VOLUME 1

1 INTRODUCTION, BACKGROUND AND HISTORY **1**
John A. Hudson and Alan J. Buglass

1.1 Alcoholic Beverages of the World: An Introduction to the Contents of This Book **3**

1.2 History and Development of Alcoholic Beverages **12**
1.2.1 The Beginnings (From the earliest Times to *ca*. 1100 AD) 12
1.2.2 Medieval Times and Beyond (*ca*. 1100–1750) 18
1.2.3 The Industrial Revolution and the Influences of Science and Technology (*ca*. 1750–1900) 24
1.2.4 Modern Times and Newer Processes (*ca*. 1900–Present Day) 28
1.2.5 The Development of Analytical Methods 35
References 40

1.3 Some Recent Trends and Developments **42**
1.3.1 Overview 42
1.3.2 Big is Beautiful: Multinational Companies and the Globalization of Alcoholic Beverages 42
1.3.3 Small is Beautiful: The Growth in Microbreweries and Craft Breweries and the Localization of Products 44
1.3.4 Revival of Traditional Beer Styles 45
1.3.5 Changes in Beer Drinking Habits 47
1.3.6 Global Growth in Wine Drinking 48
1.3.7 Development of New Wine Industries 50
1.3.8 Revival of Cider and Perry: the Magic of Ice 52
1.3.9 The Rise of Flavored Alcoholic Beverages ('Alcopops') 52
1.3.10 Calorie-Counting and Health Perception of Alcoholic Drinks 53
1.3.11 Binge Drinking 54
1.3.12 Organic and Biodynamic Production of Alcoholic Beverages 56
1.3.13 Use of Genetically Modified (GM) Crops and Microorganisms 57
References 59

2 FERMENTED BEVERAGES: BEERS, CIDERS, WINES AND RELATED DRINKS 63
Marianne McKay, Alan J. Buglass and Chang Gook Lee

2.1 Introduction: Overview of Fermentation and Microorganisms 65
2.1.1 Yeasts 67
2.1.2 Lactic Acid Bacteria 69
2.1.3 Molds and Spoilage Organisms 69
References 70

2.2 Alcoholic Fermentation 72
2.2.1 Introduction 72
2.2.2 Physiology and Morphology of Yeast 72
2.2.3 Nutritional Requirements of Yeast 73
2.2.4 The Use of Naturally Occurring ('Wild') Yeasts in Fermentations 75
2.2.5 The Killer Factor 76
2.2.6 The Use of Selected (Cultured) Yeast Strains 76
2.2.7 Fermentation Vessels 77
2.2.8 The Growth of a Yeast Population 77
2.2.9 An Overview of Alcoholic Fermentation 80
2.2.10 Flocculation 87
2.2.11 Aroma Compounds and Fermentation 88
References 93

2.3 Malolactic Fermentation 96
2.3.1 Introduction 96
2.3.2 Malolactic Bacteria: Morphology and Physiology 97
2.3.3 Identification of Malolactic Bacteria 98
2.3.4 Factors Affecting the Growth of Malolactic Bacteria 98
2.3.5 Interactions Between Bacteria and Other Organisms 100
2.3.6 Spontaneous Malolactic Fermentation 101
2.3.7 Inoculation with MLB Starter Culture 101
2.3.8 The Growth of Bacterial Populations 102
2.3.9 The Malolactic Fermentation Process 103
2.3.10 Production of Diacetyl 104
2.3.11 Microbial Stability 104
2.3.12 Monitoring Malolactic Fermentation 105
2.3.13 Finishing and/or Preventing Malolactic Fermentation 105
2.3.14 Production of Biogenic Amines by Malolactic Bacteria 106
2.3.15 Other Effects of MLF 106
2.3.16 Malolactic Fermentation and Aroma 107
2.3.17 Lactic Spoilage 111
References 112

2.4 Acetic and Other Fermentations 114
2.4.1 Introduction 114
2.4.2 Acetic Acid Bacteria 115
2.4.3 Lactic Acid Bacteria 117

2.4.4 The Activities of Yeasts other than Saccharomyces 117
2.4.5 Film Forming Yeasts 119
2.4.6 Molds 120
2.4.7 Prevention of Spoilage 120
References 121

2.5 Preservatives Used in the Production of Alcoholic Beverages 123
2.5.1 Introduction 123
2.5.2 Sulfur Dioxide (SO_2) 123
2.5.3 The Roles of SO_2 125
2.5.4 Sorbic Acid 128
2.5.5 DMDC (Velcorin) 129
2.5.6 Ascorbic Acid (Vitamin C) 129
2.5.7 Pimaricin (Natamycin) 130
2.5.8 Other Preservatives 130
References 131

2.6 Beer 132
2.6.1 The Basic Brewing Processes 132
2.6.2 Malting and Mashing 134
2.6.3 Boiling the Wort 148
2.6.4 Fermentation 157
2.6.5 Top Fermentation 163
2.6.6 Bottom Fermentation 167
2.6.7 Other Fermentations 169
2.6.8 Modern Methods of Fermentation 171
2.6.9 Beer Treatment: Fining, Filtration and Pasteurization 173
2.6.10 Packaging of Beer: Casking, Kegging, Bottling and Canning 182
2.6.11 Dispensing of Draught Beers 186
2.6.12 Oxidation and the Staling of Beer 192
2.6.13 Beer styles 196
References 207

2.7 Cereal-based and Other Fermented Drinks of Asia, Africa and Central/South America 211
2.7.1 The Rice 'Wines' of Asia 212
2.7.2 Native Fermented Drinks of Africa and South America 222
References 229

2.8 Cider and Perry 231
2.8.1 Introduction 231
2.8.2 The Basic Ingredients 233
2.8.3 Harvesting, Crushing and Pressing 238
2.8.4 Fermentation and Maturation 241
2.8.5 Traditional and Small-Scale Cider and Perry Production: Fermentation and Beyond 245
2.8.6 Large-Scale (Factory) Production of Cider and Perry: Fermentation and Beyond 251
2.8.7 Newer Techniques, Recent Developments and Innovations 254
2.8.8 Cider and Perry from Around the World 257
References 263

2.9 Wine **266**
2.9.1 White Winemaking 267
2.9.2 Red Wine Production 300
2.9.3 Sparkling Wines 324
2.9.4 Fining, Filtration and Clarification 343
2.9.5 Wine Maturation and Ageing 354
2.9.6 Some Current Trends in Wine Production 371
References 377

2.10 Fortified Wines and Liqueur Wines **383**
2.10.1 Overview and Scope 383
2.10.2 Sherry and Other Flor Wines 384
2.10.3 Flor and Oxidation in Sherry Wines 391
2.10.4 Other Flor Wines 394
2.10.5 Madeira 395
2.10.6 Estufagem and Cask Maturation of Madeira Wine 397
2.10.7 Port 399
2.10.8 Marsala and Málaga 408
2.10.9 Vins Doux Naturels, Liqueur Muscat and Similar Wines 409
2.10.10 Vins de Liqueurs and Similar Beverages 414
References 416

2.11 Fruit Wines and Other Nongrape Wines **419**
2.11.1 Overview and Scope 419
2.11.2 Comparison of Fruit for Winemaking 420
2.11.3 Making Fruit Wines 423
2.11.4 Country Wine Styles 429
2.11.5 Mead 432
References 434

2.12 Aromatized Wines **436**
2.12.1 Introduction and Brief History of Aromatization of Wine 436
2.12.2 Vermouth 437
2.12.3 Other Aromatized Wines and Apéritifs 444
References 445

2.13 Low Alcohol and Non-Alcoholic Beers, Ciders and Wines **447**
2.13.1 Overview 447
2.13.2 Production of Low Alcohol Beverages by Limited or Checked Alcohol Methods 448
2.13.3 Dealcoholization Methods 450
References 453

3 DISTILLED SPIRITS **455**
Alan J. Buglass, Marianne McKay and Chang Gook Lee

3.1 Introduction: Distillation Methods and Stills **457**
3.1.1 A Brief History and Theory of Distillation 457
3.1.2 Batch Distillation 461
3.1.3 Continuous Column Distillation 466
References 468

3.2 Scotch Whisky **469**
3.2.1 Introduction and Brief History 469
3.2.2 The Raw Materials 475
3.2.3 Malting, Mashing, Cooking and Fermentation 479
3.2.4 Distillation 487
3.2.5 Maturation, Blending and Other Postdistillation Processes 491
3.2.6 The Flavor and Styles of Scotch Malt Whiskies 498
References 512

3.3 Whiskeys **515**
3.3.1 Scope 515
3.3.2 Irish Whiskey 516
3.3.3 The Whiskeys of America 519
3.3.4 Bourbon and Tennessee Whiskey 520
3.3.5 American Rye and Corn Whiskies 527
3.3.6 Whiskies from Other Countries 528
References 533

3.4 Other Cereal Based Spirits **535**
3.4.1 Introduction and Scope 535
3.4.2 Gin and Similar Juniper Flavored Spirits 535
3.4.3 Akvavit (Aquavit) and Vodka 541
3.4.4 Asian Grain Spirits 543
References 553

3.5 Cane Spirits, Vegetable Based Spirits and Aniseed Flavored Spirits **555**
3.5.1 Overview and Scope 555
3.5.2 History and Basic Description of Rum and Cachaça 556
3.5.3 Fermentation and Distillation Practices in the Production of Cachaça and Rum 560
3.5.4 Flavor Characteristics of Rum and Cachaça 564
3.5.5 Arrack, Mezcal and Tequila 566
3.5.6 Aniseed Flavored Spirits 570
References 572

3.6 Brandy **574**
3.6.1 Introduction and Brief History 574
3.6.2 Cognac 585
3.6.3 Armagnac 588
3.6.4 Other Brandies 589
3.6.5 Quality Control in Brandy Production 591
3.6.6 Evaluating Brandy 591
References 593

3.7 Grape and Other Pomace Spirits **595**
3.7.1 Introduction 595
3.7.2 Production of Pomace Spirits 596
3.7.3 Types of Pomace Spirits and Sensory Characteristics 598
References 600

3.8 Fruit Spirits **602**
3.8.1 Introduction 602
3.8.2 Apple and Pear Spirits 603
3.8.3 Fruit Spirits of Central Europe 608
3.8.4 Plum Spirits of Eastern Europe 611
3.8.5 Other Fruit Spirits 612
References 613

3.9 Liqueurs and Their Flavorings **615**
3.9.1 Introduction and Scope 615
3.9.2 Fruit and Fruit Flavored Liqueurs 617
3.9.3 Flower, Herb, Spice and Bitter Liqueurs 620
3.9.4 Cocoa, Coffee and Tea Liqueurs 624
3.9.5 Nut and Emulsion Liqueurs 624
3.9.6 Production and Use of Essences and Concentrates 625
References 626

VOLUME 2

4 ANALYTICAL METHODS **629**
Alan J. Buglass and Darren J. Caven-Quantrill

4.1 Introduction **631**
4.1.1 Why Analyze Alcoholic Beverages? An Overview of the Need for Analysis 632
4.1.2 Process Monitoring 633
4.1.3 Identification of Origin, Determination of Authenticity and Detection of Fraud 636
4.1.4 Determination and Characterization of Beverage Components and Processes 639
4.1.5 Development of New Analytical Methods 642
References 645

4.2 Extraction and Focusing Methods in Sample Preparation **647**
4.2.1 Overview 647
4.2.2 Liquid Extraction Techniques 648
4.2.3 Distillation Methods 659
4.2.4 Solid Phase Extraction and Related Methods (Sorption Techniques) 664
4.2.5 Headspace Methods 684
4.2.6 Combinations of Methods (With Particular Application to Enological Products) 688
4.2.7 Summary 690
References 690

4.3 Chromatographic Methods **705**
4.3.1 Thin Layer Chromatography and Related Methods 706
4.3.2 Capillary Gas Chromatography 709
4.3.3 Liquid Chromatography 722
4.3.4 Counter Current Chromatographic Methods 752
References 755

4.4 Spectroscopic Methods **765**
4.4.1 Nuclear Magnetic Resonance 767
4.4.2 Infrared Spectroscopy 784
4.4.3 Colorimetry, UV-Visible Spectroscopy and Fluorometry 793
4.4.4 Atomic Absorption and Emission Spectroscopy 814
4.4.5 Mass Spectrometry 825
References 843

4.5 Electrochemical Methods **855**
4.5.1 Potentiometric Methods 856
4.5.2 Voltammetric Methods 863
4.5.3 Electrochemical Sensors 869
References 873

4.6 Other Methods **877**
4.6.1 Electrophoretic Techniques 877
4.6.2 Flow Injection Techniques 889
4.6.3 Chemical and Physical Methods 896
References 907

4.7 Sensory Analysis **913**
4.7.1 Introduction 913
4.7.2 Olfaction and Taste 914
4.7.3 Odor Theshold, Odor Activity and Low Impact Odorants 922
4.7.4 Sensory Tests 925
References 930

5 NUTRITIONAL AND HEALTH ASPECTS **933**
Nigel J. Fuller, Suk Hean Lee and Alan J. Buglass

5.1 General Introduction **935**
5.1.1 'Alcohol' in Perspective 936
5.1.2 The Extent and General Implications of Alcoholic Beverage Consumption 938
5.1.3 Ingredients, Processing and the Nutrient Content of Alcoholic Beverages 941
5.1.4 Nutritional Considerations 943
5.1.5 Summary 946
References 946

5.2 Factors Influencing the Nutrient Content of Alcoholic Beverages **949**
5.2.1 Wines 951
5.2.2 Beers 952
5.2.3 Cider and Perry 955
5.2.4 Distilled Beverages 955
5.2.5 Fortified wines 957
5.2.6 Alcopops 958
5.2.7 Cocktails 958
References 959

5.3 Macronutrient Content of Alcoholic Beverages **961**
5.3.1 Water 963
5.3.2 Alcohol 966
5.3.3 Carbohydrates (Including Fiber) 967
5.3.4 Nitrogenous Compounds: Proteins, Peptides, Amino Acids, Amines and Nucleotides 970
5.3.5 Lipids 972
References 973

5.4 Micronutrient Content of Alcoholic Beverages **975**
5.4.1 Vitamins 977
5.4.2 Electrolytes and Functional Elements (Minerals and Trace Elements) 981
5.4.3 Phytochemicals 986
References 990

5.5 Alcohol Ingestion, Absorption and Catabolism: Metabolic and Nutritional Consequences **993**
5.5.1 Alcohol Catabolism 994
5.5.2 Methanol Catabolism 997
5.5.3 Effects of Alcohol on Intake of Foods and Energy 997
5.5.4 Consequences for Intermediary Metabolism of Alcohol Catabolism 998
5.5.5 Effects of Alcohol and its Metabolites on Absorption, Metabolism and Utilization of Key Nutrients 1000
References 1001

5.6 Health Consequences of Alcohol Intake **1003**
5.6.1 Overview: Alcoholic Beverages and Society 1003
5.6.2 Harmful Effects of Excessive Alcohol Intake 1008
5.6.3 Possible Benefits of Low to Moderate Consumption of Alcoholic Beverages 1020
5.6.4 Conclusion 1022
References 1022

5.7 Carbohydrates in Alcoholic Beverages and Health **1030**
5.7.1 Metabolizable Carbohydrate 1030
5.7.2 Low Carbohydrate Beers 1033
5.7.3 High Carbohydrate Beers 1034
5.7.4 Nonmetabolizable Carbohydrate 1035
References 1037

5.8 Antioxidant Value of Alcoholic Beverages **1038**
5.8.1 Overview 1038
5.8.2 Summary of Aerobic Cell Metabolic Processes 1039
5.8.3 Short Review of Oxygen in Cell Metabolic Processes 1039
5.8.4 Incomplete Reduction of Oxygen, the Formation of Reactive Oxygen Species and Cell Damage 1041
5.8.5 Natural Antioxidants in Food 1043
5.8.6 Phenolic Substances in Alcoholic Beverages 1044

5.8.7 Some Chemical Characteristics of Phenolic Compounds 1045
5.8.8 Health Benefits and Antioxidant Potency of Alcoholic Beverages, their Phenolic Extracts and their Individual Phenolic Components 1050
5.8.9 Mechanisms of *In Vivo* Health Benefits of Dietary Phenols: Antioxidants or Otherwise? 1054
References 1061

5.9 Additives in Alcoholic Beverages 1065
5.9.1 Introduction 1065
5.9.2 Sulfur Dioxide and Other Preservatives 1065
5.9.3 Fining Agents and Adjuncts 1068
5.9.4 Other Additives 1069
5.9.5 Regulations and Legislation Relating to Additives 1071
References 1073

5.10 Residues in Alcoholic Beverages 1076
5.10.1 Introduction 1076
5.10.2 Pesticides 1076
5.10.3 Metal and Nonmetal Residues 1082
5.10.4 Industrial Contaminants 1086
References 1091

5.11 Other Trace Substances in Alcoholic Beverages 1093
5.11.1 Introduction 1093
5.11.2 Phytochemicals 1093
5.11.3 Nitrogenous Allergenic Substances 1098
5.11.4 Mycotoxins 1101
5.11.5 Other Trace Substances 1104

General Acknowledgments and Thanks

The following is a thank you note to individuals who have provided help and inspiration in one form or another and have made the writing of this book all the more enjoyable.

David Ando (publishing consultant), Dartford, UK

Roger Bennett (head brewer), Holden's Brewery, Woodsetton, UK

Winrich von Bierbrauer of Bühler GmbH, Braunschweig, Germany

Cindy Burchfield of Alaskan Brewing Co., Juneau, Alaska, USA

Philip Darby and Niven Balfour of the Nottingham Brewery Co Ltd, UK

Jenny Cossham, Richard Davies, Amie Marshall, Zoe Mills and Jonathan Peacock at John Wiley and Sons Ltd, Chichester, UK

Andrew Davis and Laura Harter of Sierra Nevada Brewing Co., Chico, USA

Bob Douglas, Ken Morrison and Nick Sewter of Magpie Brewery, Nottingham, UK

Alison Duke of Vancouver Island Brewery, Canada

Jerôme Dupont of SARL Domaine Familial Louis Dupont, Victot-Pontfol, France

George Evripiotis of Keo Ltd, Limassol, Cyprus

Julie Faber and Alex Hill of Vigo Ltd, Dunkeswell, UK

Jim Ferguson and Pete Lynn of Whin Hill Cider Co., Wells-next-the Sea, UK

Paul Gerber of the Department of Viticulture and Oenology, University of Stellenbosch, South Africa

Professor Pieter Goussard of the Department of Viticulture and Oenology, University of Stellenbosch, South Africa

Philip Haslehurst of Rum Story, Whitehaven, UK

Dr Ian S Hornsey (consultant and author of several books)

George Howell (head brewer) and Susan Fraser of Belhaven Brewery Co Ltd, Dunbar, Scotland

Jim Inkster and Jerome Schooler of Lurgashall Winery, Lurgashall, UK

Kim Jae Wook of Hite Co., Seoul, South Korea

Geneviéve Lalonde, Brasserie McAuslan, Montréal, Canada

Dirk Lindeman of Lindemans Brewery, Vlezenbeek, Belgium

Christine Logan of Lady of the Isles, Islay, Scotland

Jess Longhurst of Black Sheep Brewery Ltd, Masham, UK

Corrie W. Martin of Farnum Hill Ciders and Poverty Lane Orchards, New Hampshire, USA

Iain Masson, former head brewer of (now defunct) Hardys and Hansons Brewery, Kimberley, UK

Derek Pritchard of Dunkerley Vineyard, UK

Kelly Roberts of Coopers Brewery, Adelaide, Australia

Andi Rose of New Belgium Brewing Co., Fort Collins, USA

Jonathan Scott of Ian Macleod Distillers Ltd (Glengoyne Distillery), Scotland

Sandra Schmid of G. Schneider & Sohn GmbH, Germany

Jamie C. Smith of Firestone Walker Brewing, Paso Robles, USA

Julian Temperley of Royal Somerset Distillery, Kingsbury Episcopi, UK

Karen Varty and Peter Laws (former head brewer) of Jennings plc, Cockermouth, UK

Donna Warner of Heritage Brewing and Scotch Irish Brewing, Canada

Anthony Wills of Kilchoman Distillery, Islay, Scotland

1.1

Alcoholic Beverages of the World: An Introduction to the Contents of This Book

In many parts of the world, alcoholic beverages are an important part of day-to-day life. Their moderate consumption in a social environment is seen as a boon for both body and soul. Many are the proposals of marriage, forging of business partnerships and fruitful scientific discussions that have taken place through the centuries over a drink or two in a bar, or over dinner at home. It is not by chance that Francis Crick and James Watson celebrated their discovery of the double helix structure for DNA over pints of ale in the bar of The Eagle, an old coaching inn close to the centre of Cambridge. Indeed, public drinking places are more often than not meeting places: focal points for merriment, discussion, liaison and the sharing of dreams. From the cosy English country pub, the sunny German Biergarten and the elegant Parisian café to the tavernas of Italy and Greece, the small taverns high in the Andes, the bars of South Africa and the jumak of Korea, the multitudes of alcoholic drinks consumed in all these places are potent social lubricants.

There is truly a fantastic range of alcoholic beverages to enjoy – something to suit almost everyone for almost every occasion. At the heart of all alcoholic beverages is fermentation (Part 2), particularly alcoholic fermentation, whereby sugars are converted to ethanol and many other minor products (Chapters 2.1 and 2.2). Many different fungi are able to promote at least some conversion of sugar to ethanol, but in doing so they are often able to stamp their personalities on the beverage by producing characteristic flavor profiles (Chapter 2.2), thus contributing to the rich diversity of alcoholic drinks. Likewise malolactic bacteria, by performing malolactic fermentations under the right conditions, are able to positively influence the character of alcoholic beverages (Chapter 2.3). Fermentations caused by certain other bacteria or fungi can have undesirable influences on aroma and flavor (Chapter 2.4), but these are usually suppressed in favor of the action of desirable microorganisms by the use of antiseptics and preservatives such as sulfites (Chapter 2.5).

Beers are enjoyed all over the world: they are brewed according to many different recipes and procedures, giving many hundreds of different brands or styles, from pale Pilsners and wheat beers to brown ales, porters and stouts (Chapter 2.6). Beverages brewed from cereals other than barley or wheat, such as maize, millet and rice (and without the use of hops) are enjoyed by millions of people in Africa, Asia, and Central and South America (Chapter 2.7). Some general information on beer and cereal beverages, and where they are brewed can be found in Figures 1.1.1 and 1.1.2.

Cider and perry are produced in many countries in a wide range of styles and flavors by a variety of methods (Section 2.8). Although from a biochemical and sensory viewpoint, cider and perry are closer to wine than

2003 or 2004 Approximate beer production figures for selected European countries and the Russian Federation (in hl × 10^3): Germany (106 300), Russian Federation (70 000), U.K. (58 000), Spain (28 000), Poland (26 000), Netherlands (25 000), Czech Republic (19 000), France (18 000), Belgium (17 400), Austria (9000), Denmark (8 300), Ireland (8 000), Slovakia (4700).

Hops are grown all over Europe, the best known areas being Bavaria (Germany), Bohemia (Czech Republic), Hereford (UK), Kent (UK) and Saxony (Germany).

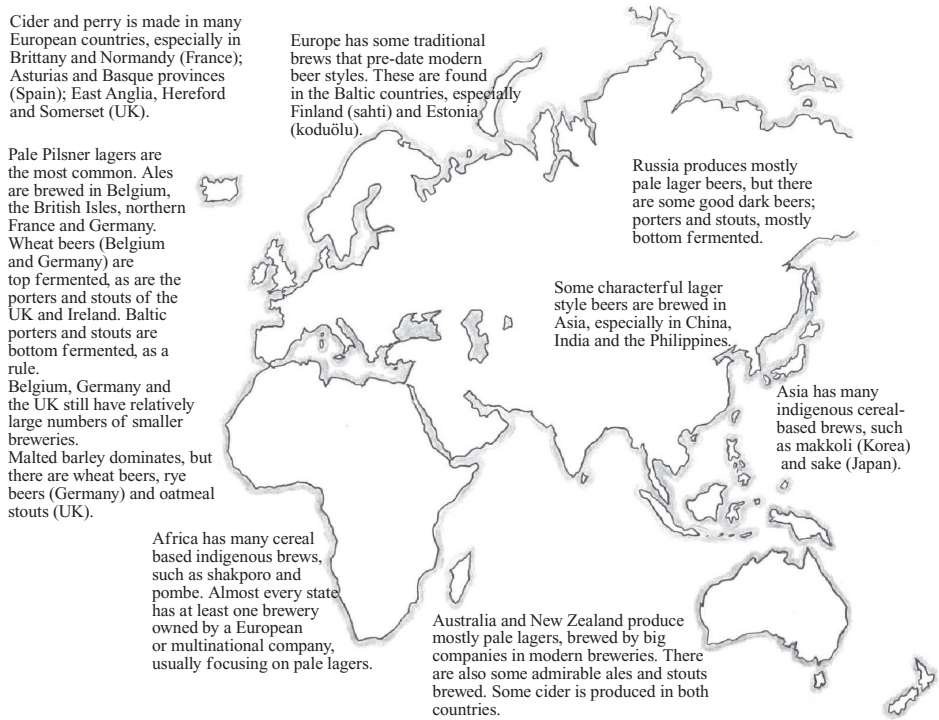

Figure 1.1.1 *Beer and Cider in Europe, Africa, Asia and Australasia. Thanks are due to Belhaven Brewery Ltd, Coopers Brewery Ltd, Domaine Familial L. Dupont, Hite Co., Jennings plc, Keo Ltd, Brasserie Lindemans, Nottingham Brewery Ltd, G. Schneider & Sohn GmbH and Whin Hill Cider for permission to use label and bottle images*

Like USA, Canada's beer market is dominated by pale lagers brewed by a handful of large companies. However, again like USA, there has been an upsurge in the brewing of ales and special lagers by a rapidly growing number of microbreweries and brewpubs since the 1990s. Cider and perry are made in nearly all the states, especially Quebec and British Columbia.

Hops are grown extensively in Oregon, Washington State and British Columbia. They are also grown in some eastern states, such as Vermont.

The Carribean islands produce some characterful lagers and stouts.

USA can be considered to be the world's prime brewing nation. Not only is the country the biggest producer of beer and the home of one of the largest brewing companies (Anheuser Busch), but also has the widest range of beer styles (although these are not necessarily universally available). Many of these styles are derived from European styles and are brewed mostly by smaller regional and (especially) by the hundreds of microbreweries and brewpubs that have sprung up since the 1980s. Although pale Pilsner style lagers dominate the everyday market, the beer drinker will find a huge range of ales of all strengths, colors and flavors, as well as wheat beers and high quality lagers. Many of these beers, however, are not widely distributed. Light beers are popular in USA and Canada. Cider and perry are produced in many states, by both large and small companies. Good cider is made from indigenous apples, but also nowadays from European cider apples.

Central and South America produce mainly pale lagers from a relatively small number of large breweries. Mexico is one of the biggest exporters of beer: much of it going to the USA. There are many indigenous brews, such as chica, usually made from maize and other grains. Two of the biggest drinks companies (which includes brewing companies) are partly Brazilian-owned. Cider is produced in some South American countries.

Figure 1.1.2 *Beer and cider in the Americas. beer, socially they are closer to beer, and so for the latter reason general information on these two drinks can be found in Figures 1.1.1 and 1.1.2, alongside beers.

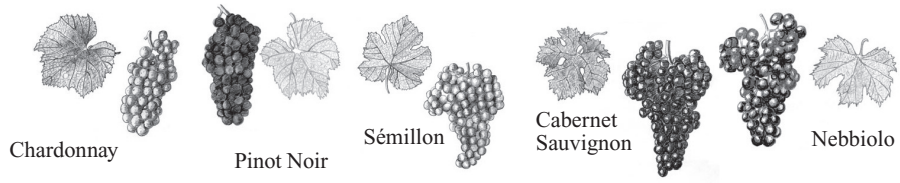
Wines are similarly enjoyed throughout the world, produced in a wide range of styles from many vine varieties by numerous methods. They range from light sparkling wines and still, dry white wines through rosé, red and sweet, white table wines (Chapter 2.9) to fortified wines (Chapter 2.10) and fortified/flavored wines (Chapter 2.12). These are all made from grapes and some general facts concerning their production and styles are given in Figures 1.1.3 and 1.1.4. Wines from fruit other than grapes or even from vegetables, flowers, honey or sap (Chapter 2.11) are made in many parts of the world: general information on these drinks can be also be found in Figures 1.1.3 and 1.1.4.

Apart from the multitude of biochemical reactions that occur during fermentation, important biochemical, chemical and physical processes occur at other stages during the manufacture of alcoholic drinks. Included here is the boiling process in the brewing of beer (Section 2.6.3); different wine maturation processes, such as those for fino Sherry (Section 2.10.3) and Madeira (Section 2.10.6); clarification processes (centrifugation, filtration and fining) and pasteurization (see for example Sections 2.6.9, 2.8.5, 2.8.6, 2.9.4, 3.2.5); and blending and packaging (see Sections 2.6.10, 2.10.2 and 3.2.5).

Certain alcoholic beverages are brewed specifically for distillation, which converts them into distilled beverages or spirits (Part 3). These are produced using a variety of distillation techniques and a range of types of stills (Chapter 3.1). Thus malted cereal beverages are used to produce Scotch whisky (Chapter 3.2) and other whiskeys (Chapter 3.3), as well as a number of other distilled drinks (Chapter 3.4) such as akvavit, gin and vodka. Canes, roots, tubers and saps can also be used to make distilled beverages, such as arrack, rum, schnapps and tequila (Chapters 3.5 and 3.8). Brandy is distilled wine and is produced in nearly all wine-producing countries (Chapters 3.6 and 3.7). Likewise, fruit wines such as plum wine or cherry wine can be converted to fruit brandies such as slivovitz and kirsch (Chapter 3.8) and spirits like brandy, gin or Scotch whisky can be infused with fruit, herbs or spices and (often after redistillation), sweetened with sugar or honey to make liqueurs (Chapter 3.9). Figures 1.1.5 and 1.1.6 give some general information on the wide variety of distilled beverages and where they are made.

Science and technology now play major roles at all stages in the production of most alcoholic drinks – from genesis in the barley field, hop garden, orchard or vineyard, through manufacture by fermentation, distillation and other processes to maturation, clarification, blending and packaging. Quality assurance and control have elevated the overall quality of many beverages to consistently high levels (Section 1.2.5). The analytical methods that are used for the maintenance of quality are described in Part 4. Many of these techniques also increase our knowledge and understanding of the various materials and processes involved in alcoholic drinks production, as well as helping the brewer or winemaker to maximize the quality of his or her product. The biological and chemical natures of the raw materials (Sections 2.6.2, 2.6.3, 2.8.2, 2.11.2, 2.12.2, 3.2.2, for example) are of prime importance in the making of alcoholic beverages, as is the chemical composition of the finished product, particularly with regard to sensory analysis (Chapter 4.7). The quality and authenticity of a beverage can often be judged by the absence or presence (and relative quantity) of certain constituents, as determined by one or more of the numerous methods described in Part 4: by chromatographic (Chapter 4.3), spectroscopic (Chapter 4.4) or electrochemical methods (Chapter 4.5), for example.

The levels of many alcoholic beverage components are now subject to legislative restriction, which means samples must be checked by government or approved laboratories from time to time to ensure such components are present below their maximum allowed levels or maximum residue levels (MRLs). Many producers also perform analyses throughout the production process, as part of their quality assurance programs. These components include some that are added deliberately as part of the production process (additives; see Chapter 5.9 and plant flavorings; see Chapters 2.12 and Sections 3.9.3 and 5.11.2), as well as some that are derived from the basic raw materials (e.g nitrogenous allergenic substances, Section 5.11.3) and some,



There are small wine industries in the UK, Belgium, Ireland, the Netherlands and even southern Scandinavia. Good wines are made, often in state of the art wineries from *Vinis vinifera* crosses and hybrids that have been bred for cool climates. These include Bacchus, Huxelrebe, Kerner, Müller Thurgau, Schönburger and Seyval Blanc. Classic varieties like Pinot Noir and Chardonnay are used to make very good sparkling wines by the Champagne method. Fruit wines are made in several northern European countries.

