oxide is required for arterial relaxation, which reduces the risk of arterial injury, inflammation and subsequent cardiovascular disease. Finally, polyphenols are known to inhibit platelet aggregation (Deana *et al.*, 2003; Bucki *et al.*, 2003).

5.9
Additives in Alcoholic Beverages

5.9.1 Introduction

Additive are substances that are intentionally added in small amounts to a foodstuff during its manufacture. In general, additives play important roles in the preparation of alcoholic drinks and are often integral parts of processing aids that are essential for their production. Additives can be used at any time during manufacture, although for a particular additive, legislation will generally specify at what point(s) in the manufacturing process it must be used. Plant materials or plant products that are an essential part of the production of particular alcoholic beverages are not classed as additives. This includes hops, other herbs and spices that are used to flavor beer (Section 2.6.3), vermouth (Section 2.12.2), spirits (Sections 3.4.2 and 3.5.5) and liqueurs (Section 3.8.3). The health values of selected plant components (phytochemicals) are dealt with in Section 5.11.2.

There are many additives that are allowed in the production of alcoholic drinks and these perform many functions, as outlined in Table 5.9.1. Permitted additives that perform specific functions, or are part of specific processes, vary from country to country, and from beverage to beverage, so the information in Table 5.9.1 is meant as a general guide only. Although undoubtedly useful, many additives have negative health benefits if ingested at high concentrations. Largely for that reason, each country has its own regulations governing additives, and each sets its own legal maximum limits permitted in alcoholic beverages. However, bilateral and collateral agreements exist between different countries or groups of countries that seek to rationalize differences in production methods (including use and nature of additives) for ease of trading (see Section 5.9.5). Analysis is carefully performed at approved or government laboratories as a periodic check on certain additive levels, as well as certain residues and trace substances (Chapters 5.10 and 5.11).

Sections 5.9.1–5.9.4, while giving some details on the major additives and processes in which they are used, emphasize health aspects. A brief account on legislation and regulation regarding additives is given in Section 5.9.5.

5.9.2 Sulfur Dioxide and Other Preservatives

Sulfur dioxide in its various forms has been used as an antiseptic agent in wines for centuries. Originally obtained by burning sulfur candles, sulfur dioxide is nowadays added in the form of potassium or sodium metabisulfite crystals, or in larger operations as gas form cylinders (Section 2.5.2). It is also used as a

Table 5.9.1 *Some permitted additives used in the production of alcoholic beverages*

Additive or process	Examples	Additive or process	Examples
Sterilization/ preservative	Sulfur dioxide and sulfites; sorbic acid and sorbates; dimethyldicarbonate; N_2; CO_2	Yeast nutrition/ fermentation aids	Ammonium phosphates; autolyzed yeast; soy flour; thiamine hydrochloride; oxygen or compressed air
Clarification, fining and stabilization	Acacia (gum Arabic); albumen; bentonite (and other clays); caseinates; gelatin; isinglass (fish collagen); PVPP; silica gel; tannin. Enzyme stabilizers include: catalase; cellulase, glucose oxidase; lysozyme; pectinase; various proteinases; urease	Color, odor and tartrate stabilization	Activated charcoal; ascorbic acid; copper sulfate; ferrous sulfate; potassium bitartrate; potassium ferrocyanide
Acidification	Citric, malic and tartaric acids; calcium chloride, calcium sulfate; Burton salts	Colorant	Caramel; natural cochineal (vermouth)
Deacidification	Calcium carbonate; other carbonates or bicarbonates; neutral tartrates	Oak flavoring/ maturation aid	Oak chips

preservative in some ciders and beers, although in the latter case at much lower levels. Sulfur dioxide in alcoholic beverages exists as 'bound' and 'free' forms, the sum of the levels of both forms giving the total sulfur dioxide concentration. The bound forms of SO_2 are reaction products with carbonyl compounds (e.g. acetaldehyde, pyruvic acid, α-ketoglutaric acid), phenolic compounds (e.g. anthocyanins, hydroxycinnamic acid derivatives) and thiamine. The main forms of free sulfur dioxide are SO_2 hydrates, hydrogen sulfites (HSO_3^-) and sulfites (SO_3^{2-}) (Section 2.5.2 – see Figures 2.5.1 and 2.5.2). The first mentioned has the most potent antimicrobial activity, and in excess, probably has the greatest allergenic and irritant abilities.

The big majority of people show no physiological reactions to sulfur dioxide at the levels found in alcoholic beverages and hence this additive poses no health hazard in these cases. However, some individuals (estimated at ~3% of the population) are hypersensitive to sulfur dioxide and some of these suffer severe asthmatic reactions, even fatal ones (caused mainly by bronchoconstriction), at low levels of ingestion (Hughes and Baxter, 2001; Vally and Thompson, 2003). Less severe allergic reactions to sulfites in alcoholic beverages include nasal congestion, abdominal pain, dizziness, skin flush and nausea (Kline, 2005).

It is thought that these symptoms are mediated by IgE associated immune responses and by genetic defects in mitochondrial enzymes, such as rodanase. Gaseous SO_2 dissolves in the moisture of the respiratory system to produce H^+, HSO_3^- and SO_3^{2-}, which affect the smooth muscles and nerves involved in bronchoconstriction, as well as influencing sodium and potassium currents in neurons (Du and Meng, 2004a; 2004b). Lipid peroxidation of cell membranes also occurs, because of inhibition of natural antioxidant (superoxide dismutase, etc.) activity (Meng *et al.*, 2003). Once sulfur dioxide is absorbed into the blood stream it becomes associated with globulin proteins. It is metabolized in the liver to sulfate and is excreted as such in urine.

People who are sensitive to sulfur dioxide are advised to drink spirits, liqueurs, certain ciders (and perry) and certain beers. As far as wines are concerned, the safest are organic wines, which by definition have the lowest SO_2 levels (although in the USA, organic wines are allowed up to 100 ppm of total SO_2), some having only natural levels, of up to 40 ppm. Nonorganic wines can have 199–450 ppm of total sulfur dioxide present, depending on the style of wine (sweet white wines tend to have the highest levels, dry red wines the lowest)

and the philosophy of the winemakers. Cask-conditioned beers may have up to 50 ppm of total SO_2, but this will often arise from the suspension of isinglass that is used as finings, as it is preserved with sulfites.

Many other beers have much less than this level of total SO_2, and some are produced with no added sulfites. High concentrations of ethanol kill or prevent the growth of microorganisms as well as providing some protection against oxidation of flavor compounds. For this reason, spirits, liqueurs and fortified wines do not need added sulfites. Similarly, beverages with high CO_2 contents – sparkling wines, sparkling cider or perry and most beers – are protected from microbial spoilage, and can be made with minimal or no addition of SO_2. Also certain wines, such as fino sherry and other flor wines (Sections 2.10.3 and 2.10.4), and some ciders (and perry) (Section 2.8.5) are deliberately made without added sulfites in order to facilitate essential processes, such as growth of flor yeasts and the occurrence of malolactic fermentation, respectively.

FDA regulations in the USA require all wines (domestic or imported) that contain more than 10 ppm of total SO_2 state 'contains sulfites' on the label. Similar regulations apply to alcoholic beverages produced in the European Union, Australia, New Zealand, South Africa and other countries.

Estimates of the toxicity of SO_2 and sulfites have reported the oral LD_5o for rates at 2 g/kg body weight, using 5% aqueous solutions (Amerine and Ough, 1980a). The acetaldehyde–SO_2 complex (the 'bisulfite complex') was found to have an oral LD_5o for rats of 1.5 g/kg body weight, making it a little more toxic than acetaldehyde itself ($LD_5o = 1.9$ g/kg). Thus, ignoring allergenic effects, the evidence suggests that no toxic effects should occur on consumption of alcoholic beverage that have less than the maximum allowed levels of total SO_2. At levels very much higher than those encountered in the most highly sulfited beverages, sulfur dioxide is cytotoxic; in particular it impairs the proper functioning of alveolar macrophages and it inhibits the production of tumor necrosis factor and interleukin-1 β-cytokines (Knorst *et al.*, 1996). At even higher levels, SO_2 is genotoxic, causing chromosome breakage (Yi and Meng, 2003). Concentrations of SO_2 as high as these are only ever met in industrial accidents and are only of passing interest to the drinker of alcoholic beverages. The Food and Agriculture Organization (FAO) and the World Health Organization (WHO) have recommended human acceptable daily intake (ADI) of sulfites to be less than 0.7 mg/kg body weight; well below toxic levels.

Production of wines with no added sulfites must be carried out with care, in order to eliminate factors that spoil wine – especially microbial spoilage (Chapter 2.4) and browning (oxidation). Thorough precleaning of wine must and rapid heat treatment prior to fermentation in a pressure controlled tank at 20 °C resulted in lower acetaldehyde concentrations upon fermentation (Seckler *et al.*, 1992). Further storage on the yeast lees with regular stirring helped to maximize the effect of reductive power of yeast cells. If such a wine was sterile filtered and hot filled into bottles, then a measure of protection against microbial infection was obtained, and the wine was claimed to be of organoleptic merit (Seckler *et al.*, 1992).

As a compromise, provided the risk of microbial infection is minimized, the use of combined antioxidants ascorbic acid and sulfites may prevent browning in white wines (Bradshaw *et al.*, 2004). Oxidation of ascorbic acid in the wine leads to a loss of sulfur dioxide, thus compromising the latter's antimicrobial potential.

There are processes for removal of SO_2 from alcoholic beverages, but these tend to adversely affect the quality of the beverage (Lin and Georgiou, 2005). These include the use of ion exchangers, membrane reactors in conjunction with nondiffusible oxidizing agents, and the use of hydrogen peroxide. Wheatgrass (*Triticum aestivum*) chloroplasts have been shown to reduce the sulfite concentration of red and white wines by up to 95% in less than 3 h, without influencing the flavor of the beverage if removal of SO_2 is carried out just before consumption (Lin and Georgiou, 2005).

Sorbic acid – (2*E*),4(*E*)-hexadienoic acid – and its potassium salt (Section 2.5.3) have long been designated as GRAS substances ('generally recognized as safe'). They are widely used as antiseptic agents in European wine and carry approved 'E-numbers': E200 and E2002, respectively. The maximum allowed levels of sorbates in wine varies from country to country, but in the EU is 200 mg/l (200 ppm). An acceptable daily intake (ADI) of sorbates, expressed as sorbic acid, of 25 mg/kg of body mass has been suggested by the

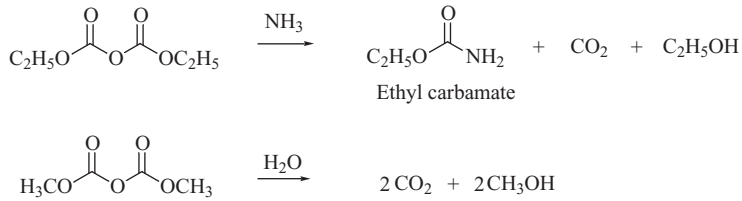

Figure 5.9.1 *Reactions of DEDC and DMDC in wine*

Joint Expert Committee on Food Additives (JECFA, 1973) of FAO/WHO. This value is far in excess of sorbate levels that are likely to be ingested in normal wine drinking.

Sorbates are used only at bottling time to inhibit the growth of yeast, especially in wines and other beverages that have significant residual sugar levels. They are ineffective against bacteria and hence are added with sulfites. This is of special importance since sorbates are metabolited by some lactic acid bacteria to the malodorous 2-ethoxyhexa-3,5-diene (Section 2.5.4). Sorbic acid is mostly metabolized to CO_2, but some is excreted unchanged in urine and a minor amount is metabolized to (*E*,*E*)-muconic acid (EEMA; 2*E*, 4*E*-hexadienedioic acid) and excreted in urine as such (Renner *et al.*, 1999). All toxicity experiments on animals proved negative at levels of feeding less than 1.5% of the diet (Amerine and Ough, 1980b). The oral LD_{50} for rats has been determined as 4.0–7.2 g/kg of body weight for potassium sorbate and 7.4–10.5 g/kg of body weight for sorbic acid.

The conjugated double bond system of sorbates is reactive to attack by nucleophiles, such as thiols, amines and nitrites, some examples of which (particularly amines) can be found in alcoholic beverages. In particular, many products of reaction between sorbates and amines have been found in other foodstuffs (Ferrand *et al.*, 2000) and it was feared that some of these may be mutagenic. A model system involving sorbic acid, sorbates and simple amines showed the formation of 2-pyridones at 50 °C (Ferrand *et al.*, 2000) – e.g. *N*-benzyl-6-methyl-3,6-dihydro-2-pyridone from sorbate and benzylamine. These compounds were shown to be neither mutagenic nor genotoxic, thus emphasizing the relative safety of sorbates as additives.

Pyrocarbonates, such as diethyl dicarbonate (DEDC) and dimethyl dicarbonate (DMDC), are powerful fungicides for many yeast species present in alcoholic beverages. They are generally more effective than SO_2, but unfortunately DEDC was found to produce very small amounts of ethyl carbamate, a known carcinogen, by reaction with ammonia (Figure 5.9.1) (Schlatter and Lutz, 1990). DMDC, on the other hand, has not been found to produce any carcinogenic hydrolysis products, although it does produce methanol (Figure 5.9.1), but not at toxicologically significant levels, when added to wine at levels of around 200 mg/l. DMDC can thus be used to supplement SO_2 in the stabilization of sweet botrytis affected wines, such as Sauternes (see Section 2.5.5) (Divol *et al.*, 2005). In this way, the maximum allowed total SO_2 level of 400mg/l can be avoided, thus decreasing the likelihood of 'sulfur stink' in young wines – a common criticism of botrytized wines.

Benzoic acid and benzoate salts (such as calcium or potassium benzoate) are used throughout the food industry as antimicrobial agents (preservatives) and flavoring agents. Use in wine has fallen in recent years in favor of sulfites and sorbates. Despite some concerns about allergenic reactions in some individuals, the JECFA of FAO/WHO advise that there are no safety concerns at normal levels of intake and recommend ADI of no more than 5 mg/kg of body weight. The EU codes for benzoate additives are E210–E213.

5.9.3 Fining Agents and Adjuncts

Like preservatives, clarification agents are very useful and find widespread use in the alcoholic beverage industry. Fining is followed by filtration in the production of many alcoholic drinks and hence there is little

chance of finding residual clarification agent in many beverages. Unfiltered drinks may have residual finings, but none of these have been found to present a health hazard. However, there is presently some public concern about the use of animal derived agents that may contain allergenic or pathogenic contaminants, or which may themselves be allergenic. In particular, isinglass has been (tentatively) listed as an allergen by the European Union, despite the fact that over decades of use in the UK and some other countries, no intolerance problems have been reported. In many countries, potential food allergens (Section 5.11.3) must be listed on food package labels (Section 5.9.5) and this is seen as a disadvantage by many producers of alcoholic beverages. Consequently, brewers and isinglass producers in the UK are investigating the potential allergenicity of isinglass in order to achieve a permanent exemption from the EU regarding labeling of (unfiltered) bottle- and cask-conditioned beers (Chlup *et al.*, 2006). To date (2008), there is no conclusive evidence that isinglass causes allergenic reactions (Baxter *et al.*, 2007). Nevertheless, in view of the relatively common incidence of allergy to fish proteins (Sagasuchi *et al.*, 2000; Hamada *et al.*, 2003) efforts have been directed to investigate the beer fining abilities of nonfish collagens (Walker *et al.*, 2007). It was found that avian collagen and pea pod extract were as effective as isinglass in laboratory trials, and in brewery trials there were few organoleptic differences between beers fined with the different agents. It is awaited with interest as to whether pea protein extract proves to be a good clarification agent on an industrial scale, as this would be an attractive option for vegetarians and fish protein sensitive people alike.

The cross linked insoluble polymer polyvinylpolypyrrolidone (PVPP) is useful in the removal of excess phenols from white wine (Section 2.9.4) and beer (Sections 2.6.3 and 2.6.9), often by incorporation into filtration materials such as kieselguhr. Because of its insolubility, only trace amounts of PVPP can be found in alcoholic beverages, although the more soluble PVP (a linear polymer) and the monomer 1-vinyl-2-pyrrolidone are often contaminants and may be found in drinks at rather higher levels. However, the World Health Organization (WHO) does not specify an acceptable daily intake (ADI) for PVPP indicating that it does not represent a hazard to health (http://www.inchem.org/documents/jecfa/jecmono/v18je01.htm). An ADI of up to 25 mg/kg body weight has been suggested by WHO (JECFA, 1973) for PVP, although this substance has been assessed, via oral dosed studies, mutagenicity studies and inhalation studies (on the monomer), to be safe for use in cosmetics (Anonymous, 1998). PVP was found to have an oral LD_{50} of over 100 g/kg body weight for both rats and guinea pigs. It is worth noting that orally administered PVP significantly reduced the incidence of bladder tumors in mice exposed to bracken fern (Anonymous, 1998). More recently, PVP was found to induce anaphylaxis in a boy's skin, but only when the skin was broken. In this case, basophils contacted PVP in the presence of serum to cause an allergenic reaction, otherwise PVP showed negative skin prick tests (Yoshida *et al.*, 2008).

Residues of other natural or nature based biological fining agents, such as albumen, carrageenan, caseinates, gelatin and gum arabic (acacia) are not considered to present health hazards to drinkers and the JECFA of FAO/WHO does not issue ADIs for these additives. Carrageenan, used as a kettle fining agent in beer production (Section 2.6.4), is the only one these agents to show toxicological properties, and hence it is not recommended for infants. Likewise inorganic fining agents based upon clay (bentonite and kaolin) and those based upon silica (silica hydrogels and kieselguhr) present no health hazard upon ingestion in small quantities. Chronic exposure to the fine dust, however, does pose some health risks to workers in the companies that produce them. The EU additive codes for bentonite, kaolin and silica are E558, E559 and E551, respectively.

5.9.4 Other Additives

The only generally allowed colorants for alcoholic beverages are caramel (E20) (for beers, ciders and certain wines, such as vermouth, and certain spirits) and natural cochineal (for some vermouths and aperitive wines) for which there have been no reported health risks. Other colorants are illegal, but in the past, elderberry juice or azo dyes may have been added to some wines.

Potassium ferrocyanide is established as an additive for removal of excessive amounts of copper and iron salts in (white) wines in the European Union and countries that have trade agreement with the EU (Australia, New Zealand and South Africa). For years it was not allowed in the USA, the fear being that prolonged contact with wine may produce cyanides, although this has never been established. Its oral rat LD_{50} is 6400 mg/kg body weight and JECFA of FAO/WHO gives an upper limit of 0.025 mg/kg body weight as the ADI for humans. Its EC approved code is E536.

Copper sulfate can be used in the European Union on wines that have excessive levels of malodorous hydrogen sulfide (H_2S) or mercaptans (thiols). The copper ions combine with sulfide species to give solid products that can be removed by racking and filtration. Nevertheless, Cu^{2+} levels must be carefully monitored and should not exceed 1 mg/l in the final product, although it is generally estimated that about 0.5 mg/l of Cu^{2+} is adequate for removed of H_2S and thiols in normal cases, so that residual levels of Cu^{2+} should be much lower than 1 mg/l. In any case, higher levels of Cu^{2+} can induce hazes and may need to be lowered by addition of potassium ferrocyanide. Copper sulfate is used in the EU, whereas copper citrate on bentonite can be used in Argentina, Chile, South Africa and Switzerland, and either copper citrate alone or on bentonite can be used in Australia and New Zealand. Copper citrate is less soluble in wine than copper sulfate and hence any excess will be removed on decanting/fining/filtration, along with copper sulfide, leaving lower levels of residual Cu^{2+}.

Copper is an essential trace element; it is a cofactor in many enzymes that participate in cell metabolism (see Sections 5.8.2 and 5.10.3). Acute ingestion of Cu^{2+} at high doses can lead to nausea and diarrhea, and at higher levels, coma and death can occur. The ionic form (i.e. Cu^{2+}) is considered to be more toxic than bound forms of copper, as it is often found in foodstuffs, including alcoholic beverages. Chronic ingestion of Cu^{2+} has led to liver failure in an extreme case (30 mg/day) and studies with mice indicate possible damage to the reproductive system. There is no evidence that copper sulfate is mutagenic (bacterial assays) and there is no evidence of copper salts being carcinogenic, although it does appear to inhibit the absorption of certain nutrients. A joint FAO/IAEA/WHO expert consultation committee established an upper limit to the safe intake of copper for adults of 0.2 mg/kg of body weight (JECFA, 1973). Its EC additive code is E405.

Artificial sweeteners are compounds that impart a sweet taste when added to foodstuffs. In the EU, Council Directive 94/35/EC (EC, 1994) (and various amendments) (e.g. EC, 2004) deal specifically with foodstuff sweeteners. There are many authorized sweeteners: acesulfame-K, alitame, aspartame, aspartame-acesulfame salt, cyclamic acid, dulcin, neotame, neohesperidine dihydrochalcone, saccharin, sucralose and thaumatin, all of which are synthetic, except neohesperidine dihydrochalcone (semi-synthetic) and thaumatin (natural) (Wasik *et al.*, 2007). Of these, all but alitame, dulcin and neotame are authorized for use in the EU. They are intensely sweet and are required to be added to foodstuffs in small quantities only, hence they have no nutritional value. This makes them valuable in the production of soft drinks, bottled or canned fruit, and yoghurt for diabetics or people avoiding a high carbohydrate diet. Within the EU, it is not legal to use intense sweeteners in beer and wine, but cider and perry in the UK and certain ciders in France are allowed to be sweetened in this way (Section 2.8.6)

Propylene glycol alginate (PGA) is used as a foam stabilizer in many beers, particularly highly refined, brewery-conditioned beers brewed from worts with low malted barley content, or beers brewed by high gravity methods (Section 2.6.8). It can be added to beer late in the process, usually at levels of around 50 mg/l. Labeling legislation in many countries now requires PGA to be listed as an additive, thus compromising the perceived wholesomeness of the product.

Other foam stabilizers used in the production of certain beers include hydrolyzed albumen (essentially a mixture of peptides) and hydrogenated hop *iso*-l-acids: tetra-and hexahydro*iso*-l-acids in particular. The latter are less polar (more hydrophobic) than the *iso*-α-acids themselves and hence make a more pronounced contribution to foam stability, even at levels of 3–5 mg/l. They are much more bitter than *iso*-α-acids but are unobstrusive when added to beer (normally late in the processing) at this concentration level.

Both *in vitro* and *in vivo* studies indicate that partial hydrolysis of PGA occurs in the gastrointestinal tract; the alginate moeity is not absorbed, whereas the propylene glycol moiety is rapidly absorbed and metabolized to lactic acid and pyruvic acid. Acute and chronic toxicity tests on ingested PGA in dogs, guinea pigs, humans and rabbits were all negative, and PGA showed no carcinogenic, mutagenic and genotoxic effects. The Joint Expert Committee on Food Additives (FAO/WHO) (JECFA, 1973), on the basis of extensive data from toxicological experiments have suggested an acceptable daily intake (ADI) for man of up to 25 mg/kg of body weight. The Committee also noted that 5% PGA in the diet of rats (≡ 2500 mg/kg body weight) had no toxicological effect and that no LD_{5O} data exists. Its EC additive code is E405.

5.9.5 Regulations and Legislation Relating to Additives

Legislation on food additives is based upon positive lists that vary from country to country. In each country, only explicitly authorized additives may be used. Also, most food additives may be used only in specified limited quantities in certain foodstuffs. Food additives for which no quantitative limits have been established must be used according to good manufacturing practice, which essentially means that only enough additive needed to achieve the desired technological effect should be used. All new additives (or modified versions of established additives) must have their usefulness well demonstrated and must pass rigorous and thorough scientific evaluation tests before approval is obtained for use. Within the greater context of food additives there exist the additives that are used in the manufacture of alcoholic beverages.

Statutory authorities exist in each country in order to protect that nation's health and safety by maintaining a supply of safe food, including alcoholic beverages. These authorities work in liaison or consultation with government ministries and representative organizations of the alcoholic beverage industry. They (via an expert group or committee within the authority) are responsible for developing, modifying and reviewing practices and procedures within the industry. This includes developing codes of conduct covering composition, contamination, labeling and fixing of maximum residue limits.

In the European Union (EU), legislation on food additives is governed by the European Council (EC) through its Scientific Committee on Food (SCF), which is advised by and works in conjunction with a number of authoritative and professional bodies. These include the European Food Safety Authority (EFSA), the Office International de la Vigne et du Vin (OIV), the European Brewing Convention (EBC) and the Institute of Brewers and Distillers. Legislation on additives is governed by Council Directive 89/107/EEC, which is amended from time to time, as the need arises. Within these directives, there are papers that refer to specific types of additives, such as SO_2, isinglass, artificial sweeteners, etc.

In the USA, the Food and Drugs Administration (FDA) is responsible for regulation and legislation relating to additives and processing associated with alcoholic beverages and labeling is regulated by the Alcohol and Tobacco Tax Bureau (TTB, formerly the Bureau of Alcohol, Tobacco and Firearms or BATF). This body may work in conjunction with the Association of Official Analytical Chemists (AOAC) and the American Society of Brewing Chemists (ASBC), the Wine Institute and other organizations.

In Australia and New Zealand, the Food Standards Australia and New Zealand (FSANZ) is the body that approves standards or variations in accordance with the general policy of the Australia and New Zealand Food Regulation Ministerial Council. FSANZ liaises with alcoholic drinks industry representative bodies, such as the Winemakers' Federation of Australia.

Also, at the international level there is the Joint Expert Committee on Food Additives (JECFA) of the Food and Agriculture Organization (FAO) and World Health Organization (WHO). This committee surveys existing toxicological and other data on food additives and publishes reports of the findings. It offers recommendations relating to additives, particularly regarding acceptable daily intake (ADI). Australia, New Zealand and South Africa have wine trade agreements with the European Union. Such trade agreements allow for differences in

permitted wine additives. For example, wines made in the EU in 2005 (say) using gum arabic (acacia) as a fining agent, were permitted for sale in Australia, even though gum arabic was not at that time on the FSANZ list of permitted additives. Conversely, Australian wines that have been treated with copper citrate can be sold in the EU, where copper sulfate, not citrate, is the allowed agent for removal of H_2S and thiols.

Any application to these statutory authorities to amend one of its articles (or standards, according to FSANZ) must include a sound rationale for the proposed changes, along with relevant data, including those relating to toxicology and residues. A relevant committee of the authority will take these into account in a draft assessment that also includes its own risk assessment using the best scientific studies available. A draft report with regulatory response will be prepared and submitted to the authority board. The draft report will then be amended as necessary and after resubmission, the board will accept or reject the final report. All these events occur with public consultation (comments, extra information, etc.) and with the appropriate government ministries. An outline of this process is shown in Figure 5.9.2, which, although relating specifically to Australia and New Zealand (FSANZ), is broadly applicable to all countries. The actual details of such processes depend on the urgency and complexity of the matter under investigation. A recent example of this process, again involving FSANZ, can be seen in the final assessment report for application A562 (2007) by the Winemakers' Federation of Australia to allow the use of copper citrate without a bentonite base (copper citrate/bentonite was already a permitted additive) (http:/www.foodstandards.gov.au/standardsdevelopment/). The request was

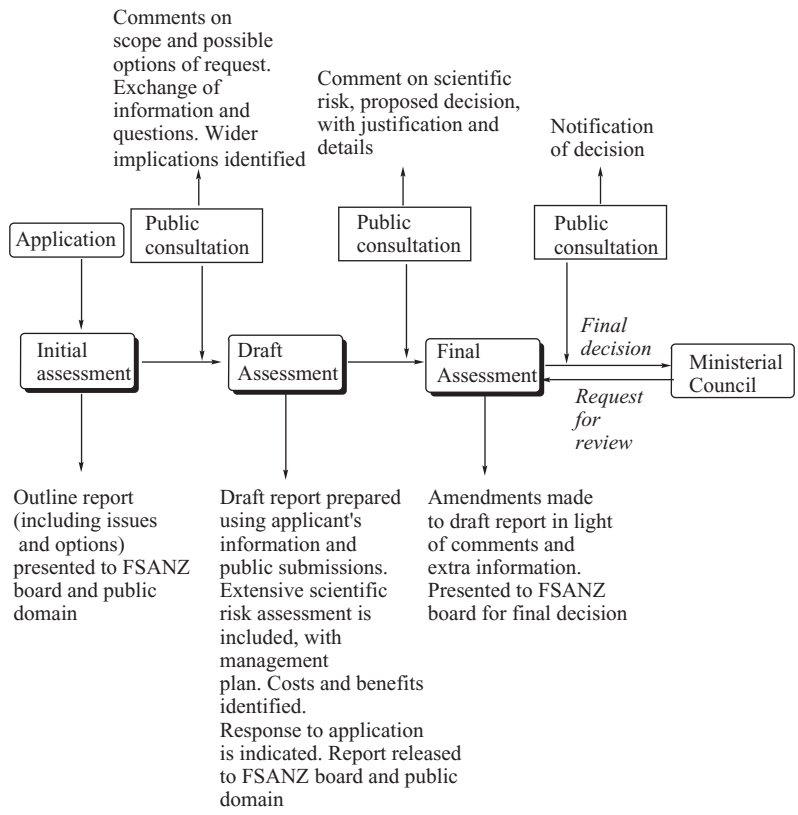

Figure 5.9.2 *Different stages in dealing with application for new or amended process in alcoholic beverage production in Australia and New Zealand (FSANZ)*

Table 5.9.2 *Legal limits for selected additives in alcoholic beverages*

Country	Beverage	Total SO_2 (mg/l)*	Total sorbate (mg/l)	Total Cu^{2+} (mg/l)*	Total $K_4Fe(CN)_6$ (mg/l)
Australia/ New Zealand	Wine (rs > 35 g/l)	400	200 (for all)	1 (for all)	
	Wine (rs < 35 g/l)	250			
	Country wines and mead (rs > 5 g/l)	300			
	Wine (rs < 5 g/l)	200			
	Mixed alcoholic drinks	250			
	Beer	25			
EU	Red wine (rs < 5 g/l)	160	200 (for all)	1 (for all)	1
	White wine (rs < 5 g/l)	210			
	Red wine (rs > 5 g/l)	210			
	White wine (rs > 5 g/l)	260			
	Various other wines (including Auslese)	300 350			
	Sweet white wines	400			
	Beer	200			
	Cider/perry	20–50†			
South Africa	Red wine (rs < 5 g/l)	150		1 (for all)	0§
	Natural wine (rs < 5 g/l)	160			
	Natural wine (rs > 5 g/l)	200			
	Noble late harvest wine	300			
USA	Wine	350 (100 for organic wine)	300	0.5	1

rs = residual sugar; *Includes contribution from natural or non-additive sources; †50 mg/l for cask-conditioned beer; §Allowed, but there must be no residue.

approved, but only after implementation of the procedures shown in Figure 5.9.2. Fixing maximum residue limits (including additives) is an important aspect of the work of statutory authorities such as SCF, USFDA and FSANZ. Table 5.9.2 shows maximum permitted levels of additives in various alcoholic beverages, fixed by various statutory authorities.

Temporary changes to legal requirements can be requested and approved in a short space of time, provided that sufficient grounds for the temporary change are demonstrated by the applicant. An example of this is the application to the European Union to amend Commission Regulation No. 1622/2000 that lays down the maximum allowed total SO_2 residue in EU wines. The application was made by the French Government to increase by a maximum of 40 mg/l, the total SO_2 content of wines from Alsace with less than 300 mg/l, as a result of very unfavorable weather conditions during the harvest (EC, 2007).

5.10
Residues in Alcoholic Beverages

5.10.1 Introduction

For the purposes of this book, the term residues refers to low levels of substances that have found their way into alcoholic drinks by routes other than deliberate addition to the beverage. These residues fall into three major categories: pesticides (Section 5.10.2), inorganic materials (Section 5.10.3) and industrial organic contaminants (Section 5.10.4).

Residual substances that exist in alcoholic beverages through the use of additives during the manufacturing process to improve the product are dealt with in Chapter 5.9.

Pesticide residues – fungicides and insecticides – arise from spraying of crop plants (cereals, fruit trees, grapevines and hop bines) to prevent insect infestation or fungal disease. Additionally, herbicides, sprayed onto land surrounding the crop plants to eliminate or minimize competition from weeds, are included in this category. Inorganic residues, on the other hand, originate from plant uptake from the soil and from contact (deliberate or accidental) between plant and contamination source. They can also be acquired during the manufacturing process, by leeching out of equipment. Similarly, industrial organic contaminants can find their way into an alcoholic beverage via contamination of the crop or production materials, or during the production process.

The following sections review the more common residues found in alcoholic beverages, with emphasis on the health risks they pose to consumers. Included here are brief accounts of legal restrictions on the mineral (metal and nonmetal species) content of alcoholic beverages and on the mineral content of water used for brewing or dilution purposes (e.g. of spirits) (Section 5.10.3). Regulation of processes, in order to limit the levels of inorganic contaminants in the finished product, is also discussed briefly (Section 5.10.3).

5.10.2 Pesticides

A wide range of pesticides is used on the raw materials used to make alcoholic beverages. These are used to control fungal infection of plants or seeds (fungicides), weed growth (herbicides) and insect infestation (insecticides). Pesticides are of great economic importance since, all other things being equal, they maximize the yield of healthy crops of cereals, fruit and hops (etc.) by minimizing weed competition for moisture and soil nutrients, by preventing attack by insects and by protecting the plants from fungal infection. On the negative side, some pesticides are known to upset the local ecological balance by killing beneficial insects

(such as bees), earthworms and aquatic life. Additionally, residues persist to certain degrees in foodstuffs and this has been the cause of much public concern over the years, despite the fact that many residues in alcoholic drinks are of exceedingly low levels. Pesticide spraying programs are designed to ensure maximum crop benefit, whilst minimizing residue concentrations in the finished product. Thus, concentrations of pesticide (g/l/ha), spraying intervals (e.g. six weeks) and the time interval between application of the last spray prior to harvest are all laid down by the pesticide manufactures and are overseen by various governmental agencies (e.g. DEFRA in the UK, European Commission in the EU, USFDA in the USA and FSANZ in Australia and New Zealand).

Extensive work has been carried out regarding the toxicological properties of all pesticides. As a result of this work, the various governmental statutory bodies have defined maximum residue limits (MRLs) relating to the raw materials that are used to make alcoholic beverages. Furthermore, FAO/WHO have suggested acceptable daily intake (ADI) for some pesticides (Amerine and Ough, 1980). Maximum residue limits have been applied to the raw materials (in mg/kg or μg/g), rather than beverages, because it is known that pesticides are often significantly degraded or removed during processing (fermentation, fining, filtration, etc.) (Navarro *et al.*, 1999; Szerletics *et al.*, 1999; Ying and Williams, 1999; Angioni *et al.*, 2005; Navarro *et al.*, 2007).

Toxicological studies often involve administration of large doses (usually by ingestion, sometimes by skin contact or by inhalation) to rats, mice or other animals and under those conditions, with respect to those particular animals, some pesticides have been shown to have specific chronic toxicities. Some have been found to be carcinogenic or mutagenic, but more have been found to be endocrine disruptors.

As a result of these findings, and also because of other considerations, some insecticides (e.g. aldrin, DDT, dieldrin, heptachlor and lindane) and some herbicides (e.g. Atrazine, paraquat and simazine) are banned for agricultural use in many (or most) countries. Other pesticides are not used in some countries, but allowed in most others (e.g. the fungicide captan is not in use in the USA, and the insecticide carbaryl is not allowed in the UK).

Acute toxicity (LD_{50}) for pesticides has been determined by experiments on a wide range of animals, including mice, rabbits and rats. Some, like diquat and paraquat have very high acute toxicities (low values of rat oral LD_{50}), but most have low (and some exceedingly low) toxicities (very high values of rat oral LD_{50}). Indeed, the acute toxicities of many pesticides, especially fungicides, are lower than many common chemicals, including natural products and those used in the production of alcoholic beverages. Nevertheless, the various statutory bodies involved in agriculture and food production have imposed maximum residue levels (MRLs) for all pesticides that are allowed for agricultural use; levels that fall far below toxic levels or acceptable daily intake levels. These are reviewed at intervals, as additional toxicological information comes to light. It is emphasized that toxic residues arising from fungal infection of plants untreated with fungicides are in general far more dangerous than the fungicides or their degradation products. These toxic residues include aflatoxins (from *Aspergillus flavus*; infection of maize in subtropical climates), trichothecenes (from *Fusarium* spp. infection of cereals in temperate climates) and others discussed in Section 5.11.4. Tables 5.10.1 and 5.10.2 display some prominent (and once prominent) pesticides used on crops used in the production of alcoholic beverages, along with their MRLs, LD_{50} and other data. Figures 5.10.1 and 5.10.2 show some of their structures, and the chemical classes to which they belong. It can be seen from Tables 5.10.1 and 5.10.2, that the acute toxicities (given by LD_{50}) of herbicides and insecticides are frequently higher (sometimes much higher) than those of fungicides. MRLs are often higher for grapes and other crops destined to produce alcoholic beverages than those for crops for eating (e.g. table grapes) (for general information regarding Europe see http://europa.eu.int/, the European Union 'on-line') or for drinking water (Section 5.10.5 – see Table 5.10.6). The reason for this appears to be that lesser amounts of alcoholic beverages are likely to be consumed compared with fresh produce, juices and drinking water. Furthermore, it is expected that some residue will be removed during the production of alcoholic beverages as a result of biochemical, chemical and physical processes.

Table 5.10.1 *Some herbicides and insecticides used on agricultural crops for alcoholic beverage production*

Herbicide	Example of trade name	CAS registry number	MRL* mg/kg	LD_{50} mg/kgbw (oral, rat)	Comments
Atrazine		1912-24-9	0.05 (USA)	3090	In general use. Banned in the EU
Bispyribac--sodium	Nominee (Kumiai)	125401-92-5	0.01 (cereal)	2635	Used on rice fields
Diquat	Aquacide	2764-72-9 85-00-7 (as $2Br^-$)	0.05	120	Dipyridinium type
Fenoxaprop-p-ethyl	Acclaim-Super (Aventis)	71283-64-6	0.05 (cereal)	>5000	New phenoxy type. Used on wild oats in rye, wheat, etc.
Glyphosate	Roundup (Monsanto)	1071-83-6	0.1	5600	In general use
Paraquat	Gramoxone	1910-42-5	0.02 (USA)	57	Banned in the EU
Metsulfuron-methyl	Escort (Dupont)	74223-64-6	0.05	>5000	New, used in barley and wheat fields. Triazine type
Nicosulfuron	Accent (Dupont)	111991-09-4	0.05	>5000	New sulphonamide type used in wheat fields
Simazine		122-34-9	0.1 (USA)	3100	Triazine type. Banned in the EU
Terbuthylazine	Clip (Sipcam)	5915-14-3	0.1	1590	Triazine type
Insecticides†					
Acetamiprid	Assail (Aventis)	135410-20-7	0.01	146	Neonicotinoid type for fruit trees
Aldricarb	Temik (Bayer)	116-06-3	0.02	7 (solid)	Carbamate type, used on citrus trees
Azadirachtin	Align, Azatin	11141-17-6	1 (grape)	3540	Natural nortetraisoprenoid from neem tree seeds
Carbaryl	Sevin	63-25-3	0.05	250	Also an acaricide. Banned in the UK
Dichlorvos	Nuvam (Amvac)	62-73-7	0.01	61	Phosphinate type used on outdoor fruit trees. Highly toxic to bees
Etofenprox	Trebon (Mistui)	80844-07-1	5	42880	Used on fruit trees
Imidaclorid	Admire (Bayer)	138261-41-3	1 (vines) 3 (hops)	450	Used on pome fruit, stone fruit, vines, hops and cereals. Affects bees
Malathion		121-75-5	5	5400	Organophosphorus type, also an acaricide
Pirimicarb	Aphox	23103-98-2	1	142	For fruit trees and cereals. Also aphicide
Pyrethrins	Alleviate	e.g. Allethrin 584-79-2	1	685	In general use
Thiamethoxan	Adage, Cruiser (Syngenta)	153719-23-4	0.5 (grape)	1563	Neonicotinoid type. Used on fruit (Adage) and on barley seed for storage (Cruiser)

*EU, unless stated otherwise; †Insecticides such as aldrin, DDT, dieldrin, heptaclor and lindane are not included in this table as they are banned in many countries.

Table 5.10.2 *Some fungicides used on agricultural crops for alcoholic beverage production*

Fungicide	Example of trade name	CAS registry number	MRL mg/kg	LD_{50} mg/kgbw (oral, rat)	Comments
Azoxystrobin	Heritage (Zeneca)	131860-33-8	2	>5000	Used on vines against powdery and downy mildew
Captan	Orthocide		0.02	>9000	General use, not in the USA
Carbendazim	Benlate	10605-21-7	0.5	>15000	General, combats downy and powdery mildew
Chlorothalonil	Bravo	1897-45-6	3	>5000	General use
Copper (II)	Bordeaux mixture		50	30	Used on vines against downy mildew
Dimethomorph	Festival (BASF)	110488-70-5 (*E*-isomer)	3	3900	Active against downy mildew on grapevines
Dithiocarbamates	Maneb, Mancozeb, Zineb etc.	12427-38-2 (Maneb) 12122-67-7 (Zineb)	5 (for all)	4100 (Maneb), 7600 (Zineb)	Active against downy mildew
Dinocap	Karathane	39300-45-3	1	980	Usually a mixture of homologues
Difenoconazole	Bardos, Score (Syngenta)	119446-68-3	0.5	1453	Used on cereal crops
Folpet	Acryptan	133-07-3	0.1	2189	Used on fruit trees and for cereal seed storage. Not used in the USA
Hexaconazole	Anvil, Planate (Syngenta)	79983-71-4	0.1	2189	Used to mildew and scabs on fruit trees, and vines (Anvil). Also on cereals (Plante)
Iprodione	Rovral (Rhone Poulenc)	36734-18-7	10	>2000	Widely used in the EU on vines (*vs.* grey mold). Also cereal seed treatment
Kresoxym-methyl	Stroby (BASF)	143390-89-0	1 (general) 0.2 (apples/ pears)	>2000	Used mainly on apple and pear trees
Penconazole	Topas (Syngenta)	66246-88-6	0.2	2125	Used on fruit, grape and hop plants
Propiconazole	Banner	60207-90-1	0.05	1517	Wide spectrum, used on fruit and cereal plants

(*Continued*)

Table 5.10.2 (Continued)

Fungicide	Example of trade name	CAS registry number	MRL mg/kg	LD_{50} mg/kgbw (oral, rat)	Comments
Pyrimethanil	Scala (Aventis)	53112-28-0	5	>4000	Used on vines (*vs.* grey mold) and apples (*vs.* leaf scab)
Procymidone	Sumisclex	32809-16-8	5	>10,000	Active against grey mold (*Botrytis cinerea*)
Sulphur		7704-34-9	50	5000	Widely used against powdery mildew
Tetraconazole	Domark 40ME	112281-77-3	0.1	1030	Useful against powdery mildew on vines
Thiophenate-methyl	Alert (Nagarjuna)	23564-05-8	3	7500	Wide spectrum, used on fruit trees and sugar cane
Thiram	Fernacol	137-26-8	3	1800	For fruit trees and cereal seed storage
Trifloxystrobin	Compass (Bayer)	141517-21-7	5	5000	
Vinclozolin	Ronilan (BASF)	50471-44-8	5	>15 000	Widely used on vines (*vs.* grey mold). Endocrine disruptor
Zoxamide	Zoxium 80W (Rohm and Haas)	156052-68-5	5	>5000	For downy mildew on vines. Also used on potatoes

Many fungicides, belonging to different structural families, act by interfering with the sterol synthesis pathway used by pathogenic fungi, thus preventing the construction of cell membranes. A common class of fungicides used on grapes and other fruits (some are authorized for use on cereal crops) are the triazoles: difenconazole, hexaconazole, penconazole, propiconazole, tebuconazole, tetraconazole and others. Their acute toxicities are often higher (i.e. they have comparatively low LD_{50} values – see Table 5.10.2) than other fungicides, although they have lower MRLs because they can be applied to crops at much lower rates (e.g. ~60 g/ha, as opposed to ~250 g/ha) (Juan-Garcia *et al.*, 2004).

A more recent family of fungicides is based on strobilurin (a natural product obtained from *Strobilurus tenacellus* and other muhrooms) and these are known as strobins. They all have the β-methoxyacrylate structural moiety and include azoxystrobin, dimoxystrobin, kresoxin-methyl and trifloxystrobin.

Other fungicide families include (with examples) anilides (carboxin), benzimidazoles (carbendazim, thiophenate-methyl), dicarboximides (captan, folpet, iprodione, procymidone, vinclozolin) dithiocarbamates (maneb, zineb), pyridines (pyrimethanil), pyrimidines (fenarimol), and sulfonamides (Euparen, tolylfluanid). To these can be added the still widely used copper (II) (as Bordeaux mixture) and sulfur, both of which can be used on crops that are used to make organic beverages.

Herbicides and insecticides are generally more toxic than fungicides and several have unfortunate environmental side effects. For example, dichlorvos is highly toxic to bees. Earlier, more toxic herbicides and insecticides that persist in the environment have largely given way to less toxic, less persistent (more easily

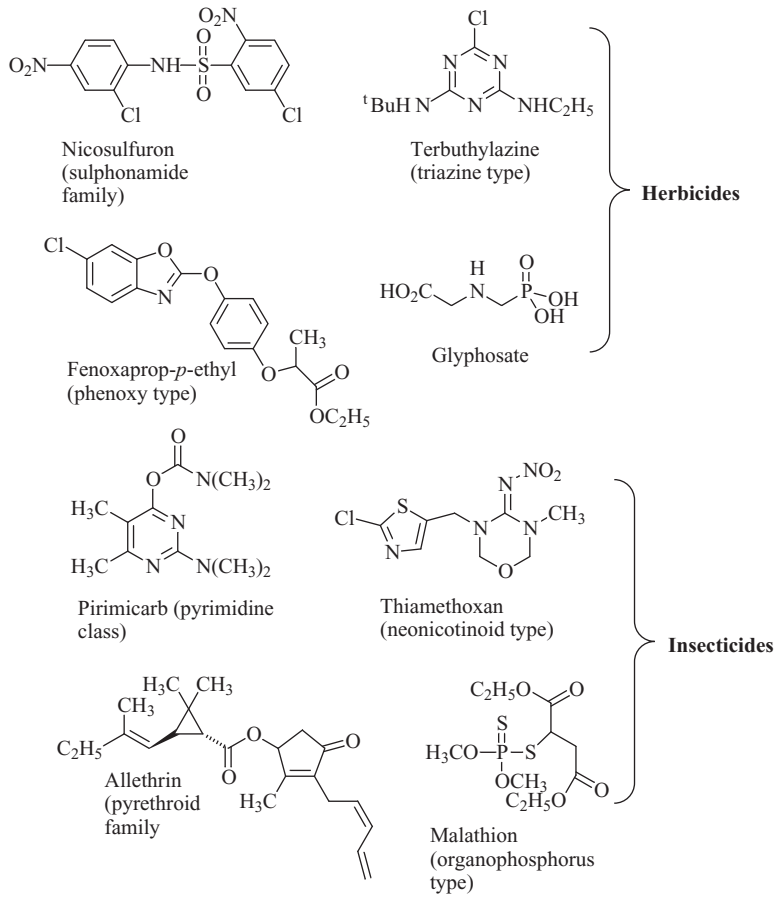

Figure 5.10.1 *Some herbicide and insecticide structures*

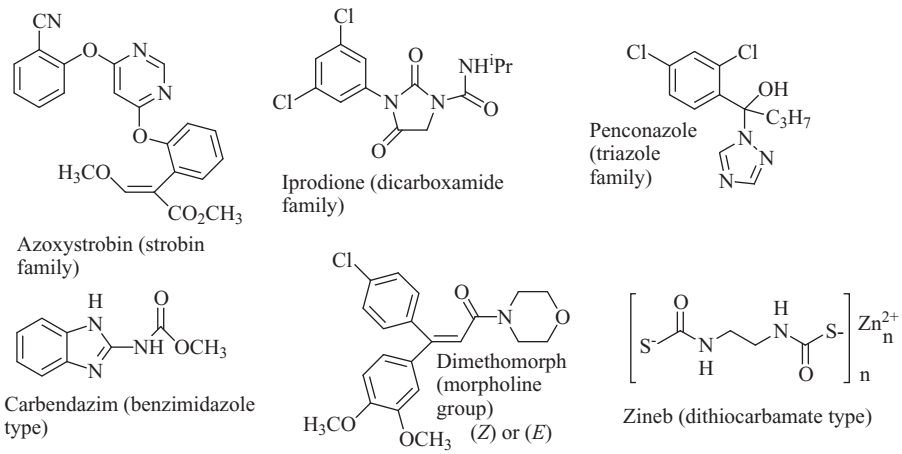

Figure 5.10.2 *Some fungicide structures*

degradable) types. Thus aldrin, DDT, dieldrin and others (insecticides) are banned in most countries, and atrazine and simazine (herbicides) are banned in the EU. Relatively few organophosphorus insecticides are now authorized, because of their high toxicities (cholinesterase inhibitors). More widely used insecticides nowadays are azadirachtin (a natural tetranorisoprenoid), pyrethrins, neonicotinoid types such as acetamiprid, imidacloprid and thiamethoxam, and pyrimidine types (e.g. pirimicarb). Prominent herbicides (used mostly on land growing cereal crops) include nicosulfuron, metsulfuron-methyl (sulfonamide types), glyphosphate, bispyribac-sodium and terbuthylazine (triazine type).

5.10.3 Metal and Nonmetal Residues

There has been much interest in the past few decades on the presence of heavy metal contaminants in alcoholic drinks, particularly Cd^{2+}, Cu^{2+}, Pb^{2+}, Mn^{3+} and Zn^{2+}. Because of the negative health consequences associated with excessive intake of certain compounds of these metals, their mere presence in alcoholic beverages can harm the reputation and commercial value of those beverages. However, in most cases, a significant proportion of the heavy metal content is derived from the soil, taken up by the plants from which the beverage is prepared and thus is difficult or impossible to avoid. These will be taken up along with a host of other metal cations (e.g. Ca^{2+}, Fe^{2+}, Mg^{2+}, K^+ and Na^+) as well as anions (Br^-, Cl^-, phosphates and sulfates), depending on the geological character of the local land and the prevailing climate. Additionally, metal and nonmetal residues can result from environmental pollution, adulteration and contamination by process equipment or methods.

The presence of certain inorganic residues in alcoholic beverages has both benefits (e.g. removal of malodorous substances and the provision of essential minerals) and drawbacks (e.g. spoilage, especially in the formation of hazes, sensory problems and health risks). This section seeks to review the range of inorganic residues in alcoholic beverages, their origins and their effects upon human health.

The inorganic components of alcoholic beverages have diverse origins; they can find their way into beverages at various stage in the production sequence, starting with the raw materials, through the various processes to storage and including adulteration (Pohl, 2007a). These possibilities are outlined in Figure 5.10.3, which also shows parts of the production sequence where metal ions in particular may be lost from the beverage. The plants from which beverages are derived obtain a wide variety of minerals from the soil, which is influenced by the use of fertilizers (K^+, NH_4^+, phosphates, Cl^-, NO_3^- and others, plus contaminants) and metal containing fungicides (5.10.2) (e.g. Cu^{2+}, Mn^{2+} and Zn^{2+} from Bordeaux mixture, maneb and zineb, respectively). Environmental pollution comes from both natural (e.g. NaCl and other minerals from sea spray on coastal crops) and industrial origin sources (e.g. Pb and Cd from factory exhaust or mining waste; F^- from ceramics factories).

Most of the Cu^{2+} and Mg^{2+} in beer are derived from the raw materials, mostly cereals. Some of the copper in wine is derived from Bordeaux mixture (Section 5.9.2), if it is used (but see next paragraph), whereas wines from coastal vineyards are richer in sodium content (Pohl, 2007a). Minerals in water or any additive or adjunct materials used in the brewing process will contribute to the mineral content of the finished product. Most of the Ca^{2+}, CO_3^{2-}, Cl^- and SO_4^{2-} content of beers comes from the brewing water.