There are small wine industries in Korea and Japan, larger ones in China. Wines are made from classic varieties, such as Cabernet Sauvignon and Rheinriesling, but also from American hybrids, such as Campbell's Early and indigenous species, like *Vitis flexuosa*. Beverages are made from fruits such as plums and raspberries, but these are often liqueur wines, rather than true wines.

France produces the biggest quantities of the world's finest wines; nearly all the great wine styles have French origins. This includes Burgundy (Chardonnay, Gamay Noir and Pinot Noir), Bordeaux (Cabernets, Merlot Noir, Sauvignon Blanc and Sémillon), the Rhone valley (Syrah for red, Marsanne, Roussane and Viogner for white), Alsace (mainly dry white wines), the Loire valley (light reds to sweet whites). Vermouth and fortified wines (e.g. Muscat de Lunel) are also made. Spain and Portugal produce a wide range of wines, from dry white to sweet red, including the great fortified wines, Madeira, Port and Sherry. Italy is the home of some great red wines, like Barolo in the north and Brunello di Montalcino further south. Italy also produces the unique styles of reciotto and ripasso. Vermouth and the fortified Marsala are also made. Germany, along with Alsace, make great wines from the Rheinriesling. Other countries of central, southern and eastern Europe also make good wines in many styles (e.g. Tokay of Hungary). Fruit wines are made all over Europe, but much of it is distilled (see Figure 1.1.5).
Australia has a large number of wineries that produce some great red wines, like Penfold's Grange, made from classic varieties such as Cabernet Sauvignon and Shiraz (Syrah). There are also good white wines made from Chardonnay, Rheinriesling, Sémillon and others, as well as great fortified Muscat wines. New Zealand makes some especially flavory white wines from Gewürztraminer and Sauvignon Blanc, and also lighter red wines from Cabernets and Pinot Noir. Hybrids are still grown in New Zealand.

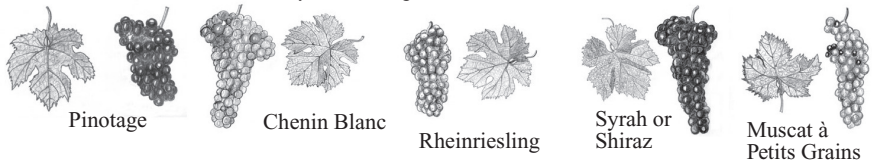

Figure 1.1.3 *Wine in Europe, Africa, Asia and Australasia*

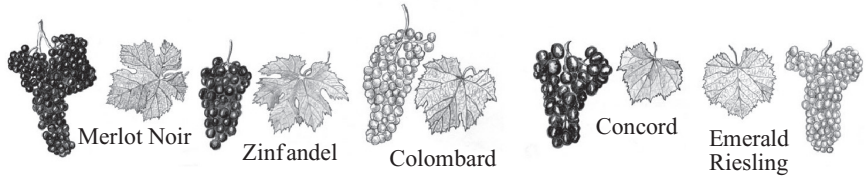

Fruit wines, from pomegranate, through cherry to black raspberry are made throughout Canada and USA, even in states with extensive vineyard areas, such as California and New York.

Many eastern, central and southern states produce wine from native American varieties such as Catawba, Concord, Delaware, Niagara, Noah and Scuppernong. Wines are also made from French-American hybrids, such as Baco Noir, Cascade, de Chaunac and Marechal Foch.

California, Oregon, Washington and British Columbia produce a wide range of wines, including sparkling wines and fortified wines. California makes some world class wines, mainly from classic *V. vinifera* varieties, like Cabernet Sauvignon, Chardonnay and Pinot Noir. *V. vinifera* crosses, like Ruby Cabernet, and less well known varieties, like Zinfandel can also give very good wines.

V. vinifera

V. labrusca, V. riparia, V. rupestris, hybrids, muscadines

V. vinifera, hybrids

Vineyards close to the Great Lakes or the Finger Lakes make wine from French-American hybrids and increasingly from *V. vinfera* varieties, like Chardonnay and Rheinriesling.

Mexico produces some good wine, mainly from warm climate *V. vinifera* varieties, like Syrah.

Although the Spanish colonized Chile, the major influence on the Chilean wine industry is Italian (through immigrants), French and lately, Californian. The very large Argentinian wine industry also owes much to Italian immigrants. Very good wines are made from classic varieties, such as Cabernet Sauvignon, Chardonnay, Merlot and Sauvignon Blanc. Argentina also makes wine from Malbec, as well as Barbera and other Italian varieties. Some South American states produce wine from other fruits, such as blackberry.

V. vinifera, some hybrids

Argentina, Brazil and Chile are the most important wine producers of South America. Wine is still made from hybrids in Brazil, because of the hot, humid climate. Uraguay makes good wine from less common *V. vinifera* varieties, like Gewürztraminer and Tannat.

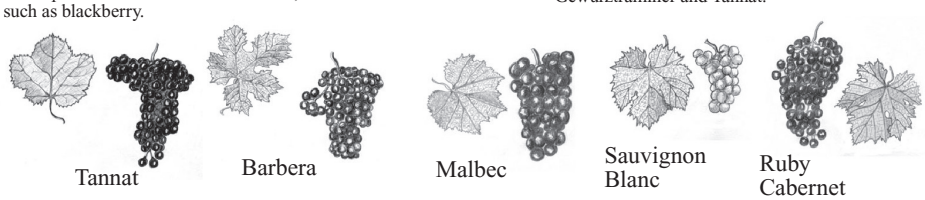

Figure 1.1.4 *Wine in the Americas*

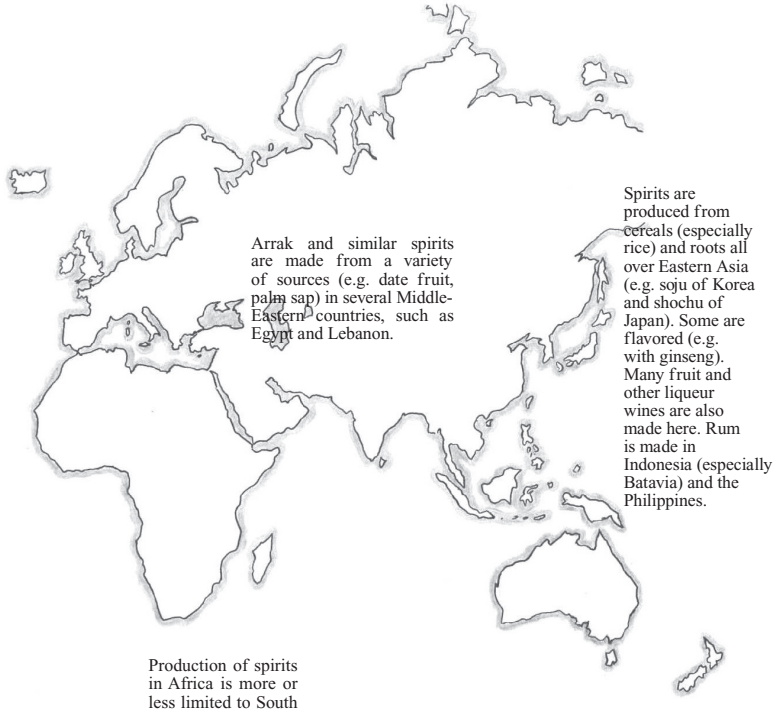
Brandy (distilled wine) is the major spirit of mainland Europe. Cognac and Armagnac are the finest and best known, but brandy is made in nearly all wine growing countries, from Spain to the Balkan countries of Greece and the former Yugoslavia. Grape pomace spirit is made in France (marc) and Italy (grappa) in particular. Fruit brandies and liqueurs (many brandy-based) are produced all over Europe. The former from Alsace are especially fine, but good fruit brandies are also made in Greece and the former Yugoslavia.
In northern Europe, akvavit (also called schnapps) is popular. It is distilled from grains, roots or even fruit and is usually flavored with herbs.
Vodka is a similar drink that is produced in Finland, Poland, other Baltic states and Russia. It is made mainly from cereals and is sold mostly unflavored, often being used in cocktails and mixes. There are flavored versions of vodka. Gin is made in the Netherlands, as are some liqueurs (e.g. cherry brandy). Russia produces brandy in the south of the country.



Scotch whisky is the most noted spirit of the British Isles: it is exported all over the world, mainly as blends and single malts. The styles range from the light Lowland whiskies, through fuller bodied highland whiskies, to the heavily peated Island whiskies. Irish Whiskey also finds world wide popularity and can be increasingly found as single malts. The Isle of Man and Wales also produce small amounts of whisky. Gin is distilled in London and Plymouth. Tiny amounts of brandy and apple brandy are made. There is small range of liqueurs, good examples being sloe gin and the Scotch whisky-based Drambuie.

Arrak and similar spirits are made from a variety of sources (e.g. date fruit, palm sap) in several Middle-Eastern countries, such as Egypt and Lebanon.

Spirits are produced from cereals (especially rice) and roots all over Eastern Asia (e.g. soju of Korea and shochu of Japan). Some are flavored (e.g. with ginseng). Many fruit and other liqueur wines are also made here. Rum is made in Indonesia (especially Batavia) and the Philippines.

Production of spirits in Africa is more or less limited to South Africa, where good brandy is made.

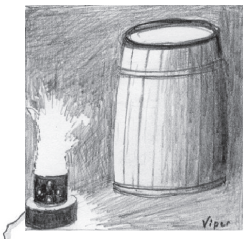
Figure 1.1.5 *Spirits in Europe, Africa, Asia and Australasia. Thanks are due to Familial Dupont, Kilchoman Distillery Co. Ltd., Keo Ltd., Glengoyne Distillery and The Rum Story, for permission to use label and bottle images*

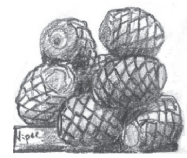
such as ethyl carbamate (Section 5.11.5) that are sometimes formed during the manufacturing process. Also included here are pesticide residues and various other contaminants (Chapter 5.10).

It has long been known that alcoholic beverages possess nutritional and health values, in both positive (beneficial) and negative (detrimental) senses (Part 5). As public awareness and interest in nutrition and health issues have grown during the past two or three decades, so scientific interest in the nutritional value

During the last decade there has been a marked growth in microdistilleries, especially in the USA. These distilleries produce a wide range of spirits, although mostly from grains: gin, rum, vodka and whiskeys of various styles, mostly using batch column or pot stills.

Whiskey (whisky in Canada), is distilled all over North America, from mainly mixed grain mashes, although maize (corn) dominates the whiskeys of USA; wheat is more important in Canada. Bourbon is made from at least 51% maize, with barley and rye. The whiskeys of Kentucky, Tennessee and Virginia are probably the most famous, but much Canadian whisky is consumed in the USA. Straight rye and corn whiskeys are making a modest resurgence in the USA and Canada (rye). Distilling is mostly by batch and continuous column stills, but a few pot stills are in use.





Tequila is the major spirit of Mexico, although brandy and rum are also produced. Tequila and mezcal are made from fermented *Agave* pulp and are much exported, especially to the USA.

Many of the South American states are wine producers and so also make brandy. Perhaps the best known brandy is pisco, made from Muscat wine in Peru, and from other wines in Chile.

The Carribean countries produce much of the world's bestrum. Light rum for mixed drinks and cocktails is made throughout the area, but is typified by those from Cuba and Puerto Rico. Likewise, Heavier darker rums are produced everywhere, but those of Demerara, Jamaica and Martinique are the best known. Both pot stills and continuous stills are used.

Cachaca is the cane spirit of Brazil. It is still produced by hundreds of small to medium distilling companies and its exports are rising. Pot stills, as well as batch and continuous column stills are used. Brazil grows much of the sugar cane used for Carribean rum.

Figure 1.1.6 *Distilled spirits and liqueurs in the Americas*

of alcoholic drinks and their components has increased (Chapters 5.1–5.5). Several alcoholic drinks are important for their macronutrients such as carbohydrates (Chapters 5.3 and 5.7) and many possess significant quantities of micronutrients (Chapter 5.4) and 'prebiotic' components, such as oligosaccharides, lactic acid bacteria and yeast. Ethanol, although it has a high calorific value itself, its presence in the diet can negatively influence uptake and metabolism of nutrients (Chapter 5.5). The past 10 years in particular have also witnessed a rapid growth in scientific interest in the health values of specific components of beverages, notably ethanol (Chapter 5.6), carbohydrates (Chapter 5.7), phenolic compounds (Chapter 5.8), additives (Chapter 5.9)

and trace components (Chapter 5.11). Similarly, growth in public interest in health, safety, pollution and environmental issues has catalyzed increased scientific activity in the study of pesticide residues and other contaminants of alcoholic beverages and the raw materials from which they originate (Chapter 5.10).

The various alcoholic drinks industries are important parts of the food and drinks industry: they contribute to a nation's economic prosperity to a significant degree. Indeed in some countries, such as several in the Caribbean area, the contribution is a major one. Moreover, the alcoholic drinks industries support numerous other diverse industries, like glass, plastics, cork, engineering and tourist industries. Additionally, agriculture has important ties with the alcoholic drinks industries: the growing of barley and other cereals for beer and spirits production, hops for the brewing of beer, apples for cider making, grapes for the production of wine and brandy, sugar cane for making rum and so on. Forestry provides cork, oak or chestnut wood to make casks for the maturation of wine or spirits and other kinds of timber to produce stakes for the support of crops such as grapevines.

According to the Wine Institute of California, in 2008, the wine industry in that state provided 309 000 jobs, produced an annual $51.8 billion in economic value for that state, generated $125.3 billion for the US economy, paid $10.1 billion in wages in Calfornia ($25.2 billion nationwide), made $13 billion in state and federal tax payments, attracted 19.7 million tourists per annum and generated wine-related tourism expenditures of $2 billion in California. The Californian wine industry also gives $115 million in annual charitable contributions and offers numerous intangible benefits to local communities, such as (amongst other things) enhancing the general quality of life, bringing positive visibility to the community, building local pride, offering cultural attractions, supporting local businesses, promoting responsible farming and winemaking, and providing scenic pastoral landscapes. The Californian wine industry can reasonably be regarded as a microcosm of the alcoholic beverage industry as a whole, where wineries, breweries and distilleries all over the world play similar roles in support of their local and national communities. Although the alcoholic drinks industry per se is not discussed in detail in this book, its presence obviously permeates the text of Parts 2 and 3 in particular, and also to a lesser extent that of Part 5.

1.2

History and Development of Alcoholic Beverages

1.2.1 The Beginnings (From the earliest Times to ca. 1100 AD)

Serendipity is defined as the art of making fortunate chance discoveries. In prehistory a number of such serendipitous events occurred, all of which were to have enormous consequences for humankind. We can only speculate as to how these discoveries were made, and they probably took place on several separate occasions. Amongst them was the observation that clay could be permanently hardened by the application of a high temperature. This discovery was probably made by a sharp-eyed individual while examining the remains of the fire around which the family had sat a few hours previously, and from this observation there ultimately arose the art of making pottery. The first tiny beads of a smelted metal may likewise have been observed in an old fire ring where hot charcoal in the fire had come into contact with a stone that contained an appropriate ore, and as a result humans eventually progressed from the Neolithic Age to the Bronze Age. The alcoholic beverages industry has over the years employed the products of both the potter and the metalworker, but a serendipitous discovery of more immediate concern to us is that of fermentation, by which sugar is converted to alcohol by microbial action. As in the cases of pottery manufacture and metal extraction, we can speculate as to how this discovery might have taken place, but in this instance there is a charming legend that describes the event.

According to the legend, the King of Persepolis is supposed to have tired of one of the ladies of his harem. Finding herself banished, the young woman decided to end her life, so she drank some liquid from a jar labeled 'poison' in the palace storeroom. The jar had originally contained grapes, the king's favorite fruit, and was thus labeled to prevent others from eating his special delicacy. The grapes in the jar had broken down and the yeast on the grape skins had caused the juice to ferment, with the result that the woman found the drink to be most pleasurable. She took a cup to the king who was likewise delighted, and the young lady was duly restored to her position in the harem (Pellechia, 2006).

The one possible glimmer of truth in this legend is that it places the accidental discovery of vinous fermentation in a location in present-day Iran. Archaeological evidence for the very early production of wine has come from excavations carried out at a site in Iran in the Zagros mountains, north west of Persepolis. Jars have been unearthed which have been dated at 5400–5000 BC and which have been found to contain residues that almost certainly indicate that they were used for storing wine. Using a combination of analytical

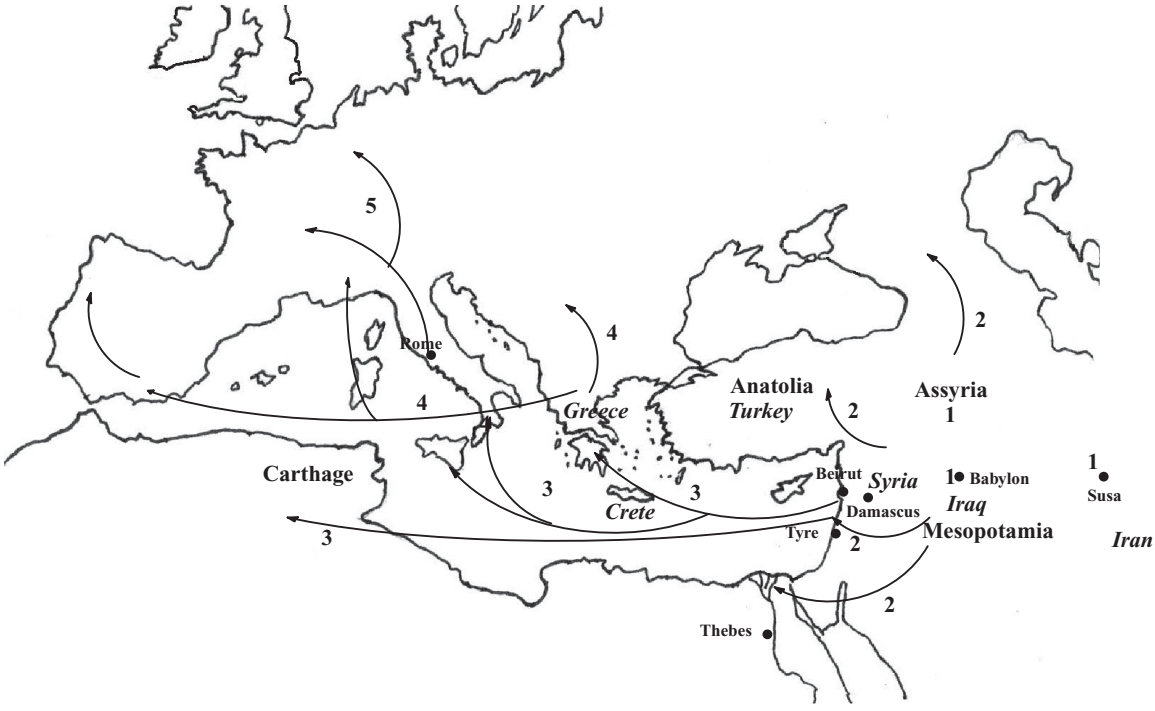
Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

methods – wet chemical analysis, infrared spectroscopy and high performance liquid chromatography – the jars were found to contain traces of tartaric acid and calcium tartrate. The only likely source of these compounds is wine, and furthermore the jars also contained traces of terebinth tree resin (Winepros, 2007). It is known that early winemakers used terebinth and other resins to help preserve wine, which would also have added a characteristic taste. The tradition of adding resin to wine survives today in the Greek *retsina* (Section 2.12.3), although this is now done solely for flavoring purposes. It should be noted that there are other contenders for the location of the first production of wine, for the wild grape grows on the slopes of mountains surrounding the Mesopotamian region, in areas in modern Syria, south eastern Turkey, Georgia and Armenia, as well as northern Iran. These mountainous areas surround the so called 'Fertile Crescent,' which is the region where it is thought that humans first made the transition from a hunter-gatherer existence to a more settled way of life in which crops were grown and animals domesticated.

The production of wine implies the deliberate cultivation of grapes, and an important early development must have been the selection of a suitable variety of vine. Plants of the wild grapevine, *Vitis vinifera sylvestris*, carry either male or female flowers, and pollination of the female flowers would therefore be a somewhat chancy business. It is surmised that one or more of the early grape growers noticed a vine that produced grapes much more consistently than was usual. This would have been a mutant that produced both male and female flowers, and was thus self-pollinating. By cultivating vines from the seeds of this hermaphroditic variety, now known as *Vitis vinifera sativum*, the early viticulturists were able to establish vineyards that gave reasonable crops.

Knowledge of wine and winemaking was spread principally by trade and sometimes by conquest. Grape cultivation was introduced into the Nile delta in Egypt in the third millennium BC, and winemaking scenes are depicted in scenes on tomb walls of the Old Kingdom period (2650–2152 BC). Dark deposits from the bottom of jars of the New Kingdom Period (1550–1070 BC) have been shown by LC/MS/MS (Sections 4.3.3 and 4.4.5) to be derived specifically from red wine (Guasch-Jané *et al.*, 2004). Traces of tartaric acid were discovered in these deposits and alkaline fusion of deposit samples produced syringic acid, a well-known product of hydrolysis of polymeric tannins derived from malvidin-3-glucoside, the major pigment of black grape skins. Although little wine was produced in Babylon, we know there must have been a flourishing import trade (probably by boat or raft down the Tigris or Euphrates), for a set of laws called the Code of Hammurabi was drawn up around 1800 BC which specified severe punishments for dishonest wine sellers. Somewhat later, between 1200 and 800 BC, the Phoenicians, a seafaring race living on the coast of what is now Lebanon and Israel, were instrumental in spreading knowledge of grape cultivation and wine production further afield. Their influence spread along the north African coast, where they founded the city of Carthage, and reached as far as the Iberian peninsular. The route by which wine became known to the ancient Greeks is unclear, but it was certainly familiar to the preceding Minoan and Mycenaean civilisations. Subsequently the Romans spread knowledge of wine even further afield into parts of Europe north of the Alps. Some ideas relating to the spread of viticulture and winemaking are illustrated in Figure 1.2.1, where dates become more uncertain the further back in time one goes.

An alcoholic beverage that almost certainly predates wine is beer, although in this case there is no attractive legend to account for its discovery. The production of beer from grain is a multistage process, and serendipity probably played a part on more than one occasion in the development of brewing. The modern procedure involves allowing grain to germinate (sprout), stopping the germination by roasting, at which stage the material is called *malt*, and then grinding the malt to produce *grist*. The grist is then mashed with hot water, the resulting extract is filtered and is then boiled with sugar and hops. The hops are strained off, the liquid (called 'wort') is cooled and run into a fermenting vessel, when the yeast is pitched in. After fermentation the beer is clarified and distributed in casks (draught beer) or in bottles or cans. During the germination process the complex polysaccharides in the seed are partially broken down into simple sugars, and these are then turned into alcohol in the fermentation stage. The first step in the process may have been stumbled upon

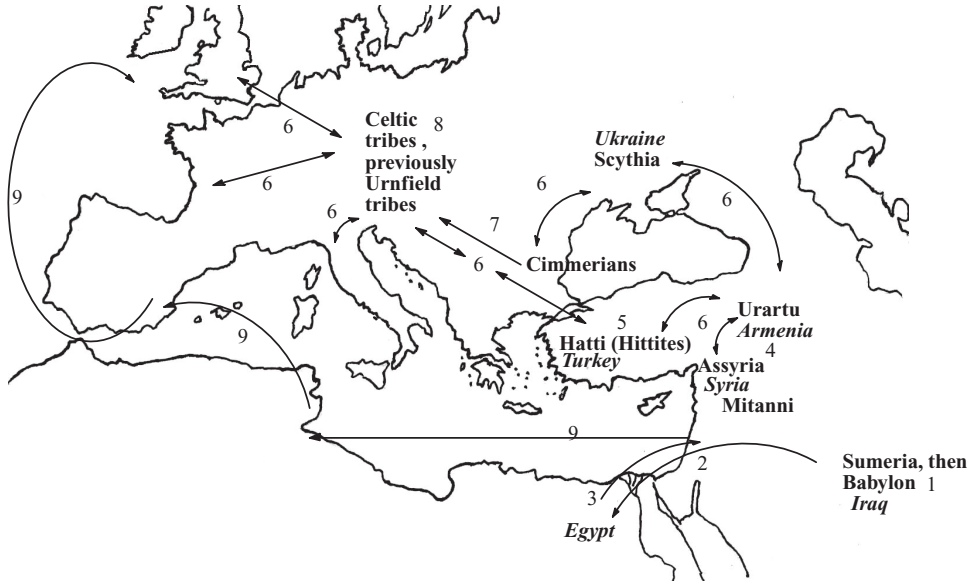


1. Records of viticulture and winemaking in the various empires of western Asia (now consisting of Caucasian states, Iran and Iraq) from ~6000 BC
2. Export of vines, viticultural and winemaking techniques to Phoenicia and Egypt and maybe other countries from ~3000 BC
3. Introduction of winemaking into Greece, Italy, North Africa, and Sicily by Phoenicians and their descendants ~2000-1000 BC
4. Greeks took their ideas of viticulture to Andalusia, Italy and Provence ~1000–500 BC
5. Roman invaders took vines and winemaking technology to northern Europe, as far as Britain from ~500 BC until the fall of the Roman Empire

Figure 1.2.1 *Early movements of viticulture and winemaking. Dates are approximate only and modern names of countries are given in Italics*

during the hunter-gatherer stage of human existence. It is possible that wild cereal seeds were collected, and once they had sprouted they were carefully heated. This primitive malt would have kept better than untreated seed, and would also have had a sweeter taste. Another accidental discovery might have occurred when malt was left in contact with water, thus allowing the production of a crude beer when fermentation of the unfiltered mash occurred as a result of infection by airborne microorganisms. All this is of course pure speculation, for as with the origin of winemaking our detailed knowledge of the discovery of brewing is nonexistent.

As with winemaking, brewing could not become properly established until an agricultural way of life had been adopted. Just as the early farmers selected a vine for cultivation that was more productive than the wild variety, so in the case of cereals, higher yielding varieties were chosen. In this case the selection was probably entirely accidental. The seeds of wild cereals are easily removed from the stem and dispersed by the wind, but in some plants there is a genetic trait in which the seeds are more firmly attached to the plant. When humans began to collect and sow seeds, more of the firmly attached seeds would have been available for collection, and gradually this gene would have predominated in the cultivated cereals. We do not even



1. Beer brewed from baked bread in Sumerian and Babylonian empires: *ca.* 4000–2000 BC
2. Beer exported to Egypt, where later it was brewed in a similar manner
3. Beer and expertise exported to Palestine and other nearby countries: 3000 BC onwards
4. Barley and wheat grown–beer brewed: *ca.* 1000 BC
5. Emmer, einkorn (forerunners of wheat) and barley grown, beer brewed: 3000 BC onwards
6. Interactions between peoples sometimes leading to possible spread of beer culture
7. Migration to central Europe, with beer culture: *ca.* 500 BC
8. There is evidence that Celtic tribes (*ca.* 500 BC onwards) were seasoned brewers, brewing from grains, not bread
9. The Phoenicians were great sailors and traders; it is possible they spread beer culture: 1000 BC onwards

Figure 1.2.2 *Origins of beer. Major early civilizations of which there are records of brewing are indicated by names and numerals. Arrows denote migrations, travels or exports. Double arrows denote interactions, including displacements and conquests, relating to the latest of the approximate dates indicated. Modern names of countries are in italics*

know which cereal (barley, wheat or oats) was used to make the first beers, or whether the first cultivation of cereals was for bread making or for brewing. Even the location of the first beer production is uncertain, and while somewhere in the Fertile Crescent is most likely (Figure 1.2.2), beer was certainly produced at an early date in Egypt. Whichever came first, brewing and baking technology developed side by side. It was known that the froth from the fermenting vessel could be used to make dough rise, and that pieces of lightly baked bread could be used to start fermentation. Neither practice necessarily implies that one technology was the forerunner of the other.

The original beers would have been very different from today's beverages. They were probably just fermented mash. They would not just have been cloudy, they might have been something more like porridge and could have been more of a food than a drink. They would have been more nutritious than the parent cereal on account of the partially broken down carbohydrates and proteins that they contained, and they would have had a pleasing inebriating effect. These original beers were probably not unlike the present day indigenous cereal beverages of Africa – boozah (Egypt), pombe and others (Section 2.7.2). Sometimes when early beer was consumed as a drink it was sucked into the mouth using a straw, and Egyptian pictograms show it being

consumed in this way. Irrespective of whether bread or beer was produced first, humans gradually perfected the art of making leavened bread and the technique of producing beer that was less like a glutinous mass and more like the drink we know today.

Barley is the most widely used cereal in beer production today, but it is very likely that in the early days oats, rye and wheat were employed as well. Indeed, maize, millet and sorghum are still used in fermented African and South American beverages (Section 2.7.2), and rice is the base of many Asian alcoholic drinks (Section 2.7.1). In Europe, brewing technology would have gradually improved, especially in respect of drawing off the fermented material from the mash tun to yield a liquid, which although still cloudy, was very different from the likely consistency of the earliest beers. This process of clarification would have been aided by the introduction into agriculture of hulled cereals. The hulls of the cereal grains would have provided an effective filtration medium through which the beer passed when being drawn off the bottom of the vessel. Both bread making and beer production would have advanced westwards from their birthplace in the near East as humans adopted a settled agricultural way of life. Some archaeological evidence suggests that a kind of beer may have arrived spread westwards much earlier than the dates indicated in Figure 1.2.2, which are based on documentary evidence. In northern Europe the analysis of pollen grains and fragments of leaves, etc., found in drinking cups from the Bronze Age would seem to indicate that alcoholic beverages were prepared at that time using malted grain and a variety of additional sources of sugar such as honey and fruit juices (Hornsey, 2003a).

From the period when the Celts had conquered most of northern Europe (i.e. from about 500 BC), we have documentary evidence concerning the drinks that were being consumed, for although the Celts left no written record, some Roman authors gave accounts of Celtic habits and practices. The general impression created by these authors is that wine was only drunk by the rulers and upper classes, being imported from the Mediterranean region, whereas the ordinary folk drank beer (Figure 1.2.2). It was possible to transport and trade good wine, but it was usually necessary to consume beer as soon as it was brewed at a place very close to the location of its production.

When the Romans started to establish vineyards in their newly conquered territories, they were so successful that wine production in Italy itself was being threatened. As a result the emperor Domitian issued a decree late in the first century AD that limited the production of wine in the provinces and forced the grubbing up of many vineyards. The decree was not revoked until late in the third century after which new vineyards were developed in Gaul, and to some extent in Britain. The remains of a 35-hectare Romano-British vineyard have been found near the village of Wollaston in Northamptonshire. After the collapse of the Roman Empire, viticulture had to wait another 1000 years before further expansion into new areas of the globe.

So far the focus has been on the Middle East and on Europe, and we have considered beverages formed by fermenting a solution of sugars obtained either directly from grapes or indirectly from cereals such as barley, wheat or oats. However, a large number of traditional alcoholic beverages have been produced from other sources by indigenous peoples in various parts of the world, and many of these are still made today. In general they are either akin to wine, in that a solution of sugar is obtained from a plant, which is then fermented, or they are like beer, in that complex polysaccharides in a plant are first broken down to simpler sugars, and then fermentation is allowed to occur. Three examples will be quoted.