During fermentation, the concentrations of many metal ions diminish, because of precipation (e.g. Ca^{2+} and heavy metal cations) and chemical reaction (e.g. Cu^{2+} forms insoluble CuS with hydrogen sulfide). Postfermentation processes, however, can lead to increases or decreases in mineral content, depending on the process. Distillation causes some minerals to be left behind in the residue, but some may be carried over in the distillate and copper ions are extracted from copper stills, which are popular in the production of many spirits, including malt whisky (Sections 3.1.2 and 3.2.2). The copper content of whisky and other spirits is thus derived mostly from the still material (Adam *et al.*, 2002), and is greater for malt whiskies (distilled

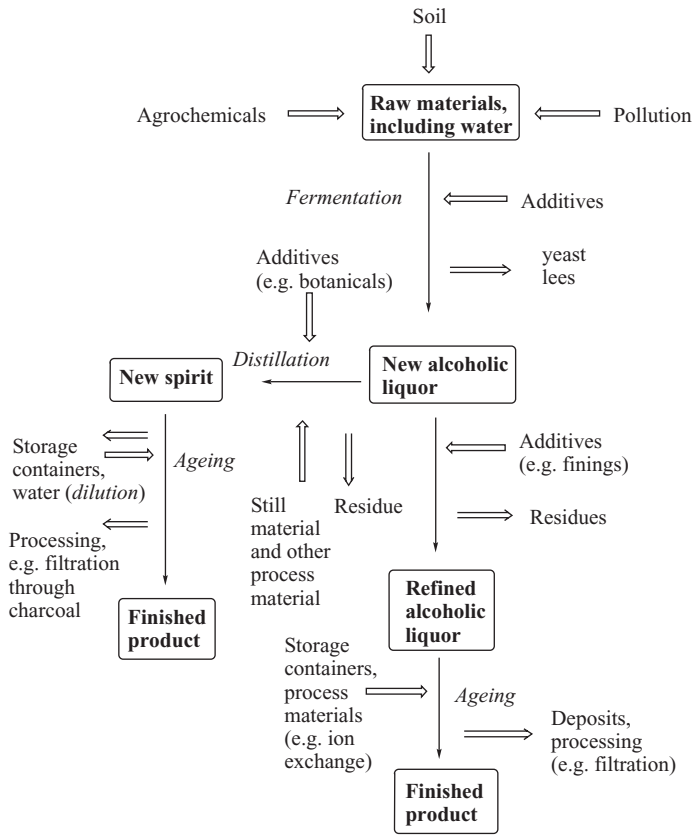

Figure 5.10.3 *Input (closed arrow) and output (open arrow) of metal and nonmetal ions during the production of alcoholic beverages*

from copper pot stills) than grain whiskies (distilled from stainless steel patent stills: continuous or Coffey stills). On the other hand, metal ions in the original fermented mash or wine are largely left behind in the residue upon distillation, explaining why higher levels of Ni^{2+} were found in beers and wines rather than in the spirits whisky and brandy (Dugo *et al.*, 2004).

The use of additives can make a significant contribution to the mineral content of alcoholic beverages. Fining agents (bentonite, isinglass, kieselguhr, silica gel, etc.) can remove metal ions bonded to proteins or adsorbed on yeast cells, but at the same time can lead to an increase of Na^+, Ca^{2+} and Al^{3+} levels in wine (Pohl, 2007b). Addition of copper sulfate or copper citrate to wine (to remove H_2S and thiols; Section 5.9.4) is the biggest contributor of the low levels of Cu^{2+} found in wines. Additionally, increased Na^+ or K^+ content of wines can come from the use of bentonite (Section 2.9.4), sulfites and sorbates (Chapter 2.5) and Ca^{2+} can come from added $CaSO_4$ (as gypsum) as in Sherry production (Section 2.10.2) or from added $CaCO_3$ (deacidification of must; see Section 2.9.1). Likewise, elevated levels of Na^+ and Cl^- can arise from the use of common salt as a clarifying agent (Amerine and Ough, 1980) and added herbs to wines or spirits can be a source of heavy metal cations (Moutatsou *et al.*, 2003).

Process equipment is often a key source of metal ions in the finished products. Copper stills provide most of the coppers content of spirits such as cachaça, rum, tequila and malt whisky (Adam *et al.*, 2002) and

relatively high levels of heavy metals in wastes from the distillation of ouzo (Section 3.5.6) are derived from the bronze pot stills (Moutsatsou *et al.*, 2003). Likewise, contact of wine with equipment materials (casks, pipes, tanks, etc.) is a major or significant source of Al (from concrete or steel), Cd, Cr (from steel), Cu (from copper pipes), Fe (from concrete or steel) and Zn (Pohl, 2007a).

The mineral content of alcoholic beverages can change as a result of certain practices that occur during ageing and in the packaging operations prior to distribution and sale. For example, the use of ion exchange resins can lower the concentrations of heavy metal ions, and K^+, but tends to increase the level of Na^+ (Amerine and Ough, 1980). The copper content of whisky decreases whilst aging in wood, as a result of Cu^{2+} binding to phenolic ligands in the wood (Adam *et al.*, 2002). Conversely, the levels of many ions (Ca^{2+}, Cl^-, NO_3^-, Pb^{2+}, SO_4^{2-} and Zn^{2+}) in Marsala wines tended to increase with increased length of cask maturation (Dugo *et al.*, 2005). At least one study on the Pb content of wines from different vintages has revealed a reverse correlation with vintage year (i.e. older wines tended to have higher Pb levels) (Ajtony *et al.*, 2008). This presumably reflects the lesser use in recent years of lead and its compounds for industrial purposes, leading to less pollution. Higher sulfate levels in wines can be traced to oxidation of some of the sulfite used to protect the wine throughout the maturation process

Many spirits are diluted with water to the required alcoholic strength before bottling (e.g. see Sections 3.2.1 and 3.5.3). Nowadays, purified or distilled water is used, after careful analysis of mineral content, although rainwater or mountain stream water is often used to dilute sugar cane spirits (Section 3.5.3). Water for spirits dilution can still be a source of Ca^{2+}, Mg^{2+}, Na^+, Cl^-, SO_4^{2-} and other ions. Many alcoholic beverages, especially beer, are offered for sale in cans, where higher levels of Cu^{2+} and Zn^{2+} are often apparent compared with glass bottled equivalents (Mayer *et al.*, 2003). On the other hand, the Ni^{2+} contents of bottled and canned beers have been found to be comparable (Dugo *et al.*, 2004). For many years, nearly all wine bottles were sealed with corks and many were 'finished' with lead capsules for attractive presentation and as an extra seal. After many years of storage, these wines may show rather elevated Pb^{2+} levels (Mena *et al.*, 1997). Nowadays, although screw cap or plastic seals for wine bottles are common, a great many wines are still bottled with cork seals. In the latter, however, lead capsules have largely given way to thinner aluminium or plastic capsules.

The mineral ion contents of alcoholic beverages are monitored regularly and carefully (see Sections 4.4.4, 4.5.1 and 4.5.2 for methods of analysis) and there are specified maximum allowed limits. Hence, although all mineral ions are toxic above certain concentrations, their actual concentrations in alcoholic beverages are very far below these levels. Typical selected metal ion contents for various alcoholic drinks are shown in Table 5.10.3, along with some recommended and legally allowed limits. The only (very rare) exceptions to the norm for alcoholic beverages are when either adulteration or contamination via use of inappropriate equipment or processes has occurred. Thus corrosion of copper distillation equipment has led to higher Cu^{2+} levels in tequila (Section 3.5.5) (Carreon *et al.*, 2001) and storage of vodka in poor quality steel or alloy vessels is known to introduce metals into the beverages, though not necessarily at toxic levels (Ibanez *et al.*, 2008).

It can be seen from Table 5.10.3 that spirits in general have lower levels of mineral salts than undistilled beverages, as might be expected from the distillation process. This is despite the fact that metal ions can be leached out of the still or storage material.

Except in the rather rare cases of contamination or adulteration, the drinker of alcoholic beverages, like the drinker of nonalcoholic beverages, can expect no negative health effects from the concentrations of cations and anions in those drinks. Indeed, moderate consumption of alcoholic beverages may provide a significant proportion of the nutritional requirements of some essential metals, notably Ca, Co, Cr, Cu, Fe, K, Mg, Mn, Ni and Zn (Pohl 2007a). Additionally, there is good evidence to suggest that some metal cations in alcoholic beverages, that are known to be harmful in higher concentrations (e.g. Cu^{2+}, Fe^{2+}, Pb^{2+} and Zn^{2+}), are present as complexes rather than 'free' ions. Some of these complexes may decrease the bioavailability

Table 5.10.3 *Metal and nonmetal ion content of some alcoholic beverages (in mg/l)*

	Ca^{2+}	Cu^{2+}	$Fe^{2+/3+}$	Pb^{2+}	Mg^{2+}	K^{+}	Na^{+}	Zn^{2+}	Br^{-}	SO_4^{2-}	PO_4^{3-}	Cl^{-}

*Most values are much lower than the maximum quoted here.

Source: Data from Amerine and Ough (1980), Dugo *et al.* (2005), Ibanez *et al.* (2008) (and references therein) and Mayer *et al.* (2003). Figures in parentheses are EU maximum allowed limits, those in square brackets are suggested maximum limits.

Table 5.10.4 *Some methods for the removal of excess metal ions from alcoholic beverages*

Method	Cations removed	Comments
Ion exchange	Cu^{2+}, Pb^{2+} and others	Used on wine and spirits, such as Tequila (Ibanez *et al.*, 2008). Can lead to high levels of Na^{+} or K^{+}
Addition of potassium ferrocyanide	Cu^{2+}, $Fe^{2+/3+}$ and others	Allowed in the EU (for wine) but not in the USA. Level of Cu^{2+} in wine must be lower than that of added Fe^{II}
Addition of chelating insoluble polymers	Cu^{2+} and $Fe^{2+/3+}$	Detering *et al.*, 1991. A commercial version is Divergan (BASF), used in matrix filter sheets (1 g/l) (Ibanez *et al.*, 2008)
Addition $MgCO_3$ or $CaCO_3$	Cu^{2+}	Can be used to decrease Cu^{2+} content of rum (Almeida-Neves *et al.*, 2007)
Electrolysis and electroless cementation	Cu^{2+}	Cementation is on Fe. Used for decreasing Cu^{2+} content of tequila (Ibanez *et al.*, 2008)

of the metal ions in the gastrointestinal tract. It appears that lead and zinc ions preferentially complex with polyphenols (Green *et al.*, 1997), Cu^{2+} binds to the thiol groups of proteins and to OH grapes of carbohydrates, whilst Fe^{3+} forms complexes with hop bittering constituents (Wiese and Schwedt, 1997). *In vitro* digestion studies on Cu^{2+} and Pb^{2+} in port wines have suggested that *ca.* 50% and 10–22% of Cu and Pb respectively were bioavailable under intestinal digestion conditions (Azenha and Vasconcelos, 2000). The Pb^{2+} ions in particular, were converted to a largely insoluble form under these conditions.

There are many methods for the removal of metal cations from alcoholic beverages, should the need arise (e.g. accidental contamination leading to levels of metal in excess of the maximum allowed limit). The more widely used of these methods are summarized in Table 5.10.4. Not all of these methods are allowed in all countries, and alternative methods can be found in Ibanez *et al.* (2008). It should be noted that a certain concentration of a certain cation or anion may be beneficial to the organoleptic quality of the beverage. For example, Cu^{2+} present in wine or spirits combines with sulfur derivatives (e.g. H_2S produced by certain *S. cerevisiae* strains) to reduce sulfury odors (Amerine and Ough, 1980, Reaich, 1998). It is also involved in the formation of desirable congeners during the distillation of whisky (Reaich, 1998), sugar cane spirits (Section 3.5.3) and tequila (Section 3.5.5).

5.10.4 Industrial Contaminants

This section is concerned with the minor organic contaminants in alcoholic drinks that arise from pollution caused by general industrial activities or from use of specific equipment or materials. Potentially, there are many such contaminants. Table 5.10.5 lists the more prominent ones, along with their sources, the ways in which they can find their way into drinks, the most likely drinks to contain them, and ways of avoiding or removing the contaminants. It will be noted that all the substances entered in Table 5.10.5 are lipophilic; that is, they are fat soluble, with only limited solubility in water or aqueous alcoholic beverages – especially beer and cider with low ethanol contents. Also, crops from which alcoholic beverages are produced (cereals, grapes, fruit, etc.) are generally of low lipid content, although fruit skins contain terpenoid and other lipophilic substances. Nevertheless, because of the extreme toxicity of many of the substances in Table 5.10.5, crops, alcoholic beverages and water used in the production of drinks are periodically monitored to ensure that concentrations of these substances fall below statutory limits, or recommended international limits.

Table 5.10.5 *Some industrial contaminants sometimes found in alcoholic beverages*

Contaminant	Sources	Route to alcoholic beverage	Most likely beverages to contain contaminants	Methods of prevention or removal of contaminants
Benzene	Degradation of aromatic compounds, e.g. benzoates. From CO_2 supplies	Most likely through carbonation processes	Carbonated drinks: processed beer, cider and aerated wine	Monitor of CO_2 supply. Pass through activated charcoal
Polycyclic aromatic hydrocarbons (PAHs)	Incomplete combustion of carbon sources, including fossil fuels	Probably via contamination of raw materials, including water	Those produced from crops grown near pollution sources	Monitor of water quality. Use of activated charcoal beds
Dioxins and polychlorinated biphenyls (PCBs)	Combustion of materials containing both carbon and chlorine	Probably via contamination of raw materials, including water	Those produced from crops grown near pollution sources	Monitor of water quality. Use of activated charcoal beds
Trihalomethanes and chlorinated hydrocarbons	General industrial activities involving solvents. chlorination sterilization of water	Most likely via polluted water or through use of chlorinated water	Diluted beverages: spirits and beers brewed from high gravity mash	Monitor of water quality. Use of activated charcoal beds
Chlorophenols	Chlorination of water, bleaching of cork, use of chlorinated compounds in pesticide sprays	Water, cork stoppers, casks and vats	Wine (cork stoppers)	Monitor of water quality. Use of activated charcoal beds
Organotin compounds	Catalysts and stabilizers for PVC production	Most likely by storage in plastic containers. Possibly via pollution of raw materials	Cider, wine and brandy	Use of nonplastic containers
Phthalates	Plasticizers	Most likely by storage in plastic containers	Spirits	Use of nonplastic containers
Vinyl chloride and styrene	Monomers used to make plastic	Most likely by storage in plastic containers: PVC or fiberglass	Cider, wine	As above: PVC not widely used, but fiberglass is still in use

Benzene is classified as a Group 1 carcinogen by the WHO International Agency for Research on Cancer (IARC) (WHO, IARC 1987). The World Health Organisation (WHO) has suggested a guideline limit of 10 μg/l of benzene in drinking water (WHO, 2001), although many statutory bodies regulating water quality set much lower limits than this, often 1 μg/l (see Table 5.10.6 and Bamforth, 2002). Benzene can be produced by the degradation of aromatic compounds in foodstuffs during processing, such as cooking and irradiation sterilization (Fabietti *et al.*, 2001). In particular, benzene is formed in soft drinks that contain both benzoates and ascorbate preservatives, in the presence of transition metals (Gardner and Lawrence, 1993). However, this is unlikely to be the source of the benzene content of alcoholic drinks, since benzoates and ascorbates are not widely used in the alcoholic beverage industry. A much more likely source of benzene contamination here in bottled liquified carbon dioxide used for carbonation of processed beers (Wu *et al.*, 2006) and other drinks.

Investigation of the benzene content of 84 beers found that only six had levels above 1 μg/l (the detection limit) and all had levels below 10 μg/l, the WHO recommended limit (Wu *et al.*, 2006). Processed beers of six breweries in the UK were found to have detectable benzene levels that were traced to the use of contaminated liquid CO_2, but even here levels were lower than 10 μg/l (Long, 2003). Breweries now operate quality control programs on CO_2 supplies, in which the internationally suggested upper limit for benzene is 0.02 ppm (v:v).

Polycyclic aromatic hydrocarbons (PAHs), dioxins and polychlorinated biphenyls (PCBs) are produced in small amounts during the combustion of organic materials, all of which contain carbon and some also contain chlorine. In particular, common sources of PAHs are automobile and factory exhausts, although catalytic converters and filters can minimize pollution of crops and groundwater by fallout from these sources. Likewise, incineration of waste materials can produce PAHs, PCBs and dioxins if carried out below a certain temperature. These highly toxic compounds (many are known carcinogens) are removed from drinking water (and that used for alcoholic beverage production) by activated charcoal filtration. Typical maximum limits in drinking water for benz(a)pyrene and other PAHs are 0.010 μg/l and 0.10 μg/l, respectively (Table 5.10.6).

Trihalomethanes and chlorinated hydrocarbons in general are common environmental pollutants, being widely used in commerce and industry, particularly as solvents and cleaning fluids. Although of limited solubility in water, they are volatile, they can pollute a wide area of land and groundwater and tend to persist in the environment. Furthermore, chlorination of untreated water can produce trihalomethanes and other polyhalogenated organic compounds by reaction of chlorine with carbonyl compounds, carboxylic acids and other substance in the water. Trihalomethanes – chloroform ($CHCl_3$), bromoform ($CHBr_3$), dibromochloromethane ($CHBr_2Cl$) and bromodichloromethene ($CHBrCl_2$) – are classed as probable carcinogens. The main route into alcoholic beverages in via water used in the manufacturing process – brewing liquor and blending liquor used to dilute high strength beers (e.g. from high gravity brewing; see Section 2.6.8), ciders (e.g. factory cider (Section 2.8.6)) and spirits (see Sections 3.2.2 and 3.5.3, for example). The boiling stage of brewing (Section 2.6.3) dispels most of these volatile contaminants, but otherwise contamination will occur if these substances are present in the water (Baxter, 1999).

Regular checks on the treated water supply will ensure that chlorinated hydrocarbons are present below national regulation limits, such as those set in the UK for tetra- and trichloroethenes (10 μg/l) and trihalomethanes (100 μg/l) (Table 5.10.6; see also Bamforth, 2002). The average and maximum trithalomethane content determined in a study on 107 beers (27 of which were Chinese) were 1.2 mg/l and 5.2 mg/l, respectively (Wu *et al.*, 2006). In comparison, the range of trihalomethane levels in water from 20 beer brewing sites in China was 2.7–46.9 μg/l, with water from one site having 79.3 μg/l. These figures illustrate the typically lower level of contamination of alcoholic beverages, as opposed to water.

Haloanisoles and halophenols, especially 2,4,6-trichloroanisole (TCA) 2,3,4,6-tetrachloroanisole (TeCA), pentachloroanisole (PCA) and 2,4,6-tribromoamisole (PLA), are sometimes present in wine at low levels, too

Table 5.10.6 *Safety and quality parameters for water used in brewing and the production of alcoholic beverages*

Parameter	Maximum concentration or value	Units
Microbiological parameters		
Coliform bacteria	0	Number/100 ml
Clostridium perfringens	0	Number/100 ml
E. coli	0	Number/100 ml
Enterococci	0	Number/100 ml
Chemical parameters

low to be a serious health hazard. They are mentioned here because even at concentrations of a few μg/l their odor threshold values (OTVs) are such as that their presence gives rise to an off odor known as 'cork-taint.' It is believed that fungi present in cork metabolize halophenols by methylating them. The phenols, in turn, may be derived from the chlorination of cork lignin molecules by the use of chlorinated solutions to bleach the cork, although there are many other possible sources involving contact between winery equipment, materials (including grapes) and chlorine compounds (Pizarro *et al.*, 2007).

Organotin compounds are widely used in agriculture and industry: mono- and dibutyl tin (MBT and DBT) are common catalysts and stabilizers in the production of certain polymeric materials, notably poly(vinyl chloride) (PVC). Some organotin compounds (e.g. tributyl- and triphenyltin) may get into alcoholic beverages as pesticide residues, but it appears that a major route is via storage in plastic (including PVC) containers, as far as wine and brandy are concerned (Heroult *et al.*, 2008). Indeed, high organotin levels in some Canadian wines were attributed to storage in PVC containers (Forsyth *et al.*, 1992). More recent analyses of wines have found concentrations of MBT and DBT between 0.1 and 0.5 μg/l (Liu and Jiang, 2002; Azenha and Vasconselos, 2002), where the main source of these contaminants was probably high density poly(ethylene) containers used at an early stage in the vinification process (Azenha and Vasconselos, 2002). International and national bodies who deal with food safety and regulations (see Section 5.9.5) are working to define recommended or statutory maximum limits for organotin compounds in food, so at the time of writing (2008), no limits have been set.

PVC containers are not used for the storage of alcoholic beverages in most countries, the preferred media being wood, stainless steel, concrete, fiberglass and glass. The most widely used plastic material is poly(ethylene) for certain beers, ciders and wines, but not spirits. Poly(ethylene terephthalate) (PET) is used to make bottles and carboys, and Tetrapak™ containers for wine, beers and cider are made from neoprene. Any plastic material destined for (short- or long-term) contact with alcoholic beverages should be of food grade, where plasticizers, stabilizers and other adjuncts have not been used in the manufacture of the material. PVC is an especially undesirable material for the storage of alcoholic drinks, because of the possibility of monomer (vinyl chloride), plasticizers (often phthalate esters) and stabilizers (such as organotin compounds) leeching into the beverage. Vinyl chloride is a carcinogen and some phthalate esters are endocrine disruptors; they are estrogenic (antiandrogenic) and, for example, can alter testes function in pubertal male rats (Gray and Ostby, 2000). Organotin compounds are discussed earlier.

Phthalate esters are common environmental pollutants because of their widespread use as plasticizers. In fact, their presence in the laboratory environment (in the air, on glassware, etc.) can lead to false determinations (Fankhauser-Noti and Grob, 2007). The potential for phthalate ester contamination of alcoholic beverages is high, because of numerous situations during processing where beverage-plastic contact can occur. Despite this, there are few literature reports on phthalate ester residues in alcoholic drinks. Two recent studies on wine found at least one phthalate in a quantifiable amount in all 62 wines analyzed and 10 wines contained quantifiable amounts of others (Del Carlo *et al.*, 2008; Carillo *et al.*, 2008). Dibutyl phthalate (DBP) and di(2-ethylhexyl) phthalate (DEHP) were the two most common contaminants, although dimethyl and diethyl phthalate (DMP and DEP) were also quite common. In one study, total phthalate concentrations were between 2.7 and 15 μg/l and these were no significant differences observed for glass or plastic container (carton or bag in box) nor stopper material (cork, agglomerated cock or synthetic) (Carillo *et al.*, 2008). From this study, the origin of the major part of the residue was deduced to be likely from earlier in the production process: grape transport containers, pneumatic press material, pump material, pump lines and additives, for example.

At the time of writing (2008), there are no statutory limits with regard to phthalate ester levels in wine or other beverages, although the Environment Protection Agency suggests a limit of 6 μg/l in water for DEHP.

5.11

Other Trace Substances in Alcoholic Beverages

5.11.1 Introduction

This section considers trace components of certain alcoholic beverages that are neither additives (as defined in Section 5.9.1) nor residues (as defined in Section 5.10.1). They include phytochemicals (Section 5.11.2), nitrogenous allergenic substances (Section 5.11.3), fungal metabolites (Section 5.11.4) and compounds that are formed naturally during some part of the processing of alcoholic drinks (Section 5.11.5). As in Chapter 5.10, health aspects are discussed in terms of toxicity studies on certain trace components, health risks for those who consume alcoholic beverages that contain these components and the regulations and legislation in force to ensure that minimal levels exist in beverages. Also considered here are phytochemicals (Section 5.11.2) that are known to have potent therapeutic value or beneficial *in vitro* activity. These are discussed in relation to their presence in either alcoholic beverages or the raw materials that are used to make them. Certain phytochemicals that are known to have toxic properties at high doses are also discussed.

5.11.2 Phytochemicals

The term phytochemicals refer here to components of alcoholic beverages originating from the plant materials used to make the beverages, as opposed to fermentation metabolites from microbiological sources. There are so many such components (usually at low or even trace levels) that it is not possible to give here a detailed account of their likely influences on health; indeed in many cases this has never been determined. Also, many different kinds of phytochemicals have been discussed with regard to a variety of alcoholic beverages (Part 2) and distilled drinks (Part 3) and earlier in Part 4 (e.g. Section 5.4.3 and Chapter 5.8). Instead, a few interesting phytochemicals have been selected for discussion here.

Consideration begins with some compounds present in ripening fruits that have not yet received much attention: chlorophyll degradation products. Chlorophyll a and b break down in ripening fruit, giving yellow nonfluorescent chlorophyll catabolites (NCCs). (Figure 5.11.1) in both skins and flesh. These NCCs (unlike the chlorophylls themselves, which are phototoxic), although only minor components, have been shown to be potent antioxidants, diminishing the rate and extent of *in vitro* linoleic acid hydroperoxidation

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass

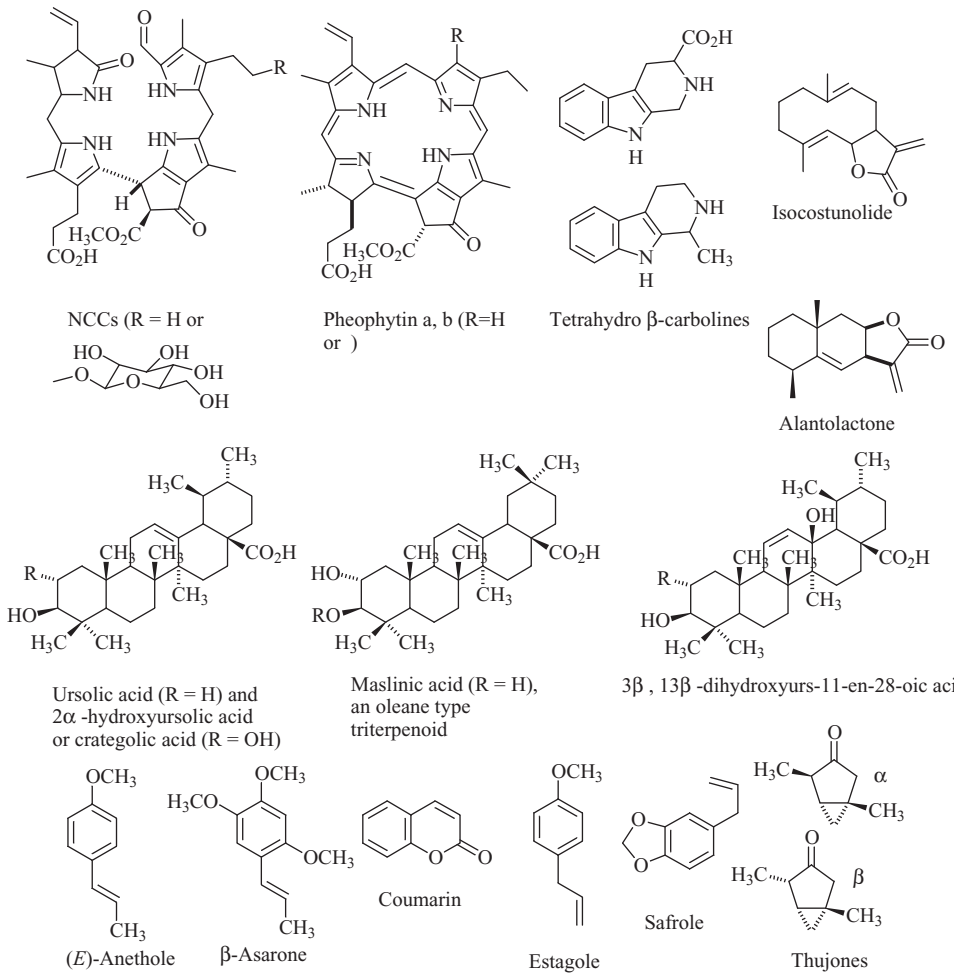

Figure 5.11.1 *A selection of phytochemicals from raw materials of alcoholic beverages*

(Müller *et al.*, 2007). Antioxidant activity, like that of bilirubin, is endowed by the tetrapyrrole structural moiety. NCCs have been found in the skins and flesh of ripe apples and pears, and from the discussion in the next paragraph it is not inconceivable that some may survive into finished cider and perry. Other chlorophyll degradation products, such as pheophytins a and b (but not NCCs) have been found in black grapes of the major port varieties (Section 2.10.7) (Mendes Pinto *et al*., 2005). Although further degradation occurs during the winemaking and ageing processes, some pheophytins survive and have been found in wine.