Rice wines, the common nondistilled alcoholic beverage of eastern Asia, probably originating in China. They include the Korean *makkoli* and the Japanese beverage *sake* and have been known since antiquity (Section 2.7.1). References to sake are made several times in the Kojiki, Japan's first written history, compiled in 712 AD. It is usually described as rice wine, but in reality it is more akin to beer. Traditionally, the process was started by chewing the rice and then spitting it into a pot, the enzymes in saliva causing the complex carbohydrates to start breaking down into sugar. Inscriptions from the fourteenth century BC mention Chinese millet wine, xiao mi jiu, being made the same way. Today the rice is treated with a mould/yeast starter (called

nuruk in Korea, *koji* in Japan and *men* in Vietnam) that contains appropriate enzymes to catalyze carbohydrate breakdown and to perform fermentation (Wikipedia, 2007a). The indigenous peoples of South America likewise consume a drink called *cauim*, made from starchy roots or from maize, with the breakdown of the polysaccharides also being initiated by an enzyme in saliva (Wikipedia, 2007b). In Mexico the traditional beverage is *pulque*, which is a kind of wine made by fermenting the sweet liquid obtained from the flower stems of the maguey plant (Wikipedia, 2007c) (Section 2.7.2). Such beverages are part of the culture of the regions in which they are made, but it is likely that primitive peoples used many other sources of sugar to make alcoholic beverages. Quite passable drinks can be made by allowing the juice of many wild fruits to ferment, and all that is needed to make a wine from a fruit such as the blackberry is a suitable container. This is where the craft of the potter would have been first used in alcoholic beverage production, but even animal skins might have served the purpose, and drinks made from wild fruits may have preceded settled agriculture. Nowadays, many palatable drinks are made by the fermentation of juice from wild or cultivated fruits (Chapter 2.11). It is probable that a fermented drink was made from the juice of the wild apple, but in the United Kingdom, which today has the world's highest per capita cider consumption, large-scale production did not commence until the Middle Ages. A nonplant source of sugar that was used in many cultures from 1000 BC or earlier is honey, which was (and still is) fermented to make mead (Section 2.11.5). It was also added to wine as a sweetener. There is a considerable body of evidence to show that honey has been used in these ways for many centuries. For example, analysis of the pollen grains in the deposit found in a bronze bowl from a rich celtic woman's grave (late Hallstadt period) in lower Bavaria revealed a wide pollen diversity, suggesting that the bowl contained mead that was produced from the honey of wild bees (Rösch, 2005). In contrast, the pollen found in the deposits in early medieval Coptic amphorae from Šaruna (Middle Egypt) was of narrow diversity, suggesting the honey was derived from domesticated bees. Whether the amphorae originally contained mead or honey-sweetened wine is not known (Rösch, 2005).

Returning to the drinks with which we are principally concerned, namely wine and beer, it was the monasteries that kept alive much of the knowledge of methods of beer and wine production in northern Europe in the centuries following the fall of the Roman Empire. The monasteries were self-contained entities, running their own farms, and as far as vineyards were concerned, the monks and nuns had the discipline to take the necessary care to maintain them in good order. Furthermore, the Christian religion demanded a supply of wine for use in Holy Communion.

The first possible evidence of distillation per se comes from the discovery of still-like clay pots, dating from the second millennium BC, in what was once Babylonia, although it is not known for certain what was distilled. Although the first drawings of stills date from the Hellenistic school of alchemists (second century AD), from written and archaelogical evidence it was probably the Arab alchemists who perfected the art of distillation to an extent necessary to obtain fairly concentrated alcohol from a fermented beverage. This was despite the teaching of Islam, which from its inception in the seventh century AD forbade the consumption of alcoholic beverages. The Arabs became the world's leading scientists, and were the first to use distilled alcohol in medicine. The earliest piece of distillation apparatus (from Iran) that has survived is Islamic and is dated between the tenth and twelfth centuries. Water cooling was not used, but it is likely that careful distillation would have produced a solution of alcohol sufficiently concentrated to burn (Hudson, 1992).

The Arab scientists originally referred to ethanol as distilled wine (خمر مصعّ), but later the word arak (عرق), meaning sweat (referring to the beads of distillate on the cooler parts of the still) came into general usage (al-Hassan, 2009) and is still used for certain distilled drinks today (see Sections 3.5.5 and 3.5.6). Early names for this spirit in European literature were *aqua ardens* (the water that burns) or *aqua vitae* (the water of life). The word *alcohol* itself was not used until the sixteenth century, and has an extraordinary derivation. It comes from the Arabic *al koh'l*, the name given to antimony sulfide, a material used by ladies to darken eyebrows and eyelashes. It was purified by sublimation, a process bearing obvious similarities to distillation, and in

time the name *alcohol* became associated with the process rather than the material. Eventually, anything purified by sublimation was known as *alcohol of*, and the spirit obtained by distillation of fermented grape juice was known as *alcohol of wine*. In time this name was shortened to *alcohol* (Flood, 1963). Now the name applies not only to ethanol (ethyl alcohol), but also to a wide range of chemical compounds bearing the OH functional group. It was not until the Middle Ages that distilled alcoholic beverages were manufactured and consumed (Section 1.2.2).

Microorganisms cannot survive in concentrated alcohol, which can be used as a preservative. However, undistilled beverages are prone to spoilage, and its prevention has always been a matter of prime concern for brewers and wine makers. We have seen how resins were used as preservatives in the earliest wines. Other strategies that were adopted at a later period included the floating of a layer of olive oil on top of the wine, and the tight stoppering of amphorae, both measures being designed to exclude the air. Sulfur dioxide, obtained by burning elemental sulfur, was used as a fumigant in ancient times, and the Romans were the first to use it as a preservative for wine (Robinson, 1995) (Section 2.5.2). The most important substance added to beer for preservation is hops, although this strategy does not seem to have been employed until about the ninth century, when a reference occurs to its use in Germany. At this time, most beers would have been either unflavored or flavored with various herbs and plants, such as juniper, sweet gale and yarrow. Although many of them would have been very strong (~8% ABV), most would be consumed while they still possessed a distinct prickle of carbon dioxide and probably within 24 h of pouring the beer from the yeast lees.

By 1100 AD Europe was beginning to emerge from its so-called 'Dark Ages.' This period is certainly dark in the sense that there are few extant records concerning alcoholic beverage production or indeed almost any aspect of human activity. However, from the Middle Ages onwards we are able to form a clearer picture of our brewers, winemakers and distillers.

1.2.2 Medieval Times and Beyond (*ca*. 1100–1750)

It is in this period that we get the first indication of the quantities of beverages consumed. In northern Europe the principal drink was beer, and at first glance the amounts brewed seem very large. Documents detailing the consumption of brewing materials during a 40-day siege of Dover Castle in 1216 indicate an allowance of half a gallon of beer per man per day (Hornsey, 2003b). Overall consumption in England and the Low Countries in the late Middle Ages is estimated at a more modest (but still considerable) 65 gallons per head per year (Wikipedia, 2007d). Beer also provided a significant proportion of the calorie intake of the population of northern Europe. In southern Europe, wine, and no doubt other fruit juices, both fermented and unfermented, remained the principal beverage.

The ecclesiastical establishments of monasteries continued to be extremely important during the early Middle Ages. They often owned large tracts of land, and controlled many aspects of local economic affairs. Among the activities of northern European monasteries was the brewing of beer, and they did good business supplying the local population. Alongside the monastic breweries, beer was brewed in smaller quantities in individual dwellings, often by the lady of the house. In some cases the product may have been solely for family consumption, but often it was sold or traded as well. In England the dissolution of the monasteries by Henry VIII put an end to their brewing activities, but by this time, many of the home breweries had been replaced by establishments that not only brewed the beer, but also provided accommodation for its consumption. It became a requirement for these establishments to be licensed, and a distinction was made between ale houses, taverns (which sold both ale and wine) and inns, which also provided food and beds. In 1577 there were 19 759 licensed premises in England, which equates to one for every 187 members of the population (Hornsey, 2003c).

With brewing being something of a cottage industry, it is hardly surprising that standards varied enormously and that in consequence attempts were made to introduce some kind of quality control. In England, the official charged with this duty was called the ale conner or ale taster. It was his job to assess the quality of ale before it went on sale, and the vendor was expected to send for the official when the brew was ready. In some areas the brewer erected an ale stake (a long pole with branches tied to the end) on the outside of the house to indicate that the ale was ready to be sampled. No doubt the ale conner relied primarily on his sense of taste, but according to legend, the conner used to pour some of the ale on to a wooden settle, and then he used to sit in the pool of ale (he wore leather breeches for obvious reasons). If at the end of about half an hour he could stand up without his breeches sticking to the settle, the ale was judged to be of a satisfactory quality. In modern terms, the rationale behind this primitive method of analysis is that stickiness in the beer would be caused by a significant quantity of residual sugar, meaning that fermentation was incomplete and hence the alcohol content was low. The ale stake also served as an advertizement to the public of the impending availability of the brew. In time different establishments started to put their own distinguishing symbols on their ale stakes, and this is probably the origin of the pictorial signs found on pubs in Britain today.

The practice of adding hops in the brewing process became much more widely adopted in the Middle Ages. Hopped beers keep for a longer period, so the use of hops gave beers of relatively low alcohol content a reasonable lifetime. Originally the term *beer* meant that the brew had been hopped, the unhopped beverage being referred to as *ale*, but now the terms are used interchangeably. In the early history of brewing, a great many different substances were added to ale to enhance the flavor, and one author has identified 175 plants or plant-derived products that have been used as flavoring, preserving or adulterating agents (Hornsey, 2003d). Probably the most widely used additive before the general adoption of the hop was *gruit*, a Dutch term that referred to a mixture of herbs whose precise composition varied, but which usually contained bog myrtle, marsh rosemary and yarrow among the ingredients. Like these plants, the hop grows in the wild in northern Europe, and its preserving effect on beer was probably discovered by accident. Hopped beers were first exported from Bremen and Hamburg in the early Middle Ages, after which the practice of hopping beer gradually spread to other parts of northern Europe. It is likely that initially hops were imported into Britain, for there is no firm evidence for the deliberate cultivation of the crop before the fifteenth century.

The introduction of hops into brewing in Britain was accompanied by considerable controversy, and at various times edicts were issued that sought to prohibit their use. The use of hops meant that the brewing process became more complicated, for the filtered wort now had to be boiled with hops. The result was the slow emergence of larger breweries, called common brewers, which supplied several retail outlets

We have seen that in the early days of brewing, not only could a number of cereals be used for making beer, but many different herbs and spices could be added as preservatives or flavoring agents. In 1516, when Duke Wilhelm of Bavaria passed the *Reinheitsbebot* (purity law), he enacted a piece of quality control legislation that remains the oldest food regulation still in force anywhere in the world. The Reinheitsgebot decreed that only barley, water and hops were to be used by commercial brewers in making beer. Over the preceding millennia, the term beer had encompassed a considerable variety of beverages; now a consensus was emerging as to what the term actually meant.

Turning our attention to the East, the history of sake, a typical rice wine, bears some resemblance to that of beer. In tenth century Japan, temples and shrines began to brew sake, and were the main centers of production for next 500 years. The *Tamon-in Diary* (1478–1618), written by monks of the Tamon-in temple, records many details of brewing in the temple. The diary shows that a process akin to pasteurization and the addition of ingredients to the main fermentation mash in three stages were established practices by this time (Section 2.7.1). During the Maiji Restoration (*ca.* 1866), the Law allowed anyone with the money and skill to construct and operate his own sake brewery, so the brewing of sake shifted away from the temples. About 30 000 breweries were established around the country within a year. However, through the years, the

government levied higher and higher taxes on the sake industry and within a few years the number of breweries had fallen to 8000. Most of the breweries that survived this period were set up by wealthy landowners, who grew rice crops and had rice left over at harvest time. Rather than letting the excess rice go to waste, they set up breweries and distilleries, thereby creating valuable extra income from sales of rice wines and spirits (*shochu*).

In southern Europe, wine remained the principal drink, being consumed by all social classes. This is not to say that beer was unknown. Brewing was undoubtedly carried out on a domestic basis, but beer did not become an article of commerce as it did in northern Europe. Methods of wine production south of the Alps remained essentially the same as in Roman times. However, the expanding population increased demand, and although beer was the common drink in northern Europe, the upper classes had a distinct taste for wine. Increasing demand, and the difficulties of transport, resulted in ever higher prices in northern Europe for wine imported from southern regions, with the result that local wine production was stimulated. Varieties of grape that grew well in northern areas were cultivated, and regional centers of excellence developed, examples being Bordeaux, Burgundy and the Rhine. The Church played an important role in this expansion, and monastic orders such as the Benedictines helped to expand the northern European wine industry.

The Greeks and Romans had transported their wine in pottery amphorae. In more northern areas, with their abundant oak forests, containers for storage and transportation were made from wood. The construction of barrels, casks and vats that were completely impervious to liquids became a highly skilled task, and the cooper became a vital craftsman in wine producing areas. Another northern European invention was the wooden press, in which the juice is gently squeezed from the crushed grapes through the slatted sides. This is in contrast to earlier techniques in which the grapes were crushed by a stone, or by human feet. Some of the bigger European wineries or estates possessed enormous wooden presses to cope with big harvests. Two very fine examples from the eighteenth century can be seen at the Stellenbosch Wine Museum, in South Africa (Figure 1.2.3). Casks are still used to age some of the finest wines, but as a result of the development of heavier and stronger glass, the bottle gradually became the standard container for the storage and transport of wine from about the seventeenth century, although many wines, including red Bordeaux and Port, were often shipped in cask to be bottled in a foreign country. Nowadays, most fine wines are bottled from casks at the domaine or in the region of production, and the bottles are then transported to the point of sale. Although some of the early bottles were sealed with wax, the use of cork stoppers soon became widespread. Cork provides an excellent seal, but over a prolonged period a cork can dry out, thus allowing air to enter the bottle.

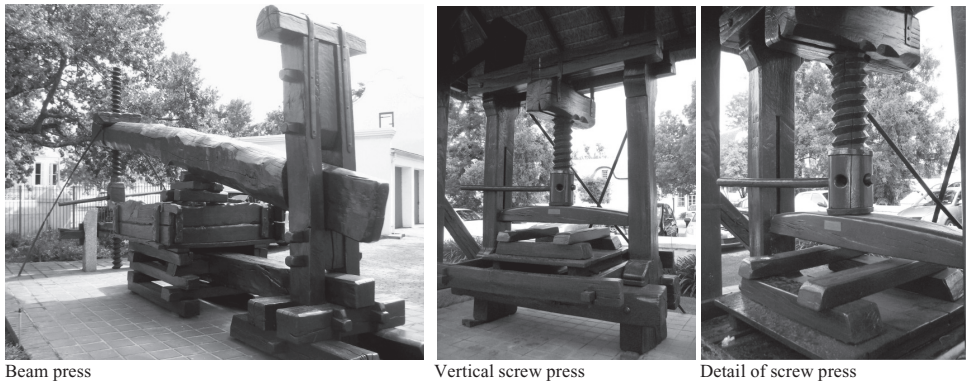


Figure 1.2.3 *Eighteenth century wine presses at Stellenbosch Wine Museum.* Photographs taken by Marianne Mackay

Figure 1.2.4 *Early wine bottles and an early corkscrew. These port wine bottles from (left to right) early, mid and late eighteenth century, early nineteenth and twentieth century demonstrate the changing shape of the wine bottle. Bottles and corkscrew are not drawn to scale*

The first wine bottles were bulbous in shape with a flat base, and could only be stored in an upright position. It was not until the latter half of the eighteenth century that cylindrical bottles with a narrow neck were made (Figure 1.2.4). These could be stored horizontally, and hence the cork did not dry out. Although some of the first corks may have been flanged or tapered, for upright storage of the bottles, later cylindrical bottles were fitted with straight corks for storing horizontally. This development gave rise to the need for a tool to extract the cork – the corkscrew. It is uncertain when the first corkscrews were used, but the first mention of the 'bottle scrue' was in 1720 (Young, 1979) and probably the earliest patent was taken out in 1795. A sketch of an early corkscrew (date unknown) is shown in Figure 1.2.4.

A further improvement in glass technology enabled the process of making champagne to be perfected. In the cool champagne region, fermentation proceeds slowly, so when the wine is bottled in the autumn some sugar remains. Fermentation recommences in the bottle in the following spring when temperatures begin to rise. The early glass wine bottles were unable to withstand the pressure of carbon dioxide, and most of the wine was lost. The seventeenth century Benedictine monk Dom Pérignon experimented with stronger bottles made from a newly invented type of glass that incorporated lead oxide, with the result that the production of the famous sparkling wine became a reliable process. Nevertheless the wine was still cloudy owing to the presence of dead yeast cells. The traditional clarification process is supposed to have been invented by a widow, Madame Cliquot. The dead yeast cells are concentrated in the neck of the inverted bottle, that portion of the wine is frozen, the bottle is opened to expel the frozen portion, and then finally recorked.

In the eighteenth century, wines fortified by the addition of brandy increased in popularity, especially in Britain. In the Douro region of Portugal, fortification was originally employed at a monastery to arrest the fermentation process, but a local aristocrat, the Marquês de Pombal, who had been Portuguese ambassador to London, realized there would be a market in Britain for the sweet, high-alcohol red wine (port), and promoted its export (Section 2.10.7). In the Jerez region of Spain, fortification was practiced for a different reason. A second type of yeast, known as *flor*, occurs in the region and forms a bread-like film on the surface of the wine maturing in the casks. It prevents the oxidation of the wine, and also imparts a characteristic flavor, but needs an alcohol content of around 15.5% to grow, hence the need for fortification. The final product, known as *Sherry* from an English corruption of the word Jerez, is a blend of the products of fermentations from several different years (Section 2.10.2). Yet another fortified wine to achieve popularity in Britain and its American colonies at this time was Madeira (Section 2.10.5). The Portuguese colony had been exporting sweet Malmsey wine to Britain for some time when the practice of fortification was introduced, partly to

improve the wine's keeping properties, and partly to satisfy the British palate. It was then found that if the fortified wine was kept in a warm environment (around 40 °C; 104 °F) for some months its quality improved and it became fully stabilized – it could keep almost indefinitely. Legend has it that the effect of warming was discovered accidentally when consignments were confined in the warm holds of ships bound for North America or the East Indies. At one time more Madeira was imported into the American colonies than any other wine.

A beverage that grew in popularity in England during the Middle Ages was cider. Although the Romans established some apple orchards, there is no evidence of cider production before the Norman conquest. The Normans brought with them the tradition of apple growing and cider making, and introduced varieties of apple such as the Permain and Costard, which were particularly suited to cider making. It was once again the monasteries that were the prime manufacturers and retailers of cider, although cider making was also practised in manor houses and on farms.

The first spirits (i.e. distilled alcoholic beverages) were almost certainly originally imbibed for medicinal rather than social reasons. The Italian city of Salerno was the location of the first medical school to be established in western Europe, and it was here that many Greek, Latin and Arabic medical texts were translated. A compendium of medicines from the Salerno school in the early Middle Ages refers to *aqua ardens* (burning water). Certainly spirits produced at this date would have been somewhat 'rough' by modern standards, and their restriction to medical applications is understandable.

Over the years distillation techniques improved, a particularly important innovation being the introduction of water-cooled condensers, but in general the principal practitioners of distillation remained doctors and apothecaries. Then in sixteenth century France the large-scale distillation of wine commenced, although it was the Dutch who provided the chief stimulus to the expansion of production. Not only was there a demand for the distilled beverage in the Netherlands, but the Dutch, being a great seafaring nation, needed large quantities of the spirit to service their ships, both because it helped to stop the drinking water going brackish and because it was a more efficient way of transporting the alcohol required for a long voyage. It was the Dutch who set up distilleries in the wine producing regions of France, calling the product *brandewijn* (burnt wine), from which the English word *brandy* derives.

At about the same time, a number of other spirits began to be made in quantity. Any fermented solution can be concentrated by distillation, and in consequence a great many kinds of spirit are made. The taste depends upon those compounds, apart from ethanol and water, which come over in the distillation process, and any flavorings that are added during the process of manufacture. A spirit that was first produced on a large scale in the late sixteenth century is vodka (Section 3.4.3), which today is almost solely ethanol and water, although various flavorings have been used in the past. Many materials can be fermented to produce the alcohol prior to distillation, but modern European legislation states that if vodka is prepared from anything other than cereals or potatoes, this must be stated on the label (Rogers, 2007). Vodka now has a world-wide popularity, but the traditional vodka belt stretches from the Nordic countries, through Poland and the Ukraine, to the far east of Russia. Another spirit originating in the sixteenth century is Akvavit (Section 3.4.3). A drink of the Scandinavian countries, it is based on alcohol distilled from potato or grain, and flavored with a variety of herbs, most commonly caraway. The name *Akvavit* is a Nordic corruption of the Latin *aqua vitae*. Gin, which was first produced in the Netherlands in around 1650 for medical purposes, is made mostly by redistillation of grain spirit, to which a mixture of spices ('botanicals') has been added. Notable amongst the botanicals in gin is the juniper berry or its essence (Section 3.4.2). In France the new spirit was called *eau de genièvre* (juniper water), which the English abbreviated to *geneva* and then to gin.

The whiskies of Scotland and Ireland are highly complex, both in their constitution and production. According to legend, whiskies have been made in these countries since Celtic times, but as with other spirits, larger-scale production commenced towards the end of the Middle Ages. The fermented malted barley is

subjected to two distillations in copper stills of traditional design, which result in the spirit containing a complex variety of compounds that contribute to the flavor. One major difference between Scotch whisky (Chapter 3.2) and Irish whiskey (Section 3.3.1) is that in the former the malted barley is dried over smouldering peat, whereas in the latter case sealed ovens are used. The distilled spirit is matured for many years in oak casks (Whisky.com, 2007). The name *whisky* or *whiskey* is an English corruption of the Gaelic *uisgebeatha*, which means water of life.

Rum (Section 3.5.2) is made by the distillation of fermented by-products of the cane sugar industry, e.g. molasses or sugar cane juice, before being matured in oak casks. Production was already established in Jamaica when the island was captured by the British from the Spanish in 1655. The British, like the Dutch, had been in the habit of issuing brandy to their sailors, but their new conquest provided them with a more reliable source of spirit, and the long association between rum and the Royal Navy commenced. Every sailor received a daily tot of rum until the practice was abolished in 1970. No doubt in part because of its naval associations, much rum was imported into Britain, via ports such as Whitehaven in Cumbria. Soon after the production of rum commenced in the Caribbean, demand in the American colonies led to the establishment of rum distilleries there, the first being in Boston in 1664. Another spirit manufactured in the American colonies was applejack from cider. The traditional method of production was not by distillation, but by freezing, when ice crystals formed leaving a more concentrated alcoholic solution behind – a process known as 'jacking.' Distillation was also used both in America and in the Calvados region of Normandy, where the famous apple brandy is still produced (Section 3.8.2).

A liqueur (Chapter 3.9) is a distilled alcoholic beverage with added flavoring and a relatively high sugar content. It was early in the sixteenth century that the first liqueur was prepared by a monk at the Benedictine Abbey of Fécamp in northern France. The monks had previously made a medicine by infusing brandy with various herbs, but it had an unpleasantly bitter taste. By adjusting the recipe the monks made a liqueur that was highly palatable (Classicliquors.com, 2007). Today Benedictine is still produced to the original recipe, although no longer by monks. Four different combinations of herbs and spices are prepared (27 ingredients being used altogether) and each mixture is soaked in brandy. Each brandy is then distilled, aged in oak casks and then the four are blended together and aged again. Another famous brandy-based liqueur, first prepared by Carthusian monks in the seventeenth century and still made by them today, is Chartreuse. Supposedly over 100 herbs are used in its preparation. A third liqueur that also has an ancient pedigree is Drambuie, which is based on whisky rather than brandy. Like many liqueurs the mixture of flavorings used is complex, and includes heather honey and a variety of herbs. The recipe is supposed to have been given by Bonnie Prince Charlie to Captain John Mackinnon in gratitude for the latter's assistance in helping the Prince evade capture by the pursuing English forces after the battle of Culloden in 1746. Drambuie was first produced on the Isle of Skye, but it is now made near Edinburgh by a company owned by one of John Mackinnon's descendants (Rampantscotland.com, 2007).

In eastern Asia, soju (Section 3.4.4) was possibly the first distilled beverage, distilled for the first time probably around 1300 AD, during the Mongol war with Korea. The Mongols had learned the technique of distilling *arak* from the Persians during their invasion of central and western Asia around 1256. The technique was then taken up by the Chinese and Koreans (and other Asian nations), whence the latter set up distilleries originally around the city of Kaesong. Indeed, in the area surrounding Kaesong, soju is still sometimes known as *arak-ju*. It is most likely that regular distilling of cereal mashes began in China and Korea at about the same time, although it is possible that distilled drinks were produced before that time in certain areas of China that were more closely linked with the trade routes to western Asia and the Arab countries.

In what is now Japan, awamori (Section 3.4.4) was probably the first distilled spirit, made from rice wine in the Ryukyu Islands in the fifteenth century, possibly from techniques acquired from Thailand, where in turn, the methods were probably picked up by traders or travellers from further west.

1.2.3 The Industrial Revolution and the Influences of Science and Technology (*ca*. 1750–1900)

Britain was the first nation to industrialize, and the so-called industrial revolution had a dramatic impact on the production of all manner of articles of commerce. The technological advance that was to transform the brewing industry was James Watt's improvement in the steam engine. This was patented in 1769, and the new engines were manufactured by the firm of Boulton and Watt from 1776. Watt's design was much more fuel efficient than the earlier Newcomen engine, which only found application in pumping coal mines where the fuel was readily available at a low price. The first steam engine to be installed by a brewery started work in London 1784 and by 1801 there were 14 in the capital. Breweries in the larger cities outside London started to acquire steam engines from 1793. Steam engines were used to grind the malt and for various pumping operations around the works. Even before the advent of the new engine, a relatively small number of breweries had grown into large concerns at the expense of their smaller competitors; now it was only the larger organizations that could afford the new machines and this further accelerated the growth of the large breweries at the expense of the small fry.

Brewing benefited from many other technological innovations during the period 1750–1900, but two in particular stand out as deserving a mention. The introduction of an effective means of cooling by refrigeration, which commenced in the late 1860s, meant that beer could now be produced all the year round. The boiled wort had to be cooled before fermentation could commence, and traditionally this had been done by simply allowing the liquid to cool in open vessels, with the consequence that in the warmer summer months there was a greater danger that spoilage would occur at this stage. Interestingly, one of the important contributors to the science of thermodynamics, which provides the theoretical basis for refrigeration, was James Prescott Joule (1818–1889), who was born into a brewing family and worked in his private laboratory adjacent to the brewery in Manchester. The other new technology that had a huge impact on the brewing industry was that of the railways. By 1860 the basic railway network of most of Britain and much of Europe had been laid out, with the consequence that breweries could transport and sell their products many miles away. This further consolidated the position of the larger breweries. When the Midland Railway opened its new London terminus at St Pancras in 1868, the cast iron pillars supporting the roof of the undercroft were spaced so that barrels of beer from Burton on Trent could be rolled between them.

Whilst Joule's scientific work was not carried out with the intention of developing a technology that would find application in breweries, other laboratory workers performed experiments that had more obvious connections with the alcoholic beverage industries. The fermentation process was studied by the famous French chemist Antoine Laurent Lavoisier (1743–1794), who weighed the sugar consumed and the alcohol and carbon dioxide produced, and found them to be equal. This was the first experimental demonstration of the law of conservation of matter, or as Lavoisier stated in 1789 '. . .in all operations of art and nature, nothing is created; an equal quantity of matter exists both before and after the experiment. . .' There was, however, uncertainty for many years over the precise nature of the fermentation process. By the late 1830s it had been established that fermentation occurred in the presence of living yeast cells, which multiplied as the fermentation progressed, and it was also known that if the yeast was killed by heating, then fermentation ceased. However the idea that a living organism played an essential role in a chemical process was contrary to contemporary chemical theory, and the idea was ridiculed in an anonymous article that appeared in 1839 in a journal edited by the famous German chemist Justus von Liebig (1803–1873).

The matter was resolved by the Frenchman Louis Pasteur (1822–1895), who in 1857 demonstrated conclusively that fermentation occurred as a result of the metabolic activity of yeast. Pasteur's first researches in this area were conducted as a result of problems experienced by a manufacturer who was producing industrial alcohol by fermenting beet sugar. Lactic acid was being formed as well, and Pasteur demonstrated

that this was caused by another microorganism (actually a bacterium). Pasteur soon succeeded in separating the microorganisms responsible for several different kinds of fermentation – alcoholic, lactic, acetic, butyric, etc. He was then able to show that many of the problems encountered in the wine industry were caused by contamination with foreign organisms during the production process. This explanation led to methods prevention of wine spoilage, among them the process of rapid heating and cooling the liquid, i.e. the process known as pasteurisation.

Pasteur also investigated problems associated with the brewing of beer, and during his research he visited Whitbread's brewery in London. As in winemaking, Pasteur demonstrated that spoilage was caused by foreign microorganisms, either added with the yeast, or introduced from the air. As a result of his work, breweries soon began to use the microscope to examine their yeasts and their beers.

The labors of well-known figures such as Watt, Lavoisier and Pasteur were of enormous benefit to producers of alcoholic beverages, but eventually the industry began to realize the advantages of employing its own chemists to work in on-site laboratories. The first breweries recorded as appointing chemists were the London firm of Truman, Hanbury and Buxton in 1831, and the firm of Allsop's in Burton-on-Trent in 1845 (Russell *et al*., 1977). By 1876 there were enough brewery scientists employed in Burton for them to form an informal dining club called the Bacterium Club (Hornsey, 2003e). The brewery chemists analyzed the quality of the water supply, monitored various aspects of the brewing process by means of instruments such as the thermometer and hydrometer, and combated problems of infection and spoilage. Probably the best-known brewery laboratory in the world was that founded by Carlsberg in Copenhagen in 1876, although from the outset it was as much a research institute as a laboratory directed towards process control in the brewery (Wikipedia, 2008). Its first director was Johan Kjeldahl (1849–1900) who devised a method of measuring the quantity of protein in the grain used by the maltsters. The technique has been much used by biochemists and food scientists ever since. His successor was Søren Peder Lauritz Sørensen (1868–1939), who devized the pH scale for measuring acidity and alkalinity. At first, some companies preferred to use consultants rather than appoint chemists as full-time employees. An example is provided by the famous English chemist (Sir) Edward Frankland, who in the mid 1850s was acting as a consultant for Watney and Co. (Russell, 1996). Not surprisingly, some chemists encountered hostility when they introduced their new ideas into a long-established industry. One new appointee in the late nineteenth century was greeted with the comment 'Mr Chemist, you know everything. I only know one thing – I know you are wrong.' (Institute of Brewing, 1986).

During the eighteenth and nineteenth centuries the major beer styles acquired the characteristics and the names by which they are known today. Traditional English beers are produced by top fermentation, i.e. the yeast floats on top of the fermenting liquid. English bitter and pale ale, two well-hopped beer styles (Section 2.6.13) are produced by this method. Porter (Section 2.6.13), which was especially associated with London breweries, has fallen out of favor, but in recent years some breweries have revived it. Porter is usually of a medium dark color as a result of the extent to which the malt is toasted. The Guinness brewery in Dublin manufactured a darker product, which from 1820 was known as extra stout porter, subsequently abbreviated to stout. However, the most popular kind of beer in the world today is lager, produced by bottom fermentation. This type of beer was first brewed in cool caves in Europe about 500 years ago. Its production on a large scale only became feasible after the introduction of refrigeration in 1876, as the fermentation is conducted at a temperature of 5–10 °C, at which temperature the yeast sinks to the bottom. The beer is then allowed to age for 60–90 days in a store designated by the German word *lager*, and hence all bottom-fermented beers are known as lagers. There are varieties of yeast that are specially adapted to bottom fermentation, and another major achievement of the Carlsberg laboratory was the isolation of one of these, *Saccharomyces carlsbergensis*, by Emil Christian Hansen in 1883. Lager beers have subsequently become enormously popular in Europe, the USA and Australia. The town of Pilsen, in the Czech province of Bohemia, gave its name to a golden colored

bottom fermented beer variously known as Pilsener, Pilsner or Pils, and other varieties of lager are associated with České Budějovice (Budweis), Dortmund, Munich and Vienna.