Carotenoids, common plant products, are well known as antioxidants and they are the precursors of important flavor compounds norisoprenoids, such as (*E*)-β-damascenone and β-ionone. Many carotenoids also survive the winemaking process and together it is likely that these compounds make a significant contribution to the antioxidant power of the wine. These compounds, as well as polyphenols, may contribute to health benefits occurring on light-moderate consumption of cider, perry or wine. See Section 5.4.3 for a discussion of nutritional value of carotenoids.

Another interesting group of compounds found in fruit such as grapes and cherries are the indole amines, melatonin and tetrahydrocarbolines, biosynthesized via the shikimate pathway, through tryptophan and serotonin (Figure 5.11.1). Melatonin has only recently been found in grapes (Iriti *et al.*, 2003), whereas the tetrahydrocarbolines were found in grape juice and wine some time ago, and are known to be antioxidants and radical scavengers (Herraiz and Galisteo, 2003). They are also reversible monoamine oxidase (MAO) inhibitors and potent *in vitro* anticancer agents (Chen *et al.*, 2004).

Isoprenoids, including terpenoids, carotenoids and norisoprenoids are ubiquitous and important constituents of nondistilled alcoholic beverages, as well as flavored distilled drinks. Some norisoprenoids, such as (*E*)-β-damascenone, also make important contributions to the aroma and flavor of certain distilled beverages, such as Bourbon whiskey (Section 3.3.4). Monoterpenoids are known to be synthesized in plastids in the skins of fruits (e.g. grape pericarp, apple skins) (Hardie *et al.*, 1996). The waxy skins of fruit such as apples are a comparatively rich source of terpenoids, including the pentacydic triterpenoids, especially derivatives of maslinic acid, oleanic acid (Figure 5.11.1) and ursolic acid (see Figures 2.12.4) (He and Liu, 2007). Ursolic acid is the most abundant triterpenoid in apple skins (~1.6 g/kg of skins). Many of these triterpenoids showed antiproliferative activity and cytotoxic activity against *in vitro* human HepG-2 liver cancer cells, MCF-7 breast cancer cells and Caro-2 colon cancer cells, with 2α-hydroxyursolic acid being generally the most potent compound. It is possible that *in vivo* these compounds act in a synergistic way, since apple phytochemical extracts were found to inhibit mammary cancer in a rat model in a dose dependent manner (Liu *et al.*, 2005).

Similarly sesquiterpene lactones are found in many plants, particularly the roots of *Inula helenium* (Horse Tail). Roots of this species are used (often as a concentrate) in certain herb liqueurs (Section 3.9.3) in order to add a mild camphor-like flavor and mild bitterness to the beverage. Sesquiterpene lactones such as alantolactone, isoalantalactone, costunolide and isocostunolide, known constituents of *I. helenium*, have been shown to possess *in vitro* anti-inflammatory properties, *in vivo* antibacterial properties and *in vitro* activity against human cancer cell lines. The eudesmane-like alantolactone (Figure 5.11.1) and isoalantalactone show either cytotoxic or antiproliferative activity (see references in Stojakowska *et al.*, 2006), while isocostunolide (Figure 5.11.1) induces *in vitro* apoptosis in human melanoma cells via a mitochondria dependent pathway (Chen *et al.*, 2007). Many plants containing these substances (including *I. helenium*) have long been used in folk and home medicine to remedy a variety of ills with some success (indeed the original purpose of liqueurs was medicinal – see Section 3.9.1), but there is nothing in the literature relating to *in vivo* anticancer activity.

The use of herbs and spices in alcoholic beverages introduces a multitude of phytochemicals into the drink, mostly at low levels (even trace levels for many), but occasionally at comparatively high concentrations. Beverages with added herbs and spices (or their oils and essences) include beer (Section 2.6.13), vermouth (Section 2.12.2), apéritifs (Section 2.12.3), retsina (Section 2.12.3), Maiwein (Section 2.12.3), some spirits (e.g. gin, Section 3.4.2) and some liqueurs (Section 3.9.3). While it is not possible to discuss in detail the health implications of such an enormous number of compounds, some of the better known or previously highlighted components of certain herbs and spices are considered here: (*E*)-anethole, β-asarone, coumarin, estragole, safrole, thujone and xanthohumol (Figure 5.11.1).

(*E*)-Anethole is a major constituent of anis and star anis, used to flavor a number of drinks, including vermouth (Section 2.12.2), anis-flavored spirits (such as arak, ouzo and pastis; Section 3.5.6) and certain liqueurs, such as anisette (Section 3.9.3). In large doses, this compound is an irritant, causing spasmolytic activity. Its LD_{50} is 2090 mg/kg body weight, although the maximum level that causes no toxicological effects in rats is 0.5% of the diet (250 mg/kg body weight). The FAO/WHO Joint Expert Committee on Food Additives (JECFA) have fixed an acceptable daily intake (ADI) of 0–2 mg/kg body weight and sees no safety concern at current levels of intake when used as a flavoring agent (JECFA, 2001a).

β-Asarone, estragole and saffrole, structural relatives of (*E*)-anethole (Figure 5.11.1), are of considerably greater health concern. β-Asarone (the (*Z*) or *cis* isomer) is a major component of certain varieties of *Acorus*

calamus Linn. (Sweet Flag); it constitutes ~75% of oil of calamus derived from the dried rhizomes of the Indian tetraploid variety, but only ~5% of the corresponding oils from the Kashmir (hexaploid) or European (diploid) varieties. It has antibacterial properties (including *in vitro* antitubercular action). The compound exhibits *in vitro* inhibition of monoamine oxidases and in higher doses causes sedative/tranquilizing action on animals (10–100 mg/kg body weight). Its acute toxicity (oral rat LD_{50}) is 1010 mg/kg body weight, whereas that of European oil of calamus (containing *ca*. 5% β-asarone, as well as many other constituents) is 3497 mg/kg body weight. Although low levels of β-asarone are nonmutagenic to various strains of *Salmonella hyphimurium* (via the Ames test), long-term oral administration to rats of high doses (1–2% of diet) caused liver and intestinal cancers. On this basis, use of the pure compound as a food additive is banned in most countries and JECFA of FAO/WHO have not allocated an ADI for this compound (JECFA, 2001b). In the European Union, the presence of β-asarone in alcoholic beverages (as a component of natural flavorings) is allowed up to 1.0 mg/kg (EC, 2008). Similarly, the Working Party on Herbal Medicinal Products of the European Agency for the Evaluation of Medicinal Products (EMEA) have recommended a temporary acceptable daily intake of β-asarone of 2 μg/kg bodyweight (EMEA, 2003).

Estragole, a constitutional isomer of (*E*)-anethole, is present in a wide range of herbs and spices: notably anis, basil, fennel and tarragon, all of which are used as flavorings in certain alcoholic beverages, particularly vermouth (see Figure 2.12.3, Section 2.12.2). It is a suspected carcinogen and genotoxic agent, as administration of large doses has been found to cause liver tumors in rats. Whilst appreciating that a number of plant materials used in the production of certain alcoholic beverages contain estragole, the Scientific Committee on Food of the European Commission (of the EU) have indicated that a safe exposure limit could not be determined (EC, 2002a). Estragole and (*E*)-anethole have also been found to be very minor constituents of certain grape musts (Caven-Quantrill and Buglass, 2006).

Safrole (EC 2002b) is a major constituent of the root bark or fruit of the sassafras plant and it is also present in basil, cinnamon and nutmeg. Like estragole, large oral doses have been shown to cause liver cancers in rats, the carcinogenic potency being low (TD_{50} = 441 mg/kg body weight/day, where TD_{50} is the dose required to produce tumors in 50% of the animals). Its acute toxicity is typically low: the rat oral LD_{50} being 1950 mg/kg body weight. Pure safrole per se is banned in the USA by USFDA as a food additive, and JECFA of FAO/WHO have not allocated an ADI for the compound (JECFA, 2001c).

Coumarin is a component of many plant materials, including bison grass, cassia bark (cinnamon), lovage, vanilla grass and woodruff (*Artemisia pontica*), some of which, especially cassia and woodruff are used to flavor alcoholic drinks such as May wine (Maiwein) and certain vodkas (subrowka). Coumarin has a moderate chronic toxicity to the liver and kidneys of rats, but not baboons. Its acute rat oral toxicity is comparatively high: LD_{50} = 290 mg/kg body weight. Coumarin per se is banned as a food additive in the USA, where it is listed by USFDA as 'a substance generally prohibited for direct addition or use in human food,' but natural additives that contain coumarin are allowed in alcoholic beverages. Likewise, in the countries of the European Union, pure coumarin may not be added to foodstuffs, only plant materials that contain it. At present, the 1988 EC ruling of maximum levels of 2 mg/kg of foodstuff (10 mg/kg of certain foodstuffs and alcoholic beverages) is still in force (EC, 1988). These levels were adopted from those in the *Codex Alimentarius* (1985). Recently, the European Food Safety Authority (EFSA, 2008) recommended a total daily intake (TDI) of no more than 0.1 mg/kg body weight to the European Council (EC) of the European Union. There were concerns about its genotoxicity in the 1980s, but more recent research has suggested that coumarin is not genotoxic (Lake, 1999).

Thujone, or more correctly α- and β-thujone (Figure 5.11.1), are terpenoids that once again can be found in a wide range of plant materials, but particularly in the leaves and stems of various *Artemisia* species, such as wormwood (*A. pontica*), mugwort (*A. vulgaris*) and common wormwood (*A. absinthium*). The two isomers are also found in green anise (*Pimpinella anisum* L.), Florence fennel (*Foeniculum vulgare* Mill.),

hyssop (*Hyssopus officinalis* L.) and lemon balm (*Melissa officinalis* L.). Many of these herbs are used to flavor certain alcoholic beverages, such as vermouth, arak and absinthe. Regarding the last named drink α-thujone was thought for decades to be the active ingredient responsible for this drink's notoriety between 1805 and 1915, when it was banned by the French wartime government. Absinthe was a green distilled drink, flavored with oil of wormwood, in which α- and β-thujone are present (Figure 5.11.1). It was popular and frequent overindulgence often led to various physical and psychological disorders, so that the drink became increasingly associated with fits and hallucinations, which contributed to a condition known as 'absinthism.' The supposed high thujone content of 'preban' (i.e. pre-1915) absinthe was for many years thought to be the cause of absinthism.

Recently, this supposition, based upon oft quoted data of unclear origin, has been found to be false (Lachenmeier *et al.*, 2008). Preban, as well as modern absinthe were both determined by precise and accurate methods to have an average thujone content of *ca.* 25 mg/l – about 10% of the claimed figure of 260 mg/l in preban absinthe. It therefore appears that the notoriety of preban absinthe is more likely to have been caused by ethanol and other components of the rough spirit that was used to make the beverage, combined with frequent overindulgence. Lachenmeier *et al.* (2009) substantiated their above claim by demonstrating the total stability of thujone (as well as fenchone and pinocamphone) in modern absinthe stored in green glass bottles (like preban absinthe) upon exposure to UV radiation over an extended period of time. Thus criticisms questioning their results, concerning decomposition of thujone in preban absinthe over the years (the last ones were produced in 1915), were refuted. It seems like old myths die hard.

Nevertheless, thujones (particularly the β-diastereoisomer) are neurotoxins for a number of animals, including insects, rats and worms. The mouse oral LD_{50} is 45 mg/kg body weight, but the presence of ethanol was found to protect some mice from otherwise lethal doses. There is one reported human poisoning by α-thujone in wormwood oil (Weisbord *et al.*, 1997). It was hypothesized in the 1970s that α-thujone activates the CB_1 cannabinoid receptors in the brain (del Castillo *et al.*, 1975), but this has been refuted by experimental evidence (Meschler and Howlett, 1999). Instead, it was found that α-thujone acts on the GABA receptors in the brain, thus modulating the GABA gated chloride channel (Höld *et al.*, 2000). Like other monoterpenoids, α-thujone is rapid acting and is easily detoxified (e.g. to hydroxy α-thujones, in the brain). In the EU, the maximum allowed levels of thujones in alcoholic beverages are 5 mg/kg for beverages of <25% ABV, 10 mg/kg for drinks of >25% ABV and 35 mg/kg for 'bitters,' such as Angostura bitters, that are used to make cocktails.

Hop bittering agents include α-acids (humulones) (Section 2.6.3) and xanthohumol. During the boiling stage of beer production humulones are isomerized to the more strongly bitter *iso*humulones (see Chapter 2.6, Figure 3.6.13) and xanthohumol is isomerized to *iso*xanthohumol, although the latter isomerization appears to be inhibited during boiling of stout worts, which have black or roast malt content (Biendl and Walker, 2004). Over the years, considerable evidence has accumulated concerning health benefits resulting from ingestion of these substances in hop products and of their isomerized equivalents in beer (Biendl and Walker, 2004, Biendl, 2007). These compounds have been shown to be estrogenic, anti-inflammatory and to have *in vitro* antimutagenic and carcinostatic properties. Thus, they may offer protection against osteoporosis (decreased bone mineral density), cardiovascular disease and cancer. Epidemiological studies have suggested a correlation between moderate consumption of alcoholic beverages and high bone mineral density and lower risk of cardiovascular disease (Section 5.6.3), so these phytochemicals could well make important contributions. Animal studies have so far confirmed their role as preventers of osteoporosis and 'metabolic syndrome' (one of whose ultimate results is cardiovascular disease) and more recently strongly hopped (freeze dried) beer were found to be more active than unhopped (freeze dried) beer in the prevention of intestinal cancers in rats (Nozawa *et al.*, 2005; Biendl, 2007).

Table 5.11.1 *Major natural nitrogenous allergenic substances in alcoholic beverages*

Allergenic compounds	Alcoholic beverage type	Typical allergic reactions	Comments
Biogenic amines: histamine, tyramine and others	Wine, especially red wine having undergone MLF	Migraine headache, hypertension.	In severe cases anaphylactic shock occurs. Ethanol enhances effect of allergens
Gliadin proteins (prolamins), notably glutens and hordeins	Beer, especially wheat beer	Coeliac disease: irritation of cells lining the stomach	Beers brewed from buckwheat, maize and rice are low in prolamins

5.11.3 Nitrogenous Allergenic Substances

In relation to foodstuffs and alcoholic beverages in particular, an allergenic substance is a component of a beverage that causes disturbing physiological reactions in certain individuals upon consumption of the beverage. The physiological ('allergic') reactions include headaches, hypertension and digestive disorders, and can be very serious for susceptible individuals. Allergenic substances include additives such as sulfites, benzoates and other preservatives (Section 5.10.2), and certain synthetic colorants (Section 5.10.4), although some of these additives are rarely or never used in alcoholic beverage production. Considered in more detail here are natural allergenic substances that are found in certain alcoholic drinks. The two major classes are biogenic amines and proteins, both nitrogenous organic derivatives of amino acids (Table 5.11.1). Biogenic amines are present in many alcoholic beverages in wide ranges of concentration, but most data available relates to beer and wine. The most biologically active (and hence most studied) amines are histamine, 2-phenylethylamine and tyramine, but agmatine, cadaverine, putrescine, spermidine and spermine are also found in alcoholic drinks (Figure 5.11.2) (Önal, 2007). They are produced by normal metabolic processes during yeast alcoholic fermentation and especially during the malolactic fermentation of wines. The monoamines are produced by decarboxylation of the corresponding α-amino acids (histidine-histamine; tyrosine-tyramine, etc.; see Figure 5.11.2), whereas the polyamines (spermidine and spermine) are formal by *de novo* synthesis from arginine, via putrescine (Figure 5.11.2) (Önal, 2007). The polyamines are involved in fruit growth and development, whereas other amines are involved in DNA, RNA and protein synthesis, where their physiological functions include cell membrane stabilization and cell proliferation regulation (Bardócz, 1995). Hence they can be found in fruit as well as wine (Esti *et al.*, 1998). Likewise histamine and other biogenic amines are formed in cereals during the malting process and hence are constituents of wort, as well as beer (Gasarasi *et al.*, 2003).

In wine production, the concentrations of biogenic amines are related to many factors, including grape variety, location and winemaking methods (especially with regard to the conduction of MLF) (Landete *et al.*, 2005; Hernández-Orte *et al.*, 2008). For example, red wine from Cabernet Sauvignon grapes had lower levels of histamine and tyramine than red Tempranillo wine, made in the same region (Huesca, Spain) under the same conditions (Hernández-Orte *et al.,* 2008). Red wines from Tempranillo grapes grown in different regions were found to contain 8.2, 2.4, and 4.5 mg/l of histamine, according to whether the wines originated in La Rioja, Utiel-Requena or Tarragona, respectively. Similarly, Tempranillo wine from these three regions had 1.9, 2.3 and 1.8 mg/l of tyramine, respectively (Landete *et al.*, 2005). Red wine samples produced in Sicily from indigenous varieties (e.g. Nero d'Avola, Aglianico), French varieties (Cabernet Sauvignon, Merlot, Pinot Noir) and one Spanish variety (Tempranillo) showed a wide variation in biogenic amine concentrations (Dugo *et al.*, 2006). In this case, the wines with highest histamine levels were made from strains of Pinot

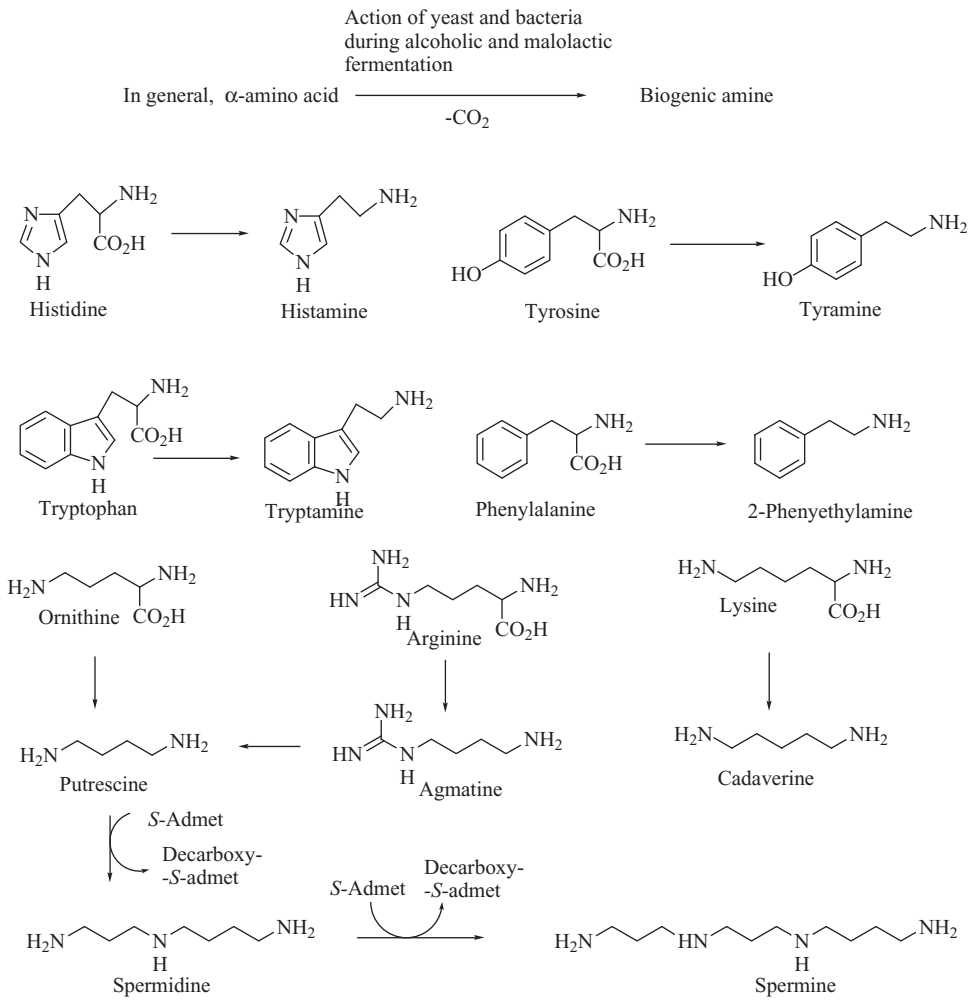

Figure 5.11.2 *Biosynthesis of biogenic amines.* S-*Admet* = S-*adenosylmethionine; decarboxy*-S-*admet* = *decarboxylated* S-*adenosylmethionine*

Noir, whilst Cabernet Sauvignon, Merlot and Tempranillo wines had no measurable histamine. In Turkish red wines (30 samples from different wine growing regions and different vine varieties), levels of histamine, 2-phenylethylamine, tryptamine and tyramine were 0–0.292 mg/l; 0–0.365 mg/l, 0–1.965 mg/l and 1.09–7.94 mg/l, respectively. It can be seen from the foregoing discussion that most of the factors that influence levels of biogenic amines in red wines, such as location, grape variety and certain winemaking techniques, cannot be modified as they are often laid down by law or are required for the production of quality wine. It does appear, however, that inoculation with strains of *Oenococcus oeni* to perform MLF leads to wines of lower biogenic amine levels than wines that have undergone MLF by indigenous bacteria, such as *Lactobacillus plantarum* (Hernández-Orte *et al.*, 2008; Landete *et al.*, 2005). The MLF bacterium species *O. oeni* exhibited lower amino acid decarboxylase (especially histidine carboxylase) activity than other MLF species, such as *L. hilgardii* and *Pediococcus parvulus* (Landete *et al.*, 2005).

In the production of beer, it has been demonstrated that typical beer worts already posses significant histamine and tyramine concentrations, which increase somewhat as a result of fermentation and standard processing (Gorinstein *et al.*, 1999). Histamine content of lager beers from Brazil, Israel and Mexico were between 3.02 and 3.23 mg/l, whilst tyramine levels were 3.61–7.4 mg/l.

Although severe allergic reactions to foods naturally rich in biogenic amines (some fish, meat, chocolate and fermented foods such as cheese and sauerkraut, as well as beer and wine) have been ascribed to the presence of those amines, there are contradictory conclusions in the literature. Histamine administered orally, by inhalation, or by subcutaneous or intravenous injection causes headaches and histamine free diets were found to reduce the incidence of headache (Steinbrecher and Jarisch, 2005). However, a meta-study of diet histamine and allergic reactions concluded that there was no correlation between oral ingestion of biogenic amines and food intolerance (Jansen *et al.*, 2003). Also, plasma histamine levels were observed to rise on consumption of wine, irrespective of the biogenic amine content of the wines (Kanny *et al.*, 2001). Nonetheless, histamine has been shown to be a vasodilator, whilst tyramine, tryptamine and 2-phenyletuylamine are vasoconstrictors, probably because they cause the release of noradrenahin and norephedrine. Histamine is released from mast cells as part of an IgE antibody dependent reaction, whereupon it is involved in inflammatory reactions. Cadaverine, putrescine and the polyamines appear to be nontoxic, although they may intensify the adverse effects of histamine, 2-phenylethylamine and tyramine, by interfering with the enzymes that metabolize them and by favoring their absorption in the intestine (Badócz, 1995).

Detoxification of amines occurs in the gut via the action of monoamine oxidases (MAOs) and diamine oxidases (DAOs). The amines are oxidized to physiologically less active degradation products. It is thought that the detoxification enzymes are unable to cope with a high intake of biogenic amines, which thus results in observed allergic reactions. Also, certain individuals are unable to metabolize even low levels of biogenic amines and so these compounds in general pose a serious threat to these individuals. The low amine oxidase activity of these individuals may arise from genetic predisposition, gastrointestinal disease or the presence of amine oxidase inhibitors, such as MAO inhibitor antidepressant drugs. In this respect, since ethanol is a mild MAO inhibitor, it is believed that ethanol may interact synergistically with biogenic amines in causing allergic reactions to alcoholic beverage in some individuals (Önal, 2008).

An alternative proposal, put forward by Kanny *et al.* (2001), was that biogenic amines in wine are not by themselves responsible for allergenic reactions. Instead, this group suggested that some other wine component, probably acetaldehyde, acts as an allergenic substance in itself and also as a plasma histamine releaser.

Gluten is the name given to the storage proteins of cereals; it is composed of albumins, globulins, prolamins and glutenins. Of these proteins, it is the prolamins that are of greatest interest here, because of their ability to cause severe allergic reactions in susceptible individuals. The prolamins are relatively rich in the α-amino acids proline, glutamine, asparagine and arginine, especially the first two. Prolamins from wheat are known as gliadins, and other cereals have related proteins: hordeins (barley), zeins (maize) avenins (oats) and secalins (rye). Gliadins are doughnut shaped glycoproteins that can be subdivided into three types: α, γ and ω. The α-types (formally called α, β) and γ-gliadins have molecular weights of 30 000–45 000 Da and have tertiary and higher structure involving disulfide formation between cysteine residues. The ω-gliadins have atomic weights of around 50 000 Da, with few cysteine residues. The gliadins are found in the endosperm of wheat seeds and pass into wort at the mashing stage of brewing (Section 2.6.2). The same applies the hordein proteins of barley. The presence of gliadins or hordeins in the diet can cause gluten sensitive enteropathy, the most severe form of which is celiac disease, caused by autoimmune reaction of the cells lining the small intestine. On the other hand, the presence of ω-gliadins in the diet can cause wheat dependent (WD) exercise induced anaphyloxis and WD urticaria (skin rashes) in sensitive individuals. Symptom types and severity vary between individuals, with about 1% of Indo-Europeans being affected, although the condition may be underdiagnosed.

During the brewing process, gliadins and hordeins extracted into wort from the malt or grains are largely removed on the grains after mashing (Section 2.6.2) and in the trub after boiling (Section 2.6.3). More will be removed by the action of fining agents, filtration or centrifugation (Section 2.6.9). The presence of celiac positive proteins in beer has not been proven conclusively (Hughes and Baxter, 2001), partly because of limitations in the analysis of beer proteins. The prolamin content of several beers was determined by sodium dodecylsulfate gel electrophoresis (SDS-PAGE) immunoblotting, as well as enzyme linked immunosorbent assay (ELISA). Wheat beers were included, but most of the beers were barley based, with varying amounts of maize or rice adjuncts. One beer, describing itself as 'gluten free' was brewed using buckwheat and rice, with no barley (Kanerva *et al.*, 2005). Proteins were found in the molecular weight ranges 8000–17 000 Da and 38 000 Da in reduced and nonreduced samples, respectively. ELISA results suggested much higher levels of prolamins in the wheat beers, although the ELISA kit antibody was designed to measure gliadins and not hordeins and so may not be well matched for determination of the latter.

5.11.4 Mycotoxins

Mycotoxins are secondary metabolites formed during the growth of various species of fungus on infected crops, such as cereals and fruit. There are many such toxins, which vary widely from species to species; the major ones found in alcoholic beverages made from infected crops are shown in Figure 5.11.3. The most serious mycotoxins are the aflatoxins, a family of structurally related compounds produced by *Aspergillus flavus* growing on crops in tropical climates. This fungus can infect a large variety of crops – from peanuts to maize – but needs a very warm moist climate to thrive. Hence it is not normally found on cereals growing in the temperate beer producing countries, like those of Northern and mid-Europe or the Northern and Mid-West states of the USA. However, there are legal controls in many countries to guard against the importation of infected produce. In the EU, the limit is 4 mg/kg for total aflatoxins and 2 mg/kg for the most toxic member of this family of mycotoxins: aflatoxin B1. This compound is a potent carcinogen, with a rat oral LD_5o value of 0.4 mg/kg body weight.

Aflatoxins are only infrequently found in wines from temperate zones. An investigation of 41 wines using an HPLC method (Section 4.3.3) that was sensitive to 0.02 mg/l of individual toxins, found aflatoxin B2a (one of the less toxic aflatoxins), at concentrations of 0.3 mg/l and 0.05 mg/l, in two wines (Takahashi *et al.*, 1997) An earlier study of 150 German wines, using a less sensitive thin layer chromatography (TLC) method (Section 4.3.1), revealed no aflatoxins (Lemperle *et al.*, 1975).

Alcoholic beverages thus provide an insignificant contribution to dietary intake of aflatoxins in temperate climate zones. In tropical (or at least warm, moist) climates, significant contamination of a wide variety of crops can occur, including those, like maize, that form the staple diet. Eating foodstuffs that are consistently infected with *A. flavus* or *A. parasiticus* has been correlated with incidence of primary liver cancer in several African locations (Sibanda *et al.*, 1997), although there was no link with alcoholic beverages. Aflatoxin M_1 have been found in the biological fluids of individuals in these locations. This substance intercalates into DNA and alkylates bases (notably guanosine) via its epoxide moiety. This is thought to cause p53 gene mutation, an important gene that prevents cell cycle progression following DNA mutation.

Ochratoxin a (OTA: 7-(L-β-phenylalanylcarbonyl) carboxy-5-chloro-8-hydroxy-3,4-dihydro-(3*R*)-methyl isocoumarin) (Figure 5.10.3) is a secondary metabolite produced by many species of fungus growing on cereal and fruit crops in temperate climates. Thus crops infected by *Pencillium verrucosum*, *Aspergillus ochraceus*, or *A. niger* can produce alcoholic beverages containing quantities of ochratoxin A, depending on the level of infection and the processing conditions. Although OTA is considered to be less toxic than, say, aflatoxin B1, it is classed as a possible carcinogen to humans (Group 2B) by the International Agency for Research on Cancer (IARC) (IARC, 1993); it has been shown to produce kidney and liver tumors in mice and rats (JECFA, 2001d).

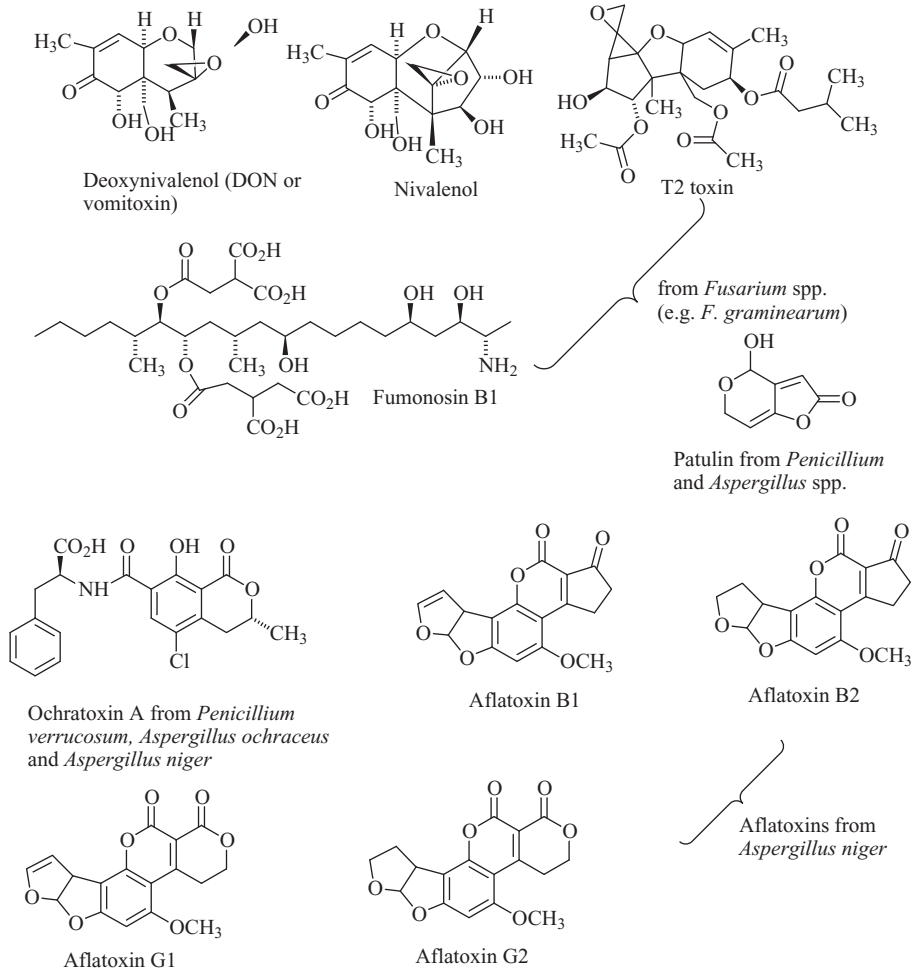

Figure 5.11.3 *Some mycotoxins sometimes found in alcoholic beverages.*

The panel on Contaminants in the Food Chain (CONTAM) of the European Food Safety Authority (EFSA, 2006) has suggested a provisional tolerable weekly intake of OTA of no more than 120 mg (0.12 mg) per kg of body weight. Regulatory limits for OTA content of beverages are in force in many countries; the EU has set a maximum allowable concentration of 2.0 mg/l in wine (EC, 2005). Likewise the EU has set maximum levels for OTA in cereal crops at 3 mg/kg. Wine is acknowledged to be a major dietary source of OTA in Europe (ECSCOOP, 2002), although most wines have been found to have levels of OTA well below the maximum allowed level of 2.0 mg/l (Bellí *et al.*, 2004; Aresta *et al.*, 2006; Mateo *et al.*, 2007 Valero *et al.*, 2008).

In general, wines from warmer climatic zones are higher in OTA content than those from cooler areas, and red wines have higher contents than rosé or white wines Bellí *et al.*, 2004; Mateo *et al.*, 2007). Interestingly, the levels of OTA in wine seem to have a definite dependence on specific production processes, especially with regard to dessert wines (Valero *et al.*, 2008). Wines made using fortified must (giving early stopped fermentation, such as Muscat VDN – see Section 2.10.9), those made from sun dried grapes (such as certain

Sherry and Montilla wines – see Section 2.10.2) and those made from fresh chamber dried grapes (such as Amerone) tend to have higher OTA contents. On the other hand, wines made using flor (e.g. fino Sherry – Section 2.10.3), fortified wines having had long ageing in cask (e.g. Madeira, Port, Sherry – Sections 2.10.5, 2.10.7 and 2.10.2, respectively), Marsala (Section 2.10.8), wines made with warm chamber-dried grapes (e.g. vin santo) and dessert wines made from botrytized (nobly rotted) grapes or late harvested grapes tend to have lower OTA contents (Valero *et al*., 2008).

Harvesting grapes with minimal damage, cool storage, rapid processing and sanitary winery conditions all help to minimize postharvest OTA contamination (Hocking *et al.*, 2007). Flash pasteurization of the must or addition of bisulfite prevents fungal growth and OTA formation (Roset, 2003). Up to 80% of OTA is lost on separation of the wine or juice from the skins (Fernandes *et al.*, 2007). However ochratoxin A is not metabolized by yeast, but some can be lost, via adsorption on yeast cells during fermentation, by racking the wine off the lees (Caridi, 2006). The action of malolactic bacteria, the use of fining agents and storage for over 10 months may also help to reduce the OTA content of wine (Fumi *et al.*, 2005; Leong *et al.*, 2007). In the vineyard prior to harvest, spraying with fungicides minimizes the growth of *Penicillium* and *Aspergillus* species.

Beer appears to be less affected by OTA residues, probably because the conditions under which barley and other cereals are stored and malted are unsuitable for the growth of *Penicillium* and *Aspergillus* species (Hughes and Baxter, 2001). For example, barley seeds for malting are dried to 12–14% moisture content and stored at low temperature until required. After malting, the moisture content of the grains is usually closer to 5%. It is known that the above fungi require a moisture content of at least 16% at ambient temperatures (say, *ca.* 20 °C) to grow on cereal grains. Nevertheless, recent investigations have shown that a high percentage of beers contain OTA, although often at levels below 0.2 mg/l; very much below the EFSA limit of 120 mg/kg of body weight/week (Mateo *et al.*, 2008), which means that beer is not a relevant contributor of dietary OTA. On the other hand, some of the indigenous brews of Africa (Section 2.7.2) have been found to possess in excess of 3 μg/l of OTA, with one having 2.3 mg/l – possibly the highest ever reported OTA content for a grain based alcoholic beverage (Odhav and Naicker, 2002). See also the review of Sibanda *et al.* (1997).

Of rather greater concern to maltsters and brewers is infection of grains by *Fusarium* species (eg. *F. graminearum*). These fungi, which are responsible for the scab (ear rot or Fusarium head blight) disease of cereal crops, produce a number of secondary metabolites known as trichothecenes, which includes deoxynivalenol (DON or vomitoxin), nivalenol and T-2 toxin (Figure 5.11.3). *F. graminearum*, along with *F. culmorum*, are important in temperate zones; they both produce trichothecenes. *F. arenaceum* is more common in Scandinavia and produces different metabolites (e.g. enniatins) (Uhlig *et al*., 2007).

The estrogenic (endocrine disruptor) zearalenone is also produced by *F. graminearum* on infected crops, although DON appears to be the mycotoxin produced in greatest quantity in scab-infected grain (Wolf-Hall, 2007). This compound seems to be very stable thoughout the normal brewing process, up to 93% remaining in the final beers (Schwarz *et al.*, 1996). Other *Fusarium* mycotoxins, such as zearalenone, were not detected in the final beer. Apart from its toxicity, DON in beer is undesirable; its presence has been correlated with 'gushing' – an overproduction of foam when the container of beer is opened (Schwarz *et al.*, 1996).

The most effective method to limit the occurrence of *Fusarium* mycotoxins in beer is to avoid the use of scab infected grains. Maltsters will refuse supplies of infected grains from growers, and malting companies in the USA have set an upper limit of 0.5 mg/kg in purchased grain. However, avoidance is not always feasible, and so with the present ineffective control of *Fusarium* head blight in the field, there are various ways of using part of the crop while keeping mycotoxin contamination to a minimum. These include separation of infected grains (e.g. the shriveled 'tombstone' grains of wheat), decontamination and prevention of further fungal growth (Wolf-Hall, 2007). It seems likely that beer provides an insignificant contribution of dietary

DON, since a survey of work carried out on mycotoxin contents of commercial beers indicated that these are found largely at trace (μg/l) levels (Scott, 1996).

Patulin (4-hydoxy-4H-furo-(3,2c)-pyran-2-(6H)-one (PAT) (Figure 5.11.3) is a mycotoxin produced by *Penicillium expansum* growing on infected fruit and cereals. Apples are particularly susceptible to infection, so that apple juice and products such as cider may become contaminated by patulin. The substance is genotoxic, although carcinogeneticity studies on animals have proved inconclusive. The World Health Organization (WHO) have recommended a maximum allowed level of 59 mg/l for apple juice, and in the EU the maximum allowed level for patulin in foods containing or derived from apples (including ciders) has been fixed at 50 mg/kg. Contaminated apple juice can be detoxified in several ways, including heat treatment (not fully effective), the addition of sulfites or ascorbates and treatment with ozone gas or γ-irradiation. It was found that just 100 ppm of SO_2 was sufficient to reduce the PAT content of grape juice to 50% in 15 minutes (Ough and Corison, 1980). In a model solution of pH 6 held at 100 °C for 1 h, 50% of the patulin content was degraded, the main degradation product being 3-keto-5-hydroxypentanal (Collin *et al.*, 2008).

Avoidance of contamination of cider by patulin residues can be effected by the rejection of moldy apples; indeed the patulin content of apple must can be used as an indicator of fruit quality. Such control is not possible when using apple juice concentrate (AJC), although analysis of samples of imported AJC should reveal levels of patulin below regulatory limits. Although some of the detoxification methods mentioned previously could result in negative organoleptic changes, it appears that PAT can be totally removed from apple juice within three weeks, by the addition of ascorbate with no significant effect on organoleptic quality (Lai *et al.*, 2000).

Considering the precautions and treatments that are available, it is not surprising that patulin levels are consistently low in commercial ciders.

5.11.5 Other Trace Substances

Ethyl carbamate (EC) and *N*-nitrosamines are the most important trace substances in alcoholic beverages that arise from natural processes during the manufacturing procedure.

Ethyl carbamate is a noted carcinogen. The Joint Expert Committee on Food Additives (JECFA) of FAO/WHO has advised that although intake of EC was generally of low concern, there is a definite need to continue to seek ways of lowering the levels of this compound in certain alcoholic beverages (JECFA, 2005). Few countries have yet set acceptable limits, but in Canada these are 30 μg/l (table wines); 100 μg/l (fortified wines); 150 μg/l (distilled spirits); 200 μg/l (sake) and 400 μg/l (fruit spirits and liqueurs).

Ethyl carbamate is a byproduct of fermentation and is found in many drinks, notably distilled spirits, stone fruit spirits and liqueurs, Asian rice wines and wine. It is formed in two major ways:

- Reaction of nitrogenous compounds (e.g. citrulline or urea) with ethanol
- Reaction of cyanide with ethanol.

Nitrogenous compounds – amines, amino acids and ammonia – are found in both must and fermented liquors. Some yeasts have the ability to metabolize certain of these compounds to urea during fermentation and certain lactic acid bacteria are able to metabolize arginine and glutamine to citrulline and carbamyl phosphate, two possible precursors of EC (Section 2.3.9).

Reaction between urea and ethanol, especially at elevated temperatures, produces small quantities of ethyl carbamate (Figure 5.11.4). High temperatures are used in the processing of various alcoholic beverages, notably distillation to produce spirits (some of which is used to make fortified wines) and various wine

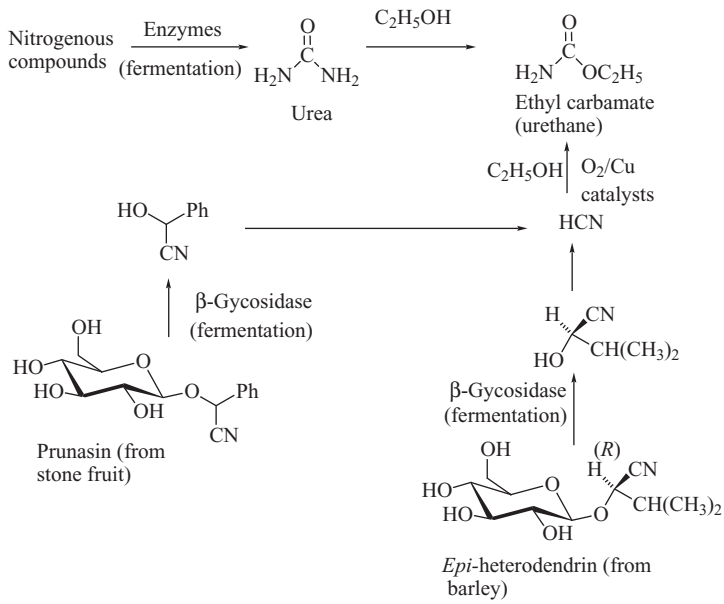

Figure 5.11.4 *Pathways for the formation of ethyl carbamate during the production of alcoholic beverages*

baking or grape drying processes used to make fortified wines such as Madeira (Section 2.10.6) and Sherry (Section 2.10.2).

Hydrogen cyanide is produced by the hydrolysis of natural cyanogenic glycosides during alcoholic fermentation (Figure 5.11.4). These glycosides are found in most barley varieties and are released into the wort on mashing of the malted barley grains in the production of beer and whisky (Swanston, 1999). In the brewing of beer these glycosides are hydrolyzed and the small amounts of hydrogen cyanide are driven off during the boiling stage (Section 2.6.3). However, in the production of whisky there in no boiling stage (Section 3.2.2) and so the glycosides survive into the fermentation stage, where they are hydrolyzed by yeast β-glucosidases to a heat labile product. This product is hydrolyzed to HCN during distillation, which then produces ethyl carbamate by reaction with ethanol (in the presence of O_2 and Cu^{2+}) during distillation. Ethyl carbamate is also formed from cyanide precursors in the kernels of stone fruit during the production of fruit brandies and liqueurs (Figure 5.11.4).

A survey of EC in alcoholic beverages sold in the UK during 2004, (Hasnip *et al.*, 2007), it was found that spirits, fruit brandies and fortified wines had the highest concentrations, wine had intermediate levels and beer (as well as the single cider sample) had none (i.e. in this study <10 μg/kg). Two sake (Section 2.7.1) samples had high levels of ethyl carbamate, and although the data was from just two samples it was in agreement with earlier work (Kitamoto *et al.*, 1991). Ethyl carbamate concentrations of all the wines that proved to be positive were quite close to the lowest quantifiable level of 10 μg/kg, with the highest concentration being 24 mg/kg. An earlier survey in Canada showed 74 wines contained up to 84 mg/kg and 155 stone fruit spirits had up to 4330 mg/kg of EC (Zimmerli and Schlatter, 1991). A survey of Korean liquors indicated very low levels of ethyl carbamate (close to the limit of detection) in fermented beverages and rather higher, though modest levels (up to 15.4 mg/kg) for indigenous distilled beverages (soju) (Section 3.4.4) (Ha *et al.*, 2006). Although concentrations of ethyl carbamate in alcoholic drinks appear to be erratic, the big majority of cases possess levels below those generally regarded as acceptable limits. Nevertheless, as JECFA (2005)

suggested, there is still a potential for reduction of levels via changes in production methodology. The use of genetically modified yeasts that do not produce urea during fermentation may be of particular value, provided that the organoleptic qualities of the beverage are not impaired. Sake fermented by such yeasts does not have quantifiable levels of ethyl carbamate (Kitamoto *et al.*, 1991). In the production of stone fruit spirits (Sections 3.8.3 and 3.8.4) or liqueurs (Section 3.9.2), rejection of some or all of the kernels may give beverages with lower ethyl carbamate levels, although this may also give altered flavor profiles. In the production of whisky, selection of barley varieties that do not produce *epi*-heterodendrin during malting is highly desirable. A gene marker for non-*epi*-heterodendrin producing varieties of barley was described by Swanston *et al.* (1999), which has been used by some barley breeders to develop recombinants, such as Decanter. Application was limited, however, because the marker (Bmac213) was some distance from the gene. More recently a direct gene marker that can reliably identify nonproducers of *epi*-heterodendrin has been developed by Hedley's group at the Scottish Crop Research Institute (Rae *et al.*, 2006). Aspects of this are discussed further in Section 3.2.2.

N-nitrosamines, sometimes present in the environment and in a wide range of foodstuffs, are known to be carcinogenic, mutagenic and teratogenic in a substantial number of cases. Of particular interest are the volatile nitrosamines, especially *N*-nitrosodimethylamine (NDMA), shown in Figure 5.11.5, as most of them are highly carcinogenic. As with ethyl carbamate, not all countries have set regulatory limits on the levels of *N*-nitrosamines in foodstuffs and present regulatory limits vary widely. The maximum level of total *N*-nitrosamines in beers in set at 5 mg/kg in the USA, 0.5 mg/kg in the EU, 0.5 mg/kg in Switzerland and 15 mg/kg in Russia (Sung, 2004). The carcinogenic potency of these volatile *N*-nitroso compounds lies in their ability to provide strongly electrophilic alkylating agents in a biological environment. These alkylating agents react with nucleophilic sites on nucleic acid bases and proteins, thus leading eventually to mutations and ultimately to carcinogenesis.

Surveys of the *N*-nitrosamine content of alcoholic drinks have generally revealed that only certain beers and whiskies contain one or more of these compounds at quantifiable levels (Jurado-Sánchez *et al.*, 2007), where

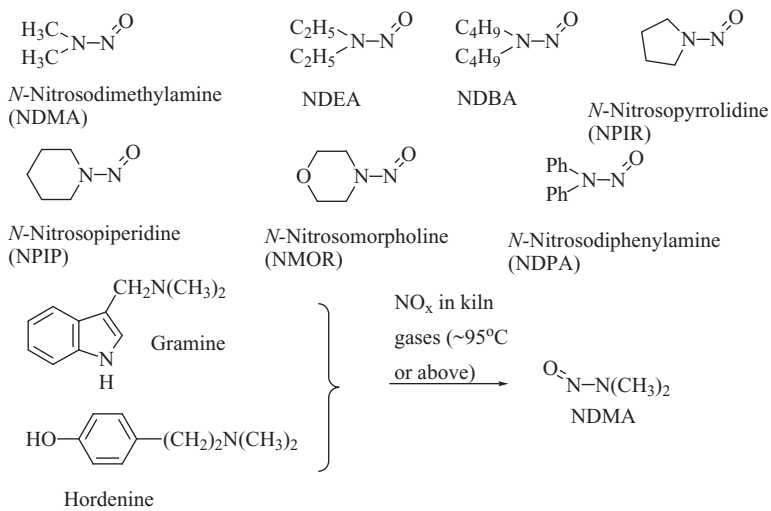

Figure 5.11.5 *Some volatile* N*-nitrosamines sometimes found in alcoholic beverages, and showing the formation of NDMA from NOx and barley amines*

NDMA and *N*-nitrosopiperidine appear to be the most common. In this recent survey, the total *N*-nitrosamine contents of beers (including nonalcoholic beers) were all below 1 μg/kg.

The major route to *N*-nitroso compounds such as NDMA in beer is via reaction of oxides of nitrogen (NO_x) and amines in the malted barley grains (Figure 5.11.5). This occurs during kilning through contact between the kiln gases and grains. In modern malting plants the kiln is fired externally and hence kiln gases do not come into direct contact with barley grains. Consequently, over the years there has been a general drop in the levels of NDMA and other nitrosamines in beer (Sen *et al.*, 1996).

Other routes to *N*-nitrosamines in foodstuffs involve the presence of nitrite salts (Sung, 2004). As far as alcoholic beverages are concerned, nitrite ions are most likely to originate in water used during the production process. There are strict regulatory limits on the nitrite content of water destined for human consumption (Section 5.10.4), but nitrite salts, originating from extensive use of nitrogen fertilizers in agriculture, are present in many public and private water supplies. Hops can also be a source of small amounts of nitrite salts in beer wort (Hughes and Baxter, 2001). In the brewery, continued use of a yeast strain can sometimes lead to bacterial infection. Some spoilage bacteria, notably *Obesumbacteria proteum*, can reduce nitrate to nitrite during the fermentation process. In the acidic fermenting wort, nitrite can react with secondary amines to from *N*-nitrosamines. These *N*-nitroso compounds are not necessarily volatile (like NDMA) and they have not been so extensively characterized as their volatile cousins: they are known generally as ATNC or apparent total *N*-nitroso compounds (Hughes and Baxter, 2001).

Appendix 1

Units of Measurement and Interconversions

Note that the text uses SI (metric) units, with occasional inclusion of the corresponding US or British units. Nevertheless, readers may find the following SI–US–British unit conversion factors useful.