The winemaker, like the brewer, is faced with the problem of avoiding unwanted processes occurring during production and storage, which will spoil the final product. It has already been noted that the Romans used sulfur dioxide as a sterilant. The technique was to burn a sulfur candle in the vessel before adding the wine. Sulfur dioxide acts both as an antimicrobial agent and as an antioxidant, and today it can be used at all stages of the wine making process, from crushing to bottling. Fortunately the yeasts that cause fermentation are less susceptible to sulfur dioxide than the spoilage organisms. Another practice dating from ancient times was the addition of lead compounds to wine. Lead in solution inhibits the growth of microbes, and if lead oxide is added to wine in which acetic fermentation has occurred, or in which the ethanol has been oxidized significantly, it will react with the acetic acid to form lead acetate. This has a sweet taste, so lead oxide not only arrested the spoilage of wine, but restored its taste. However, lead is poisonous to humans, and wine that contained lead was responsible for a range of illnesses amongst consumers, which on occasions were fatal. It was not until the eighteenth century that the dangers of adding lead compounds to wine were generally accepted and the practice was outlawed.

Apart from Lavoisier and Pasteur, a number of other French scientists performed important work of relevance to the alcoholic beverages industry, especially winemaking. In 1801 Jean-Antoine Chaptal (1756–1832) published a book on winemaking, which had a significant impact, advocating that some traditional practices should be discarded in favor of a more rational approach. Among his recommendations was that sugar could be added to grape juice if without it the resulting wine contained too much acid relative to the alcohol to be palatable. Although this idea had earlier been suggested by others, it was Chaptal's advocacy that resulted in its adoption, and the process is known today as *chaptalisation.*

In Europe in the nineteenth century, a series of disasters befell the wine industry. In the 1840s, powdery mildew, a fungus native to the USA, was first found on European vines. It had the effect of reducing yields and producing off flavors in the affected grapes. The problem gradually increased, especially in France, where the vintage of 1854 was disastrous. Sulfur is an effective fungicide against powdery mildew, but it was only after the crisis of 1854 that most French growers adopted the remedy. But much more serious was the phylloxera epidemic, which commenced in the 1860s. Phylloxera are tiny yellow sap-sucking insects that attack the roots of the vine, causing damage which, coupled with the secondary fungal infections introduced by the insects, is lethal to the plant. Phylloxera was endemic in North America, where the native grapes species were naturally resistant, but the European *vinis vinifera* was highly susceptible. The effect was devastating, especially in France, where total wine production fell from 84.5 million hl in 1875 to 23.4 million hl some 20 years later. Many remedies were tried, which ranged from the rational (injecting insecticide into the soil) to the superstitious (burying a dead toad under each vine), but the eventual solution was to graft European grape varieties on to North American rootstocks. Suspicions that the taste of the grapes might be affected proved unfounded. The two scientists most closely involved with developing this remedy were Charles Valentine Riley (1843–1895), an entomologist working at the US Department of Agriculture, and Jules Émile Planchon (1823–1888), head of botanical sciences at the University of Montpellier. As a result the European wine industry recovered, but nevertheless many vineyards were never replanted. The solution to phylloxera brought another problem in its wake, namely that of downy mildew, which was introduced on the imported rootstocks. An effective agent to combat this fungus, a mixture of copper sulfate and hydrated lime, was developed by Pierre-Marie-Alexis Millardet (1838–1902), professor of botany at the University of Bordeaux. It is still used as a fungicide under the name *Bordeaux mixture*.

Just as the term 'beer' had come to acquire an agreed meaning, it was during this period that regulations were first established concerning what practices were permissible for a certain type of wine and what nomenclature could be adopted. An early demonstration of the importance of having agreed procedures associated with a particular product was provided by port wine in the early eighteenth century. By 1730 the English thirst for

port had risen so much that the producers were unable to meet the demand so they began to blend inferior wines with the genuine ones from the Douro. They also added extra sugar for sweetness and elderberry juice to obtain the required color, and they flavored the wine with pepper, cinnamon and ginger. The consumers soon detected the reduction in quality, and in consequence the amount of port shipped to England fell by more than 50% between 1728 and 1756, and the price fell by more than 80%. The Portuguese government reacted by designating the area within which Douro wine could be made, thus creating the world's first officially controlled wine-growing region. The wine-making process was also supervised. These measures were extremely effective, and by the 1770s exports to England were about 50% higher than they had been before the malpractice commenced.

Legislation similar to that pioneered by Portugal now exists in many wine growing countries for their high quality wines; an example being France which awards the designation Appelation Contrôlée (or Appelation d'Origine Contrôlée). This delimits the geographical boundaries of the area in which the named wine can be grown, and governs matters such as which grape varieties can be planted, how they should be pruned, when the harvest may begin, etc. However, with the exception of Portugal, such legislation was not introduced into most countries until the twentieth century, but well before that time distinctive styles of wine had come to be associated with certain countries or regions. Thus the Bordeaux region of France became associated with a style of high quality red wine called claret by the British, although the region is also famous for its white wines. Other regions of France associated with particular wine styles are Burgundy (Bourgogne) and Champagne. In 1855, prior to the Universal Exhibition in Paris, Napoleon III requested that a quality ranking be given to the best Bordeaux wine-producing châteaux whose products were to be on display to visitors. The result was the *cru* system of classification, in which the 61 best red wines were placed in five categories ranging from Premières Crus (first growths) to Cinquièmes Crus. All the wines were from the Médoc region with the exception of one of the four Premières Crus (Château Haut-Brion), which was from the Graves region (Pessac). The white wine classification was limited to the sweet wines of Sauternes and Barsac, and comprised one Première Cru Supérieur (Château d'Yquem), with 11 Premières Crus and 15 Deuxièmes Crus. The classification has remained almost unchanged ever since, the only significant modifications being the addition of another Cinquième Cru in 1856, and the elevation of Château Mouton Rothschild from Deuxième to Première Cru in 1973. Not to be outdone by Bordeaux, Burgundy soon introduced its own cru classification, with the result that about 600 vineyards now qualify for the appellation Premier Cru, and 33 Grand Cru. The Champagne region also introduced its own cru classification in which each of the 300 villages in the region was given a percentage score indicating its grape growing potential. Grand Cru status is held by the 17 villages graded at 100%, and Premier Cru by the 38 villages graded at 90–99%. No village producing grapes for Champagne is graded at less than 80%. Some growers make their own champagne, but most sell their produce to the champagne houses or to cooperatives. Most champagne is therefore made from grapes from a variety of sources, but the famous champagne houses (the Grandes Marques) strive to use grapes with the highest possible average percentage score.

The story of whisky production in Scotland in this period is not so much one of changes in the methods of production, but one of an ongoing battle between the thousands of illicit distillers and the excise men. The Scottish Parliament had already started to tax the whisky in the preceding century, but after the Act of Union between England and Scotland in 1707, the taxes became ever more oppressive. Evasion of an unreasonable duty on the national beverage imposed by a government regarded as foreign was seen as acceptable behavior, and anecdotes abound of illicit stills in the countryside, of whisky being stored under pulpits or being transported in coffins, and there is one story of a 70 yard underground flue being constructed from an illicit still to a cottage chimney so that the smoke would not arouse suspicion. The situation was eventually brought under control when the Duke of Gordon, on whose land a number of illicit distillers operated, proposed in the House of Lords that all distilleries should be licensed, and that a fair duty should be paid on the whisky produced. This eminently sensible proposal was incorporated into the Excise Act of 1823,

and enabled whisky distillers to operate legally and to make a fair profit. Within 10 years almost all the illicit stills had disappeared.

A very similar situation existed in eighteenth century Ireland with the illicit production of their whiskey, but in this case one of the hated excise men was to perform an a valuable service for the industry. In 1821 Aeneas Coffey (*ca*.1780–1852) commenced experiments to devise a still, which made illicit abstraction of the product impossible. In 1824 Coffey resigned from the excise service to continue his experiments, and by 1830 his design was perfected. Aside from any possible benefits to the revenue, the Coffey still performed fractional distillation on a continuous basis and thereby produced spirit more quickly and more cheaply than the traditional pot still, which distils one batch at a time. The Coffey still (Section 3.1.3) continues to be widely employed in the production of spirits.

Licensed Scotch whisky distilleries increased in number and size as a result of the 1823 Excise Act, and this enabled modern whisky styles to evolve. The Coffey still was introduced for the manufacture of grain whisky, which is made by adding unmalted barley or other grains to malted barley prior to grinding. Malt whiskies are produced solely from malted barley, with two distillations being performed on the fermented wort using traditional pot stills. Blended whiskies contain 10–50% malt whisky mixed with grain whisky. In 1877 the Distillers Company was formed by the amalgamation of six grain distilleries, and it eventually grew to dominate the Scotch whisky industry. Whiskies are made in many countries, but to be called 'Scotch' a whisky must have been distilled at a licensed Scottish distillery and must have been matured in oak casks in Scotland for at least three years. Among the more famous whiskies produced outside Scotland is Bourbon, which gets its name from a former county of that name in the state of Kentucky. It was first produced there in the eighteenth century, and is made from a grain mixture containing mainly corn (maize), the remainder being wheat and/or rye, and malted barley (Section 3.3.4). It is aged in charred oak barrels. At around the same time the first whiskies were made in Canada by Scottish immigrants, and as a result the Canadian beverage is spelt the Scottish way (whisky) rather than in the Irish or American manner (whiskey).

Like the whiskies, other spirits acquired their modern characteristics during this period. Cognac (Section 3.6.2) emerged as one of the most famous brandies, and to be called a cognac the brandy must be distilled from wine made from certain specified white grape varieties grown in the Cognac region. The classification system was introduced by Hennessy, the firm founded in Cognac by the Irish immigrant Richard Hennessy in 1765, and indicates what period of aging in oak barrels the cognac has undergone, although the system is used on other brandies as well. The letters 'AC' indicate two years' ageing, 'VS' indicates three, 'VSOP' four and 'XO' six. In the nineteenth century, the Coffey still started to be used in the rum industry, and now the majority of rum is distilled by this technique (Section 3.5.3). The Coffey still produces a lighter rum than the pot still. After distillation the product is aged for at least a year, and is then usually blended to ensure consistent quality. In the nineteenth century the liqueur industry expanded considerably, especially in France. The most widely used technique is to add fruit or herbs to a spirit and then redistill (Sections 3.9.2 and 3.9.3). The distillate is then sweetened and possibly further flavoring may be added in the form of essential oils or clear vegetable extracts (Section 3.9.6)

1.2.4 Modern Times and Newer Processes (*ca*. 1900–Present Day)

In the early years of the twentieth century, the alcoholic beverages industry faced a threat that had been growing slowly for many years. This came from various temperance groups and societies opposed to the activities of the industry. They argued that alcohol consumption was a social evil, stressing that drunkenness resulted in family poverty, domestic violence, crime, insanity, immorality and suicide, to name but a few. Almost every country in the western world had its societies opposed to the industry, although their character varied considerably (Section 5.6.1). The movement was weakest in France, where the production of wine was

of huge economic importance and a matter of national pride, and its consumption was a national pastime. In as far as there was opposition to alcohol in France, it was mainly spirits which came in for criticism, for there was a reluctance to believe that the intoxicating principle in wine and spirits was the same substance in different concentrations. The temperance movement was stronger in Britain and the USA, although the many groups had different objectives. Some campaigned for an outright ban, while others wanted to ban just the sale of spirits or restrict the locations where alcohol could be sold and the times at which it could be purchased. In Britain it was the outbreak of World War I in 1914 that was the spur to the enactment of the first legislation (Section 5.6.1). There was a fear that inebriated personnel might disclose information to enemy spies, especially in the ports, and that drink might result in a reduction in efficiency of workers in factories producing goods for the war effort. Accordingly, restrictions were placed on the opening hours of public houses, brewers were forced to reduce the strength of their beer and excise duty was increased substantially. By the end of the war, beer consumption in Britain had fallen dramatically.

In the USA, individual States had on occasions banned alcohol at various times in the nineteenth century, but in 1920 the temperance movement achieved what it must have regarded as a triumph when prohibition was introduced. Although this had a serious effect on the alcoholic beverages industry, not all producers were forced to close. Products containing up to 0.5% alcohol by volume were permitted, and breweries produced drinks marketed as 'cereal beverages' which satisfied this criterion. They were known by the public as 'near beer.' An illegal practice was to add alcohol to near beer through the cork using a syringe, and the product was called 'spiked' or 'needle' beer. Some vineyards sold grape juice or bricks of dried grapes. These were often marketed with the warning that they could produce an alcoholic beverage if mixed with sugar, water and yeast – just what one needed to know for clandestine operations in the back kitchen. Not surprisingly alcohol continued to be available through illicit shops and bars ('speakeasies'). The ban undoubtedly encouraged criminality, and the Chicago gangsters Al Capone and his rival Bugs Malone made millions of dollars by selling illegal alcohol. In 1933 prohibition was rescinded. Prohibition was also in force in Canada around the same time, but the laws were enacted (and repealed) on a province-by-province basis and in a much looser and less well-defined manner. Nordic countries, with the exception of Denmark, also had periods of prohibition, and they still strictly control the sale of alcohol.

In Britain demand for beer picked up after World War I, and the industry revived in the USA after prohibition. However, in Britain, after the post World War I peak, there was a gradual decline in beer consumption. At the same time the number of common brewers decreased, as a result of closure, merger or takeover, while the size of the remaining companies increased. A typical example of this can be seen in Table 1.2.1, which traces the number of breweries in the (now) city of Cambridge from the late nineteenth century to the present day. This situation was partly due to the same factors that had started the process in the nineteenth century, especially the continuing improvement of the transport system, but also the rise of the advertising industry resulted in the promotion of nationally recognisable brands. Another reason was that many brewers owned a considerable number of pubs (tied houses), and as a result they were taken over by larger brewers who wished to increase the number of outlets for their products. The process of amalgamation has occurred the world over, with the result today that the largest breweries (along with their brands) in many countries are owned by national or international companies, most of which have diversified interests in other areas of the food, drink

Table 1.2.1 *Decline in number of breweries in the borough (now city) of Cambridge, UK*

Year	1888	1900	1925	1950	1975	1984	2008
Number of breweries	30	13	6	5	0	1	1*

*There are also two small breweries just outside the city boundary: one in Milton and one in Chittering.

or leisure industries. Most of the world-famous beers are owned by these companies: for example Beck's (Germany) is owned by Anheuser Busch InBev, Pilsner Urquell (Czech Republic) by SABMiller and Guinness (Ireland) by Diageo. By1999, the 10 largest groups controlled half the world beer market (see Section 1.3.2, Tables 1.3.1 and 1.3.2).

Scientific research and technical innovation continued to play a crucial role in the development of the industry. Beer was sold in bottles in England as early as the seventeenth century, but sealing the bottles was a problem. Holding down conventional corks with copper wire was not always successful. The crown cork (or crown cap) was invented in 1891, which not only provided a reliable seal, but meant that the bottling process could be automated. Another problem that technical developments were able to overcome around this time was that the bottled beers displayed cloudiness unless poured very carefully. This was due to a yeast suspension from secondary fermentation occurring in the bottle. Cloudiness was not really noticeable in the darker colored beers (porter and stout), but in the paler products that were gaining in popularity at this time it was undesirable. A variety of techniques were employed to render the beer completely clear and prevent further fermentation occurring. These included pasteurization, refrigeration and filtering (Section 2.6.9). Once the possibility of secondary fermentation had been removed there was no way that further carbon dioxide could be generated in the bottle to render the product sparkling, so the beer was artificially carbonated. These technologies were developed for bottled beer at the end of the nineteenth century, but were also applied when canned beer was introduced in 1935. Initially the cans were made of tinplate, but aluminium cans began to be used from 1959. At about this time breweries started to supply bars and public houses with beer treated in a similar manner and delivered in aluminium containers called kegs (Section 2.6.11). The barperson, rather than pump the beer up from a wooden barrel by a hand pump (Section 2.6.11), merely turned a tap and the beer was forced up by the pressure of carbon dioxide from a cylinder of the gas connected to the keg.

In the latter part of the twentieth century many breweries replaced their fermenting vessels with much larger cylindroconical tanks (Section 2.6.8). At the end of the fermentation, the yeast sinks into the conical lower portion of the vessel where it can be easily removed. An innovation for which there was initially much enthusiasm around 1960 is continuous fermentation (Section 2.6.8). In principle the idea is very attractive, for the yeast is immobilized and the wort passes through it on a continuous basis. This should result in a shorter production time being required to produce the beer, involve less time spent on cleaning operations than with the batch process, and hopefully give a more consistent product. However, although the process is used by some breweries, particularly for rapid maturation, it has proved to be difficult to operate and it has not been generally adopted.

Guinness's bottled stout was a famous drink throughout Britain during the first half of the twentieth century, advertized under the slogan 'Guinness is Good for You.' In 1964 draught Guinness was introduced, with the kegs containing nitrogen under high pressure, which resulted in a creamy head of fine bubbles forming on the drink when the liquid was forced through fine holes in a plate in the tap. So successful was this that the company embarked on research to replicate the effect on Guinness sold in cans. The result was the widget, a hollow plastic insert in the can that contains both the beer and nitrogen under pressure. Opening the can causes beer to squirt out of the widget, thus stirring the beer in the can and causing the release of further dissolved nitrogen as small bubbles. The idea has been adopted by a number of other brands, which are known as cream flow beers.

Towards the end of the twentieth century increasing health concerns created a demand for beers of reduced alcohol and/or carbohydrate content (Chapters 2.13 and 5.7, respectively). These are variously marketed as light (or lite), diet or low calorie beers. In the UK, for a beer to be described as alcohol-free it must contain no more than 0.05% alcohol, whereas up to 0.5% alcohol is permitted in the rest of the European Union. In the UK a beer designated as low alcohol must have no more than 1.2% alcohol. Thus consumer demand has led to the production of beers somewhat similar to those forced on an unwilling American public during prohibition.

A much more significant example of consumer pressure altering the practice of breweries in the UK is provided by the activities of CAMRA (Campaign for Real Ale) and similar groups. CAMRA was founded in 1971 to put pressure on breweries and public houses to provide traditionally produced cask-conditioned ales as an alternative to the keg beers, which by then had become almost universal (Section 1.3 4). Older styles of beers such as porter have been reintroduced, and the use of older flavorings such as coriander has been revived (Section 2.6.13). The campaign has been an undoubted success and cask-conditioned ales are now available in 65% of all public houses in the UK, and while overall beer consumption in the UK continues to fall slowly, the sale of cask-conditioned ales continues to rise. An allied change is that many public houses are once again brewing their own beer (real ale) in so-called microbreweries (Sections 1.3.3 and 1.3.4). This section of the market is growing strongly, aided by the introduction by the UK Government of a lower duty on beer produced by small breweries, and by increasing environmental concerns expressed by consumers (a locally produced beer has fewer 'beer-miles'). Among the many examples of microbreweries that can be cited is that owned by the Kirkstile Inn in the small village of Loweswater in the English Lake District. The landlord currently sells 30 000 l per annum of his own beer, 6000 l per annum of cask conditioned ales from other local breweries and 9000 l per annum of other beer, lager, Guinness and cider. If these figures seem large for a village with a total population of around 200, it must be remembered that a large part of the consumption is by visitors who come to this beautiful part of England and visit this lovely traditional hostelry. Another consumer demand that has grown recently is that for organic beer (Section 1.3.12). Although sales are still small, beers produced from organically grown barley and hops are increasing in popularity.

Looking again to the East, rice wine brewing technology advanced steadily during the twentieth century, particularly in Japan. The Japanese Government opened the Sake Brewing Research Institute in 1904, which was to become the focus of developments in sake brewing. Yeast and mould strains were isolated and those that were most beneficial to the brewing process were identified and cultured. Amongst other changes, enamel-coated steel tanks replaced wooden vats for the storage of sake. The tanks were not only considered more hygenic than wooden vats, but they also prevented the 30% loss due to evaporation in wood vats, thereby increasing the government's tax revenue from sake. Like its western counterparts, sake has long been taxed by the government. Again, like its western counterpart, the fortune of rice wine in general has been has been subjected to the vagaries of ecomomic and social changes, including wars.

During the Russo-Japanese War in 1904–1905, the government banned the home brewing of sake and toward the end of World War II, limitations were imposed on the use of rice for brewing, because of rice shortages. The World War II period also witnessed necessary production changes and innovations, some of which are still in use today. In the late seventeenth century, it had been discovered that small amounts of rice wine spirit could be added to sake before pressing to extract extra aromas and flavors from the rice solids, but during World War II, pure alcohol and glucose were added to relatively small quantities of rice mash, giving a considerably increased yield of sake. Today, much of Japan's sake is produced by a similar method, although more traditional methods are still in use (Section 2.7.1). The popularity of sake in Japan has more or less waned since 1945, in favor of shochu, domestic and imported whisky, wine and other drinks. However, sake has become a popular drink in many other countries, new sake breweries springing up in countries as far apart as Australia and the USA.

Prior to the annexation of Korea by Japan, rice wines were, along with soju, the everyday alcoholic drink of the Korean people, much of it home-brewed. However, during the period of Japanese occupation (1907–1945), the Government General of Choson collected a liquor tax from Korean people, which eventually led to the near disappearance of traditional brewing in Korea. Even as early as 1916, the severe control of alcohol liquor manufacture had reduced the variety of Korean alcoholic drinks to basic yackju, makkoli and soju and the production of high quality Korean traditional alcoholic beverages had diminished. By 1930, the recipes for brewing unique regional and provincial liquors had been put aside and these special drinks had disappeared.

After the liberation of Korea in 1945, a frequent shortage of rice and other grains led to a marked deterioration in the overall quality and consistency of Korean rice wines. Since the 1990s, however, the consistent use of rice for brewing, along with technical advances in the brewing process, has resulted in a steady increase in quality of all the different kinds of rice wine, so that today the consumer has a wide choice of high quality rice wines, including flavored versions (Section 2.7.1).

The grape wine industry in the twentieth century saw a series of dramatic changes, especially after the end of World War II. Shifting patterns of demand and supply, changing consumer preferences and continued improvement in transportation systems (especially containerized freight) all conspired to create opportunities for some wine producers and problems for others. Demand fell steadily in the traditional wine consuming countries of Europe, whereas production increased. In the late 1940s, per capita consumption of wine in France stood at 150 l, but 50 years later it had declined to 60 l. The social and cultural changes responsible for the decline have been much discussed, but one reason seems to be that as the standard of living has improved, the average French family, instead of consuming large quantities of *vin ordinaire* with every meal, now drinks smaller quantities of better quality wine. Another reason is the growing awareness of the dangers of consuming alcohol at the workplace or before driving a car. The reduced consumption in France, which was mirrored in other countries such as Italy, resulted in a vast European stockpile, called the 'wine lake.' In the early 1980s, the European Economic Community (as it was then called) sought to remedy the situation by forcing the distillation of some of the surplus to produce industrial alcohol, and introducing a compensation scheme to encourage farmers to pull up their vines and grow something else instead. This policy had the effect of reducing the total area of vineyards in Europe from 4.5 million hectares in 1976 to 3.4 million in 1997, and the huge surplus of European wine has almost disappeared.

As demand was declining in Europe, more efficient methods of production were being introduced around the world. Traditionally, caring for a vineyard had been a very labor intensive business, but the introduction of tall tractors with wheels that could straddle a row of vines meant that operations such as spraying could be carried out much more quickly and more thoroughly, and picking could be mechanized. Many changes have been introduced into the winemaking process itself, the aim being to improve efficiency or quality (or both). Refrigeration is often employed to preserve the quality of grapes or juice prior to fermentation, and some winemakers delay fermentation for long periods so that production can be continued in batches for much of the year. Although some winemakers still use traditional wooden vats and barrels for fermentation and maturation, vessels made out of stainless steel are now common (Sections 2.9.1 and 2.9.2). These can be very large compared to their wooden counterparts, and careful temperature control and cooling by refrigeration may be required to dissipate some of the heat produced in fermentation. This is especially important for white wines for which low temperature fermentation produces the best results. To press the juice from the grapes, the traditional wooden basket press has now largely been replaced by the pneumatic press, in which a slowly inflating airbag within a rotating perforated steel cylinder gently expresses the juice (Sections 2.9.1 and 2.9.2). Pumps and pipes are now universally employed to move liquids around. Sulfur dioxide is now added to wine in the form of potassium or sodium metabisulfite, which being solid is much easier to handle (Sections 2.5.2 and 2.5.3).

Traditional fermentation relies on yeasts existing on the skins of grapes or in the winery to enter the vat naturally. Usually inoculation by these so-called wild yeasts occurs satisfactorily, but sometimes a fermentation is slow to start, and a batch becomes stuck. Cultured yeast strains are now available to initiate fermentation in a reliable and consistent manner, but their use is still attended by considerable controversy. Another possibility available to the modern winemaker is to induce malolactic fermentation, the process by which malic acid is converted to lactic acid. The organisms responsible are bacteria (e.g. *Oenococcus oeni*) (Section 2.3.2) rather than yeasts. The process can occur naturally during primary alcoholic fermentation, but the winemaker usually suppresses this using sulfur dioxide to prevent undesirable strains of bacteria producing off flavors. Malolactic fermentation is then induced at a later stage by inoculation with a suitable

strain of bacteria. Most red wines and an increasing number of whites now undergo this process, the effect being to increase the stability of the wine, and to make it taste softer, but more complex. Research has been done to investigate the possibility of carrying out wine fermentation on a continuous basis. Experiments have been performed using yeast cultures immobilized on cuts of apple or quince, but so far this has not become a standard method in wine production.

While few would disagree that the traditional Champagne method (Section 2.9.3) produces the best sparkling wine, new (and less expensive) techniques were devised in the twentieth century. A simple method, which is only used for the cheaper wines, is to pump in carbon dioxide under pressure immediately before bottling. A more sophisticated process is one in which the carbon dioxide is produced by a second fermentation in a large tank (*cuvée close*), rather than in the individual bottles as in the true Champagne method.

Beaujolais is a wine that has received more attention in the second half of the twentieth century, mainly through the clever marketing of Beaujolais Nouveau. The fermentation technique employed is that of carbonic maceration (Section 2.9.2), in which whole bunches of grapes are allowed to ferment in an atmosphere of carbon dioxide. To a certain extent this used to occur naturally in barrels of grapes awaiting processing, when the grapes at the bottom became crushed, started to ferment and the carbon dioxide released displaced the air from around the grapes higher up. The process is now done on a controlled basis by pumping carbon dioxide into tanks containing the grapes. Fermentation takes place within the intact grapes, and after pressing and pasteurization to inhibit malolactic fermentation the wine is bottled. The carbonic maceration method produces a light fruity wine low in tannins that is best if drunk young. Sales have soared as a result of publicity surrounding the races to get the new wine to markets around the world immediately after the official release day a few weeks after harvest.

There is general agreement that good quality wines benefit from being aged in new oak barrels, but this is of course an expensive process and a modern alternative is to allow the wine to mature in a tank containing oak chips (Section 2.9.5). Traditionalists rightly point out that the effect is not quite the same, but their opposition to another innovation, namely plastic stoppers or screwcaps in place of corks, would appear to have little foundation. Prior to bottling, most wine is clarified to remove any traces of sediment or any remaining organisms. The new method of achieving this is by centrifugation or filtration, but the traditional method of fining is still much used (Section 2.9.4). Beaten egg whites are often added to wine matured in wooden barrels, while a type of clay called bentonite is used in larger tanks.

The alcohol content of wines varies considerably. Wines produced in cooler areas will, unless chaptalized prior to fermentation, be lower in alcohol (sometimes lower than 9%), but in general the alcohol content of wines has tended to increase in recent years, now typically being of the order of 12–14%, although fashions change from country to country and from year to year. In consequence a demand has grown for lower alcohol wines, and in the UK in 2007, the supermarket chain Sainsbury's launched their 'Ten%' range of wines. However in the same year the UK Food Standards Agency banned a company from selling wine reduced to 8% alcohol because the technology used to reduce the alcohol content (spinning cone column) (Section 2.13.3) was unauthorized. In California the Ariel company produces nonalcoholic wine (less than 0.5% alcohol) by the use of reverse osmosis (Section 2.13.3). Starting with wine of normal composition, the process removes both alcohol and water, so the resulting syrup is diluted with pure water. In the same way that a demand has arisen for organic beer, there is now likewise a market for organic wine, with the grapes being grown without synthetic fertilizers fungicide or pesticides, and without the use of sulfur dioxide.

While wine continues to be by far the most popular drink based on a fermented fruit juice, cider sales have been growing in recent years. In the UK one company, H.P. Bulmer, has more that 50% of the market (Sections 2.8.6 and 2.8.8). Perry experienced a surge in popularity in the UK after the launch of the Babycham brand in 1953, but its popularity declined in the 1970s. However, it was probably Babycham more than any other drink that introduced ladies in Britain to the pleasures of alcohol consumption. For many years concentrated grape juice has been imported into Britain to be diluted and fermented to produce so-called 'British' wines.

In the days when no grapes were grown in Britain for commercial production of wine, this labeling did not cause confusion. Nowadays, as a result of the efforts of an intrepid band of pioneers (such as Ray Barrington Brock, Edward Hyams, Gillian Pearkes, Sir Guy Salisbury-Jones and Jack Ward) and a warmer climate, the country boasts over 350 vineyards and in consequence there is now an element of misunderstanding. The wine from these British vineyards is labeled 'English,' 'Welsh' or 'United Kingdom.' Most of the vineyards are located in the southern parts of England and Wales, but a bold experiment is taking place in the north of England at High Cup Wines on the edge of the Pennines in Cumbria. The principal products are wines made from fruits such as elderberry and damson, but six varieties of grapevines are grown. The most successful at yielding wine so far has been the red *V. vinifera–V. amurensis* hybrid *Rondo*.

We have seen how international companies emerged in the brewing industry in the twentieth century. A similar process occurred in the wines and spirits industries. One such company is the French concern Pernod-Ricard, which was formed in 1975 by the merger of the rival Pernod and Ricard concerns. They both manufactured pastis, a drink similar to absinthe, but with a lower alcohol content and without wormwood, which was introduced after absinthe was banned in 1915. In recent years the company has acquired Irish Distillers, Orlando Wyndham (makers of Jacob's Creek wines), 38% of Seagram's wines and spirits business and Allied Domecq. Another large concern is the Japanese company Suntory, which produces beer and spirits in Japan, and has also branched out into the genetic engineering of plants with the Australian company Florigene, in which it now holds a 98.5% share. In 1987 a significant proportion of the Scotch whisky industry came under the ownership of United Distillers, which was formed from the merger of the Distillers Company Limited with Arthur Bell and Sons. It is now part of the Diageo group, which owns many world famous brands of beers, wines and spirits, producing one third of all Scotch whisky.

In the second half of the twentieth century, the pattern of whisky consumption changed. In the 1950s, the consumption of single malts was largely confined to Scotland, with the export trade consisting mainly of blended whisky (that is to say malt whiskies blended with grain whiskies). Somewhat confusingly, the term single malt refers to a blend of malt whiskies from a single distillery. In most cases, these will be malt whiskies from different casks and from different distillation batches (from different years) vatted together in a tank or vat for consistency, although the age statement on the bottle label (e.g. 15 years old) must reflect the wood-maturation age youngest component (Section 3.2.5). Gradually the rest of the world acquired a taste for single malts, with the result that they are now the flagship product of the industry worldwide. Demand for blended whiskies, including 'de luxe' blends, is still high, especially in some European countries (France and Italy) and in Asian countries such as India and South Korea.

Production of Korean soju, like rice wines, suffered under Japanese rule, but was revived after the liberation of the country in 1945. However, Korea at that time was a poor country, a situation not helped by the Korean War (1951–1953), and many of the traditional recipes had been obscured or even lost. On top of that, raw materials for the production of soju, especially rice, were periodically scarce. During the period 1965–1991, the Korean government amalgamated and reorganized the distilleries into regional and provincial conglomerates and forbade the direct production of soju from fermented rice mash. Instead, highly rectified spirit from any source was mixed with water and flavorings to create what is known as diluted soju. Although the restriction has now been lifted, this cheaper version of soju continues to be made this way and is presently the more popular form of the drink, and altogether, soju may well be the world's most highly consumed spirit (Section 3.4.4).