Units of Length

SI: 100 cm = 1 m; 1000 m = 1 km
US/British: 12 in = 1 ft; 3 ft = 1 yd; 1760 yd = 1 mile

Interconversions

1 cm = 0.3937 in (1 in = 2.540 cm)
1 m = 39.370 in = 3 ft 3.370 in
1 km = 1093.6 yd = 0.62137 mile (1 mile = 1.6093 km)

Square Measure

SI: 10 000 m^2 = 1 ha; 100 ha = 1 km^2
US/British: 1 acre = 4863 yd^2 = 0.001570 $mile^2$

Interconversions

1 ha = 2.471 acres (1 acre = 0.4047 ha)

Cubic Measure

SI: 1000 cm^3 = 1 dm^3; 1000 dm^3 = 1 m^3
US/British: 1728 in^3 = 1 ft^3; 27 ft^3 = 1 yd^3

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

Interconversions

1 $cm^3 = 0.061025\ in^3$
1 $dm^3 = 0.035315\ ft^3$
1 $m^3 = 1.30795\ yd^3 = 61\ 024\ in^3$

Weights

SI: 1000 g = 1 kg; 1000 kg = 1 tonne
US/British: 16 oz = 1 lb; 2240 lb = 1 ton

Interconversions

1 g = 0.035274 oz (1 oz = 28.350 g)
1 kg = 35.274 oz = 2.203 lb (1 lb = 0.4539 kg)
1 tonne = 0.984 ton = 2204 lb

Capacity or Volume

SI: 10 ml = 1 cl; 100 cl = 1 l; 100 l = 1 hl
US/British: 8 pints = 1 gallon
US: 16 fl oz = 1 pint; British: 20 fl oz = 1 pint

Interconversions

1 l = 2.113 US pints = 1.760 British pints = 0.2641 US gall = 0.2200 British gall = 33.81 US fl oz = 35.20 British fl oz
1 hl = 26.41 US gall = 22.00 British gall
1 US gall = 3.785 l; 1 British gall = 4.546 l
1 US gall = 0.8326 British gall (1 British gall = 1.201 US gall)
1 US fl oz = 1.041 British fl oz (1 British fl oz = 0.9606 US fl oz)

Energy

The **SI unit** is the joule (J) (kg m^2/s^2).

1 cal = 4.184 J

Note: 1 Cal = 1000 cal or 1 kcal.

1.129	129	30.0	16.6	31.7	18.3

Table 2 *Temperature correction table for must or cooled wort specific gravity measurement*

Temperature/°C	Correction	Temperature/°C	Correction
10.0	−0.6	21.0	+1.1
11.0	−0.5	22.0	+1.3
12.0	−0.4	23.0	+1.6
13.0	−0.3	24.0	+1.8
14.0	−0.2	25.0	+2.0
15.0	0	26.0	+2.3
16.0	+0.1	27.0	+2.6
17.0	+0.3	28.0	+2.8
18.0	+0.5	29.0	+3.1
19.0	+0.7	30.0	+3.4
20.0	+0.9		

Approximate Relationships

°Brix, Balling or Plato = 1.8 × °Baumé
% sugar content (v:v) = (°Oechsle/4) – 2.5
% alcohol (v:v) = °Balling (°Brix or °Plato) × 0.55

Appendix 3

Pressure and Temperature Unit Conversions, and Numerical Values of Constants

Pressure Units

The official (SI) unit of pressure is the pascal (Pa); 1 Pa = 1 N (newton)/m^2 = 1 kg/ms^2

1 bar = 10^6 dyn/cm^2 = 10^5 Pa
1 atmosphere (atm) = 1.01325×10^5 Pa = 760 mm Hg
1 Torr = 1 mm Hg = 1.333×10^{-3} bar = 133.3 Pa = 0.001316 atm
1 psi (pound per square inch) = 0.07 atm (1 atm = 14.97 psi)

Temperature Units

The SI unit of temperature is the Kelvin (K), but °C (Celsius) is in common use, and in the USA °F (Fahrenheit) is often used.

°C = K − 273.15
°C = 0.5556 (°F – 32) (°F = 9/5 °C + 32)

Important Constants

The gas constant $R = 0.0802$ l atm/K mol or 8.314 J/K mol or 1.987 cal/K mol
Planck's constant $h = 6.626 \times 10^{-34}$ J s
Speed of light $c = 2.998 \times 10^8$ m/s

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

Glossary

A

Acescence. Sourness, probably due to the presence of extraneous acetic acid.

ADY. Active dried yeast for winemaking, brewing and cider production.

Etiological. Scientific description of cause of disease.

Alembic (Alambic). A kind of pot still with a bulbous lower part for heating the liquor, and a well-fitting upper head with a long tube for condensing and collecting the distillate. Nowadays, the name is sometimes used loosely to indicate a pot still.

Alquitara. A type of ***alembic*** still (see above) used to distil wine pomace or wine, especially in the northern provinces of Spain.

Amylopectin. A highly branched polymer of α-D-glucose, found as a food reserve in seeds and plants. It is one of the two components of starch, the other being the linear polymer amylose.

ANOVA. Analysis of variance; statistical methods in which observed variance is divided into components due to different sources of variation.

Apéritif. Generally, any alcoholic beverage that is taken before a meal. It can be dry (e.g. Champagne or fino Sherry) or sweet (e.g. ruby Port). More specifically, the term refers to a range of flavored, fortified alcoholic drinks often of ethanol content close to 20% (v:v), such as Dubonnet, Lillet, vermouth and many others. See also ***bitters***.

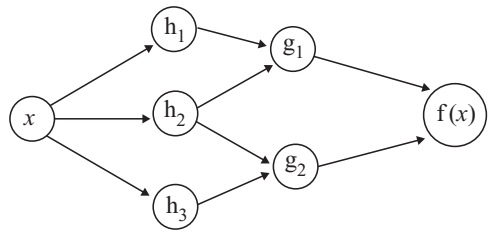
ApoE knockout mouse. Mutant strain of mouse lacking the gene for synthesis of ApoE, an ***apolipoprotein*** that plays an essential role in the transport and catabolism of triglyceride esters. ApoE knock-out mice suffer from ***atherosclerosis*** from an early age and are often used to study that condition.

Apolipoprotein. A lipoprotein without its fatty inner part (e.g. cholesterol, cholesteryl esters or triglyceride esters, enveloped in a phospholipid monolayer). The synthesis of apolipoproteins in vertebrates is essential for the transport of lipids between organs via the blood stream. See also HDL and LDL.

Apoptosis. The process of programmed cell death, apoptosis is essential for the wellbeing of multicellular organisms. Insufficient apoptosis is a contributing factor to cancer and excessive apoptosis causes atrophy (tissue wasting), such as ***ischaemic*** damage. Apoptosis is controlled by many cell signalling processes, involving many proteins, including caspases, which eventually bring about destruction of the cell into membrane bound fragments that are eliminated by shedding or by ingestion by ***phagocytes***.

Artificial neural networks (ANNs). ANNs are computational models that simulate structural and functional aspects of biological neural networks. Generically, the method is a nonlinear statistical data modeling tool for investigating complex relationships between input (x) and output ($f(x)$) or to find patterns in data. It does this by imitating a neural network, with nodes or axons, as shown below, where $f(x)$ is a component of other functions, $g_i(x)$, which in turn are defined as components of other functions, $h_i(x)$.

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9



Atherosclerosis. Sometimes called arteriosclerotic vascular disease, atherosclerosis refers to hardening of the arteries caused by the formation of atherotomatous plaque. This is produced initially by immunoresponsive reply to damage to the arterial walls caused by oxidized ***LDL***. White blood cells (***macrophages*** and T-***lymphocytes***) are unable to fully destroy the oxidized LDL particles, leading to a gradual build up of plaque (consisting of oxidized LDL, cholesterol, foam cells and other fatty deposits, with concurrent increase in inflammation. The condition is compounded by inhibition of ***HDL*** to collect cholesteryl esters and transport them to the liver for processing. In an inflamed artery, muscle cells enlarge and form a fibrous layer over the inflamed area, thus constricting the artery and giving rise to increased blood pressure. The plaque is often unstable, with ruptures resulting in complete blockage, thereby denying blood (and hence oxygen) supply to organs, such as the heart or brain.

Autolysis. Self-digestion of dead or dying cells by the action of their own enzymes, released by the lysosomes. In yeast alcoholic fermentation, yeast cell death occurs when nutrients are short and when the alcohol level is high (∼15% ABV, but higher or lower for some strains). Autolysis releases polysaccharides, proteins and amino acids into the beverage, if 'lees contact' time is prolonged (i.e. with no racking or filtration), which can be detrimental (as in the production of many beers and wines) or beneficial (as in Champagne production).

B

Bacteriophage. A virus that selectively infects bacteria (such as lactic acid bacteria), sometimes causing loss of malolactic activity.

Barrel. This term is often used loosely to describe a cask. More strictly, it refers to a cask of 36 Imperial gallons (∼160 l), once a standard cask size for cask-conditioned beer. Other cask sizes related to this are kilderkin (18 Imp. gall.), firkin (9 Imp. gall.) and pin (4.5 Imp. gall.).

Bilirubin. Sometimes known as hematoidin, bilirubin is a normal yellow breakdown product of heme catabolism. It is a potent *in vitro* antioxidant and is probably a major cellular antioxidant.

Bitters. Liquors, usually of alcoholic strength greater than 20% (v:v) and flavored with various bittering botanicals, such as cinchona bark, gentian or wormwood. They are used to make a wide range of cocktails, but some can be used as apéritifs or digestifs. Examples include Abbot's, Amer Picon, Angostura Bitters (containing essence of gentian), Boonekamp, Campari, Fernet Branca, Law's, Orange Bitters, Pommeranzen, Secrestat, Toni Kola, Underberg, Unicum and Welling's.

Botrytis cinerea. A fungus that belongs to the *Ascomycota* phylum and is characterized by hyaline conida (asexual spores) carried on grey tree-like conidiophores. It infects a variety of fruiting plants causing diseases such as ***grey mold*** with resultant loss of quality and yield. However, infection of fully ripe white grapes is usually beneficial, causing ***noble rot*** (pourriture noble, Edelfäule) and producing some of the greatest sweet wines of the world.

Brij 35. A surfactant, polyoxyethylene[23]dodecanol, used to form micelles in micellar liquid chromatography, thus enhancing the selectivity of the method.

Butt. A size of wine cask. It is equivalent to two hogsheads (= 108 Imperial gallons, or 480 l). It is also known as a 'pipe.'

C

cfu. Colony forming unit is an estimate of the number of viable microorganisms (bacteria or fungi) or basal cells. It is usually quoted as CFU/ml or CFU/g.

C-reactive protein. A member of the pentraxin family of proteins, which are involved in lipid metabolism. C-reactive protein is an acute phase reactant – its concentration (e.g. in blood) rises dramatically during inflammatory processes – hence it is used as a marker of inflammation (e.g. of arterial walls).

Calcofluor White. A tissue stain reagent used to produce fluorescence (green or bluish) in the presence of viable fungal cells, upon receiving incident light of the correct wavelength (440 nm). It binds to the cellulose and chitin on the cell walls. It is the disodium salt of 4,4′-bis-[4-anilino-bis-diethylamino-*s*-triazin-2-ylamino]-2,2-stilbene disulfonic acid (CAS registry number: 4404-43-7).

Canonical variation analysis (CVA). Statistical method for analysis of group structure in multivariate analysis. Sometimes known as canonical discrimination analysis (CDA), it is a one way multivariate analysis of variance, often used to study change of variables with time.

Cardiomegaly. Enlargement of the heart. The pathological form of cardiomegaly is caused by response to stress or disease. The increase in heart weight is the result of increased collagen content, which instead of contributing to the pumping rate, can lead to dysfunction and failure.

Cardiomyopathy. Relates to the deterioration of the myocardium (heart muscle) function, which is often caused by ischaemia (restriction of blood supply), caused either by local thickening of arterial walls (vasoconstriction) or via local blockage by a blood clot (thrombosis) or via blockage by a blood clot transported from elsewhere (embolism).

Catabolism. The oxidative degradation of nutrient molecules (carbohydrates, fats and proteins) obtained from the environment or from cellular reserves. Catabolic pathways are generally overall energy yielding.

Chemiosmotic. Pertaining to chemiosmosis – diffusion of ions across a selectively permeable membrane. For example, chemiosmosis of H^+ is important in the production of ATP by ATP synthase in ***mitochondria*** or plasmids, during respiration.

Chronopotentiometry. An electrochemical method, by which the rate of change of electrical potential (at constant current) is measured versus time.

Cocktail. A mixed drink, dating from the early nineteenth century, usually made with a distilled spirits base (e.g. brandy, cachaça, gin, rum, tequila, vodka and whisk(e)y and other ingredients, frequently fruit juices, but also sometimes ***bitters***, fruit, honey, liqueur, milk (or cream) or spices. Some cocktails are based on beer or sparkling wine (e.g. Buck's Fizz). There are many cocktails, and although each has a specific name, flavor can vary considerably due to differences in composition and method of preparation. Cocktails are usually made to order at a bar, but particularly over the past few decades, many have become available as ready to drink items, but even these can be further mixed (e.g. Pimm's No. 1 cup). Cocktails are usually served cold or with ice, and with a slice of lemon or lime, or an olive or Maraschino cherry as garnish.

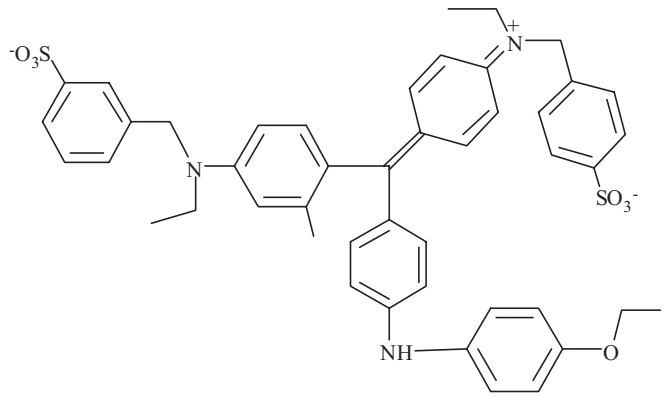
The following table gives a short list of cocktails with a summary of ingredients. They are grouped according to the major distilled spirit base.

Cocktail base	Examples
Brandy	Brandy Manhattan (as Manhattan, but with brandy in place of rye whiskey), Brandy Sour (brandy, curaçao, sugar, lemon juice and soda), Pisco Sour (Pisco, syrup, lime, egg white, bitters)
Cachaça	Batida (cachaça, fruit juice, sugar), Caipirinha (cachaça, lime, sugar)
Gin	Martini (gin, dry vermouth), Monkey Gland (gin, orange juice, absinthe, grenadine), Pall Mall (gin, dry and sweet vermouth, white crème de cacao), Pink Gin (gin, Angostura Bitters), Vesper (gin, vodka, Lillet Blanc)
Rum	Bacardi (white rum, lemon or lime, grenadine), Daiquiri (as Bacardi, except with gomme syrup – sugar, water, gum arabic – in place of grenadine), Piña colada (white rum, crème de cacao, pineapple juice), Planter's Punch (dark rum, fruit juices, soda, curaçao, Angostura Bitters)
Tequila	Margarita (tequila, Cointreau, lemon or lime juice), Tequila Sunrise (tequila, orange juice, grenadine)
Vodka	Bloody Mary (vodka, tomato juice, lemon juice), Harvey Wallbanger (vodka, Galliano, orange juice), Screwdriver (vodka, orange juice), Vodka Martini (as Martini, but with vodka in place of gin).
Whisk(e)y	John Collins (Bourbon, lemon juice, sugar syrup, soda), Manhattan (rye or Canadian whisky, red vermouth, bitters), Mint Julep (Bourbon, mint leaves, sugar), Rob Roy (Scotch, sweet vermouth, Angostura Bitters), Sazerac (Rye whiskey, Bitters, sugar, absinthe)

Celiac disease. This is an autoimmune disorder of the small intestine that occurs in genetically predisposed persons in response to the presence of ***prolamins*** in the diet.

Conchae. Organ structures that resemble a shell in shape. Nasal conchae provide humidity for the proper functioning of the olfactory epithelium.

Coomassie Brilliant Blue. A Coomassie type dyestuff used to stain (visualize) proteins in SDS-PAGE analysis. It interacts with proteins via ionic and ***van der Waals forces***. The structure of Coomassie Brilliant Blue G-250 is shown below.



CAS registry number: 6104-58-1.

Copigmentation. Interaction of pigment molecule (e.g. an anthocyanin or derivative) with a cofactor (e.g. a polyphenol) via **π-π *attractions***, causing stacking of molecules. The color of black grapes, red wine must

and new red wine is due largely to copigmentation, which decreases during maturation, leading to marked color changes.

Cyanogenic glycosides. Cyanohydrin {NC-C(R)(OH)-} derivatives of sugars, found in cereal kernels (e.g. *epi*-heterodendrin in barley), cereal roots (e.g. dhurrin in sorghum), nuts (e.g. amygdalin in almonds) and stone fruit (e.g. prunalin). They are natural plant defence compounds. The cyanohydrin moiety is easily cleaved from the sugar and can be hydrolyzed chemically or enzymically to produce HCN.

Cyclic AMP. Cyclic adenosine monophosphate is a second messenger that is important in signal transduction. Its participation is important in many biochemical processes, such as glycogen, sugar and lipid metabolism, via the activation of certain ***protein kinases***.

Cyclooxygenases. Members of the COX family of enzymes, which catalyze reactions that produce ***prostaglandins*** and related molecules from arichidonic acid. COX-1 and COX-2 are the best known. Sometimes known as prostaglandin endoperoxide synthases.

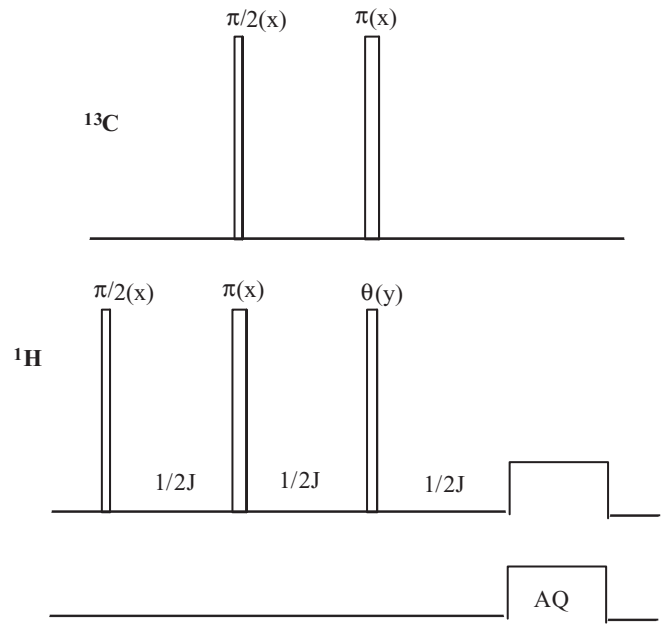
Cytochrome isoenzymes. A superfamily of heme containing enzymes in the endoplasmic reticulum membrane of cells. They catalyze the oxidative metabolism of many endogenous and exogenous molecules (including drugs). They are known as isoenzymes (or isoforms) because each one is derived from a different gene; in humans, 21 families, 20 subfamilies and 57 genes have been so far described. CYP 2E1 is the main component of ***microsomal*** ethanol oxidizing system.

Cytolysis. Sometimes called osmotic lysis, cytolysis refers to cell rupture due to osmotic imbalance, and is caused by extraneous water entering the cell.

D

Density function theory (DFT). A quantum mechanics based theory used to study the electronic structure (distribution of electron density) of the ground states of atoms and molecules, and also of condensed phases, particularly solids. The time dependent version can be used to describe excited states.

DEPT. This is short for **D**istortionless **E**nhancement by **P**olarization **T**ransfer, an NMR spectral editing technique that indicates ^{1}H–^{13}C connectivity in molecules. The pulse sequence is shown below.



The final proton pulse is often set at $\pi/2$ (giving a 'DEPT-90' spectrum, indicating CH) and $3\pi/4$ (giving a 'DEPT-135' spectrum, indicating CH again, and CH_3, as negative peaks). Methylene and unprotonated carbons can be found by difference.

Digestion. With respect to atomic spectroscopy, digestion refers to the method of dissolution of the sample in a concentrated acid medium, such as aqua regia ($HCl + HNO_3$). The elements in complex molecules of the sample are thus converted to simple ionic species.

Diploid. A diploid cell is one that contains two sets of homologous chromosomes, one donated from each parent. *Saccharomyces cerevisiae* is a single cell eukaryote with both diploid and *haploid* (with single chromosome set) forms.

Dipole–dipole forces. Attractive (stabilizing, energy lowering) forces between opposite ends of molecular or covalent bond dipoles, either in the same molecule (intramolecular) or in different molecules (intermolecular). Hydrogen bonding, where one of the involved atoms is hydrogen, is considered by many to be a special kind of dipole–dipole force (e.g. $>C^{\delta+}=O^{\delta-} \ldots . {}^{\delta+}H\text{-}^{\delta-}O\text{-}$). Bond strengths are low (2–10 kJ/mol, but higher for some hydrogen bonds, compared with 200–400+ kJ/mol for most covalent bonds), but these forces can be significant if the number of interactions is large.

Diuretic. A drug that increases the rate of excretion of water from the body, by increasing the urination rate. They are used to treat kidney diseases, heart failure and hypertension.

Dysplasia. A condition in which cell maturation and differentiation are delayed, resulting in increased numbers of immature cells with respect to mature cells of the same type. It is often an indication of an early neoplastic (cancerous) process.

E

Ebulliometry. The precise measurement of the boiling points of solutions, which can be used to determine the composition (e.g. the ethanol content) of the solution. It is based on the colligative properties of matter; the presence of a solute increases the boiling point of a solvent (by lowering the vapor pressure) in accordance with the concentration of the solute.

Eigenvalue and eigenvector. An eigenvector is a nonzero vector x, such that $Ax = \lambda x$, for a particular matrix A. The eigenvalue of x and the matrix is λ.

Electrokinetic. This term relates to the motion of particles or fluid that results from or produces an electrical potential difference. Electrokinetic motion is of special importance in electrophoretic methods of analysis, where application of an electrical potential causes the tangential motion of the diffuse layer of a fluid with respect to an adjacent interfacial double electrical layer.

Electrophiles. Electron deficient species, such as cations (e.g. H^+, R_3C^+), molecules containing group IIA or IIIA elements, and positive ends of polar groups (e.g. $>C^{\delta+}=O^{\delta-}$). They react with ***nucleophiles***.

ELISA. Enzyme linked immunosorbent assay is a method used mostly to detect the presence of an antibody or antigen in a sample. There are several variations of the method, but briefly, a sample containing an antigen is immobilized on a solid support (usually a polystyrene microtiter plate). The detector antibody (usually linked to an enzyme) is added, forming reactive complexes with the antigen molecules. An enzymic substrate is then added, whose reaction with the immobilized enzyme is accompanied by change in color (absorbance) or produces fluorescence that can be related to the concentration of the antigen in the original sample.

Ellman's reagent. This is 5.5-dithio-bis(2-nitrobenzoic acid), a sensitive reagent for the detection of sulfydryl (thiol; SH) groups in samples, by forming a yellow product that absorbs strongly at 412 nm. CAS registry number: 69-78-3.

Endosymbiosis. A theory that postulates that all mitochondria and plastids (organelles in eukaryotic cells) are evolved from prokaryotic bacteria that once lived in symbiosis with their host cells.

Endotoxins. These are toxins associated with certain bacteria; they are secreted when the cells are lysed (ruptured) or during normal cell division. Many are lipo-oligosaccharides, some are proteins, but all cause

immunoprotective responses. Their presence in the blood stream can lead to septic shock if the immune response is pronounced.

Enterocytes. This is the name for intestinal absorptive cells, which are simple columnar epithelial cells found in the small intestine and colon. They are responsible for the uptake of nutrients and the excretion of ***immunoglobulins***, such as IgA, which provide protection against microbes.

Estrogenic. Any substance that produces physiological behavior like that of estrogen is called an estrogenic substance. It disrupts the physiological action of endogenous estrogen, by binding to cellular estrogen receptors, thus up regulating the expression of many genes. More generally, endocrine disruptors influence the balance of body regulation by interfering with hormone action.

F

FAN. The free amino nitrogen (FAN) content of wine must or beer wort is a measure of the nitrogen available to yeast as nutrition during alcoholic fermentation. It is often related to the α-amino acid concentration, but ***yeast assimilable nitrogen*** (*YAN*) measurement takes into account ammonium salts.

FPD. A flame photometric detector is a largely specific GC detector, used mainly to determine P and S containing compounds. It works on the principle of excitation of atoms in a hydrogen flame. Light emitted by the excited atoms can be related to the concentration of the substance that gives rise to those atoms. Band pass filters are used to detect P (526 nm) and S (394 nm) with very high sensitivity; other elements can be detected, but at much decreased sensitivity.

Ferredoxins (ferrodoxins). Redox proteins containing iron–sulfur clusters that mediate electron transfer in a wide range of metabolic reactions and organisms. They act as 'biological capacitors,' being able to accept and donate electrons. Some ferredoxins, such as chloroplast-like, mitochondrial adrenodoxin type and thioredoxin types, have an Fe_2S_2 cluster linked to four CYS units, whereas others, such as bacterial types, possess an Fe_4S_4 cluster bound to four CYS units.

Filiform papillae. Swallow tail-like papillae with hair-like structures found in most areas of the upper tongue surface. They are the most common papillae, their action being mechanical (e.g. trapping food particles to assist in taste), rather than related to taste as such, since they do not possess taste buds.

Foliate papillae. Leaf shaped papillae found mostly on the sides of the upper tongue surface at the back. They contain taste buds.

Fungiform papillae. Mushroom shaped papillae on the upper tongue surface, found mostly at the front and middle. They contain taste buds.

Friability. This is the ability of a solid object to be reduced to small pieces upon the application of a modest pressure or frictional force. High friability is a desirable property of malted barley and other grains used in the brewing of beer and production of whisky.

Fourier transform (FT). A mathematical operation that transforms one complex valued function of a real variable to another. In signal processing used in FT spectroscopy (e.g. IR, MS, NMR), a time domain function is transformed into a frequency domain function.

Freon. Generic name of chlorofluorocarbons (CFCs), very useful extraction solvents for low to mid polarity compounds from an aqueous matrix or solids. However, due to environmental considerations, large-scale manufacture of Freons is being phased out. In the usual molecular nomenclature (e.g. Freon-12 or CFC-12) there are three possible digits: the left most indicates the number of carbons minus 1; the middle digit gives the number of hydrogens plus 1 and the right most digit indicates the number of fluorine atoms. Thus all CFCs based on methane have only two digits, e.g. CF_2Cl_2 is Freon- or CFC-12.

G

GABA. Gamma-aminobutyric acid is a γ-amino acid (not found in proteins). It is the main inhibitory neurotransmitter in the central nervous system of mammals. In vertebrates, GABA acts at inhibitory synapses in the brain by binding to transmembrane receptors, thereby regulating ion channel function.