The Korean government regulates the alcohol content of diluted soju to less than 35% ethanol by volume; in practice it is usually 20–25% ABV. Since the 1990s, several regions have resumed the traditional production of soju, by the distillation of grain (especially rice) mashes or wines, resulting in what is known as distilled soju, the original version. The soju from the city and environs of Andong is the most famous of all, with an ABV around 45% and having a powerful, malty character. There is now (2009) a trend amongst distillers to produce lighter, less powerful traditional versions of soju with alcohol contents of around 20%

(v:v) in reply of the popular move towards milder, less alcoholic spirits (a trend also occuring in Japan) (Section 3.4.4).

1.2.5 The Development of Analytical Methods

We have seen how during the nineteenth and twentieth centuries there was an improving level of understanding concerning many of the processes involved in alcoholic beverage production. The scientific explanations of what had for many years been the work of craftsmen, and the introduction of new techniques, had resulted in many changes in the production of beers wines and spirits. But not surprisingly there was an increasing demand for the application of analytical methods to assist in achieving consistency by monitoring the various stages of production of beverages, and assessing the quality of the final products.

Aside from the antics of the ale conner, an early method of quantitative measurement was the application of the thermometer, used by brewers from around 1760 to measure the temperature of the hot water in the mash tun prior to the grist being added. Previously the brewer had judged the temperature to be appropriate if he could just tolerate immersing his hand in the water, or if the reflection of his face in the surface of the water was just not obscured by the steam. A few years later the saccharometer was introduced. This was a hydrometer that measured the specific gravity of the wort, and hence provided a measure of its sugar content. These two pieces of apparatus remained the sole monitoring devices in use until the nineteenth century, when breweries started to use the microscope. More recently an enormous number of analytical techniques have been developed, many of which have found application in the alcoholic beverages industries.

The application of the thermometer and saccharometer did not require specialist staff working in a laboratory for their application. When brewery laboratories were established from the mid nineteenth century, the trained chemists hired to work in them introduced methods such as gravimetric and volumetric analysis. Both found application in the analysis of water supplies used by breweries. Volumetric analysis was also used to measure the acidity at any stage of production (Section 4.6.3). The Kjeldahl method for nitrogen (mentioned previously) operates by converting the nitrogen to ammonia, which is then distilled off, absorbed into water and titrated with standard acid (Section 4.6.3).

The importance of close analytical control in beer production was demonstrated by the so-called Manchester beer epidemic of 1900, when about 7000 people became ill, of whom 70 died. It was discovered that all had been consuming beer from the same two breweries, who in turn had obtained their sugar from Bostock and Co. of Liverpool. The sugar contained arsenic, derived from the sulfuric acid used in its manufacture, which in turn had been made using iron pyrites containing arsenic compounds, common impurities of iron pyrites. Two years later arsenic was detected in beer from a Halifax brewery. On this occasion there were no fatalities, and the source of the contamination was found to be the coke over which the malt had been dried. In 1903 a Royal Commission recommended that liquid foods should contain no more than 0.14 parts per million of arsenic. The quantification of arsenic at such concentrations was achievable by the methods available at the time, but previously the tests had not been carried out.

Almost all the techniques used to analyze beers wines and spirits were developed in other contexts, and then found application in the alcoholic beverages industry. However, one very important method was developed by an industry insider. He was Joseph William Lovibond (1833–1918), the son of a London brewer. He worked with his father until 1869, when he went to be director of another brewery in Salisbury owned by the family. Once there, he set about devising an objective method of measuring the color of wort and of beer. The color of the wort provides an indication of its quality, and measuring the color of beer itself was important because consumers were now demanding that it should be of a consistent appearance. This demand had arisen partly because pewter tankards were being replaced by transparent beer glasses, and partly because the traditional dark and somewhat murky porter beers were being superseded by the newer pale ales. In so far as attempts

had previously been made to record the appearance of beer, it had been done solely by visual inspection, using terms such as 'very pale,' 'fairly dark,' etc. Lovibond devised an instrument called a tintometer in which a sample of beer or wort was placed in a small glass cell and viewed with one eye down a narrow tube at the base of which was a white screen. The other eye looked at the same screen down a parallel tube into which could be inserted up to three colored pieces of glass. Different glasses were inserted until the two shades perceived by the observer were identical. The instrument was supplied with 450 standard glasses of red yellow and blue colors of different intensities. Lovibond devised a notation system to describe the color of the sample based on the combination of glasses used. From 1863 it had been permissible to add colorants such as caramel to beer, and the tintometer also found application in the evaluation of colorant preparations. In 1885 Lovibond founded a company to manufacture the tintometer. The company is still in existence, and an updated version of the instrument continues to find application in breweries and in whisky distilleries, and it can also be used to measure the color of wine (Section 4.4.3).

The Lovibond tintometer is an example of a kind of colorimeter called a comparator, as the color being measured is compared to a previously prepared colored standard. Of much more widespread application today are instruments that measure the proportion of light absorbed over a narrow band of wavelengths (photoelectric colorimeters) or at an individual wavelength (spectrophotometers). A spectrophotometer can also record the absorption spectrum over the entire visible (and ultraviolet) range, and therefore provides an objective graphical representation of the light absorbing characteristics (and hence color) of a sample. Colorimeters and spectrophotometers find important application in the quantitative estimation of individual compounds in a mixture (Section 4.4.3). The usual procedure depends upon employing a chemical treatment to react the compound being sought to yield a colored substance, whose absorbance (which is directly related to concentration) is measured using a colorimeter or spectrophotometer. Two examples of this technique in use at the present time are the Folin–Ciocalteu method for measuring phenolic antioxidants in wines, and the Rebelein method for measuring the concentration of tartaric acid and tartrates in wine (Section 4.4.3).

The spectrophotometer provides an example of the entry into analytical chemistry of the kind of equipment that is now widespread and commonplace. Using instruments containing sophisticated electronics and linked to computers, the capabilities of analysts have been greatly extended. Alcoholic beverages, especially wine, contain an enormously complex mixture of organic compounds, and until the middle of the twentieth century the identification and quantification of most of these substances appeared to be a superhuman task. However, there was an overpowering need to obtain a better understanding of beverage composition, partly to assist in more rigorous quality control, and partly to quantify components that might convey health benefits or health risks to consumers (e.g. anthocyanins and *N*-nitroso compounds, respectively). Modern instrumentation has provided the means by which much of that need can be met.

Another benefit of the introduction of modern methods has been the increase in the speed at which analyses can be performed. This is well illustrated by the various methods that have been used to analyze metals in water and in drinks. The classical method of gravimetric analysis provides a very accurate measure of the concentration of a metal such as calcium, but it is a slow procedure. In the 1920s the method of flame photometry (Section 4.4.4) was developed, in which the solution under test is sprayed into a flame, with the consequence that some of the metal atoms are excited and then emit light of characteristic wavelengths as they return to the ground state. The light is passed through a suitable filter, and its intensity is measured, thus providing a measure of the concentration of the metal. The method is reasonably sensitive for metals such as sodium, potassium and calcium, but less so for metals such as copper (which could be in wine as a result of treating the vines with Bordeaux mixture), since the proportion of excited atoms is very low. In the 1950s the alternative technique of atomic absorption spectroscopy (Section 4.4.4) was developed, in which the much greater proportion of unexcited atoms is measured by passing an intense beam of light of a suitable wavelength through the flame and recording the resulting reduction in intensity. This technique can measure a much greater number of metals to an acceptable degree of accuracy. However, more recently still,

emission techniques have staged a comeback as a result of the development of plasma sources. In a plasma, a much higher proportion of metal atoms are excited and then emit light, and the intensity of the emission is measured. This technique (called inductively coupled plasma spectroscopy) is now the method of choice in many laboratories (Section 4.4.4).

Today, rather than using a titrimetric procedure, the acidity of a beverage is measured using a pH meter (Section 4.5.1). Although Sørensen introduced the pH concept in the early years of the twentieth century, direct reading pH meters were not available until soon after World War II, by which time the glass electrode, sensitive to hydrogen ion concentration, had been perfected, and suitable electronics had been developed for measuring the potential between the glass and reference electrodes. More recently a range of electrodes sensitive to other ions have been developed, and these ion-selective electrodes provide a rapid and nondestructive method of analysis (Section 4.5.1). One of the most important developments in this area has been the development of electrodes responsive to sulfites in wine. One recent publication described such an electrode that owed its sensitivity to sulfite by having the enzyme sulfite oxidase immobilized on its surface (Situmorang *et al.*, 1999).

Another electroanalytical method that has found increased application in recent years is that of conductivity measurement (Section 4.5.1), which is used to measure tartrate concentration in wine. Tartaric acid and tartrates are naturally present in grape juice, and may form crystals in the bottom of the wine bottle. Traditionally this presented no problem, but many contemporary consumers dislike seeing the crystalline deposit, and so tartrate removal, by cooling and filtering or by electrodialysis, is employed. Removal is continued until the conductivity has fallen to a level that indicates that tartrate crystals are unlikely to be deposited on storage.

The three techniques that have done most to revolutionize the identification of organic compounds are infrared spectroscopy (IR) (Section 4.4.2), nuclear magnetic resonance (NMR) (Section 4.4.1) and mass spectrometry (MS) (Section 4.4.5). An IR spectrophotometer records the various wavelength ranges at which a compound absorbs in the infrared, the pattern being due to the various types of chemical bond present in the molecule. In NMR the parameters under which a certain nucleus (e.g. ^{1}H or ^{13}C) resonates under the influence of radiofrequency radiation in an intense magnetic field are recorded; the exact conditions depend on the environment of that atom in the molecule. In MS a positive ion is generated from the molecule, which may then fragment, and electrical and magnetic fields are used to focus the various ions in turn on to a detector. The mass of the parent molecular ion and its fragmentation pattern are characteristic of the compound under investigation.

These methods are most frequently employed for qualitative analysis on individual compounds once they have been separated from the matrix in which they occur, but recently some quantitative applications have been developed for the beverage industry in which the entire sample is subjected to analysis. Thus an NMR spectrometer has been adapted in which an unopened bottle of wine can be placed in the machine to measure the ethanoic (acetic) acid concentration (Section 4.4.1) (Weekley *et al.*, 2003). This enables a judgement to be made as to whether an old bottle of wine has been spoiled by oxidation occurring as a result of a porous cork. Recent research has also been directed at the use of IR (Section 4.4.2) to monitor the progress of wine fermentation. Fructose, glucose, ethanol and a number of organic acids are measured on a continuous basis. Such methods are currently in their infancy, but they are likely to find wider application in the future.

However, more frequently, an individual compound is isolated from the matrix prior to analysis, and the most widely used separation technique is that of chromatography. This term covers a range of methods in which a sample of the mixture is injected into a mobile phase, which passes through a stationary phase. The compounds in the mixture will be attracted to both phases, and if different compounds experience differential relative degrees of attraction for the two phases, they will travel through the system at different rates. The technique was first demonstrated in 1903 by the Russian botanist Michel Semenovich Tswett (1872–1919), who separated a mixture of plant pigments using a vertical column containing calcium carbonate as the stationary phase, down

which was passed benzene as the mobile phase. Since that time a variety chromatographic methods have been developed, examples being thin layer (TLC) (where the stationary solid is coated on to a glass or plastic plate and the mobile phase rises up the plate by capillary action) (Section 4.3.1), paper (where the stationary phase is water held on paper and the water-immiscible mobile phase is soaked up by the paper) and gas-liquid chromatography (GC) (Section 4.3.2), where the mobile phase is gaseous and the stationary phase is a liquid held on solid beads). The technique most resembling Tswett's original method is high performance liquid chromatography (LC) (Section 4.3.3) where the mobile liquid is pumped through a column of stationary solid under pressure. All these methods have found application in the beverages industry.

The straightforward application of chromatography in qualitative analysis involves identifying the separated components by running known compounds under the same conditions. This is achieved in thin layer and paper chromatography by placing the sample and known compounds side by side on the same plate or paper, and then spraying the resulting dried chromatogram with a developing agent to reveal the final position of the compounds. In the case of GC and LC a detector is employed to signal a change in composition of the stream emerging from the column. The most widely used method of detection in GC is flame ionization, in which the gases emerging from the column are combusted in a stream of hydrogen in a burner. As they decompose, organic compounds produce ionic intermediates, which are detected by a pair of electrodes in the flame. Spectrophotometric detectors are most common in LC. These are set to a wavelength at which the analytes are known to absorb. Whatever the detection method, the retention time of a component in the mixture is noted, and this is compared with the retention times of known compounds run under identical conditions. The magnitude of the detector response (i.e. the area under the sample peak) provides a measure of the quantity of the analyte. Such techniques are well suited to detecting adulterants that have been added to alcoholic beverages. An infamous case occurred in 1985, when small quantities of Austrian wine were found to contain diethylene glycol, which had been added to make the wine smoother and sweeter (and able to command higher prices) (Prial, 1985). As a consequence, Austrian wine regulations are now some of the most stringent to be found anywhere, and the Austrian wine industry has recovered from the serious setback it received (Jarvis, 2005; Mariani, 2007).

Whilst chromatographic methods are by far the most important separation techniques employed in the beverages industry (and in chemical analysis generally), methods based on the phenomenon of electrophoresis are used as well (Section 4.6.1). The original method, introduced in the 1930s, used the application of an electric field to separate charged molecules applied to a horizontal support medium of paper or gel soaked in buffer. The rate of migration of an individual species depended on its size and charge. More recently the method has been miniaturized and automated and is known as capillary zone electrophoresis (CZE) (Section 4.6.1). The separation is achieved in a capillary tube up to 100 cm long and up to 100 μm internal diameter, and the emerging species are detected and quantified. An advantage of the method is that the bands of the various substances are much sharper than with LC. The method is applicable to the separation of uncharged molecules provided these can be converted to charged complexes (e.g. with borate), an example being its application to the quantitative determination of anthocyanins in wine. A technique that is to some extent a hybrid of CZE and LC is capillary electrochromatography (CEC). In CZE the buffer solution in the tube migrates under the influence of the electric field, a process known as electro-osmotic flow. CEC likewise employs as its mobile phase a buffer migrating under the influence of an applied electric field, but the capillary tube also contains a stationary phase similar to that used in LC. The high pressures of conventional LC are thereby avoided, and the method has the advantages of sample microvolume and sharp bands associated with CZE.

Most beverages are such complex mixtures that the analyst frequently requires a technique that will not only separate the individual components, but identify them as well. This can be achieved by linking a GC or LC apparatus to a mass spectrometer. Each compound yields a characteristic molecular ion and fragmentation pattern that are identified by reference to a computer database. The classical methods of ionization are

by electron impact (electron ionization or EI), which produces positive ions by electron loss, or by the gentler method of chemical ionization (CI), which produces positive ions by protonation. These methods are applicable to low mass thermally stable analytes. A more modern and even milder method of ionization for thermally sensitive compounds is atmospheric pressure chemical ionization (APCI), which, however, results in very little fragmentation of the positive ion. All these methods of ionization are applicable to small molecules, but it is also necessary to be able to detect and characterize large molecules such as proteins, as they affect the taste, clarity and stability of a beer or wine. For these samples a technique known as electrospray ionization (ESI) is used. The protein molecules are not fragmented, but emerge with a range of positive charges, typically in the range +10 to +22, and thus a spectrum of mass/charge ratios is produced.

It is frequently the case that the substances to be analyzed by GC-MS or LC-MS are present in such low concentrations in the matrix that some kind of prior concentration stage is necessary. Sometimes solvent extraction can be used, and on other occasions simultaneous distillation-extraction is appropriate (Sections 4.2.2 and 4.2.3). Other possibilities are the so-called sorptive methods, in which the solid phase sorbent and liquid containing the components (the matrix) of interest are allowed a certain contact time. During this time, components are selectively partitioned between sorbent phase and the matrix, usually according to their relative polarities (Section 4.2.4). The major techniques are known as solid phase extraction (SPE), solid phase microextraction (SPME) and stir bar sorptive extraction (SBSE). The sorbent material is often silica-based, crosslinked polystyrene-divinylbenzene (e.g. for SPE) or polydimethylsiloxane (PDMS) (e.g. for SPME and SBSE), but other materials are used. The sorbent and matrix are then separated and subjected to either a thermal desorption process or solvent extraction to free the extracted components in a more concentrated form. If thermal desorption is used, the liberated compounds are usually subjected to GC-MS (Section 4.3.2), whereas if a solvent is used in the desorption stage, then LC-MS (Section 4.3.3) is employed. These methods find considerable application in the estimation of a wide variety of compounds occurring in beers, wines and spirits. Sometimes an analysis is required of the volatile compounds given off by a beverage, in which case the sample is confined until the air in the space above (the headspace) is saturated with the volatile compounds (Section 4.2.5). A sample from the headspace can then be injected into a GC-MS apparatus, or if a concentration stage is necessary, a fiber of an SPME material can be employed.

The mass spectrometer can also determine the ratios of isotopes of a particular element in a compound (Section 4.4.5). This is most useful, because the ratio of $^{13}C/^{12}C$ or $^{2}H/^{1}H$ in a sugar or in ethanol depends upon the plant from which it was derived and the climatic area in which it was grown. As a result, fraudulent practices such as the mislabeling of a wine to suggest it comes from another country or area, or the addition of more than the allowed quantity of sugar during chaptalization, can be detected.

An even more sophisticated isotopic ratio technique is to use NMR (Section 4.4.1) to deduce the relative abundance of a particular isotope (e.g. deuterium, ^{2}H or D) at two different sites within a molecule. The principal example has been to measure the ratio of methylene deuterium (CH_3CHDOH) to methyl deuterium (CH_2DCH_2OH) in ethanol by comparing the intensities of the deuterium NMR signals for the CHD and CH_2D peaks. The technique, known as site-specific natural isotopic fractionation NMR (SNIF-NMR) can be applied directly to spirits, when it is found that the ratio depends upon the plant from which the ethanol was derived (e.g. potato or sugar cane) and the area of the world in which the plant was grown. The ethanol in wines and beers is too dilute for direct application of the technique, so these beverages need to be concentrated by distillation beforehand.

The ultimate analysis of any beer, wine or spirit is that performed by the consumer. His or her opinion is what matters to the producer, and throughout the alcoholic beverage industry, expert tasters assess the quality and development of their company products and give valuable advice on blending and adjustments to be made before sale. Organoleptic assessment and sensory analysis are still of prime importance in the production of alcoholic drinks (Chapter 4.7). Analytical instruments will continue to improve in their sophistication, and

the individual components of the complex matrix that makes up any beer wine or spirit will be quantified with ever greater accuracy. But in the future a totally new kind of instrument, the so-called artificial nose, may play a significant role in assessing the quality of beverages. Such instruments are currently under development, and consist of an array of sensors (Section 4.5.3), which detect individual compounds or specific groups of compounds. In one design, the sensors are made of different types of electrically conducting plastic. The conductivity of the sensors changes when the volatiles in the air are absorbed by the plastics. The changes in conductivity of the various sensors is relayed to a computer, which is 'taught' to interpret the new pattern. Artificial noses will probably find application in areas such as medical diagnosis (patients with diseases such as cirrhosis exhale characteristic odors), airport security and in detecting spoilage in foods. In the beverages industry, artificial noses have already found application. In the brewing process, a buttery off flavor can develop owing to the presence of diacetyl, which is converted to tasteless butanediol if the batch is rested (Section 2.6.4). An artificial nose can detect if a resting period is required.

The long history of alcoholic beverages commenced with a wine being tasted by a lady from the harem of the king of Persepolis, and has now reached the stage when some degree of assessment can be achieved by an artificial nose or a portable artificial tongue (Moreno i Codinachs *et al.*, 2008). The enormous improvement in the quality and consistency of alcoholic drinks over a period of thousands of years has been due to the combined skills of craftsmen, technologists and scientists. There is no doubt that continuing changes, both in the various production processes and in the methods of performing analyses on the intermediate and final products, will yield further benefits for the industry and the consumer.

1.3
Some Recent Trends and Developments

1.3.1 Overview

This section highlights some recent issues, developments and trends relating to alcoholic beverages and the drinks industry. Generally, it is hoped that the topics of this section give some pointers to the near future of alcoholic beverages. However, the authors feel disinclined to try to predict the detailed future of alcoholic beverages, even after a good session in the public bar of the Kirkstile Inn. The selected topics relate to what are perceived as major influences on the direction being followed by the world of alcoholic beverages and some of these are presently major points of discussion or even controversy. They are, allowing for a certain amount of overlap and connectivity between topics:

- Giant multinational companies and globalization of products
- Microbreweries, craft breweries and individualization of products
- Renaissance of cask-conditioned and top-fermented beers: revival of traditional styles
- Changes in beer drinking habits
- Global growth in wine drinking
- Growth of wine industries in countries with marginal climates
- Revival of cider and perry
- The rise of flavored alcoholic beverages ('alcopops')
- Health awareness, calorie counting and changes in social attitude towards alcoholic drinks
- Binge drinking
- Organic and biodynamic alcoholic drinks
- Use of genetically modified (GM) crops and microorganisms.

Some of the above issues have already been referred to briefly in Section 1.2.4, but will now be discussed in greater detail.

1.3.2 Big is Beautiful: Multinational Companies and the Globalization of Alcoholic Beverages

Like other industries, the alcoholic drinks industry has witnessed the growth of national conglomerates since the latter half of the nineteenth century and into the closing years of the twentieth century. The past 20 years

*Projected values on sale of Anheuser-Busch to InBev in July 2008.

or so have seen the rapid growth of multinational companies so that today national and international markets are dominated by a relatively small number of companies who own facilities (e.g. bottling plants, breweries, cider factories, distilleries, malting houses, orchards, vineyards, farms, wineries, etc.) and employ thousands of people in several countries. Although these companies tend to have diversified interests, many concentrate on the production of particular beverages, such as beer (Table 1.3.1) or distilled beverages, liqueurs and wine (Table 1.3.2). Several of these companies have interests in nonalcoholic beverages: for example, SABMiller is the main bottler and distributor of Coca Cola, and Anheuser-Busch InBev is a large producer of soft drinks and sports drinks. With the merger of Anheuser-Busch (USA) and InBev (Belgium/Brazil) in July 2008, the resulting company (Anheuser-Busch InBev) is the world's largest brewing organization, overtaking SABMiller. Anheuser-Busch held this accolade (calculated on revenue) for many years and was the last large American brewing company to be majority owned and operated in the USA (Miller merged with South African Breweries, and Coors merged with Molson earlier this century). It is estimated that the new company will have yearly sales of around \$36.4 billion (the sum of their individual annual sales before merger) and will control around 25% of the world beer market (Spain and Goldstein, 2008).

Diageo, formed in 1997 from the merger of Guinness Plc and Grand Metropolitan Plc, is the world's largest broad-based alcoholic drinks company, closely followed by Pernod-Ricard (Table 1.3.2). Their businesses are firmly based on aperitifs, liqueurs, spirits and (for Diageo) beer. Constellation Brands is the world's biggest producer of wine, with interests principally in the USA (especially California and New York State), Australia and New Zealand. The company also owns the UK firm of Matthew Clark, the world's second largest producer of cider and perry, noted for Blackthorn cider and Babycham.

Apart from providing work and economic prosperity, these companies provide valuable social benefits by sport sponsorships (e.g. of clubs or leagues), by organizing special events, by sponsorship of academic posts and research programmes, and by making charitable donations at local and international levels. At a more local level, the same can be said of many smaller alcoholic drinks companies.

Advancing technology and improved communications have helped the growth of these companies, and although they possess production plants in many countries (or have some of their products made under license by contract companies), there is a heavy reliance on transport, with its attendant rising costs and increasing

Table 1.3.2 *Spirits- and wine-based alcoholic drinks companies (2007)*

Company (main products in order of importance)	Revenue	Employees	Typical brands
Diageo (s, b, w)	7260 million GBP (2007) $16 142.8 million (2008)	24 373 (2008)	Bailey's Irish Cream, Captain Morgan, Guinness, Johnnie Walker, Piat (wine), Red Stripe (beer), Smirnoff, Crown Royal
Pernod[#] Ricard (s, w)	€6443 million (2007)	17 680 (2007)	Chivas Regal, Martell, Mumm, Pernod Anise, Ricard Pastis, Wild Turkey, Wyborowa
Baccardi (s, w)	$5500 million	–	Baccardi Breezer, Baccardi Oro, Benedictine, Bombay Sapphire, Dewar's, Drambuie, Martini & Rossi
Fortune Brands (s, w)*	$7300 million (2007)	34 000 (2007)	Fundador, Canadian Club, Cockburn, Courvoisier, Harveys, Jim Beam, Teachers
Constellation Brands (w, b, c, s)	$5200 million (2007)	7700 (2007)	Corona (beer), Hardy, Matthew Clark (cider/perry), Paul Masson, Robert Mondavi, Taylor, Tsingtao (beer)
Brown-Forman (s, w)	$2 444 million (2006)	3350 (2006)	Bolla, Casa Herradura, Fetzer, Finlandia, Jack Daniels, Southern Comfort

b = beer, c = cider/perry, s = spirits and liqueurs, w = wine (including fortified wine).
[#] After Pernod Ricard's acquisition of Vin & Sprit from the Swedish government in 2009, that company is now (2010) estimated to be the biggest.

pollution issues. These companies are also facing rising costs of basic materials, such as aluminium (for cans), barley and hops. Furthermore, some of the products of these large companies are not viewed altogether favorably by minor, but significant (and growing) consumer groups in a number of countries. Although the companies all have wide portfolios of products, the beers in particular are predominantly of a uniform type – pale lager. At least, this is the beer type that is promoted most heavily, through advertizing.

1.3.3 Small is Beautiful: The Growth in Microbreweries and Craft Breweries and the Localization of Products

Numerous consumer groups and commercial associations have appeared over the past few decades in many countries, notably Britain and the USA. Their aims vary, but are generally to protect and promote small-scale operations, traditional minority products and traditional methods. The activities of some of these groups and associations have fostered the growth in numbers of small-scale producers, the revival of dying minority products and a great increase in consumer choice, through a greater diversity of products. In the UK, the Society for Preservation of Beer from the Wood (SPBW) and the Campaign for Real Ale (CAMRA) have been fighting against the monopolizing and rationalizing tendencies of big breweries and cider companies since 1963 and 1972, respectively. CAMRA, in particular, has been successful in saving cask-conditioned ales and ciders from possible extinction. It has revived the fortunes of the once popular mild ale and its successes have inspired the setting up of many microbreweries and brewpubs in the UK and other countries, notably

the USA, from the late 1970s to the present day. Additionally, CAMRA has inspired the establishment of similar beer consumer groups in Europe, such as Objective Bierproevers (Belgium) and PINT (Netherlands). Indeed, CAMRA, along with the two aforementioned groups set up the European Beer Consumers Union (http://www.ebcu.org/) in 1990, which now has member groups in most European countries, with CAMRA having over 95 000 members, Danske Ølentusiaster (Denmark) over 10 000 and Zythos (Belgium) over 1000 members.

The interests of small-scale brewers in Britain are catered for by the Society of Independent Brewers (SIBA), and in America by the Brewers Association. SIBA, which set up in 1980 as the Small Independent Brewers Association, aims to provide high quality products and to protect and promote traditional styles, whilst encouraging creativity, invention and innovation. It acts as a general focus point (http://www.siba.co.uk) and helps its members promote, sell and distribute their beers via a 'direct delivery system.' Likewise in Belgium, the more specialized Hoge Raad voor Ambachtelijke Lambrikbieren promotes and protects lambic beers: many famous lambic brewers (such as Lindemans and Timmermans) are members of this council. In the USA, the Brewers Association (http://www.beertown.org/), formed from the Association of Brewers and the Brewers Association of America promotes and protects American craft beer, American craft brewers and the community of brewing enthusiasts.

1.3.4 Revival of Traditional Beer Styles

The late nineteenth and early twentieth centuries witnessed the growth of large regional and, eventually, national brewing companies and the disappearance of many local breweries in many countries (for an example, see Table 1.2.1 in Section 1.2.4). This was accompanied by the rapid domination of the brewing industry by pale, bottom-fermented beers and the decline or loss of traditional styles (both top- and bottom-fermented). An account of various styles of beer can be found in Section 2.6.13. Since the late 1970s, largely as a result of the activities and influence of consumer groups such as CAMRA, there have been revivals in both the numbers of small-scale brewers and of the brewing of traditional styles of beer, particularly top-fermented cask- and bottle-conditioned beers. Table 1.3.3 illustrates the growth in the number of breweries in many countries since the late 1970s. Previous to that, all countries witnessed dramatic declines. The growth trend is more or less worldwide, but is more pronounced in the USA and Britain, being most rapid in the 1980s and 1990s: it has leveled off in some countries, but growth continues in others, like the USA (Tables 1.3.4 and 1.3.5). A delayed growth rate in brewery numbers is apparent for some countries, notably Denmark (Table 1.3.3) and the other Scandinavian countries not listed in Table 1.3.3. Judging by the general level of interest in the revival of traditional beer styles (and cider), as indicated in the web pages of the Scandinavian members of

Table 1.3.3 *Numbers of breweries in various countries from 1956 to 2006*

*Beer brewed under contact for microbreweries and regional craft breweries.

the European Beer Consumers Union, the future promises some further growth of choice in these countries. Of course, a greater number of small breweries does not necessarily mean higher quality, but it does mean greater choice. With the level of education, assistance and expertise offered by both commercial/professional societies like SIBA, the Brewers Association and the Master Brewers Association of America, and consumer groups such as EBCU, it is likely that quality will be generally high.

Naturally, most of the breweries that have sprung up since the late 1970s were originally either brewpubs or microbreweries. Some have gone and some have expanded into altogether bigger concerns. Based on 2007 sales, two (originally) craft brewers (Boston Beer Co. and Sierra Nevada Brewing Co. are number 5 and number 7 (respectively) in the top 50 breweries of the USA. The Brewers Association in the USA defines craft brewers as those producing less than 2 million barrels per year, where at least 50% of the production is all malt beer and where less than 25% of the brewery is owned by an industry member who is not a craft brewer. A microbrewery is one that produces less than 17 600 hl of per annum, with 75% of sales being off site, whereas a brewpub is defined as brewing beer primarily for sale at a bar or restaurant: at least 25% of its beer must be sold on site.

A considerable growth in craft beer output in both Britain and America has been in cask-conditioned ales. In the UK, in 2008 (first half of year) although the volume of pub trade was down 8% on 2007 figures, sale of cask-conditioned beers of SIBA members was up 8% during the same period (http://www.siba.co.uk). Similarly in the USA, growth in craft beer production was up 12% during 2007 (Tables 1.3.4 and 1.3.5), whilst the growth rate for imported beers and domestic noncraft beer production was just 1.4%, and it is evident that cask-conditioned beers are gradually acquiring a wider audience (Garbee, 2008). However, to bring some perspective into the picture, the overall US beer market in 2007 was 211 489 982 (US) barrels. So, although craft beer production in the USA is only 4% or so of total production (Brewers Association, 2008), growth is steady (Tables 1.3.4 and 1.3.5), and it is worth remembering that just three decades ago craft beer production in the USA was almost nil. Bottle-conditioned beers (especially ales) have also been

Table 1.3.5 *Numbers of breweries according to type in the USA, 2005–2007*

Brewpub	979	977	975

Data from the Brewers Association (2008).

on the increase in many countries over the past decade – to such an extent that all the big UK supermarkets (e.g. Asda, Budgen, Co-op, Marks and Spencer, Sainsbury, Tesco, Waitrose and others) and smaller chains now (2009) normally stock several such beers. The past two or three decades have witnessed the rejuvenation of some declining and even extinct beer styles such as Dampfbier, mild ale, oatmeal stout and porter. New styles or extensions of already established styles have also appeared, especially in the area of flavored beers (Section 2.6.13). In America, the last few years have witnessed the large brewing corporations turning their hands to producing (relatively) small quantities of specialty beers with real character, such as Molson-Coors Blue Moon brands and Michelob chocolate beers (Section 2.6.13).