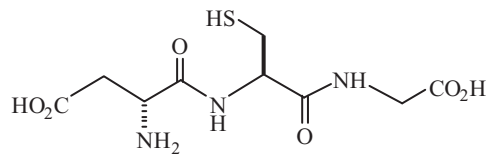
G proteins. Guanine nucleotide binding proteins are involved in the regulation and control of a range of cellular processes, such as function of ion channels and transcription. They are essentially signal transducers (they convert an extracellular signal into intracellular action), they are associated with cell membranes and are activated by G protein coupled receptors. Their action involves the interconversion of GDP and GTP.

Glassy carbon disk (disc). A type of electrode used in electrochemical analysis. The disks, typically 5.0 mm diameter × 4.0 mm thickness, are cut from glassy carbon rods, often using submicron alumina powder to achieve a mirror polish.

Glucogenolysis. This term is usually referred to the metabolic (catabolic) processes that generate glucose from noncarbohydrate sources, such as proteins and fats contained in body tissues, such as muscle. It is usually significant following vigorous exercise in the absence of dietary amino acids.

Gluconeogenolysis. The process of conversion of glycogen polymers (animal energy reserves) to glucose monomers, via hydrolysis of glycosidic bonds, following initial phosphorylation of a terminal glucose unit.

Glutathione. A tripeptide cell antioxidant that helps protect cells from damage by reactive oxygen molecules. It is present in healthy cells entirely as the monomeric reduced form (GSH – see below; it is oxidized to glutathione disulfide, GSSG) at concentrations of around 5 mM.



Glycoside. This is the generic name given to molecules in which a noncarbohydrate moiety (e.g. a phenol or a ***terpenoid***) is bonded to a sugar moiety (usually a monosaccharide or disaccharide) through the latter's anomeric carbon atom, via a glycosidic bond.

Grain neutral spirit. GNS refers to spirit of 85–95% ABV that has been produced by repetitive distillation/condensation cycles of a wash derived from cereal grains. It is thus almost pure ethanol–water, with only a very small concentration of flavor compounds (congeners), such as esters and higher alcohols. It is nearly always produced using continuous (usually two column) stills.

Gravimetric analysis. An analytical method for the quantitative determination of analyte based on accurate and precise weighing, and usually involving the conversion of a soluble analyte into an insoluble form of known composition via a precipitation reaction.

Grey mold. Often known as grey rot or botrytis bunch rot, grey mold is a disease of many plant species caused by *Botrytis cinerea* infection of the tissues, particularly in warm, humid conditions. Fruit are affected, resulting in loss of yield, quality and (in the case of colored fruit, such as black grapes) color. Other parts of the plant (e.g. leaves and stalks of grape vines) may also be seriously affected).

Gushing. The term given to the excessive, even violent frothing of carbonated alcoholic drinks, notably beer, upon opening the container. The phenomenon can be caused by the presence of mycotoxins from fungus infected grains used in brewing.

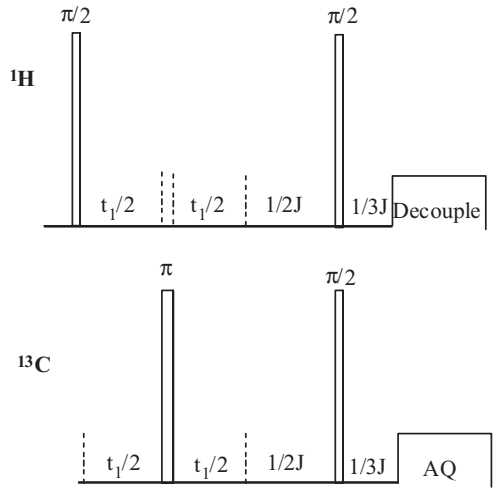
H

Haploid. The haploid number (n) is the number of chromosomes in a gamete (a germ cell), or alternatively, a haploid cell or organism is one that has half the number of chromosomes in somatic cells (normal body cells). In humans, sperm or egg cells (germ cells) contain only one of each of the 23 chromosomes of the human genome. In contrast, somatic cells are ***diploid*** and contain 2 × 23 chromosomes.

HDL. High density lipoproteins belong to one of five major groups of lipoproteins that transport lipids through the bloodstream. They are composed of ***apolipoproteins*** ApoA-I or ApoA-II wrapped around a phospholipid monolayer, collecting or surrendering lipids (cholesteryl esters or triglyceride esters), with the

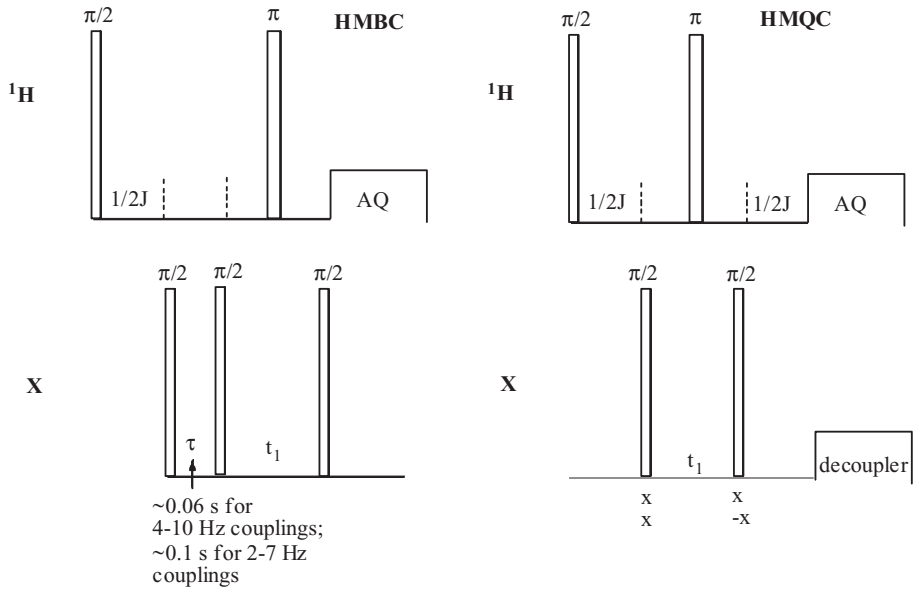
help of various transfer proteins. In particular, HDL contributes to the transport of lipids from cholesterol laden foam cells of ***atherosclerotic*** arteries to the liver for excretion into the bile duct.

HETCOR. This is the name of a family of 2D NMR **HET**eronuclear **COR**relation techniques that are used to demonstrate connectivity between different magnetic nuclei (e.g. ^{1}H and ^{13}C) via transfer of polarization. See also HMBC and HMQC. The pulse sequence used in HETCOR spectroscopy is shown below.

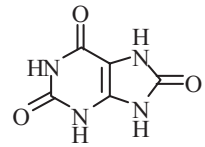


HGCA. The UK's Home Grown Cereals Agency, which is responsible for 'the production, wholesomeness and marketing of UK cereals and oilseeds, so as to increase their competitiveness in UK and overseas markets in a sustainable manner.' HGCA board members are appointed by the UK agricultural ministers.

HMBC and HMQC. Heteronuclear **M**ultiple **B**ond **C**oherence and **H**eteronuclear **M**ultiple **Q**uantum **C**oherence are 2D NMR inverse (usually proton-^{13}C) correlation techniques, giving atomic connectivity information. HMBC gives long-range (2–4 bond) couplings, whereas HMQC is selective for direct one bond (such as C–H) coupling. The pulse sequences for HMBC and HMQC are shown below.



Hyperuricaemia. This term refers to the condition where the level of uric acid (below) in the blood is abnormally high (>400 μmol/l for men). Crystallization of this substance may sometimes occur at joints, tendons and surrounding tissues, giving rise to the painful condition known as gout. A major cause of hyperuricaemia (though not necessarily of gout) is excessive alcohol consumption, which results in both increased production and decreased excretion of uric acid.



Hypocholesterimic. An agent (e.g. a specific substance such as niacin or a foodstuff such as garlic) that lowers the concentration of cholesterol in general in the bloodstream.

Hypoglycaemia. This is the medical term for a condition where an abnormally low level of glucose is present in blood. A principal cause is a complication of treatment of diabetes mellitus, from increased levels of insulin.

Hypokalaemia. This describes a condition in which the blood potassium level is abnormally low (≪3.5 mEq/l). It may be caused by a number of factors, including gastrointestinal loss, inadequate uptake and excessive secretion of K^+ ions, which in turn can be influenced by high alcohol consumption. Symptoms include cardiac arrythmias and impairment of muscle function.

I

Ideal. With reference to gases, an ideal gas is one that obeys the ideal gas law ($PV = nRT$). Ideal gases are hypothetical gases in which the interparticle forces are zero and the particles have zero volume, but at lower pressures and higher temperatures, some real gases (e.g. H_2, He and Ne) exhibit very close to ideal behavior. Many other gases (e.g. N_2, CO_2) behave approximately like ideal gases under these conditions.

Interleukins (IL). Sometimes known as *cytokines* or interferons, interleukins are small proteins that are secreted by certain cells of the immune system in order to carry signals locally between cells. For example, the two forms of IL-1 (IL-1α and IL-1β) are proinflammatory cytokines involved in the body's defence mechanism against infection. It is produced by ***macrophages***, ***monocytes*** and other cells and it functions by increasing expression of adhesion factors on endothelial cell walls, thus enabling transmigration of ***leukocytes*** (cells that destroy pathogens) to sites of infection. It also resets the hypothalamus temperature regulation center, causing fever.

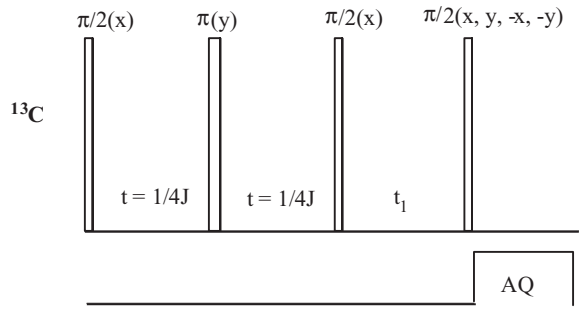
Iodometry. This is the name of an important method of volumetric chemical analysis and involves redox titrations in which appearance or disappearance of I_2 occurs suddenly at the equivalence (end) point. Usual reagents are sodium thiosulfate as titrant, starch or polyvinyl alcohol as indicator and an iodine compound that is either reduced (e.g. iodate, IO_3^-) or oxidized (e.g. iodide, I^-) by the analyte being studied. For example, iodometry can be used to determine the chlorine content of water used in brewing, distilling or winemaking and the sulfur dioxide content of beverages.

Isoprenoids. Often called ***terpenoids***, they constitute a very large and diverse group of natural products found throughout the plant and animal kingdoms. Their structures are based upon that of isoprene (2-methyl-1-butene), but biochemically they are synthesized either from acetate via isopentyl pyrophosphate and the mevalonic acid pathway or via the 2-*C*-methylD-erythritol 4-phosphate/1-deoxy-D-xylulose 5-phosphate pathway. They are generally prone to complex rearrangements in mildly acidic conditions or upon mild heating and many are important flavor compounds in alcoholic and other beverages.

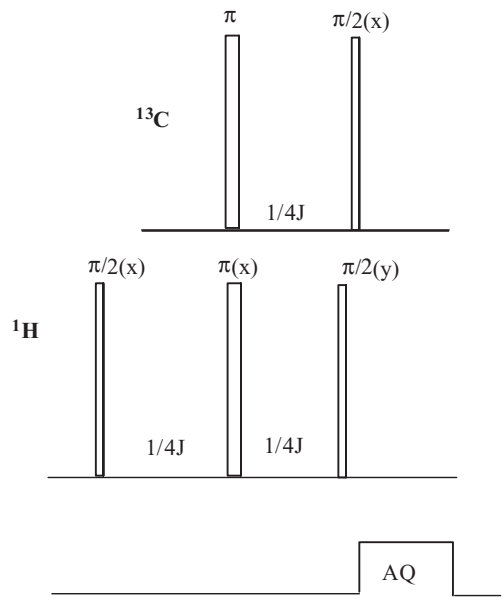
Immunoglobulins (Ig). Also known as antibodies, immunoglobulins are glycoproteins found in blood and other body fluids, such as saliva, mucus and colostrum. They are used by the immune system of vertebrates to identify and destroy foreign entities (immunogens or antigens), such as parasites, bacteria and viruses.

Millions of immunoglobins exist, each with slightly different tip structures (for binding with specific antigen receptors), but with overall very similar structures, thus allowing the recognition of a huge range of antigens. Immunoglobulins can act as part of a cell membrane (e.g. up to 100 000 surface Ig sites on effector B cells) or can be secreted into mucus or serum without their transmembrane regions. When Ig molecules bind to surface antigens on a bacterium, a 'complement cascade' is activated, in which the tagged microbe is either attacked by effector cells (mast cells, natural killer cells, neutrophils or *phagocytes*), which are attracted to the microbe by the presence of complement molecules produced in the cascade, or more directly by a membrane attack complex of complement system components and antibody molecules.

INADEQUATE. A 1D or 2D NMR experiment that reveals carbon–carbon connectivity. The 1D form provides a means of measuring (natural abundance) ^{13}C–^{13}C coupling constants and for establishing carbon–carbon connectivity on the basis of coupling magnitudes that are common to the two particular carbon atom types. The 2D form uses the pulse sequence below, where the fixed time period t_1 is used to encode the double quantum frequency domain (that of the satellite resonances, caused by ^{13}C–^{13}C coupling; $^1J \sim 30$–70 Hz), and the phase of the final pulse is cycled through the directions shown. The 2D plot shows no diagonal peaks (unlike COSY), but connectivity is obtained from cross peaks after drawing in a diagonal.



INEPT. This is short for **I**nsensitive **N**uclei **E**nhancement by **P**olarization **T**ransfer. The pulse sequence shown below results in enhanced signals for insensitive nuclei, such as ^{13}C and ^{15}N.

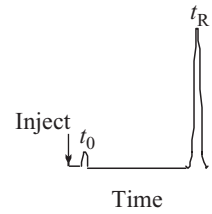


Ischaemic. Local lack of blood supply, caused by narrowed arteries (vasoconstrction) or by a local blockage by some obstacle.

K

***k′* (‘*k* prime’).** In HPLC, k′ is known as the retention or capacity factor; it measures the retention time (t_R) of a particular analyte under a particular set of conditions with respect to the solvent front or an unretained solute (t_0).

$$k' = \frac{t_R - t_0}{t_R}$$



Its optimum value is 2–10, giving optimum resolution ($R_s = {}^1/_4\ (\alpha - 1)\ \sqrt{N}\ \{k'/(1 + k')\}$, where N is the efficiency factor and α the selectivity factor), but without inconveniently long retention times.

Kinetic stabilization. This term describes the stabilization of a molecule due a high transition state energy of a particular reaction, causing that reaction to be very slow. It is often provided by the presence of bulky groups around a reaction center (‘steric hindrance’), thus causing the reaction transition state to be too high in energy, because of serious repulsive interaction.

L

Landrace. This term refers to domesticated plants that have adapted to the local natural environment in which they exist. They are often of variable appearance, but are morphologically identifiable and have a certain degree of genetic integrity. Landraces are grown from seeds that have been systematically selected for desirable characteristics.

LD_{50}. A measure of the toxicity of a substance; it is the dose required, usually expressed as mg/kg body weight, to kill 50% of the animals (usually rat, but should be specified) on oral or other administration (which should also be specified) of the substance.

LDL. Low density lipoprotein is, like ***HDL***, one of five main groups of lipoproteins and is responsible for the transport of cholesteryl esters through the bloodstream. The ***apolipoprotein*** is Apo B-100 (molecular weight ~514 000 D), which combines with a phospholipid monolayer and cholesterol to trap cholesteryl ester molecules in its center, giving LDLs of differing sizes and densities. The smaller, more dense LDL particles are thought to pose a greater risk factor than larger particles, but high LDL content in general is associated with increased risk of cardiovascular disease.

LOD and LOQ. Limit of detection (LOD) is the lowest quantity or concentration of analyte that can be distinguished from a blank (containing no analyte), within a defined confidence limit, usually 1%. Instrumental detection limit is usually taken as 3 × standard deviation (SD) of the noise level, whereas method detection limit is derived from the SD near the LOD and the one sided *t* distribution. The limit of quantification (LOQ) is the limit at which the difference between two different values can reasonably be detected. It is usually 10 × SD of noise level.

Leukocytes. This is the general name for white blood cells involved in the body’s immune defence system. The major groups are basophils, eosinophils, ***lymphocytes***, ***monocytes*** and neutrophils.

Leukoplakia. (leukoplasia). White patches on skin of say, mouth, which are the result of mucus membrane dysfunction and can be caused by alcohol abuse. They are sometimes associated with a precancerous condition.

Leukotrienes. Unsaturated compounds produced by degradation of arachidonic acid and other unsaturated membrane long chain fatty acids. They are local chemical messengers involved in inflammation; they help regulate the state of blood vessels and airways, and they influence the activity of ***leukocytes***. High levels of serum leukotrienes have been correlated with oxidative stress and increased risk of cardiovascular disease, which sometimes can be linked to excessive alcohol consumption.

Lignins. This is the general name for large, complex phenolic molecules, often derived from woody materials. Lignin breakdown products (phenols) are often important in the wood maturation of wines and spirits. Lignins form an integral part of plant cell walls, being covalently bonded to hemicellulose and they are found sandwiched between cellulose, hemicellulose and ***pectin*** components.

London dispersion forces. The induced dipole/induced dipole attractive forces that contribute to the ***van der Waals*** intermolecular forces are known as London dispersion forces. They are very weak forces ($\sim$1 or 2 kJ/mol), but nevertheless play a fundamental role in the formation of condensed phases and they can be important in attractive interaction between or within large molecules, such as proteins and nucleic acids, or between an enzyme and its substrate.

Lymphocyte. There are several types of white blood cells involved in immune response; lymphocytes are one type, being composed of two subtypes: large granular lymphocytes, including natural killer cells (NKC), and smaller lymphocytes, which include B cells and T cells. All are involved in the vertebrate immune system, offering protection from a wide range of foreign entities, including bacteria, cancer cells and viruses.

Lymphokine. These proteins belong to a subclass of cytokines, proteins produced by ***lymphocytes*** (certain types of cells of the immune system), such as T cells. Lymphokines aid immune response through intercellular signaling.

Lyophilized. Refers to freeze drying used to preserve or to concentrate perishable material, making it more suitable for long keeping and transportation. Lyophilization (also known as cryodesiccation) is a dehydration process that is achieved by the sublimation of the water content of frozen material at low pressure.

M

MAPK. Mitogen-activated protein kinases are SER/THR specific ***protein kinases***. They respond to extracellular stimuli, such as stress, proinflammatory agents, cytokines and mitogens – compounds that stimulate cell division. They regulate many cellular processes, including ***apoptosis*** (cell death), differentiation, gene expression, mitosis and proliferation.

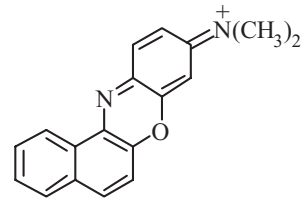
Marangoni current. A flow (convection) in liquids from areas of low surface tension to those of higher surface tension. The surface tension gradient may be formed by temperature differences in a pure liquid or by concentration differences in a solution containing water, ethanol and other solutes, for example.

Macrophages. These important cells of the vertebrate immune defence system are produced by stimulated differentiation of ***monocytes*** at the site of infection. As stationary cells (e.g. in the lungs) or as mobile cells, they nonspecifically engulf cell debris and foreign bodies (such as bacteria), breaking them down into simpler products. They also stimulate ***lymphocytes*** and other more specific immune cells to respond to the presence of a pathogen.

Matrix metalloproteinases. MMPs are zinc dependent endopeptidases; they hydrolyze proteins at nonterminal amino acids. They can degrade extracellular matrix proteins, such as collagen; in fact they are the only known proteases able to hydrolyze the triple helix of collagen. MMPs are known to be involved in a number of cellular processes, including the cleavage of cell surface receptors, the release of apoptotic

proteins (such as FAS) and cytokine activation/deactivation. Hence, they play a role in cell ***apoptosis***, cell differentiation, cell migration/adhesion and cell proliferation. MMPs are also known to be involved in angiogenesis (production of new blood vessels). They are deactivated by proteins known as tissue inhibitors of matrix metalloproteinases (TIMPs).

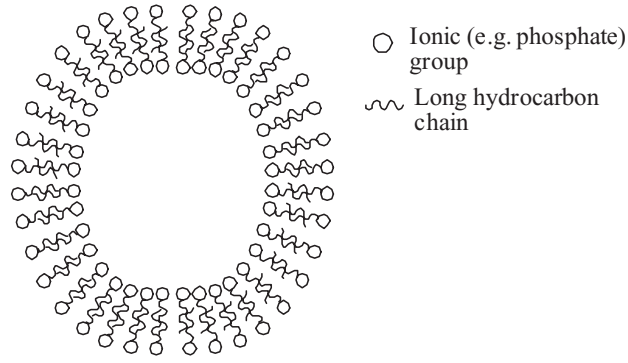
Meldola's Blue. Often known as Basic Blue 6, Meldola's Blue (CAS registry number 7057-57-0; see below) is sometimes used, along with metal oxides such as ZnO as a coating on electrodes (e.g. ***glassy carbon electrodes***) in electrochemical analysis. The dye is strongly adsorbed on ZnO surfaces.



Microalbuminuria. A condition that involves the leaking of small amounts of albumin proteins into urine. The presence of albumins in urine can be used as an indicator of not only kidney disease, but also cardiovascular disease and endothelial dysfunction. The condition can result from alcohol abuse.

Mitochondrion (pleural: mitochondria). This is an important membrane enclosed organelle found in most eukaryotic cells. Mitochondria generate most of the cell's ATP, itself a major store of energy required for cell metabolism, and are involved in aerobic respiration, the catabolism of glucose and other molecules being used to generate ATP.

Microsomal. This term refers to microsomes, vescicle-like (spherical bilayer micelles – see below for a schematic representation of a section through a microsome) structures formed from the endoplasmic reticulum when eukaryotic cells are broken up by mechanical action. They can trap globular enzymes, such as ***cytochrome*** P450 in their hydrophilic centers.



Monocytes. Immunological or white blood cells, that are produced by the bone marrow and circulated throughout the bloodstream, about half of them being stored in the spleen. Their basic function is to respond to inflammation signals, moving quickly to the site of infection, where they differentiate into ***macrophages*** or dendritic cells (antigen binding/presenting cells) to illicit a full immune response.

Myofibillar. Relates to myofibrils, cylindrical organelles found in muscle cells. They are composed of proteinaceous filaments running from end to end and are attached to the cellular membrane at both ends.

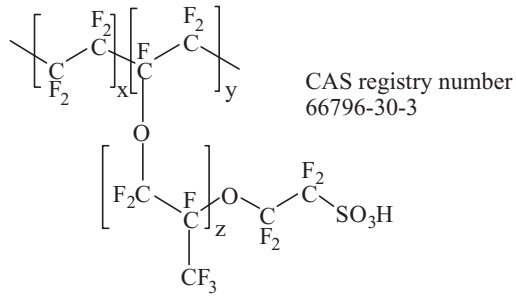
The filaments are of two types – thin, consisting of proteins actin and nebulin, and thick filaments, consisting of proteins myosin and titin (connectin).

Myelin. This is the name for the electrically insulating sheath that protects axons of the nervous system and regulates the conduction of electrical impulses. It is composed of about 80% lipid (mostly galactocerebroside and sphingomyelin) and 20% protein, including myelin basic protein. In the peripheral nervous system (as in the olfactory system), ***Schwann cells*** are responsible for wrapping a myelin sheath around neuron axons.

Myoglobinuria. This describes a condition that is characterized by the presence of myoglobin in urine. It is usually associated with muscle deterioration or ***rhabdomyolosis***, both of which can result from alcohol abuse.

N

Nafion. This is the trade name (Du Pont) for a sulfonated tetrafluoroethylene (Teflon) based fluoropolymer copolymer, containing many perfluorinated ether side chains terminating with sulfonate groups (see below). It is used as a proton exchange membrane, and as a 'superacid' catalyst. It is also used in the production of sensors.



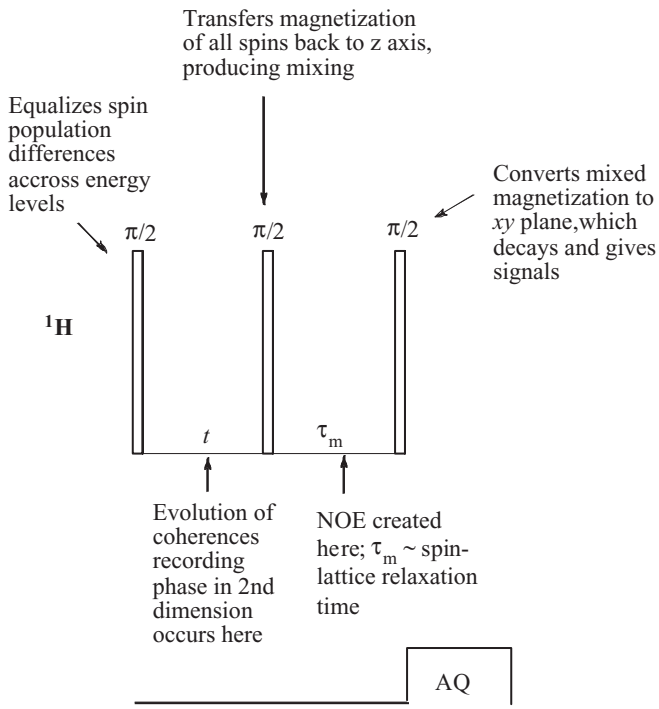
Necrosis. The term used to indicate premature cell (or tissue) death. It is caused by external factors, such as bacterial infection, cytotoxins, trauma or viral infections – in contrast to programmed or naturally occurring cell death (***apoptosis***). The lack of signals from prematurely killed cells to the immune system prevents detection and treatment by immune cells (***macrophages***, ***monocytes***, etc.) and hence leads to build of dead tissue, which must be removed.

NF-κ-B. 'Nuclear factor kappa light chain enhancer of activated B cells' is a protein complex found in most cells and is involved in cellular response to external stimuli, such as bacterial infection, cytokines, free radicals, oxidation of *LDL*, UV-radiation and viral infection. NF-κ-B plays a major role in the regulation of immune response to infection, but incorrect regulation has been linked to a number of pathological conditions, including autoimmune diseases, cancer and inflammation.