1.3.5 Changes in Beer Drinking Habits

Over the past two decades, there have been gradual changes in the beer drinking habits of consumers in certain European countries (Table 1.3.6). In particular, there has been a general shift away from drinking in bars, pubs or restaurants to drinking at home, in Belgium and Britain. Likewise, in the UK, drinkers have been gradually shifting away from draught beers to canned beers, indeed gradual shifts toward canned beers can be seen for all the countries listed in Table 1.3.6. This trend can be correlated with the trend towards greater beer consumption at home, but it should be noted that canned beers are available in some bars of certain countries. Denmark is remarkable for having virtually all its beer being sold in draught or returnable bottle form. From an ecological and environmental viewpoint, this is highly commendable, since these two forms of beer packaging use less energy and cause least pollution. Most nonreturnable bottles and cans are probably recycled, but these processes require considerable energy input, with the possibility of pollution. It can be seen from Table 1.3.6 that the beer drinkers of Denmark, Germany and Ireland are the most conservative. In Germany, since nonreturnable bottled beers are more likely to be bought in supermarkets and beers in

Table 1.3.6 *Changes in beer package type by country (Europe, 1998–2001) and beer consumed at home (1998–2001, with 2004 figure in square parentheses) (d = draught, rb = returnable bottle, nb = non-returnable bottle, c = can)*

Data from http://www.europeanbeerguide.net (2008).

returnable bottles are more likely to be bought from breweries or in bars, it can be concluded that the average German beer drinker prefers bottled beers at home, but bottled beers are also popular in bars. The Irish are easily the top draught beer drinkers of Europe, which means that they are also the most enthusiastic pub goers. Britain and Belgium are not far behind, but shifts away from draught beer consumption in bars are more pronounced in these two countries.

1.3.6 Global Growth in Wine Drinking

As far as beer drinking with respect to the consumption of other alcoholic beverages is concerned, there is some evidence that the beer market in many countries has been unsteady or in decline for a number of years. As long ago as 2005, the large US brewing companies of Anheuser-Busch and Molson-Coors reported a 2–3% loss in net sales (Gross, 2005), which was blamed on younger consumers turning to wine and spirits. It was also suggested that the reason for the switch was the growing gap between East/West Coast professionals, who are more inclined to buy wine and spirits, and interior working people who are cutting back on six-packs of Bud or Miller. Another reason contributing to the diverging fortunes of beer on the one hand and wine and spirits on the other, is the general perception of wine (in particular) as a healthier drink than beer – this is discussed in Section 1.3.10. The USA is a major wine producer (28 750 000 hl in 2005 – see Chapter 1.1, Figure 1.1.4) and is also a keen wine importer. Growth in the number of Californian and total number of US bonded wineries since 1970 is indicative of the rapid growth of the US wine market (Table 1.3.7). California still provides the lion's share of production, but there are now large industries in New York State and other eastern and central states, as well Oregon and Washington States. In 50 years (1957–2007), wine consumption in America has risen from 0.89 to 2.47 gallons per head of population per year (Table 1.3.8 and Figure 1.3.1; 1 US gallon $\sim$ 3.8 l).

World wine consumption is also increasing (Figure 1.3.2): between 2001 and 2005 there was a 4.15% increase in consumption and it is estimated that between 2005 and 2010 there will be a further increase of 4.8%, giving a total of 238 825 million hl (30 384 billion bottles) of wine consumption (Wine News, 2007). Table 1.3.8 shows trends in per capita wine consumption for selected countries between 2001 and 2005. It can be seen that consumption is more or less level or slightly in decline in some major wine producing countries, notably Argentina, France, Italy, South Africa and Spain. On the other hand, there are marked upward trends in other wine producing countries, such as Australia, Chile, China, New Zealand, Portugal, Russia and the USA. It is not certain whether political events have any influence on the data in Table 1.3.8 (e.g. Russia/Moldova and Czech Republic/Slovakia).

There is evidence that traditional wine drinking countries (mostly also wine producers) outside the European Union are driving the growth in global wine drinking (Wine Business Insider, 2007). Between 1986 and 1990, the five leading exporters of the EU (France, Germany, Italy, Portugal and Spain) held an average of 78.8% of the world wine market, whilst the major producers of the southern hemisphere (Argentina, Australia, Chile,

New Zealand and South Africa) held only 3.1%. In 2006, these figures were 62.2% and 27.4%, respectively, if the output from the USA is included with that of the southern hemisphere. The countries with the largest populations (China, Russia and the USA) all show markedly increased per capita wine consumption between 2001 and 2005 (Table 1.3.8) and so will make major contributions to the world upward trend. It is estimated that by 2010, China and Russia will be in the world top 10 of both producers and consumers of wine (Wine News, 2007).

Increase in wine consumption is more pronounced for more expensive wines and is projected at 17.12% for wines selling for more than $10 per bottle, compared with 2.44% for wines that sell for under $5 per

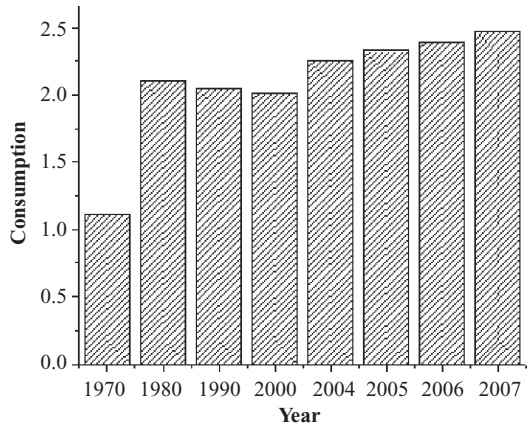

Figure 1.3.1 *Per capita wine consumption in the USA, 1970–2007 (gallons per head per annum). Data from the Wine Institute, 2008.*

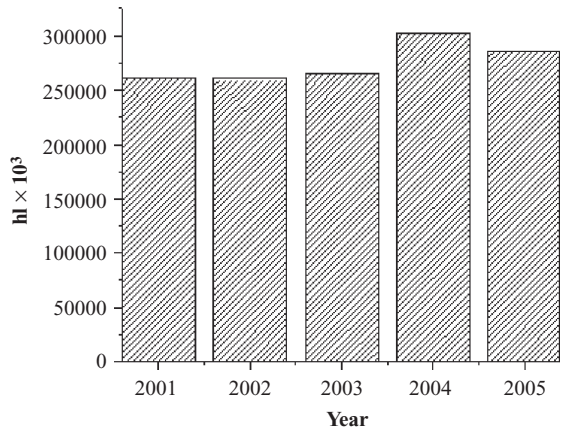

Figure 1.3.2 *World wine production 2001–2005 in hl × 103. Data from the Wine Institute, 2008*

bottle during 2005–2010 (Wine News, 2007). This supports the notion that it is the more affluent members of society who are either turning to wine or are increasing their consumption. Wine prices do not necessarily reflect wine quality and upward trends in wine consumption according to wine type or style may be largely driven by clever marketing and advertizing, perceived fashionability, status indication and perceived health benefits. Red wines show the biggest increase in consumption between 2001 and 2005 (7.48%) and there has been a renewed interest in rosé wines during this period (3.45% increase in consumption) (Wine News, 2007). It should be remembered that two decades ago, rosé wines were unfashionable. Sweet wines and sweet fortified wines are currently unfashionable, for obscure reasons, but possibly because they are considered to be 'high calorie' and 'old people's' drinks' by the young upwardly mobile consumers who spearhead the global growth in wine consumption. Domestic sales of Australia's fortified wines dropped from 27 million l per annum in 1993–1994 to 18.5 million l per annum in 2005–2006, although export trade remained fairly firm (Shiraz, 2007). Home sales of liqueur Muscat and Tokay styles have become so low that a project jointly financed by the government and the Muscat of Rutherglen group has been set up (2007) to revitalize this section of the industry. Many wine savants are of the opinion that these wines and many of the sweet wines of Europe constitute some of the greatest gems of the wine world. Many currently sell at prices that are far below their real value, so developments in this area are awaited with interest.

1.3.7 Development of New Wine Industries

Over the past three decades, wine industries have started (or have significantly increased in size) in a number of countries, many of which must be rated as marginal for the production of wine. For example, there are now small industries in the UK (England and Wales), Belgium, the Netherlands, Denmark and other Baltic/Scandinavian countries. Three of these countries, Belgium, England and Wales, have more or less revived their wine industries following a period of zero commercial production. In the case of England and Wales this was a centuries-long period (interrupted by just two or three localized short commercial eras) brought about by the abundance of cheap wine from Europe. In the case of Belgium, commercial production has been influenced by the proximity of France and by the devastation caused by two World Wars. In the UK, wine production peaked in the early 1990s, but has leveled off in recent years to around 100 wineries and about 700 hectares of vineyards (English Wine Producers, 2008). Average yield varies considerably from

year to year, from over 30 hl/hectare (1992, 1996, 2006) to 10 hl/hectare or less (1988, 1997). Likewise, in recent years total production varied widely from 1 280 000 l in 2005 to 2 526 700 l in 2006.

The small vineyard areas of the Netherlands are in the south of the country near the Belgian border, whilst the Belgian vineyards are mostly in the Ardennes area, not far from Luxembourg vineyards. *Vitis vinifera* crosses and hybrids have been bred in France and Germany (mostly) to perform well in marginal climates. *V. vinifera* crosses include Bacchus, Dornfelder, Faber, Huxelrebe, Kerner (and Kernling), Madeleine Angevine 7672, Müller Thurgau, Ortega, Reichensteiner and Schönburger, and hybrids include Orion, Phoenix, Regent, Rondo and Seyval Blanc. Classic *V. vinifera* varieties such as Chardonnay, Gamay Noir, Pinot Blanc, Pinot Gris, Pinot Meunier and Pinot Noir are also grown. Although contribution to world growth in wine production by these countries is and will remain very small, they do add to the overall variety, and sparkling wines made in England from Chardonnay, Pinot Meunier and Pinot Noir by the méthode champenoise have won many international awards. Most of the wines from these countries are dry or medium white, but rosé wines are also made and the proportion of red wines in UK wine production has risen from 7.1% in 1990 to 25.2% in 2006 and 28.3% in 2007 (English Wine Producers, 2008). It is more difficult to produce good red wines in marginal growing conditions, so increase in red wine production and general quality may be attributed to both increased expertise and generally warmer summers. Many established UK winemakers have reported longer growing seasons, indicated by earlier blossoming and fruit maturation, in recent years, compared with, say, the 1960s.

Wine industries are also growing in warmer climatic areas, which have been only recently globally recognized as winegrowing areas. An example is given by British Columbia, whose wine industry has grown rapidly since 1990, as shown in Table 1.3.9. The vineyards of BC range from the cool coastal areas around Vancouver, where typical cool-climate, mild-winter varieties like Huxelrebe, Müller Thurgau and Seyval Blanc are grown, to the vineyards of the much warmer inland area of the Okanagan Valley. It is here that most of the expansion described in Table 1.3.9 has occurred: French-American hybrids are grown for winter hardiness and classic *V. vinifera* varieties such as Chardonnay, Merlot, Pinot Noir and Riesling will generally ripen well in these vineyards.

India has a small but rapidly growing wine industry. Here, there is no worry about inclement summer weather, or hard winters, provided the vines are pruned in September and cropped in February or March. This southern hemisphere regime is required because of the searing heat and heavy rains in the middle months of the year. Wines are made from *V. vinifera* varieties, such as Cabernet Sauvignon, Chenin Blanc, Sauvignon Blanc and Syrah, but in some vineyards' harvest must be carried out in the relative cool of night, using refrigerated containers to convey the crop to the winery. Wineries such as Chateau d'Ori, Sula Vineyards (at Nasik, near Mumbai) and Chateau Indage (near Pune) can look forward to supplying the blossoming

Table 1.3.9 *Growth of the wine industry in British Columbia*

Year	Area under production (hectares)	Number of wineries	Wine production (l)
1990	597	17	–
1994	870	–	–
1999	1700	–	6 574 200
2004	2210	102	9 985 200
2006	2684	131	13 802 563
2008	3683	143	–

upwardly mobile Indian middle classes (with an estimated potential of 300 million!) over the next 10 years (Fabricant, 2007).

1.3.8 Revival of Cider and Perry: the Magic of Ice

The 1950s and 1960s saw renewed interest in cider and perry, as larger companies such as H.P. Bulmer, Gaymers, Merrydown, Showerings and others expanded, making their streamlined, industrialized and consistent products widely available (Section 2.8.8). Although many smaller cider firms were swallowed up by the larger companies, others survived and continue to produce distinctive and often traditional cider and perry. Brittany, Normandy and northern Spain did not experience such a marked expansion of industrial cider as the UK, and today most cider and perry from these areas is traditional.

In the UK, after a period of slower growth or equilibrium, revitalization has occurred in recent years in two quite different directions. Firstly, demand for craft (mostly traditional) cider and perry has increased, and this has been accompanied by a rise in the number of small-scale producers. No doubt this success is partly influenced by the successes of the big cider companies (see next paragraph), but greater public interest in health issues, natural or organic products and speciality or distinctive products must also be included as contributing to this success. Likewise, the support of the European Union and the establishment of cider production sites as major tourist attractions (like vineyards and wineries) have both helped boost sales. The EU has promoted cider and perry in an attempt to revitalize rural economies by providing profitable markets for apples and pears. New craft cider and perry producers have grown up alongside well-established companies in all of the specially designated cider and perry areas of the EU.

In the other direction, large-scale factory cider has received an enormous boost in the UK through advertizing that presents the drink to young consumers as chic and fashionable. In particular Magners, (C&C, Ireland), Bulmer's Original, Frosty Jack's and others have seen large increases in sales over just two or three years, largely because of their association (through advertizing) with an otherwise humble commodity – ice. The 'over ice' phenomenon, no doubt boosted by the warm summers of 2003–2007, has probably done more than anything else toward the 26% increase in 2007 UK cider sales over 2006 figures. Between March 2006 and March 2007, cider sales in the UK reached 1 003 050 401 pints (569 732 628 l): the first time that cider sales have exceeded 1 billion pints (Anon, 2007).

In America, the cider/perry (pear cider) market is dominated by factory products, such as those of E. & J. Gallo, HardCore, Woodchuck and Wyder's (Canada). In 2005, US cider production was estimated at 6 000 000 US gallons (~22 800 000 l) (Merwin, 2005): small compared with UK production and considering the size of the US population. Although annual cider production has increased substantially since 2000, growth in craft cider and perry production has not yet equaled growth in craft beer manufacture (Merwin, 2005) (Section 1.3.3). This may be because the American public is less familiar with cider (hard cider in the USA – cider is carbonated apple juice) and US bankers are reluctant to lend money for the expansion of an unfamiliar market. It appears as though craft cider and perry makers, like Fox Barrel (Colfax, California), are having trouble securing loans to finance expansion to cope with a threefold increase in demand over two years (Anderson, 2007). Indication that the production of craft (or 'high end') cider is gaining interest is shown by the establishment of many new companies, mainly in winegrowing areas, such as California, the Finger Lakes (New York), Oregon and Virginia (McNeill, 2008).

1.3.9 The Rise of Flavored Alcoholic Beverages ('Alcopops')

Alcopop is the common name for a flavored alcoholic beverage (FAB) that may be a pre-packed spirit (PPS), a wine cooler type drink or a flavored malt beverage (FMB). Another collective term for these drinks is ready

to drink (RTD), used in Australia and New Zealand. Essentially, FABs are distilled spirits, wine or malt beverages to which fruit juice or other flavorings have been added. They are often available in 330 ml or 355 ml bottles, with ethanol contents of between ~4% and ~18% (v:v). Although prepacked versions of sangria (red wine and orange juice), various wine coolers, gin and tonic and others have been around for some time, the current popularity of FABs began in the late 1980s and early 1990s with the introduction of Bacardi Breezer (rum-based), Two Dogs, Hooper's Hooch, Smirnoff Ice (vodka-based), Mike's Hard Lemonade, Zima (malt beverage-based) and other brands. Slick advertizing, aimed at younger consumers led to rapid success in the 1990s. Indeed, the falling sales of cider and perry in the UK during the mid to late 1990s (after a period of growth – see Section 1.3.8) have been blamed on the rise of FABs (Pratley, 1996).

The very success of FABs, along with the character of the advertizing led to criticisms and complaints in several countries that, these drinks were being consumed in significant quantities by underage drinkers (under 18 in Europe; under 21 in the USA). The popular term alcopops was coined by critics in order to link alcoholic and soft drinks ('pop') and to imply that FABs were aimed explicitly at underage consumers. Numerous complaints from newspaper columnists and various 'watchdog' groups have been issued since the 1990s, relating to advertizing and underage drinking. In the USA, the Federal Trade Commission (FDA), acting on complaints from the Center for Science in the Public Interest (CSPI) in 2001 and on a directive from the House and Senate Appropriation Committee in 2003, investigated the possibility that FABs were aimed specifically at underage drinkers (Evans *et al.*, 2003). In both cases, the FDA found no evidence for such assertions and concluded that the majority of FAB drinkers were over the age of 27.

In Europe, the most popular FABs are those of the premixed spirits type, but wine cooler type drinks and beer cocktails are also popular in some countries. In Canada, PPS type beverages tend to dominate FAB sales, whereas in the United States FMBs are more in evidence. Some of the spirits-based beverages have high alcohol contents, which has led to several countries imposing higher excise taxes on FABs, bringing the level of taxation up to that of spirits. This has happened in Ireland (2003), Germany (2004) and more recently in Australia (2008) (Herald Sun, 2008). Additionally labeling and other legislation has been imposed in several countries and certain states of the USA in order to remove any ambiguity regarding alcohol content. In EU countries, FAB bottles carry the warning that they are not meant for consumption by people under the legal drinking age. The state of California has recently (2008) passed legislation that compels manufacturers of FABs for sale in California to include the label warning 'Attention: this drink contains alcohol' (PRNewswire, 2008). Earlier the same year, the state of Illinois passed a similar law, whilst also restricting advertizing and other promotions away from the attention of children (Illinois Compiled Statutes, 2008). Labeling laws for FABs need not be regarded as draconian, since similar laws are already in force, or will soon be in force, for other alcoholic beverages in many countries. Despite other restrictions, many people (like the Australian Opposition leader Brendan Nelson) feel that consumption of FABs (RTDs in Australia) will increase despite extra taxation, but some people may turn to full-strength spirits (Herald Sun, 2008). The FDC report (Evans *et al.*, 2003) also mentioned that industry-based research suggested that most FMB drinkers regarded their drinks as substitutes for beer and were unlikely to consume more than two or three drinks in a session, thus indicating that this type of FAB at least is not associated with binge drinking (Section 1.3.11).

1.3.10 Calorie-Counting and Health Perception of Alcoholic Drinks

The past two decades have witnessed a surge in the general public's interest in health issues, particularly with regard to balanced, nutritional diets and exercise. This interest has naturally extended to alcoholic drinks, where health-conscious people, influenced by advertizements promoting healthy lifestyles and by dietary trends, generally perceive normal alcoholic beverages as being undesirable in a healthy, balanced diet. In general, alcoholic drinks, especially beer, have not been promoted as being healthy by modern diet

trendsetters, such as the South Beach diet (Agatston, 2003). The exception to this is red wine, which is frequently promoted for its nutritional and beneficial health values. On the other hand, with regard to health, beer is often regarded by people who are not primarily beer drinkers as the worst alcoholic beverage. In particular, it is considered to be fattening by people who like alcoholic drinks, but who are seeking to control their daily calorie intake ('calorie counters'). This perception is considered by some brewers in Japan to be a significant contributor to the decline in domestic beer sales over the past few years, with people either abstaining or turning to shochu, the traditional distilled spirit (Anon, 2008). It will be demonstrated in Section 5.7.1 that beer and red wine are nutritionally similar and the major health benefit of low alcohol intake (reduced risk of cardiovascular disease for certain individuals) is more or less the same for beer, spirits and wine (Section 5.6.3).

The first reaction of brewers to win over health-conscious potential beer drinkers was the launching, in the 1990s onwards, of many brands of low carbohydrate beers, variously known as 'low carb', 'light' or 'lite' beers (Sections 5.7.1 and 5.7.2), although some well-established low carbohydrate beers for diabetics already existed. The second reaction of brewers occurred this century with the launching of web-based educational campaigns by individual brewery companies (e.g. Coors Brewing Ltd, 2002; Anheuser-Busch Inc., 2006) and by other commercial organizations (e.g. the British Beer and Pub Association, 2005). The aim here was to focus on beer's natural, nutritional and health-giving values (assuming low to moderate intake) by providing a general educational background. Apart from these, many of the normal brewery websites also mention the naturalness or health-giving properties of beer.

Labeling legislation in many countries now requires the inclusion of nutritional information (per serving) somewhere on the product container. For example, in the USA, the regulations set by the Alcohol and Tobacco Tax and Trade Bureau (TBB) (2004) require average analysis values to include the number of calories, along with the number of grams of carbohydrate, protein and fat per serving size. Other information (on the main or on a subsidiary label) will include % alcohol (v:v) and in some countries, information regarding contribution (per serving) to daily requirements and information on specific components, such as additives, cholesterol or sodium content, also may be required. Legislation of this kind is really bringing alcoholic beverage labeling in line with general packaged foodstuff labeling, legislation for which has existed in many countries for a number of years.

How nutritional label information regarding alcoholic beverages influences the attitude and behavior of consumers is not well understood and there are conflicting conclusions in the literature (Wright *et al.*, 2008). In a recent survey of consumers' perceptions of alcoholic and nonalcoholic beverages, it was found that red wine was perceived to be the overall most healthful drink (Wright *et al.*, 2008). The consumers were visitors to a craft brewery and two wineries in northern California, who answered a verbal questionnaire on their perception of the health value of drinks before and after being given nutritional information on the beverages. The results showed that people at the wineries (mostly wine drinkers) and those at the brewery (mostly beer drinkers) viewed beverages differently and their perception altered after seeing the information. It was concluded that perceived health quality of a beverage is, in general, not the major driving force for choosing that beverage: the brewery visitors thought red wine the most healthy drink. Also, beer drinkers were more heavily influenced by the nutritional information, suggesting that inclusion of such information on product labels will increase beer drinkers' perceptions of the health quality of their beverage of choice.

1.3.11 Binge Drinking

Binge drinking can be defined in different ways, but it generally refers to the consumption of five or more standard drinks in a relatively short space of time (e.g. part of an evening), so that blood alcohol concentration reaches at least 0.08%. In Britain, binge drinking is sometimes defined as the consumption of more than 50%

of the maximum weekly number of alcohol units in one session (i.e. on one night out or at one party). Of course binge drinking, even amongst young people, is not a new phenomenon. However, the perceived scale and severity of binge drinking amongst young adults and underage drinkers is a more modern phenomenon, as is the strong drinking culture that accompanies it. Nowadays binge drinking often involves medium to large groups of youths drinking 'shots' while playing drinking games such as 'scrumpy hands,' 'Edward wineyhands' or 'Edward fortyhands.' Antisocial and even violent behavior is a frequent result of binge drinking, as are drink-induced accidents or illnesses, such as those caused by ruptured bladders (Atkins, 2007). The latter place strains upon the hospital accident and emergency services, especially on Friday and Saturday evenings, the main binge drinking times (BBC, 2003). There is little doubt that binge drinking is more damaging to the health than drinking the same number of alcohol units over a much longer period of time (Section 5.6.2).

Binge drinking takes various forms and varies in frequency and severity from country to country, but appears to be most prevalent in northern Europe, Australia, New Zealand and the United States. All kinds of alcoholic beverages can be used in binge drinking, but beer, cider, cocktails, FABs and spirits appear to prevail over wine and related drinks. The origins of binge drinking cultures in different countries with quite different sociological and political backgrounds are unknown, although many try to relate it to the legal age of drinking, the availability of alcohol or the degree of severity of drinking laws. It seems likely, however, that the desire to socialize and the potency of peer pressure (being seen to be fashionable or 'part of the crowd') play major roles. Remedies suggested by various governmental, health, drinks industry, educational and other organizations range from drastic curtailing of the availability of alcoholic beverages (e.g. by increasing the legal drinking age, increasing excise tax or deceasing the number of outlets) through further liberalization of drinking laws (e.g. decreasing the drinking age limit and making alcoholic drinks more freely available) to stricter enforcement of existing drinking laws, particularly with regard to antisocial or violent behavior. Naturally, these suggestions have led to controversy and even greater media coverage. For example, in the USA, the suggestion made by a group of college administrators that lowering the legal drinking age from 21 to 18 may help curtail the growth of binge drinking by university and college students (the main binge drinkers in America, it appears) has caused predictable reactions from the media (Editorial, New York Times, 2008). The growth of binge drinking this century has triggered specific governmental and other campaigns in a number of countries: in March 2008, the Australian government provided 53 million Australian dollars for an advertizing and educational campaign against binge drinking (Cooper, 2008) and the EU wine producers have launched a campaign designed to promote the cultural dimension of wine and to contribute to the reduction of alcohol abuse (Euractiv, 2008; CEVI (Confédération Europeénne des Vignerons Indépendants), 2008). Opposing remedial regimes suggested for application to the most modern form of alcohol abuse are nothing new: in the past there have always been organizations that argue for restriction (or even prohibition) and those that advocate liberalization to solve the same problem. Some argue that liberalization doesn't help, for example extension of UK bar opening times to 24 hours has not been seen as a cure for binge drinking (Johnston, 2006). However, history has shown that it is simply impossible to take care of every potential alcohol abuser and restriction or prohibition can lead to numerous other problems (as in prohibition America, 1919–1933). There is no historical precedent to modern binge drinking, as it involves most forms of alcoholic drinks, but it should be remembered that the British 2nd Gin Act of 1736, in which licence and excise duties were imposed on gin distillers and penalties were imposed for sale without licence, had the effect of doubling gin consumption in England. Ultimately, the 1751 Gin Act, preventing distillers selling by retail or to unlicensed owners of inns and public houses saw an end to the 'gin epidemic.' The act also raised the duty on spirits and prevented recovery of drinking debts through the courts. Additionally, the duty of £1 on a gallon of beer had been dropped in 1743 (Young, 1979). On this basis, raising taxes or decreasing the availability of all types of alcoholic beverages is unlikely to curb modern binge drinking.

1.3.12 Organic and Biodynamic Production of Alcoholic Beverages

The term 'organic' applied to foodstuffs and alcoholic beverages generally refers to the production of crops within a balanced farm ecosystem, without the use of artificial fertilizers or pesticides. Certain agricultural practices, such as the use of cover crops, green manuring, crop rotation and crop diversity (growing several crops together) are also features of organic farming. The last-mentioned is designed to provide a better ecosystem for the farm, so that pests and diseases are minimized. For example, it is not uncommon for viticulturalists in southern Europe to grow other fruit trees (e.g cherry trees) or walnut trees amongst the vines. Additionally, the processes that convert the crop into an alcoholic beverage should be as natural as possible and involve no or minimal additives. In practice, certain pesticides (e.g. sulfur, Bordeaux mixture and preparations made from natural sources) are allowed and sulfur dioxide is allowed in winemaking up to certain low levels (depending on the prevailing legislation – see Section 5.9.5). Organic beers are produced from organically grown barley (and other cereals) and hops, but these beers may well have been filtered and pasteurized. The same applies to organic cider, perry and wine.

Various nongovernmental organizations exist to oversee and help the production of organic crops, to promote organic products, to expand the organic marketplace, to liaise with governmental bodies, such as USDA (USA), DEFRA (UK) and the EU (most of Europe) and to issue certificates of guarantee for organic products. These organizations include the Soil Association (UK), California Certified Organic Farmers (CCOF) (USA), Stellar Certification Services (USA), Verein Deutscher Prädikatsweingüter (Germany) and the Soil and Health Association (New Zealand). The biodynamic organizations Demeter and Biodivin are mentioned later.

In parallel with the rise in health awareness, growth of organic beer, cider and wine production and consumption has been rapid during the past two decades: the California crop reports for 2005 showed the area of certified organic vineyards constituted 18% of total bearing vineyard area in Mendocino County, accounting for 1142 ha out of a total 6512 ha. Likewise, there are now (2008) over 2000 ha of organic vineyards in Germany. Less than 20 years ago, both these figures would have been much closer to zero. The CCOF reports that the vineyard area certified by itself has increased from 7761 acres in 2004 to 9240 acres in 2007. For a number of notable, but relatively small-scale winemakers, such as E. Dürrbach at Domaine de Trévallon (France), Frey (USA), Guerrieri-Rizzardi (Italy), Heller (USA) and J. Palacios (Spain), their output is entirely organic, but much larger producers such as Fetzer (California) and Penfold's (Australia) also make solely organic and biodynamic wines or make an organic series of wines alongside their conventional wines. Some breweries, such as Caledonian Brewery, Samuel Smith (both UK), Anheuser-Busch InBev (USA), Pinkus Müller and Riedenburger (Germany) brew organic beers along with conventional beers, whilst there are some purely organic breweries (e.g. Peak, Otter Creek Brewing and Santa Cruz Brewery – all from the USA). Organic beer sales are increasing, the 2005 sales being 40% up on 2004 sales (Associated Press, 2006).

Organic beverages tend to be more expensive than their conventional counterparts and although it is probably true that some of the produce is market orientated, it appears that many producers use organic techniques because they truly believe in them. Indeed, the organic (or biodynamic) aspect of some wines (e.g. those of Guerrieri-Rizzardi, Jasper Hill and Descendientes de Palacios) takes a low profile. Because of the meticulous care generally given to organically produced alcoholic beverages, their quality is usually high, but whether they are better than their conventional equivalents depends very much on the taster. What can be said is the presence of organic beverages greatly enriches the choice for the consumer.

From its genesis in the form of a series of lectures in 1924 on agriculture by the vitalist Austrian philosopher Rudolf Steiner, biodynamic (BD) viticulture has been making big ethereal waves in the world of wine over the last 10 years. BD wines are often mentioned in the same breath as organic wines, and indeed, under the auspices of the Demeter and Biodivin certification bodies, organic vineyards can convert to BD by adopting the special soil and plant preparations with reference to astrology, as originally advocated by Steiner. This

involves making mixtures of animal, mineral and vegetable origin for soil improvement and highly diluted plant preparations for crop spraying to improve plant health. It also involves keeping animals for biodiversity and ecological balance. These, and the various winery operations (such as racking and bottling) are carried out with strict reference to cycles of the moon and relative positions of constellations of the zodiac (Zacharkiw, 2008). The whole purpose of these procedures is to balance lunar and zodiacal influences in favor of the vineyard, its workers and its products: in this way, the wine expresses its 'terroir' to maximum degree.

Biodynamic viticulture has become popular and much more high profile over the past few years. It now includes some the world's finest wine producers as adherents, including Castagna (Australia), Domaine Chapoutier (France), Coulée de Serrant (France), Descendientes de J. Palacios (Spain), Grgich Hills (USA), Millton Vineyard (New Zealand), Domaine Leroy (France) and Domaine Zind Humbrecht (France) (Crosariol, 2008). Critics often argue that improvement in vineyard health and wine quality may have occurred anyway if standard organic farming had been used, without the mysticism and considerable extra effort of biodynamics (Smith and Barquín, 2007; Chalker-Scott, 2004; Treue, 2002). Other critics say that the success of BD viticulture owes more to the consummate skill of the winemakers: they would make superlative wine whether or not BD practices were used.

Evidence for the efficacy of BD farming is mixed: in Switzerland, a 21-year project found that soil fertility and biodiversity were improved by BD methods over organic or conventional culture (Mäder *et al.*, 2002). On the other hand, the only detailed vineyard study (conducted between 1996 and 2003) concluded that BD farming gave improved grape sugars and tannins in one year, but otherwise gave no further improvement on those obtained using standard organic practices (Reeve *et al.*, 2005). Wines of unquestionably high standard are produced using the biodynamic method, although for the onlooker the controversy regarding exactly how much the method itself contributes to high quality remains unsolved.

1.3.13 Use of Genetically Modified (GM) Crops and Microorganisms

Genetic modification of any kind remains a highly controversial issue and the first introductions of GM foods has met with a good deal of consumer resistance in many countries. However, GM foods are now approved in many countries, including those of the European Union (since 2004), subject to fulfillment of labeling requirements. Genetic modification is carried out on crop plants in order to give them an additional genetic characteristic (trait) that is beneficial to producer and consumer alike. Otherwise the genetic characteristics of the original and modified plant remain identical. Alien genes, often from bacteria or fungi, are incorporated into the plant genome, often by microparticle bombardment of plant cells or tissue. For example, an additional gene may be added to confer disease resistance, insecticidal properties, resistance to herbicides or improved food value. Before being released for general agricultural use, GM plants undergo extensive laboratory and field trials that look for unfavorable influences on the environment (affects on beneficial soil bacteria, fungi, beneficial insects, etc.), as well as examining the possibility of cross-pollinated propagation.

The first beer to be brewed using GM produce as part of the grain bill was Kenth Beer of the Oesterienbryggarna Brewery (Sweden) in 2005. This beer was brewed using maize that has a specific genetic modification that makes it resistant to attack by *Ostrinia nubilatis* – the European corn borer. The variety, *Zea mays* L. Yieldguard, has an added gene that expresses a truncated version of the insecticidal protein Cry1Ab, derived from *Bacillus thuringiensis* (Bt) (Agrobios, 2008). Cry1Ab is lethal only to the juveniles (caterpillars) of *Lepidoptera* species (butterfies and moths) and only then if the insects attempt to feed on the plant. Other insects and animals are unaffected by this protein, their gut linings not having the required receptors. An added advantage arises from the fact that minimization of insect feeding damage also minimizes attack by pathogenic fungi, so the GM plants are effectively protected from fungal diseases.

More recently, two GM barley lines have been investigated at trial field sites by researchers at the University of Giessen and the Friederich-Alexander University of Erlangen-Nürnberg (Kogel, 2006; GMO Compass, 2006). One barley line has an additional gene that expresses endochitinase (derived from *Trichoderma herzianum*), an enzyme that hydrolyzes fungal (but not insect) chitins. The plants are resistant to attack by the soil fungi *Rhizoctonia solani* and *R. oryzae*, which cause barley root rot, a disease that is widespread in many countries, especially the United States. The field trials are being conducted partly to determine whether the presence of this GM barley line affects beneficial soil fungi: laboratory trials have already shown that there is no effect. The second GM barley line has an extra gene that expresses a glucanase enzyme in the kernels. Glucanases (Section 2.6.2) hydrolyze β-glucans in the cell walls of cereal kernels during malting, hence they contribute much to the production of a haze-free beer. The German field trials are also testing whether this GM barley line also affects beneficial soil fungi (supposing that some kernels drop to the soil and decompose), since β-glucans occur in the cell walls of almost all fungi. If these and other trials are successful it is expected that GM barley may be commercially available in the near future, depending on the extent of consumer resistance, which still tends to be high in some countries, especially in Europe. Here, it is not unknown for GM opponent groups to exhibit rather more than passive resistance, as witnessed by the persecution of Kenth beer (Moore, 2005) and the destruction of part of the University of Giessen's GM barley field (Kogel, 2006). A survey of consumer attitudes in Western Australia toward hypothetical GM beer (brewed with either GM barley or GM yeast) indicated a general aversion to GM products, but significant numbers of the survey subjects were willing to choose a GM beer at lower cost or even at premium cost if the product could demonstrate additional health benefits (Burton and Pearse, 2002).

The use of GM yeasts in winemaking has been a battleground since the early days of the century (Lawton, 2002) and has continued for several years (Goode, 2005). At the time of writing (2008), two GM yeasts, ML01 (developed in South Africa by Volschenk and coworkers in 1997)) and ECMo01 (developed in the USA) have been approved by the Food and Drugs Administration in the United States, in 2005 and 2006, respectively. The FDA treats the organisms as substances and has granted 'generally recognized as safe' (GRAS) status (see Section 5.9.5) to both. These yeasts are now available to winemakers in Canada and the USA, and commercial wines (which at present do not need to be identified as being made using GM yeast) have been produced. In many other countries, there are restrictions on the use of GM organisms, such as yeasts, in foodstuffs, although in some of these countries research is taking place on producing genetically engineered yeast for research or analysis purposes (Chambers, 2007; Cummins, 2007). There is a certain natural genetic variation in wine yeasts, giving rise to a wide range of fermentation characteristics that result in differences (though often subtle ones) in finished wines (Chapter 2.2). Non-GM mutagenic techniques have the potential for producing tailor-made novel yeasts, but GM techniques are generally recognized as offering greater scope (Chambers, 2007).

Genetic engineering of crops differs considerably from yeast genetic engineering. The former is based on illegitimate recombinations resulting in unpredictable and uncontrollable sites of gene insertions, whereas the latter uses legitimate recombination, which allows gene insertion at specific sites. Genetic engineering of yeast falls into two major categories: transgenic and self-cloning. The former involves insertion of heterologous genes (derived from different species or organisms) into *S. cerevisiae*, whereas the latter involves insertion of genes from a different strain of the same species. The GM yeast ML01, is *S. cerevisiae* with two extra genes, one of which is a malate transporter gene from *Schizosaccharomyces pombe* (another fungus) and the second is the malolactic enzyme gene from *Oenococcus oeni* (a bacterium) (Section 2.3.2). The advantage of this yeast is that it performs alcoholic and malolactic fermentation at the same time, thus cutting back wine processing time and producing wines with lower levels of biogenic amines, which are sometimes produced during conventional MLF with certain lactic acid bacteria (Sections 2.3.14 and 5.11.3). The second commercially available GM yeast ECMo01, derived from Davis (California) *S. cerevisiae* strain 522, contains three genes derived from other strains of *S. cerevisiae*. These, DUR1,2 gene, a promoter gene and a terminator gene, increase the

expression of urea amidolyase (urease), which catalyzes the hydrolysis of urea, a byproduct of alcoholic fermentation (Sections 2.2.3 and 2.2.8). Urea reacts with ethanol during winemaking (and distillation) processes to give the carcinogenic ethyl carbamate (urethane) (Sections 2.2.3, 2.2.8 and 5.11.4), although other biochemical routes to this compound exist (Section 2.3.6). Fermentation trials have revealed that ECMo01 produces red wines with levels of ethyl carbamate reduced by up to 89%, but with similar qualities and characteristics of red wines produced by the parent strain (Heller, 2007). Other, as yet noncommercial, GM yeasts include those possessing genes that facilitate glycoside hydrolysis to liberate aroma compounds, those that allow production of more glycerol and those that endow antimicrobial power. There are many others (see Cummings, 2005).

Scientific objection to the widespread commercial use of GM yeasts are centered on the possibility of mutations caused by unknown chromosome rearrangements, with the possible formation of toxic end-products (Cummings, 2005). Wine yeast cells have been shown to be hyperactive in mitotic recombination and this is considered to be a contributor to the well-known genetic instability of wine yeasts (Sections 2.2.3 and 2.2.4). There is also concern about GM yeast cells (and their degradation products, such as RNAs) found in bottles of wine being consumed and also there is fear of GM cells persisting in wine and in wineries (and their environs) (Cummings, 2005). More generally, there is fear of contamination of native or traditional specialized yeasts in wineries (Martenson, 2006). It is also felt by some that not enough health and safety groundwork has been done regarding already sanctioned GM yeasts, and a rush of newly approved GM yeasts would indeed exacerbate this situation (Cummings, 2005).

There have been field trials with GM grapevines since the late 1990s in many countries, including Australia, France, Germany, Italy and the United States (Information Systems for Biotechnology, 2008). The aim is mostly to breed plants that are resistant to attack by pathogenic fungi (e.g. *Uncinula necator* or *Oidium Tuckeri*), bacteria or even viruses (e.g. *nepovirus*). The inserted genes include synthetic genes that express antimicrobial peptides, or genes from *Trichoderma harzianum* that express fungal chitinase. Other aims of transgenic vine breeding include modification of grape color or quality and regulation of the plant hormone auxin, thus altering the vine's life cycle. The majority of field test release applications are from university departments, such as California, Cornell and the State University of New York, but field trials are also conducted by private companies and wine research institutes (Cummings, 2005). There is concern over what happens to GM-expressed compounds (e.g. antimicrobial agents) or to the inserted genes themselves during winemaking (Cummings, 2005). Vines are rather prone to mutations (e.g. bud mutations) that produce different strains of the same variety (a recent example is Kernling, derived from Kerner), which may differ, for example, in grape skin color, vine life cycle, disease resistance or grape quality. What would happen to donor genes in such a situation is unknown at the present time and may need longer trials to establish.

2.1

Introduction: Overview of Fermentation and Microorganisms

Natural fermentations have played a vital role in man's development. Some of these fermentations made changes in food materials that were quickly recognized as desirable.

—N. Potter, 1986

Consumers have a considerable portion of their nutritional needs met through fermented foods and beverages. Fermentation is of great significance because it provides mankind with a way to preserve foods and beverages in a wide diversity of flavors, aromas and textures. The affluent Western world has the technology to preserve food through canning and freezing, but the developing world still relies upon fermentation and dehydration (Steinkraus, 1997). The microorganisms associated with fermentation constitute a diverse group, including both prokaryotes (bacteria) and eukaryotes (yeasts and molds). The manufacture of alcoholic beverages and cultured dairy products represent the leading fermentation industries worldwide. The word 'fermentation' can have a variety of meanings, from informal to more scientific definitions. Any definition needs to include activities that produce alcoholic beverages or acidic dairy products, large-scale microbial processes occurring with or without air, or any energy-releasing reaction that occurs under anaerobic conditions. It also covers the spoilage of food by microbes, like the transformation of wine to vinegar by acetic acid bacteria.

In its broadest definition, fermentation is the anaerobic catabolism in which an organic compound serves as both electron acceptor and donor, and in which ATP is produced by substrate level phosphorylation. In catabolism (the breakdown of molecules), the electron donor, or more accurately, the chemical reaction in which the electron donor is oxidized, is the source of energy. For chemotrophs (organisms that rely on a chemical electron donor), two mechanisms of energy conservation are known, respiration and fermentation. The final result is the production of ATP for the organism, which is then used in further reactions. Fermentation and respiration differ in that respiration requires oxygen, or some other externally supplied terminal electron acceptor, whereas in fermentation, the electron acceptor is generated from the initial substrate. In addition, ATP is produced by different mechanisms during the two processes. In fermentation, as previously stated, it is generated by catabolism of an organic compound (substrate-level phosphorylation), while in respiration, ATP

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass

is produced through coupling to the proton motive force in oxidative phosphorylation. Glycolysis (also called the glycolytic pathway) is a series of 10 reactions that take place in the cytoplasm of all cells, beginning with the metabolic process of chemical breakdown of glucose, and producing a three-carbon product, pyruvate. These reactions are accompanied by the production of two molecules of ATP, and the reduction of two molecules of NAD^+ to NADH and H^+.

Under anaerobic conditions, the total useful energy yield per glucose molecule is only two ATPs. When oxygen is involved, and pyruvate can be completely oxidized, about 38 ATPs are produced. Looking at the processes from a different perspective, cellular respiration occurs when the pyruvate is converted aerobically to energy-poor carbon dioxide. Fermentation produces relatively energy-rich molecules such as lactic acid or ethanol in anaerobic conditions, so the energy extracted from the original glucose molecule is far less (Purves *et al.*, 2001). Fermentation is therefore an incomplete oxidation, and organisms that are unable to carry out aerobic respiration are energetically disadvantaged. However, some organisms are confined to totally anaerobic environments, and their survival will be dependent on their ability to ferment, so it is a ubiquitous process in nature. Catabolic targets can be as diverse as cellulose in the rumen of terrestrial herbivores, or the simple monosaccharides found in the juice of various fruit. A medium such as grape juice, with a high concentration of monosaccharides represents a nutrient-rich environment in which a host of organisms could respire or ferment, if permitted. Management of the conditions in which grapes and their juice are protected from, or exposed to, microorganisms is initially the job of the viticulturalist, and then the winemaker or oenologist.

It could be argued the management of microorganisms is the most important task in the quest for excellence in wine quality, but opinions on this vary. Robinson (2003), for example, writes, 'It is a healthy sign that more and more winemakers are admitting wine is made in the vineyard and not in the cellar,' whereas Fleet (2003) states that '. . .although grape cultivar and cultivation provide the foundations of wine flavour, microorganisms, especially yeasts, impact on the subtlety and individuality of the flavour response.' Goode (2005) argues, '. . .yeasts don't get enough credit. When it comes to wine, grapes get all the glory.' The fact is that no matter how good your grapes, without yeast to transform them, they would not become wine. Indeed, even in the most modern production facilities, incorrect microbial choices and poor fermentation practices will produce a bad product from good starting material.

In addition to yeast needing management, other organisms including fungi, acetic acid bacteria and lactic bacteria also produce substances that can add to the organoleptic (sensory) qualities of the a product (positively or negatively), and may affect the progress of fermentation. It is important to understand the impact of microorganisms, and identify as many of the ecological interactions that occur between the different microbial groups, species and strains involved in a single fermentation as possible. These interactions encompass yeast–yeast, yeast–filamentous fungi and yeast–bacteria responses (Fleet, 2003).

The general processes involved in fermentation by yeast are discussed in more detail in Chapter 2.2, as well as in the winemaking sections 2.9.1, 2.9.2 and 2.9.3. There is also discussion of alcoholic and other fermentations relating to the brewing of beer (Sections 2.6.4, 2.6.5, 2.6.6 and 2.6.7), other cereal-based beverages (Chapter 2.7) and to cider making (Section 2.8.4).

Malolactic fermentation is discussed in Chapter 2.3, as well as with respect to various drinks (Sections 2.8.4, 2.9.1, 2.9.2 and 2.9.3). Additionally, Section 2.10.3 deals with some of the special characteristics of flor yeasts and the fermentations performed by a broad spectrum of microorganisms are discussed in Sections 2.6.7, 2.7.1 and 2.7.2.

Finally, the influence of microbiological activity (especially lactic acid bacteria, LAB) on the organoleptic character of certain spirits is discussed in Sections 3.2.3, 3.5.4, 3.5.5 and 3.7.2, and the activities of spoilage organisms are discussed in Chapter 2.4.

2.1.1 Yeasts

Yeasts are ubiquitous in soils and on plant surfaces, but the microbial population found on fruit will vary according to a number of factors, including the type of fruit, climatic influences and agricultural practices. The developmental stage at which fruit is examined, and any physical damage will also play an important role in which organisms are present. Although rich in sugars and other nutrients, the majority of microorganisms will not thrive in grape juice and must, due to high acidity and low pH, high osmotic pressure of the concentrated sugar in solution and (in a wine-making context) added sulfur dioxide.

Recent ecological evidence shows that the main yeast involved in most industrial alcoholic fermentations, *Saccharomyces cerevisiae,* is isolated with extreme difficulty from conventional habitats, such as soil or the surface of ripe fruit, but it is almost the only species colonizing the surfaces of the winery equipment (Martini, 1993). In fact, for all the importance of this yeast to mankind in brewing, baking, research and winemaking, the origins and natural habitat of the species are still uncertain (Jackson, 2000). *Saccharomyces cerevisiae* is unable to utilize the starch of barley, so when beer is produced, the grain is first germinated and the resulting malt is extracted with hot water to yield wort containing fermentable mono-, di- and trisaccharides and other yeast nutrients (Campbell, 2000) (Section 2.6.4).

The most frequently isolated species from grapes is the apiculate yeast, *Kloeckera apiculata* (and its sexual counterpart *Hanseniaspora uvarum*), identifiable by its lemon-shaped cells, which normally accounts for 50% or more of the yeast population present (Pretorius, 2000). The other significant but smaller populations identified on the surface of healthy grapes are the so-called 'wild' species of *Candida, Cryptococcus, Pichia, Klyveromyces, Brettanomyces, Hansenula, Aureobasidium pullulans, Metschnikowia* and *Rhodotorula*, depending on the stage of grape maturity (Fleet, 2003). In enology, a distinction is made between wild and wine yeast by Boulton *et al.* (1996), who define those genera which are found on the grape and can carry out a limited alcoholic fermentation with production of volatile esters, as 'wild yeast,' and those that will carry out a complete fermentation of grape juice without producing any atypical sensory effects, as 'wine yeast.'

The 'bloom' on the cuticle of the grape, previously thought to consist of wine yeast in their millions, has been proved to be a relatively dry and sterile environment of overlapping waxy plates where any yeast cells will be in a dormant state (Jackson, 2000). Yeasts require moisture in order to be metabolically active and unless the berry is damaged, the right conditions only occur on the cuticle when there is precipitation of some sort in the vineyard. Actively metabolizing yeast are most frequently found around stomata or next to cracks in the cuticle, where they form small colonies on nutrients seeping out of openings in the fruit (Martini *et al.*, 1996). Few yeasts grow on grape leaves or stems, but they may be found on the receptacle and pedicel.

Despite being present in very low numbers in the vineyard, crushing grapes under aseptic conditions, and sampling during active fermentation will provide evidence that *Saccharomyces cerevisiae*, with its combination of an efficient fermentative catabolism and relatively good alcohol tolerance, is the dominant, and sometimes the only species that survives in a wine fermentation, with most others declining after a few days (Pretorius, 2000). See also Sections 2.8.3 and 2.8.4 for details of microorganisms found on the skins of apples and pears and their involvement in the production of traditional cider and perry.

The choice and treatment of the yeast by the producer can have a huge influence on the quality of the beverage. Goode (2005) observes that of the 1000 or so volatile and flavor compounds that have been isolated in wine, yeasts are responsible for the production of about 400 of these. This figure is also the one used by Campbell (2000) to enumerate the metabolites that contribute to beer flavor. The effects of fermentation on aroma are outlined in more detail in Section 2.2.9 and more specific discussions can be found in Sections 2.6.4 (beer), 2.8.4 (cider and perry) and 2.10.3 (flor Sherry).

It is fairly routine in wineries these days for the inoculum of *S. cerevisiae* to be rehydrated from a freeze-dried form (known as active dry (wine) yeast or ADY), chosen for a particular set of characteristics

by the winemaker, and added to achieve a population of 10^5–10^6 cells/ml of juice or must. Although the inoculation of juice with selected strains of *Saccharomyces cerevisiae* is routine in many wineries, there are really only a few circumstances in which it is essential. If the grapes are in poor condition and harbor a large population of wild yeasts, fungi and bacteria, an inoculation with a commercial killer yeast strain will give the yeast a competitive advantage, and hopefully lead to a clean fermentation. After thermovinification, microbial populations on the grapes have been killed off by high temperatures, and trying to conduct a fermentation with natural yeast will be difficult, if not impossible. In the event that fermentation slows and sticks, inoculation with a large population of actively fermenting yeast cells can kick-start the process, and ferment any residual sugar. In order to initiate the secondary fermentation in sparkling wine production, an inoculum of an appropriate strain is necessary, because conditions in the bottle or tank (fairly low pH, presence of sulfur dioxide and reasonably high concentrations of alcohol) are not normally conducive to yeast growth (Section 2.9.3).

The alternative to inoculation is to use the natural yeast populations on the grapes, in which case the alcoholic fermentation will be characterized by the successional growth of various yeast species and strains, where yeast–yeast interactions determine the ecology, (Fleet, 2003). The advantages of this practice are that it costs nothing and very often the yeasts found naturally in an area are particularly suited to the type of wine produced. The wild yeast may be responsible for the initiation of fermentations, but by mid fermentation, *S. cerevisiae* represents almost all of the yeast isolatable, due to its tolerance of low temperature and pH, and higher alcohol concentrations. It is widely acknowledged that non-*Saccharomyces* species are not as ethanol tolerant as *Saccharomyces* species, resulting in S. *cerevisiae* dominating the fermentation at around 4% (v:v) alcohol, reducing the impact of non-*Saccharomyces* species on the aroma and quality of the final product. *K. apiculata, C. stellata* and *C. krusei* produced maximum ethanol concentrations in the range 2.7–6.6% when grown as single cultures in grape juice (Heard and Fleet, 1988). These authors also noted that an increase in pH from 3.0 to 3.5 increased the tolerance of apiculate yeasts to alcohol. Although the addition of SO_2 is thought to inhibit or kill indigenous yeasts it is unlikely to kill the *S. cerevisiae* present (Jackson, 2000). The presence of 'killer' yeast strains in either the inoculated or indigenous yeast can have an effect on the make up of the populations of yeast present. Killer strains produce exocellular toxins that have a lethal effect on more sensitive strains. Dominance of the inoculated strain if it does not possess a killer factor, is not always assured. Killer activity has been observed in the genera *Saccharomyces*, *Kluyveromyces* and *Hansenula* (Palpacelli *et al*., 1991). Killer factors are now deliberately included in many commercial dried yeast strains in order to ensure their domination in solution.

Wild yeasts in low concentrations, at the beginning of fermentation, are known to provide depth and complexity to the flavor and aroma of wine. A similar situation is believed to exist in the production of traditional cider and perry (Section 2.8.4). However, if the species is able to withstand conditions that allow it to completely ferment grape sugars (e.g. *Schizosaccharomyces* and *Zygosaccharomyces* species), the product is far less appealing. It has long been advocated that the distinct nature of wines from long-established vineyards and famous wineries come from the various yeast genera in residence, and even *Brettanomyces* ('brett') character is now thought to be part of the 'terroir' character of a particular wine. The decision to inoculate with a reliable, 'designer' *S. cerevisiae* strain, or go with a natural fermentation and its associated complexity is a stylistic choice or it is made according to the philosophy of the winemaker and brand. There are certainly many winemakers who shy away from New-World techniques, and advocate a natural fermentation from juice with a high solids content (rather than cultivated yeast-inoculated fermentation of sterile juice), with the aim of producing a more characterful, individual product.

Traditional brewing yeasts are unlikely to be pure cultures, so there is also the requirement to maintain a constant composition of the mixture (Campbell, 2000). One strain of the yeast population may predominate in the early stages of the fermentation, another strain later and a third strain later still. The yeast 'head' must be skimmed off several times during the fermentation to prevent it collapsing back into the beer and creating

off flavors, but only part of the recovered yeast is selected for reuse in subsequent fermentations (see Sections 2.6.4 and 2.6.5). Flocculation of yeast in beer production is also an important characteristic, as too early flocculation brings the fermentation to a premature end. Nonflocculent yeasts, however, remain in suspension and have to be removed by centrifugation or filtration. Pioneer yeast taxonomist E.C. Hansen first recognized pure brewing strains from beers in Belgium, Britain and Germany as *S. cerevisiae*, and differentiated them from strains isolated from Czech and Bavarian beers (*S. carlsbergensis*, now known as *S. ovarum*). Pure cultures of the latter yeast are now used worldwide for production of the Pilsener style of beer (Campbell, 2000) (Section 2.6.6).

Although yeasts are the organisms primarily associated with alcoholic fermentation, bacteria (and body cells) perform innumerable anaerobic conversions that are as useful and important. Different fermentations are distinguished by the final product of the process. In lactic acid fermentation, pyruvate is reduced to lactate. This fermentation takes place in a number of different environments, as well as in muscle cells in the human body. Lactic acid will accumulate in muscles that undergo anaerobic metabolism, leading to stiffness and pain. Nerve cells, however, are unable to reduce pyruvate to lactic acid, as they lack the enzyme, and therefore, without adequate oxygen, these cells (including those in the brain) rapidly cease functioning (Purves *et al.*, 2001).

2.1.2 Lactic Acid Bacteria

The fermentation carried out by lactic acid bacteria (LAB) is crucial in the production of other foodstuffs like yogurt, cheese, sauerkraut and pickles. Traditionally, bacteria do not play a role in winemaking until after the alcoholic fermentation. Nearly all red wines, and certain styles of white wine undergo the second or malolactic fermentation (MLF), during which malic acid, and occasionally other substrates, are converted to lactic acid (and other products) by lactic acid bacteria. This fermentation tends to happen naturally in the barrel during red wine maturation, but can also be deliberately induced through inoculation with a bacterial starter culture. The species most commonly used for this purpose in winemaking is *Oenococcus oeni* (previously known as *Leuconostoc oenos*). As well as making wine 'softer,' by converting malic to lactic acid, this fermentation adds complexity to the wine and increases microbial stability by removing an important metabolic substrate from solution. Lactic acid bacteria, like *Saccharomyces cerevisiae*, are unusual in their preference for fermentation over respiration, and their ability to survive in the relatively harsh conditions in wine. They occur in grape juice at low concentrations (10^3 cfu/ml) and usually decrease to even lower numbers during fermentation unless there is a delay in the onset of fermentation, in which case they grow and utilize substances otherwise available for the yeast. They can also produce acetic acid, which can limit yeast growth. Some authors therefore consider inoculation with bacteria for malolactic fermentation before alcoholic fermentation to be unwise. Swiegers *et al.*, (2005) noted that during malolactic fermentation, bacteria do not only provide deacidification, but they are also able to enhance the flavor profile of the wine. Malolactic fermentation is considered in more detail in Chapter 2.3.

2.1.3 Molds and Spoilage Organisms

The influence of molds (filamentous fungi) on the modification of the composition of the grape juice is not a subject of much investigation in the current literature. Their main influence occurs during grape cultivation, when they cause grape spoilage. Damaged and diseased fruit may also have populations of filamentous fungi such as *Aspergillus*, *Botrytis*, *Penicillium*, *Plasmopara* and *Uncinula* species. Fungal growth on grapes can produce various metabolites and conditions that may disturb the ecology and growth of yeasts during

alcoholic fermentation. There are reports that *Botrytis cinerea*, *Aspergillus* spp. and *Penicillium* spp. produce metabolites that retard the growth of yeasts during fermentation (Fleet, 2003). The activities of *Botrytis cinerea* in the vineyard may lead to high quality noble wines, or spoilage and taints, depending on climatic conditions at the time of their involvement with the grapes. If wet conditions persist in the vineyard during a period of infection, other organisms will become involved, leading to the formation of the notorious 'grey rot.' There is little that can be done with grapes in this condition. If weather conditions are conducive to the formation of noble rot (i.e. short damp periods, followed by dry, warm conditions, when the grapes are ripe) the effect of the mold will be to concentrate the sugar and flavor compounds in the berries through desiccation. Good quality noble rot wines can fetch high prices, which will offset the loss of income normally achieved through volume.

The role of specific species of molds in the notorious cork-taint problem and the microbiota associated with various cork manufacturing processes are still not fully understood (Álvarez-Rodríguez *et al.*, 2002), but *Trichoderma* and *Fusarium* were able to carry out the conversion of 2,4,6-trichlorophenol to 2,4,6-trichloroanisole when grown on cork. The role of *Penicillium* and *Aspergillus* in the production of corky and moldy taints was also noted (Jackson, 2000).

Damaged grapes have increased populations of lactic and acetic acid bacteria that impact on yeasts during alcoholic fermentation. Acetic acid bacteria have the ability to oxidize ethanol to acetic acid (vinegar) in the presence of oxygen. Under anaerobic conditions, they are able to use quinones as hydrogen acceptors and maintain a limited metabolism (Jackson, 2000). Their survival in tanks and bottles of wine without oxygen present, while being unexpected, is therefore still possible. If there are traces of oxygen present, such as those absorbed by wine during transfer operations or while in barrel, the survival of a population of acetic bacteria is almost guaranteed. The bacteria grow on damaged fruit and the population may reach 10^6 cfu/ml, in affected juice with the species *Gluconobacter oxydans* dominating. During alcoholic fermentation, populations of the bacteria tend to decrease, but given the right opportunities, *Acetobacter aceti* may grow. The most well known consequence of acetic acid bacterial activity is the production of volatile acidity, comprising mainly acetic acid. Ethyl acetate, also an important component of volatile acidity, is produced through nonenzymic esterification, as well as by other organisms and is not necessarily associated with acetic bacteria (Swiegers, *et al.*, 2005). The significance of acetic acid bacteria is greater than the production of 'vinegar' characters, however. Acetic acid is known to be a growth inhibitor for yeasts, and the presence of a large population of acetic or lactic acid bacteria can be antagonistic to yeast growth and may assist in causing stuck fermentations. Spoilage organisms are discussed in more detail in Chapter 2.4.

Alcoholic fermentation and associated topics, covering all alcoholic beverages, are the subjects of a very large number of research papers and have also been reviewed and summarized in many book chapters, including Zoecklein *et al.* (1995), Boulton *et al.* (1996), Jackson (2000), Ribéreau-Gayon *et al.* (2000), Boulton and Quain (2001) and Berry and Slaughter (2003).

2.2
Alcoholic Fermentation

2.2.1 Introduction

Mankind has harnessed the abilities of yeast in brewing and bread making since the beginning of recorded history, and yeasts are probably one of the earliest organisms to be domesticated. However, it was only clearly established in the mid nineteenth century that conversion of glucose and fructose to ethanol and carbon dioxide (fermentation) is a microbial process. Pasteur, in around 1876, showed that fermentation did not arise spontaneously and isolated the yeasts responsible for it (Madigan *et al.*, 2003). He also demonstrated the effect of oxygen on the assimilation of sugar as well as the production of secondary products by fermentation, i.e. glycerol and carbon dioxide. As noted in Chapter 2.1, the most significant species involved in winemaking and brewing are *Saccharomyces cerevisiae.* According to Ribereau-Gayon and coworkers (2000a), after investigating the delimitation of winemaking species, all the strains of '*bayanus*' isolated in their study were found to belong to the species *S. cerevisiae*. On the other hand, yeast called '*uvarum*' principally belong to the species *S. bayanus*. In short, yeast species involved in commercial fermentations for wine and beer comprise a very large number of genetically similar strains, with varied technological properties. Yeast strain can affect the rate of fermentation, the efficiency and success of conversion of sugar to ethanol, and the nature and quantity of by-products.

2.2.2 Physiology and Morphology of Yeast

There are over 100 genera of yeast, representing around 700 species (Swiegers *et al.*, 2005), but a limited number are used in the production of beverages. In a winemaking context, for example, there may be up to 16 species involved, of which only one (*S. cerevisiae*) is of any real significance. Despite the considerable phenotypic differences among the yeast strains used for commercial brewing and winemaking purposes, most of them are now considered to be physiological strains of *S. cerevisiae.* The assignment of most of the traditional wine yeast strains to a single species does not, however, imply that all strains of *S. cerevisiae* are equally suitable for the various wine fermentations; they differ significantly in their fermentation performance and their contribution to the final bouquet and quality of wine and distillates (Pretorius, 2000).

Yeasts used in brewing and winemaking (e.g. *S. cerevisiae)* are unicellular fungi that mainly belong to the *Ascomycetes* (sac fungi) and *Deuteromycetes* (imperfect fungi) classes. They do not possess chlorophyll, cannot photosynthesize (Madigan *et al.*, 2003), and therefore utilize complex foods for their nutrients,

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

which they can metabolize with or without oxygen present. Each yeast cell possesses one membrane bound nucleus enclosing the chromosomes (in contrast to other fungi which may be multinuclear). The genome of *S. cerevisiae* has been under scrutiny for decades, with no less than 12 genetic maps of the organism published between 1960 and 1997 (Boulton and Quain, 2001a). It is probably reasonable to claim that *S. cerevisiae* are genetically the best understood of all organisms, and this intimate knowledge of the genome has many applications in fermentation technology. As fungi, *S. cerevisiae* are classified as ascomycetes because they produce ascospores through meiosis (sexual reproduction). This is triggered when yeast are nutritionally stressed, for example by deprivation of a carbon or nitrogen source. The diploid yeast in the population produces four haploid nuclei, which are incorporated into four stress-resistant ascospores, encapsulated in the ascus. Another characteristic of *S. cerevisiae* is that they are also able to grow vegetatively, i.e. they can reproduce asexually by budding multilaterally or extruding a bud from a point on the mother cell (Jackson, 2000a). When this extrusion reaches about half the size of the parent cell it is pinched off and becomes a daughter cell, leaving a 'budscar' on the mother cell. Buds may arise at any point on the mother cell surface, but never again at the same site. Branched chaining (pseudohyphae) may occasionally follow multilateral budding when buds fail to separate. Under optimal nutritional and cultural conditions *S. cerevisiae* double their mass every 90 minutes (Pretorius, 2000). Vegetative reproduction is normal under the conditions found in must and wine, as ascal development is suppressed by high concentrations of glucose, ethanol or carbon dioxide.