Noble rot. Otherwise known as Edelfäule, pourriture noble and muffa, noble rot describes the infection of ripe or over-ripe white grapes by *Botrytis cinerea*. It is a most beneficial condition for the production of most sweet wines, particularly Beerenauslese and Trockenbeerenauslese wines of Germany and Austria, Sauternes and similar wines of Bordeaux, the sweet Chenin wines of the Loire region and Tokaji aszú wines of Hungary. For noble rot to develop properly, alternating moist and dry (but warm) weather conditions are required in the autumn. Infection by *B. cinerea* at this late stage causes the grapes to shrivel, thereby concentrating the contents (but decreasing the yield!) and also producing beneficial components, such as glycerol and polyols (like sorbitol). The fungus dominates, thus minimizing infection by spoilage fungi, such as *Aspergillus* and *Penicillium* species.

NOE. The '**N**uclear **O**verhauser **E**ffect' is named after the physicist Albert Overhauser. In NMR spectroscopy, it describes the transfer of spin polarization from one nuclear spin population to another in the same molecule, via cross polarization, although originally the term was used to indicate the polarization transfer between electron and nuclear spins in metals. It is a through space effect, the magnitude (enhancement or diminution of signal) of which depends on the spatial proximity of interacting nuclei and hence the phenomenon can be used to determine complex structures, such as carbohydrates and large cyclic ***terpenoids***.

NOESY. '**N**uclear **O**verhauser **E**ffect **S**pectroscop**Y**' is just one (but an important) application of the *NOE*. It is used mainly as a 2D method, where the cross peaks in the spectrum connect signals from nuclei that are spatially close. A 1D version involves selecting a particular signal, then radiating it at its frequency, and observing the changes in signal intensity elsewhere in the spectrum. The 2D NOESY pulse sequence is shown below.



Norisoprenoids. This is the name for a large family of compounds that are biochemically derived from carotenoids or other compounds that have been biosynthesized from acetate via the mevalonic acid pathway. They contain 13 carbon atoms and are produced by the enzymic degradation of carotenoids to C13 ketones, which then undergo rearrangement to norisoprenoids. Over 300 of these compounds have been identified in wine, and some, like β-damascenone, make an impact on aroma.

Nucleophiles. Electron rich species, such as an anion (e.g. phosphate), a molecule with lone pair electrons (e.g. H_2O and NH_3) or a multiple bond (such as alkenic or aromatic C=C). They react with ***electrophiles***. Electrophile–nucleophile steps are important in a large number of biological reactions (e.g. phosphorylation, hydration, hydrolysis) and in many reactions involved in the maturation of alcoholic beverages (e.g. ester formation, polyphenol formation, hydrolysis of lignins).

O

Orbital. Wave mechanical representation of electrons in atoms and molecules; actually relating to allowed solutions of the Schrödinger or similar equations, and is most often given as a boundary surface, defining the volume of space in which an electron has a 95% chance of being found.

Organoleptic. Relating to the perception by a sensory organ or involving the use of sensory organs in an assessment of beverage character or quality. Hence the term refers to the sensory properties of a drink, involving color, odor, taste and feel. Organoleptic or sensory analysis involves an examination of a beverage using the above senses and is usually carried out and interpreted according to a set of protocols. Sensory analysis is often used in conjunction with analytical methods (e.g. GC, HPLC) at all stages of alcoholic beverage production.

Orocecal transit. This term refers to the movement of food through the alimentary tract. The transit rate can be estimated by the measurement of expired H_2 after ingestion of lactulose.

P

t-PA. Tissue plasminogen activator is a serine ***proteinase*** that catalyzes the conversion of plasminogen into plasmin, a fibrolytic protein, thus influencing blood clotting. This enzyme has been implicated in helping normal neural function, cell migration and tissue remodeling. It is used to treat stroke.

Pascal. The SI unit of pressure (Pa). Its basic units are N/m^2 or kg/ms^2.

Phagocytes. White blood cells that protect the host by first engulfing and then ingesting foreign entities, such as bacteria and dead or dying cells. There are many types, but the more aggressive kinds, those that attack directly, include dendritic cells, ***macrophages***, mast cells, ***monocytes*** and neutrophils. These have surface receptors that can recognize 'tagged' (ligand coated) particles that need to be ingested. Other phagocytes are more selective in their action; these include endothelial cells, epithelial cells, erythrocytes, fibroblasts and *lymphocytes*.

PDMS. Polydimethylsiloxane, an organosilicon polymer that is inert and nontoxic. It is used as a low to mid polarity sorbent in solid phase microextraction and stir bar sorptive extraction of organic compounds from aqueous or aqueous-alcoholic matrices. Its formula is $CH_3[Si(CH_3)_2O]_nSi(CH_3)_3$, and when n is large, the polymer is a viscous liquid or flexible semi-solid.

PLSR. Partial least square regression is a bilinear factor statistical method related to principle components regression. It finds a linear regression model by projection of predicted and observed (measured) variables to a new space.

Pectinase. Pectolytic enzymes, those that hydrolyze ***pectins***, are generally known as pectinase. They include pectolyase, pectozyme and polygalacturonase and (usually of *A. niger* origin) are useful in winemaking for increasing extraction efficiency, by helping to break down plant cell walls.

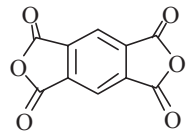
Pectins. Like cellulose and other carbohydrates, pectins form part of the primary cell wall structure in nonwoody parts of plants. They are also present in the middle lamella between plant cells, thereby helping to bond the cells together; most fruits used for winemaking have a significant pectin content. Pectins are not digested in the small intestine, but act as dietary fiber in the colon, where there is some decomposition by gut microflora, releasing beneficial compounds. There are several classes of pectins, including homogalacturonans, which are linear polymers (1–4 linked) of α-D-galacturonic acid and α-L-rhamnose, with branches containing L-arabinose, D-galactose and D-xylose. Pectins vary in the extent of methylation of the carboxylic acid groups and many contain acetylated or amidated carboxyl groups. In general, they are used as gelling agents in the food industry, but a high pectin content in wine is undesirable, hence the use of ***pectinase*** by some winemakers.

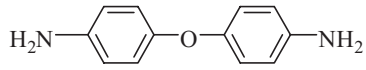
Peristaltic. This refers to pumps that operate by performing successive wave-like contractions and relaxations, usually by use of a rotor. Such pumps are used for pumping aggressive solvents and solutions, for example to the nebulizer in ICPMS.

π–π (pi–pi) attractions. Weak ***van der Waals*** type forces between multiple bonds, both aliphatic and aromatic. They are believed to arise from oscillating induced dipoles in the π-bonds, and although π–π forces between individual multiple bonds pairs are weak, if there is a stack of such bonds (as in DNA and stacked anthocyanins in fruit juice), then their influence is significant. Also, if they act in conjunction with other intermolecular forces, such as ionic forces and/or hydrogen bonding (as in protein–polyphenol interactions), they are likewise significant.

Plummer. This is the name given to a category of medium bodied pot still Jamaican rum that was much exported to the UK and formed an important part in numerous blends. It is still produced from sugar industry products and by-products and can be found, for example, in a 1:1 blend (with Wedderburn) of Smith & Cross, at 57% ABV ('navy strength').

Polyimide. Polymers that are frequently used as inner coatings ('cladding') of fused silica capillary GC columns, upon which the stationary phase is then coated. They are generally very strong, heat resistant and solvent resistant. Typical monomers include mellitic dianhydride and 4-oxydianiline (below).





Preservative. Any substance, that when added to a foodstuff, protects it from microbiological spoilage. The most widely used preservative in the alcoholic beverage production is sulfur dioxide, usually added as potassium or sodium metabisulfite. This particular preservative also offers some protection against chemical oxidation.

Prolamins. Plant storage proteins with high GLN and PRO content, found in cereal grains; avenin (oats), gliadin (wheat), hordein (barley), secalin (rye) and zein (maize). Some, like gliadin, induce celiac disease in genetically predisposed persons.

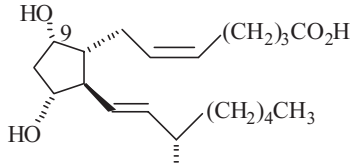
Promyelocytic. Refers to promyelocytes, immature granulocytes, which are a kind of ***leukocyte***. They are derived from stem cells in the bone marrow.

Protein kinases. These are enzymes that catalyze the nucleotide dependent phosphorylation of proteins at the OH function of SER, MET or TYR residues at specific sites. The presence of a large dianionic group on the protein causes a change in conformation, thus changing the reactivity of the target protein. Protein kinases constitute a superfamily of proteins that differ widely in size, subunit structure and localization within the cell. Many depend on cAMP and cGMP for activation and many, such as tyrosine kinases, are involved in cellular signaling pathways and may be influenced by the presence of ethanol (or acetaldehyde) and phenols in the diet. Other kinases, such as hexokinase, phosphorylate (with the aid of ATP) nonprotein OH groups, such as the 6-OH group of glucose, an important step in glycolysis.

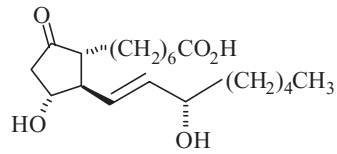
Proteinase. This is the generic name for enzymes that break down (catabolize) proteins by hydrolysis of peptide (amide) bonds. These enzymes are also known generally as proteases or peptidases. Proteinases that hydrolyze peptide bonds at specific site within the molecule are known as endopeptidases, those that hydrolyze terminal links are called exopeptidases. They are important in the digestion of dietary proteins and some proteinases also play a part in blood clotting.

Prostaglandin. A member of a group (along with leukotrienes and thromboxanes) of naturally occurring lipid compounds known as eicosanoids, which are derived from arichidonic acid and other cell membrane unsaturated fatty acids, via enzymic action. They contain 20 carbon atoms, a cyclopentane or cyclopentene ring, or sometimes other ring types (as in thromboxanes). Prostaglandin nomenclature is based on the type of five membered carbocyclic ring, ranging from PA to PI (nine types) and, where appropriate, a subscript

Greek letter is used to denote the carbocyclic ring C9 configuration; α indicating down and β indicating up. A further numerical subscript is used to denote the number of exocyclic alkenic double bonds. See examples, $PGF_{2\alpha}$ and PGE_1 below. Thromboxanes are given the symbol TX. Prostaglandins are short lived local chemical messengers with many functions; they are regulators of cell growth, inflammation mediators and regulators of smooth muscle tissue function and calcium transport.



$PGF_{2\alpha}$



PGE_1

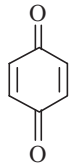
Prussian Blue. A dark blue pigment discovered in the early eighteenth century. It is $Fe^{III}{}_3[Fe^{II}(CN)_6]_3$. Prussian Blue is electrochromic, changing from blue to colorless upon reduction and hence is used in a colorimetric test for phenols. It is also used as an electrode coating in electrochemistry.

Pseudomolecular ion. In mass spectrometry, this term refers to ions that are related to the true molecular ion ($M^{+\bullet}$) by either inclusion of adducts (e.g. MH^+, $MCH_4{}^+$ or MNa^+) or by loss of hydrogen ($\{M - H\}^-$). These are sometimes known as quasimolecular ions.

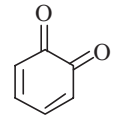
Q

Q (Quadrupole). In mass spectrometry, this term stands for quadrupole detector. It consists of four parallel metal rods (hyperbolic or more likely, circular), with each opposite rod pair electrically connected and a radiofrequency (alternating) voltage applied between both pairs of rods. A direct current is superimposed on the RF voltage. It is a much used detector in GCMS and also in LCMS.

Quinone. This term describes a fully conjugated diketone structure that can be derived from an aromatic structure (e.g. via the oxidation of a polyphenol). See also ***ubiquinones***.



1,4-benzoquinone
(cyclohexadienedione)



1,2-benzoquinone
(*ortho*-benzoquinone)

R

RAPD. Random **A**mplification of **P**olymorphic **D**NA is a form of polymerase chain reaction (PCR), a technique used to amplify one or a number of copies of a section of DNA across many orders of magnitude, thus giving millions of copies of a particular DNA sequence. Heat stable polymerases (such as Taq polymerase) are generally used along with a thermal cycling method, but there are many variants, one of which is RAPD, where the DNA segments to be amplified are random.

Repeatability. Refers to the closeness of agreement (precision) of measurements or test results using a particular method, the same equipment and the same experimenters, often performed sequentially. It is often reported as ***standard deviation*** or ***% relative standard deviation*** (%RSD) (coefficient of variance, CV).

Reproducibility. Refers to the ability of a method to produce results that may be closely reproduced by other experimenters at other times and in other laboratories.

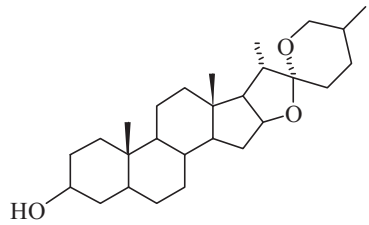
Rhabdomyolysis. This is a term for a medical condition that results when severe injury causes rapid breakdown of skeletal muscle. Breakdown products (including myoglobin) can be released into the bloodstream

and can cause kidney damage. The condition can be caused by the presence of an arterial thrombosis or embolism.

Root mean square error. This is a measure of the differences between values predicted by a model and the actual observed values. It is sometimes known as 'residual' error.

S

Saponins. These are C27 steroids with a spiroketal side chain; that is they contain six rings – the standard four carbocylic rings of steroids, plus two oxygen containing heterocyclic rings. As glycosides, they are present in plant tissues, such as roots, sometimes in substantial concentrations, but their biological functions are largely unknown. They have detergent properties (hence the generic name) and some are very toxic. The aglycosides are known as sapogenins (see below).



Sarsasapogenin

Schwann cell. A type of large cell in the peripheral nervous system, whose plasma membrane wraps spirally around the axon of a myelinated neuron to form a protective ***myelin*** sheath.

Sequelae. A pathological condition resulting from disease, injury or trauma. Typically, sequelae refers to a chronic condition that arises from an acute condition and is essentially a complication of that condition. For example, sequelae of traumatic brain injury include anxiety, dizziness, headache and personality changes.

Sorption. With respect to the analysis of the components of alcoholic beverages and their precursors, this term refers to the distribution of analyte between a liquid solution phase and a sorbent phase, according to the Nernst partition law. The latter phase is essentially a liquid phase (e.g. *PDMS*) coated or bonded to an inert material, such as silica particles, a fused silica microfiber or a stir bar.

Standard deviation and % relative standard deviation. These are two accepted ways of assessing the precision associated with a set of N experimental results.

$$\text{Standard deviation (s or } \sigma) = \sqrt{\frac{\sum_{i=1}^{N}(x_i - \bar{x})^2}{N-1}}$$

x_i is a particular result
$\bar{x}$ is the arithmetical mean of the results
N is the number of results

$$\%\text{Relative standard deviation (\%RSD)} = \frac{100\,\text{s (or } \sigma)}{\bar{x}}$$

$\bar{x}$ and s or σ are defined as above

Percent standard deviation is sometimes known as the coefficient of variance (CV).

Steatosis. This term is used to describe the abnormal retention of lipids in a cell. It is also known as fatty charge, fatty degeneration or adipose degeneration. Steatosis is primarily associated with fatty liver disease, but it can also occur in the heart, kidneys and muscle. Chronic excessive alcohol consumption produces high levels of NADH, discouraging the cell to break down fatty acids and, at the same time, encouraging fatty acid synthesis.

Support vector machines (SVM). This term relates to a number of supervised learning statistical methods used for classification and regression. An SVM training algorithm builds a model from training examples, each belonging to two or more categories, and this model is used to predict the category to which a new example belongs. Various extensions to the basic method have been introduced fairly recently in order to include mislabeled samples or to reduce the effect of outliers on the outcome of the statistical analysis.

Supramolecule. This is a stable, organized molecular system formed by two or more molecules being held together by many intermolecular (noncovalent) interactions, such as dipole–dipole forces, electrostatic forces, hydrogen bonding and ***London forces***.

Synergesis. A term used to describe a situation where one factor helps another, so that the total result is greater than that of either of the two factors acting separately.

T

t_R. In chromatography, this is the abbreviation for retention time; it is the time between injection of the sample and detection of a particular analyte.

Terpenoids. See ***isoprenoids***.

Tetrapoid. This term refers to organisms that have four times the ***haploid*** number of chromosomes in the cell nucleus. Tetrapoidy is particularly common in the plant kingdom (as is polypoidy in general) as in the strain of wheat known as durum wheat, but also occurs in animals, such as salmon and salt water prawns.

Thermodynamic stabilization. Any physical effect or process that leads to an overall lower Gibbs free energy of the system. It can include stereochemical effects; proteins exist in certain preferred conformations because extensive intra- and intermolecular attractions are maximized, hence lowering the system energy.

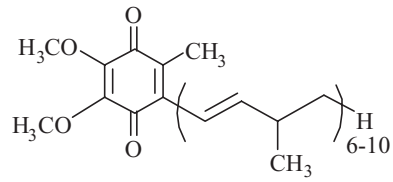
TOCSY. TOtal **C**orrelation **S**pectroscop**Y** is a homonuclear 2D NMR technique that shows the connectivity within an entire spin system, such as an isopropyl or butyl group. The TOCSY experiment as rather like the COSY experiment, except that on the second pulse, the magnetization is locked along the *y* axis, so that all the protons have the spin lock frequency. All coupled spins within a spin system become closely coupled and magnetization is transferred from one nucleus of the spin system to all the others. TOCSY is especially useful in the analysis of large molecules with specific repeating units, such as nucleic acids and proteins.

Transversely heated graphite tube atomizer. This refers to a kind of graphite furnace used in atomic spectroscopy in which the graphite tubes used to atomize the sample are heated transversely rather than longitudinally. This gives a more uniform temperature from end to end, so the method does not suffer from sensitivity losses and contamination caused by lower temperatures at the ends of the tubes. Moreover, the temperatures needed are substantially lower than those needed for their longitudinally heated equivalents, this giving extended tube life and saving energy.

Tumor Necrosis Factor. TNF belongs to a family of proinfammatory cytokines that are produced by ***macrophages*** and circulating ***monocytes***, and is involved in host defence and the pathogenisis of certain diseases. It is also involved in sleep regulation. TNF signaling can lead to three distinct results, each of which is initiated by different signaling pathway complexes; survival mode (gene induction), *apoptosis* mode and ***necrosis*** mode.

U

Ubiquinones. Sometimes called coenzyme Q, ubiquinones (below) are membrane coenzymes (especially in mitochondria) involved in aerobic cellular respiration, and participating in the electron chain mechanism and the generation of energy in the form of ATP. They are also antioxidants and their highest concentrations in the human body are in organs that need most energy, such as the heart. Their biosynthesis involves both the shikimate route (for the ***quinone*** unit) and the mevalonate route for the ***terpenoid*** side chain. Coenzyme Q_{10} is the best known, and is used as a dietary supplement.



Ultrasound. A cyclic sound pressure of frequency 20 kHz to over 200 MHz (i.e. greater than the upper frequency limit of human hearing). It can be used to aid various extraction processes in brewing and winemaking and is used in the measurement of fluid flow or liquid density.

V

V-PDB and V-SMOW. V-PDB stands for Vienna Peedee Belemnite Standard, which defines the carbon isotope composition of beleminite (marine cephalopods of the Cretaceous period) guard fossils found in the Pee Dee region of South Carolina, USA. It is used for calculating $\delta^{13}C$ of samples, usually by IRMS. V-SMOW stands for Vienna Standard Mean Ocean Water. It is a standard defining the isotopic composition of water and was set up by the International Atomic Energy Agency. It refers to pure water (distilled ocean water) with a fixed composition of H and O isotopes and is used as a reference standard for comparison of H and O ratios in samples, often determined using IRMS. $^{1}H/^{2}H = 155.76 \pm 0.1$ ppm; $^{3}H/^{1}H = 1.85 \pm 0.36 \times 10^{-11}$ ppm; $^{16}O/^{18}O = 2{,}005.20 \pm 0.43$ ppm; $^{16}O/^{17}O = 379.9 \pm 1.6$ ppm.

Vallate papillae. Large, flat papillae each surrounded by a trench, contained in a V shaped group close to the base of the upper tongue surface. Also known as circumvallate papillae.

Van der Waals forces. This is the collective name often given to attractive and repulsive intra- and intermolecular forces other than covalent and ion-ion forces. The attractive forces, all of which are relatively weak and of varying ranges, include ion–dipole (induced dipole) (Keesom) forces, dipole–dipole (induced dipole) (Debye) forces and induced dipole induced dipole (***London dispersion***) forces. Quadrupoles and higher can be involved too.

Volumetric methods. Analytical chemistry methods that involve accurate and precise measurement of volume. Titrations are the best known volumetric methods and require high precision volumetric equipment, such as burettes, flasks and pipettes.

Vomeronasal organ. An auxiliary olfactory sense organ located in the nasal cavity of many animals. It is sometimes known as Jacobson's organ. Although its level of development differs from animal to animal, the vomeronasal organ is a chemoreceptor organ whose main role is thought to be the detection of pheromones; chemical signals between individuals of the same species.

W

WALTZ. A modern form of broadband heteronuclear decoupling, used routinely in ^{13}C NMR spectroscopy. The decoupling irradiation is applied as a series of pulses ($\pi/2, -\pi, 3\pi/2$), in which phase cycling eliminates pulse imperfections. The minus sign in the second pulse indicates that this pulse is 180° phase shifted, i.e., magnetization is rotated counterclockwise about the x axis.

Wedderburn. A heavy style of Jamaican rum, produced using pot stills from a combination of sugar production products and by-products (cane juice, molasses, skimmings and 'syrup bottoms'), as well as dunder (the residue from previous distillations). Fermentation is traditionally carried out using wild yeasts and the rum is characterized by fruity, spicy notes. Wedderburn rum was one of the main types to be exported to the UK, where it was usually blended with other rum types.

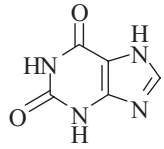
WET. This is an NMR spectroscopic shaped pulse sequence that is used to suppress solvent signals. There are several versions, but the composite pulse sequence $\pi/2(x)$, $\pi/2(y)$, $\pi/2(-x)$, $\pi/2(-y)$ and the '270' WET sequence (as the composite sequence, but with a 3/2 π pulse in the fourth scan) are common.

Wistar rat. A strain of albino rat that has been developed and bred specifically for scientific research. The strain was developed originally at the Wistar Institute (Philadelphia, USA) and is still much in use, although other strains have been developed from it.

X

XAD. The generic trade name for a group of cross linked polymer resins that are used in the purification of substances and in sample preparation for analysis (e.g. chromatographic analysis). They are highly porous macroreticular polymers based on styrene–divinylbenzene, acrylates or formaldehyde–phenol, with varying degrees of cross linking, hydrophobicity and selectivity. Macroreticular means that the pore size is stable and is not dependent upon swelling by an appropriate solvent.

Xanthine. A purine base found in tissues (see below). It is formed in the degradation of adenine and guanine to uric acid. Xanthine is also the generic name for compounds that possess the skeletal structure below, including methylated xanthines, such as caffeine, theobromine and theophylline.



Y

YAN. Short for yeast assimilable nitrogen or 'fermentable' nitrogen. It is the total nitrogen as ammonia and free α-amino acids (***FAN***) in must or wort and is essential for the yeast in order to conduct a healthy fermentation.

Z

Zeeman correction. A background correction technique used in atomic spectroscopy to eliminate the broad background molecular absorption that can interfere with the measurement of the absorbance of the atomic element under investigation. The total absorbance is measured in the absence of a magnetic field and then remeasured in the presence of a magnetic field (e.g. applied to the atomizer) at the same wavelength. The Zeeman effect in the presence of the magnetic field splits the atomic line into two lines of different wavelengths. Thus this measurement gives the background absorbance and the difference between the two is the corrected atomic absorbance.

Zygosterol (zymosterol). This sterol is a precursor of ergosterol and, like ergosterol, is found in the cytoplasmic membrane of fungi, such as yeasts. See below.

A comprehensive two-volume set that describes the science and technology involved in the production and analysis of alcoholic beverages

HANDBOOK OF ALCOHOLIC BEVERAGES

Technical, Analytical and Nutritional Aspects

Editor **Alan J. Buglass** *Department of Chemistry, KAIST, Republic of Korea*

At the heart of all alcoholic beverages is the process of fermentation, particularly alcoholic fermentation, whereby sugars are converted to ethanol and many other minor products. The *Handbook of Alcoholic Beverages* tracks the major fermentation process, and the major chemical, physical and technical processes that accompany the production of the world's most familiar alcoholic drinks. Indigenous beverages and small-scale production are also covered to a significant extent.

The overall approach is multidisciplinary, reflecting the true nature of the subject. Thus, aspects of biochemistry, biology (including microbiology), chemistry, health science, nutrition, physics and technology are all necessarily involved, but the emphasis is on chemistry in many areas of the book. Emphasis is also on more recent developments and innovations, but there is sufficient background for less experienced readers. The approach is unified, in that although different beverages are dealt with in different chapters, there is extensive cross-referencing and comparison between the subjects of each chapter.

Appropriate for food professionals working in the development and manufacture of alcohol-based drinks, as well as academic and industrial researchers involved in the development of testing methods for the analysis and regulation of alcohol in the drinks industry.

Divided into five parts, this comprehensive two-volume work presents:

- **INTRODUCTION, BACKGROUND AND HISTORY:** a simple introduction to the history and development of alcohol and some recent trends and developments.
- **FERMENTED BEVERAGES: BEERS, CIDERS, WINES AND RELATED DRINKS:** the latest innovations and aspects of the different fermentation processes used in beer, wine, cider, liqueur wines, fruit wines, low-alcohol and related beverages.
- **SPIRITS:** covers distillation methods and stills used in the production of whisky, cereal- and cane-based spirits, brandy, fruit spirits and liqueurs.
- **ANALYTICAL METHODS:** covering the monitoring of processes in the production of alcoholic beverages, as well as sample preparation, chromatographic, spectroscopic, electrochemical, physical, sensory and organoleptic methods of analysis.
- **NUTRITION AND HEALTH ASPECTS RELATING TO ALCOHOLIC BEVERAGES:** includes a discussion on nutritional aspects, both macro- and micro-nutrients, of alcoholic beverages, their ingestion, absorption and catabolism, the health consequences of alcohol, and details of the additives and residues within the various beverages and their raw materials.