Like all plant cells, yeast have two cellular envelopes, the cell wall and cell membrane – the properties of which distinguish them from other eukaryotes. The cell envelope, comprising a cell wall, periplasm and plasma membrane, surrounds and encases the yeast cytoplasm. It makes up 15 to 20% of the dry weight of the cell, and incorporates chitin, a major constituent of the cell walls of other fungi, but only as a component of bud scars. The cell wall is fairly rigid, but a little elastic, and consists of mannoproteins and β-glucans (Feuillat, 2003). The β-glucans are of three types: fibrous (β-1,3), amorphous (β-1,3) or ramified β-1,6 glucans. The mannoproteins can be extracted and are important in the stability and clarity of the product. The cell membrane is a selective barrier controlling exchanges between the living cell and environment. Like the membranes of most eukaryotes, it is stable and mainly hydrophobic in nature. The principle components of the membrane are lipids and proteins, as well as a number of other factors important in selectivity and efficiency as a transport organ and barrier. The concentration of sterols in the cell membrane, for example, affects the penetration of glucose into the cell, as well as yeast survival during fermentation (Larue *et al.*, 1980). Ribereau-Gayon and coworkers (2000b) stated that ergosterols are indispensable to yeast in complete anaerobiosis. Membrane ATPase has a role in yeast resistance to alcohol, and the presence of ethanol will slow the penetration of glucose and arginine into the cell and limit the output of protons from the membrane. The membrane also permits the yeast to react to external stimuli like sex hormones. Optimum functioning of the cell wall and membrane are essential for a successful fermentation, flocculation of the cells after fermentation, the release metabolic products from the cell that add to flavor of the product, and autolytic characters during *sur lie* (on lees) maturation after fermentation (Ribereau-Gayon *et al.*, 2000c).

The structural organization of the cytoplasm, containing organelles such as the nucleus, endoplasmic reticulum, Golgi apparatus, mitochondria and vacuoles, is maintained by a cytoskeleton. Several of these organelles derive from an extended intramembranous system and are not completely independent of each other (Pretorius, 2000).

2.2.3 Nutritional Requirements of Yeast

Yeasts have relatively simple nutritional needs. Unable to carry out photosynthesis, they require a reduced carbon source, which can be as complicated a compound as a disaccharide or as simple as acetate. In addition, they need the vitamin biotin and an organic nitrogen source such as ammonium, urea or the amino acids.

Like most eukaryotic organisms, they also require nitrogen in an assimilable form, and a variety of salts and trace elements for metabolic purposes. In brewing and winemaking terms, however, the most important nutritional ability of yeast (specifically *S. cerevisiae*) is that in the absence of oxygen, they are able to transform mono- and disaccharides to alcohol through the process of fermentation. As will be discussed subsequently, they are also capable of respiration (using oxygen as a final electron acceptor during metabolism) under specific conditions.

Of all nutrients assimilated by yeast during wine fermentations, nitrogen is quantitatively second only to carbon. Research has found that the total nitrogen utilized during the catabolism of 200 g/l glucose when all amino acids are in excess is around 400 mg/l, and nitrogen utilization is influenced by the presence of air in the fermentation headspace, ammonium supplementation and initial glucose concentration (Jiranek *et al.*, 1995). *S. cerevisiae* is incapable of adequately hydrolyzing grape proteins to supplement nitrogen deficiency, and relies therefore on the ammonium and amino acids present in the juice. Wine yeasts can distinguish between readily and poorly used nitrogen sources. Ammonium is the preferred nitrogen source and, as it is consumed, the amino acids are taken up in a pattern determined by their concentration relative to the yeast's requirements for biosynthesis and to total nitrogen availability. Deficiencies in the supply of assimilable nitrogenous compounds remain the most common causes of poor fermentative performance and sluggish or stuck fermentations, as nitrogen depletion irreversibly arrests hexose transport (Pretorius, 2000). Other problems related to the nitrogen composition of grape must include the formation of reduced-sulfur compounds, in particular hydrogen sulfide, and the potential formation of ethyl carbamate from metabolically produced urea. The ability to utilize a specific nitrogen-containing compound as a carbon source depends on a variety of factors, e.g. the degradation of the amino acid proline for use as a nitrogen source requires molecular oxygen. Addition of ammonium delays metabolism of amino acids, but increases the total nitrogen consumed (Jiranek *et al.*, 1995). The metabolism of individual amino acids varies between strains of yeast, but arginine, serine, glutamate, threonine, aspartate and lysine typically comprise the bulk of nitrogen used by yeast. Proline and arginine account for 30–65% of the total amino acid content of grape juices, with high proline accumulation in grape must associated with grapevine stress, in particular with low moisture (Pretorius, 2000). When a readily used nitrogen source (such as ammonium, glutamine or asparagine) is present, genes involved in the uptake and catabolism of poorly utilized nitrogen sources (including proline) are repressed. This repression impairs the assimilation of proline, as well as arginine, since both amino acids depend on the proline utilization pathway. Since the proline content of wine is generally not less than grape juice, it appears that proline is not taken up by wine yeast under anaerobic fermentative conditions.

Bell and Henschke (2005) state that both the form and amount of yeast-assimilable nitrogen (YAN) have implications for quality. Low must YAN leads to low yeast populations and poor fermentation vigor, increased risk of sluggish fermentations and production of thiols and higher alcohols, and low production of esters and long chain fatty acids. High must YAN increases biomass production, greater fermentation vigor, increased production of volatile acidity, the possibility of protein hazes due to higher levels of protein and microbial instability. Injudicious use of diammonium phosphate supplements often results in excessive levels of residual nitrogen, leading to microbial instability and ethyl carbamate (and phosphate in the case of DAP) accumulation in wine (Pretorius, 2000). The degree of supplementation of inorganic nitrogen in grape juice is usually regulated. This implies that knowledge of the nitrogen content of grape juice and the requirement for nitrogen by yeast are important considerations for optimal fermentation performance and the production of wines that comply with the demands of regulatory authorities and consumers. Urea, short peptides and nitrogenous bases (excluding thymine) can also be degraded by *Saccharomyces*. Nitrates, nitrite and most of the other organic amines cannot be utilized (Jiranek *et al.*, 1995). For more discussion on metabolism of amino acids by brewers' yeast in beer production, see Section 2.6.4.

The only vitamin that is required by *Saccharomyces* is biotin, although other vitamins can stimulate growth. *Saccharomyces* quickly depletes the supply of vitamins in the medium. A number of metals, including

iron, copper and manganese are also required at trace levels (Jackson, 2000b). *Saccharomyces* species are somewhat limited in the compounds that can be used as carbon and energy sources, when compared to other microorganisms. The monosaccharides glucose, fructose, mannose and galactose support growth and metabolism, and the disaccharides sucrose, maltose and melibiose can be utilized by most strains of *S. cerevisiae*, depending on their genetic background. Raffinose, a trisaccharide can also serve as substrate. Substrates that support oxidative or respiratory growth are also limited: pyruvate, lactate, ethanol, acetate and glycerol. Glycerol provides weak support when it is the only carbon source and energy source in a minimal, defined medium (Walker, 1998a). Other organic acids or alcohols cannot be utilized as carbon and energy sources by *Saccharomyces*, although some, such as malic acid, are metabolized to other compounds by some strains. Pentoses are not utilized by the strains of *S. cerevisiae* used in winemaking.

2.2.4 The Use of Naturally Occurring ('Wild') Yeasts in Fermentations

Formerly, producers relied on making yeast starter cultures from juice (sulfited to eliminate wild yeast and promote *S. cerevisiae*), which were inoculated into fermentors at 2–5% after several days of spontaneous fermentation. Spontaneous fermentation can be regarded as a heterogeneous microbiological process involving the sequential development of various yeasts and other microbiological species, affected by the prevailing fermentation conditions in a particular vat or tank (Pretorius, 2000). When grape must is used as a culture medium, selective pressures favor the yeasts with the most efficient fermentative catabolism, particularly strains of *S. cerevisiae* and perhaps strains of closely related species such as *S. bayanus*. For this reason, *S. cerevisiae* is almost universally preferred for initiating alcoholic fermentation, and has earned itself the title of 'the wine yeast.' For winemaking purposes, yeasts are frequently categorized as 'wild' yeasts or 'wine' yeasts. Generally speaking, these terms differentiate between yeast that are present naturally in the fermentation medium as a result of contamination of surfaces of substrate and equipment with organisms or spores, and yeast that is inoculated via a commercial starter culture (usually a single strain). All yeasts are wild in the sense that they may occur naturally in the environment, however the majority are not well suited to the conditions of alcoholic fermentation. Most wild yeasts are aerobic (Ribereau-Gayon *et al.*, 2000d) and they stop metabolizing when alcohol levels reach around 4%, or must density drops to 1.070–1.060. Although they can play a positive role in the character of the product through ester formation, some wild yeast may produce unwanted characters like volatile acidity, acetaldehyde and hydrogen sulfide. The practice of spontaneous fermentations remained prevalent in 'Old World' wine-producing areas until the 1980s because of the popular belief that superior yeast strains associated with a particular 'terroir' gave a distinctive style and quality to wine. The final product of spontaneous grape must fermentation is a result of the combined action of different yeast species, which contribute in different ways to the organoleptic properties of wine, (Shimazu and Watanabe, 1981). Conversion of grape sugars to alcohol and other end products by mixed populations of yeast may undoubtedly yield wine with distinct sensorial quality, often described as wine with a fuller, rounder palate structure. This may well be the consequence of higher concentrations of glycerol and other polyols produced by indigenous yeasts. Producers may utilize the various fermentative characteristics of wild yeast in the early phase of fermentation to potentially improve the product, and achieve stylistic distinction and vintage variability, as long as the process is managed carefully. Using natural flora also reduces costs to the producer, if all goes as planned (quite the opposite if not). The outcome of spontaneous fermentation depends not only on the numbers and diversity of yeasts present in must, but also upon grape chemistry and processing protocol, and is difficult to predict.

The characteristics and metabolism of non-*Saccharomyces* yeasts are discussed in more detail in Chapter 2.4. Also, further discussions on spontaneous fermentations can be found in Sections 2.6.7 (lambic beers), 2.7.2 (indigenous African beverages and Mexican pulque) and 2.8.4 (cider and perry). Also, the influences

of various non-*Saccharomyces* yeasts and other microorganisms on the organoleptic qualities of spirits are discussed in Sections 3.2.3 (Scotch whisky) and 3.7.3 (grape pomace spirits).

2.2.5 The Killer Factor

Certain yeast species, known as killer (zymocidal) strains, secrete exocellular toxins into their environment, which are lethal to other, sensitive strains of yeast and therefore provide a competitive advantage in fermentations (Ribereau-Gayon *et al.*, 2000e). The killer phenomenon in *S. cerevisiae* is associated with the presence of a proteinaceous toxin (zymocin), which is secreted by the zymocidal strains and is lethal to sensitive strains of the same species. Some yeast strains are immune to these zymocins, but do not produce active toxin. These are the so-called 'neutral' strains (Pretorius, 2000). The killer factor exists in most strains of *S. cerevisiae,* as well as other genera including *Hansenula, Kluyveromyces* and *Candida.* Killer yeasts offer both control (when inoculated to achieve a desired result) and a risk (when working as contaminating agents). When used as inoculants they offer certain benefits, including domination over wild yeasts which may cause delayed fermentation or production of off flavors, and protection in the wine from subsequent infection by spoilage yeasts. Shimizu and coworkers (1985) studied the distribution of killer yeast strains by geographical location. Australian wild yeast analysis showed killer strains only in *S. cerevisiae*. In Japan similar analysis showed killer properties in *S. cerevisiae* and *Hansenula* strains whilst Beaujolais (France) showed very high incidences (83%) of killer strains amongst a greater range of wild yeasts, including *Saccharomyces*, *Kloeckera*, *Candida*, *Hansenula and Torulaspora.* Most Mediterranean vineyards showed higher incidences of killer properties (65–90%), probably due to a combination of viticultural practices, climate and the extent of continual cultivation. In red wines, the killer function appears to be inactivated after about three days, possibly due to complexing of the toxin proteins with tannins. As the killer factors are proteins, their stability will be affected by ethanol levels, SO_2 concentration and by interactions with tannins and fining agents. The killer function is also inactivated by high temperature and high pH (Shimizu, 1993), but is favored by the acidic conditions of grape must (pH 2.8–3.8). Apart from sporadic reports, which imply that the presence of killer yeast could contribute towards stuck (incomplete) or sluggish fermentations, zymocidal *S. cerevisiae* strains have no negative effect on the wholesomeness and sensorial quality of wines that are produced (Pretorius, 2000).

2.2.6 The Use of Selected (Cultured) Yeast Strains

In 1890, Müller-Thurgau from Geisenheim introduced the concept of inoculating wine fermentations with pure yeast starter cultures (Pretorius, 2000). Currently, yeast manufacturing companies market a wide variety of dehydrated cultures of various *S. cerevisiae* strains. Most commercial freeze-dried cultures (or active dry yeast, ADY) contain yeast that was originally selected by various manufacturers from successful natural fermentations. In large-scale wine production, however, where rapid and reliable fermentations are essential for consistent wine flavor and predictable quality, the use of selected pure yeast inocula of known ability is preferred. These large wineries will be the main beneficiaries of programs aimed at producing new yeast strains with even more reliable performance, reducing processing inputs and facilitating the production of affordable high quality wines. The brewer or winemaker now has the option of selecting a commercial strain for a specific attribute (for example, the ability to hydrolyze monoterpenes from glycolysated precursors). There is a strong incentive to develop wine yeast strains with an ability to accumulate trehalose and glycogen as starter cultures, because trehalose appears to stabilize cell membranes of lyophilized yeast, as well as their cellular proteins by replacing water and forming a hydration shell around proteins. Glycerol accumulation

seems to control the concentration of solutes inside the cell relative to that of the culture medium, thereby counteracting the negative effects of dehydration.

The choice of yeast will be based on previous experience, the style of beverage required and the technical specifications of the yeast culture. Selected ADY is sold freeze-dried in packets which should be stored in a cool place and resealed if opened and not fully used. Yeast will still be viable if a packet is left unopened until the next season (or the use by date). Rehydration according to the manufacturer's recommendations is important for the survival of the yeast, as it affects the cell membranes and if the wrong method is used, viability will be reduced, for example if the recommended rehydration temperature is 35–40 °C, 100% of the yeast should be viable in this range (Morgan *et al.*, 2006). In inoculated fermentations, the actively growing starter culture dominates the native yeast species present in grape must, as long as the manufacturer's rehydration protocols are followed. There should be sufficient yeast to ferment the required juice if the dose rate recommended by the manufacturer is used, (usually 10–15 g/hl or 10^6 cells/ml in a winemaking context (Ribereau-Gayon *et al*., 2000f), giving a cell density upon inoculation of 1–3 million colony forming units (cfu)/ml (Pretorius, 2000). Walker (1998b) noted the absolute requirement of oxygen by *S. cerevisiae* for build up of cell numbers in the yeast starter, and ensuring adequate synthesis of sterols that aid yeast growth and survival during fermentation. Hence the starter should be aerated before addition to must to ensure a high count of active cells. If oxygen is deficient in the must, the lag phase between yeast addition and fermentation onset will be prolonged, thereby increasing the chances of infection by spoilage organisms.

2.2.7 Fermentation Vessels

Fermentation systems will reflect the type of beverage being made, the tradition of the country of production and the throughput of the producer. Vessel design, the method of operation and the variety of yeast used are related. Traditional vessels continue to be used and replaced, even in newer concerns, as brewing and winemaking tend to be conservative industries, and shortcomings of the systems are accepted as the price to be paid for continuity of style and the perceived quality of the product (Boulton and Quain, 2001b). In many countries, however, there is a trend towards fewer and larger producers with ever increasing batch sizes. Larger fermentation vessels represent a considerable risk if the product in them is in any way atypical. Material of construction, ease of cleaning, capacity, geometry, and monitoring and control facilities are all important when a system is being considered for use.

2.2.8 The Growth of a Yeast Population

A typical fermentation is almost completely anaerobic. The molecular oxygen that is available in the processed must or juice is quickly utilized by any microorganisms present in the medium. Yeasts require oxygen to synthesize and assimilate substances vital to their reproduction. If the must is not aerated, oxygen will become the limiting factor, yeast numbers will be too low to ferment effectively and the fermentation may end prematurely. In these circumstances it is not unusual for the fermentation medium to become reductive and hydrogen sulfide may be formed (Morgan *et al.*, 2006). The modern trend in winemaking is to use large doses of selected yeasts that have been grown in hyperaerated media and are rich in the necessary growth factors. If aeration is required in order to enhance aromatic complexity, exposing the must to oxygen at the beginning of the fermentation is much less risky and more effective then at the end, when the yeast growth factors are depleted. Musts from rotted vintages should be aerated as little as possible due to the presence of oxidative enzymes in solution. Red musts can be aerated to a greater extent to increase the rate of fermentation (Morgan *et al.*, 2006).

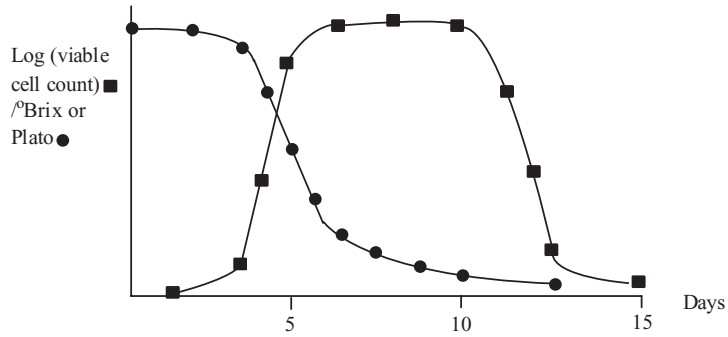

Figure 2.2.1 *Fermentation profile. This is a general profile; actual profiles depend on temperature and other factors. See also Figure 2.6.17, Section 2.6.5*

As stated previously (see Chapter 2.1), although *Saccharomyces* is virtually untraceable in the microbial flora of the grape, it very quickly dominates the fermentation so that at completion a nearly pure culture of this yeast is observed. Inoculation of the fermentation with *Saccharomyces* causes a faster domination of the fermentation by this organism. The reason for this domination can be found in the specific adaptation to high sugar, virtually anaerobic environments. Indeed, such environments appear to be the specific ecological niche in which this organism can flourish and dominate all other microorganisms. Yeast cells multiply during grape juice fermentation and their growth kinetics follow a typical microbial growth curve (Figure 2.2.1) which reflects the growth of cell number and decrease in sugar concentration (° Brix).

Margalit (1996) identified four key stages in the growth pattern of yeasts, a 'lag' period during which the yeast cells become acclimatized to conditions in the must and start multiplying; a period of rapid, exponential growth to a final population of around 2×10^8 cells/ml; a stationary phase during which the number of cells undergoing fission equals those dying, and a decline or death phase in which the number of cells dying exceeds the number undergoing fission. Sugars are metabolized through the first three phases.

Factors affecting the growth of a yeast population, and therefore the progress and efficiency of a typical fermentation are as follows: The sugar concentration can cause problems if it is too high, or too low. If it is too low, the yeast will respire if there is any oxygen present, producing carbon dioxide and water instead of ethanol. If it is too high, the osmotic pressure exerted on the yeast can delay the onset of fermentation. Approximately 50% of the total available sugar is used during the exponential growth phase, while the rest is fermented by the cells during the stationary phase. Sugar concentration may also influence the composition and concentration of aroma compounds produced by the yeast (see Section 2.2.2).

Apart from the inhibitory effect of excessive sugar content on yeast growth and fermentation, the production of excessive amounts of ethanol, coming from harvest of over-ripe grapes, is known to inhibit the uptake of solutes (e.g. sugars and amino acids) and to inhibit yeast growth rate, viability and fermentation capacity. The concentration of ethanol, as stated, can have an effect on yeast as it is a physiological toxin. The physiological basis of ethanol toxicity is complex and not well understood, but it appears that ethanol mainly impacts upon membrane structural integrity and membrane permeability (Pretorius, 2000). Resistance to ethanol toxicity is strain dependent, and factors increasing resistance are linked to decreased membrane permeability, for example the uptake of palmitic acid into the cell. Several factors are known to enhance the inhibitory effects of ethanol. These factors include high fermentation temperatures, nutrient limitation (especially oxygen, nitrogen, lipids and magnesium ions) and metabolic by products, such as other alcohols, aldehydes, esters, organic acids (especially octanoic and decanoic acids), certain fatty acids, and carbonyl and phenolic compounds. The effect of ethanol on suppression of sugar uptake by cells has been documented,

and this effect is increased with increasing temperature. Higher alcohols are even more toxic than ethanol, but normally do not occur in high enough concentrations during a normal fermentation to cause problems (Pretorius, 2000). Cell viability and sensitivity to alcohol toxicity are increased at higher sugar levels, and above 250 g/l, the likelihood of a stuck fermentation increases considerably (Jackson, 2000c), with ethanol production declining significantly. The producer is confronted with the dilemma that, while ethanol is the major desired metabolic product of grape juice fermentation, it is also a toxin that can lead to sluggish or stuck fermentations. A sluggish fermentation is more likely in small volume fermentations and occurs when the yeast ferment slowly and sometimes stop before the medium is dry.

Most so-called survival factors (e.g. certain saturated long chain fatty acids and sterols) are formed only in the presence of molecular oxygen, which in part explains the great success in the use of commercial starter cultures that are cultivated under highly aerobic conditions and in low glucose concentrations. These starter yeast cells contain high levels of the survival factors that can be passed onto the progeny cells during the six or seven generations of growth in a typical fermentation. Successful yeast cellular adaptation to changes in chemical or physical environmental parameters during fermentation requires the timely perception (sensing) of these parameters (e.g. fermentable sugars, assimilable nitrogen, oxygen, vitamins, minerals, ergosterol, ethanol, acetic acid, fatty acids, sulfite, agrochemical residues, killer toxins and unsaturated fatty acids), followed by accurate transmission of the information to the relevant compartments of the cell (Pretorius, 2000). Signals of a physical nature include factors such as temperature, pH, agitation and osmotic pressure in a complex, interconnected network.

Nutritional shortages can also give rise to a lagging or incomplete fermentation, naturally depending on the degree of the limitation. As well as causing fermentation to slow down, a shortage of nutritive substances, particularly nitrogen, can give rise to the formation of undesirable end products of metabolism, such as hydrogen sulfide and acetic acid. Under most winemaking conditions, a minimum of 150–250 mg/l assimilable nitrogen is recommended, and some authors have suggested levels as high as 500 mg/l (Jackson, 2000c). Nitrogen utilization usually occurs early during fermentation, before 5% ethanol has accumulated in the medium. Excess nitrogen has been linked to the formation of urea, which has been implicated in the formation of ethyl carbamate, a carcinogen (Bell and Henschke, 2005) (see Section 5.11.5). Mid chain length (C_8–C_{10}) saturated fatty acids and phenols are also known to affect yeast if present in high enough concentrations, affecting the progress of fermentations. Most manufactured lyophilized yeast has been grown in the presence of sufficient sulfur dioxide to provide some sort of resistance, but this is strain variable, and the preservative in high enough concentrations will impede membrane function in yeast, but at moderate concentrations (50 mg/l), most fermentations will progress unimpeded. Sulfur dioxide does have some other effects, for example, it inhibits acetic acid production, but favors glycerol synthesis. Elemental sulfur, if present in the medium as a result of antifungal treatment of fruit, can be assimilated, and in the worst case, reduced to hydrogen sulfide, thiols and mercaptans, thus adversely affecting the aroma of the resulting product. It is usually a complex problem. Other factors affecting yeast growth include build up of toxic by products, oxygen depletion, and carbon dioxide and osmotic pressure.

The lag phase usually lasts for 1–2 days, but may be longer if SO_2 concentrations are high, there is insufficient yeast present or there are other inhibitory substances such as spray residues in solution. The temperature should be controlled during the exponential growth phase to give the desired rate of fermentation. During the exponential and stationary phase, the bulk of the sugar is converted into alcohol. Towards the end of the stationary phase the population decreases, but significant sugar metabolism still takes place in the absence of growth of the population. The sugar is utilized exclusively as an energy source during this stage, and not as a carbon source in the production of biomass. The conversion to alcohol slows down towards the end of the stationary phase as the yeasts run out of food and die. In the death phase, the total number of cells remains constant but viability decreases. After this, there is little activity and fermentation finishes. Yeast cells will precipitate, and form a dense layer at the bottom of the fermentation vessel. Depending on

the strain, and temperature during this '*sur lie*' period, autolysis will set in and cell contents will be released back into the medium.

2.2.9 An Overview of Alcoholic Fermentation

Under anaerobic conditions, deprived of oxygen, yeast can only convert sugars to carbon dioxide and ethanol, recovering less of the energy stored in the substrate molecules:

$$C_6H_{12}O_6 + \text{Yeast} \rightarrow 2C_2H_5OH + 2CO_2 + \text{ATP(Energy)} + \text{Heat}$$

A carbon compound (acetaldehyde) acts as terminal acceptor of electrons, which are generated during the conversion of sugar metabolites to energy in the form of ATP, and ethanol is formed. The final concentration of ethanol depends on the initial concentration of sugars (or other substrate) in the must or juice, as well as the fermentation temperature, since some ethanol is lost during warmer, faster fermentations. In winemaking, the sugar content of the grapes is therefore a very important factor when the time of harvesting is chosen. The amount of residual sugar in solution after fermentation is also an important stylistic consideration and the final sugar, acid and alcohol levels must be balanced in the finished product. Residual sugar is desirable in dessert or sweet wine, but not in most table or dry wines. A better understanding of the factors that influence sugar utilization and fermentation rate will allow for greater control over the fermentation parameters and therefore allow better diagnosis of problem fermentations.

The main sugars present in grape must, glucose and fructose, are metabolized to pyruvate via the glycolytic pathway in *S. cerevisiae* (as well as the majority of other organisms). In yeast, under fermentation conditions, the pyruvate is then decarboxylated to acetaldehyde, and further reduced to ethanol. The rate of fermentation and the amount of alcohol produced per unit of sugar during the transformation of grape must into wine is of considerable commercial importance. During wine yeast glycolysis, one molecule of glucose or fructose yields two molecules each of ethanol and carbon dioxide. However, the theoretical conversion of 180 g sugar into 92 g ethanol (51.1%) and 88 g carbon dioxide (48.9%) could only be expected in the absence of any yeast growth, production of other metabolites and loss of ethanol as vapor. In a model fermentation, about 95% of the sugar is converted into ethanol and carbon dioxide, 1% into cellular material and 4% into other products such as glycerol (Pretorius, 2000).

All fermentation pathways are anaerobic. Fermentation is a complex process, involving around 30 different steps, each with its own enzyme. Each 100 g of glucose theoretically produces 51.1 g of ethanol and 48.9 g of carbon dioxide. As discussed previously (Chapter 2.1), yeasts draw their energy from degradation of organic nutrients and the useful ('free') energy obtained is transported within cells as ATP. Depending on aerobic conditions (with or without oxygen), yeast can degrade sugars using two metabolic pathways: alcoholic fermentation and respiration. These two processes begin in the same way, glycolysis, where one sugar molecule produces pyruvate and a net gain of two ATP molecules. The process of fermentation requires two enzymes to metabolize pyruvate, the first is involved in the decarboxylation of pyruvate to acetaldehyde; the second reduces the acetaldehyde to NAD^+ and H^+ as well as ethyl alcohol (Purves *et al.*, 2001). It does not need oxygen or an electron transport system, and uses an organic molecule as the final electron acceptor. When phosphate groups are removed from ATP to produce ADP or adenosine diphosphate, 30.5 kJ (7.3 kcal) worth of energy per mole of compound is released, and some of this energy is coupled to useful activities within the cell like transport, movement or synthesis. The rest is dissipated as heat.

In a liquid environment like grape juice, yeasts will settle to the bottom of the container and grow anaerobically, consuming any dissolved oxygen as they oxidize simple carbon sources, such as monosaccharides, ethanol, acetate or glycerol, to carbon dioxide and water. On a nutrient surface or in a ventilated container,

they grow aerobically, with each cell (or colony forming unit) forming visible colonies within a few days. The pathway that operates is determined by the available substrate and the growth conditions.

A complete fermentation pathway begins with a substrate, includes glycolysis and results in various end products. The different fermentation pathways typically are named for the end products that are formed. As far as energy is concerned, fermentation itself does not generate ATP directly, but recycles a limited amount of NAD^+ back into glycolysis to keep the process going, and each pass through glycolysis generates two ATP molecules by substrate level phosphorylation. The change in free energy degrading a mole of glucose, via pyruvate to acetaldehyde and ethanol (and CO_2) is 167 kJ (40 kcal). Two ATP molecules are produced yielding about 63 kJ/mol glucose of useful energy, the rest (around 104 kJ) is dissipated in the form of heat (Jackson, 2000b). In respiration, the pyruvate is used with oxygen to produce nearly 15 times more biologically usable energy, as described later in this section. The availability of oxygen plays an important role in the metabolism, as molecular oxygen is the terminal electron acceptor during respiration, but it is needed for other reasons during high sugar, anaerobic fermentations. Despite the gains to be made from respiration, it is only in low sugar environments that yeast will respire pyruvate in preference to fermenting. In high sugar environments (e.g. musts) yeasts can only metabolize sugars by the fermentative pathway. Even in the presence of oxygen, respiration is impossible. This is known as the 'Pasteur effect' (Ribéreau-Gayon *et al*., 2000g). The aeration (oxygenation) of musts can still help alcoholic fermentation, but only because it enhances the production of fatty acids and sterols required by yeast cell membranes for proper function. According to Larue and coworkers (1980), aeration conditions of the medium determined the sterol content of yeasts which act as growth factors, fermentation inhibitors and survival factors for the yeast, particularly important if cells are to survive adverse conditions later in the fermentation. Ergosterol is the predominant sterol in yeast cells, but zymosterol, lanosterol and others are also present. In the cells, sterols account for 6% by weight of the protoplasmic membrane dry matter. The sterol content of the cells also differs with the strain of yeast and the conditions of culture. Molecular oxygen is also needed for the synthesis of the vitamin nicotinic acid (Jackson, 2000b).

The first step in alcoholic fermentation is the transport of sugars into the cell. This can be done in one of three ways: simple diffusion, facilitated (or carrier-mediated) diffusion or active transportation. Glucose, fructose and mannose are transported via facilitated diffusion, a process that does require energy and shares the same transportation system. Sucrose is sometimes used for enrichment, or chaptalization, in cool climate wine areas. Yeast cannot metabolize this disaccharide directly and it is hydrolyzed outside the cell by an excreted enzyme, invertase. The monosaccharides that result (glucose and fructose) are then transported into the cell (Jackson, 2000c). The disaccharide maltose is transported into the cell via an active transport mechanism, which requires energy. In other words, the rate of alcohol production by wine yeast is primarily limited by the rate of glucose and fructose uptake, and the loss of hexose transport towards the end of fermentation may result in reduced alcohol yields. Based on the spectacular increase in the amount of information on sugar sensing and their entry into yeast cells that has come to the fore over the last few years, several laboratories have identified this main point of control of glycolytic flux as one of the key targets for the improvement of wine yeasts (Pretorius, 2000).

The most common pathway for glucose (as well as fructose and mannose) catabolism is glycolysis, and the main purpose of this pathway under anaerobic conditions is energy production. It is noteworthy that when cells capable of fermentation like *S. cerevisiae* become anaerobic, the rate of glycolysis speeds up 10 times or more (Purves *et al.*, 2001), so a growth-sustaining level of energy generation is achieved despite the low yield of ATP generated by the metabolism of glucose through this pathway. During glycolysis, parts of the original glucose carbon skeleton will also be used for biomass formation or anabolism (the synthesis of biological molecules, amino acids, nucleic acids, lipids etc., according to the need of the growing and multiplying cells).

The glycolytic pathway (or glycolysis) (Figure 2.2.2), the conversion of glucose to pyruvate, is a universal pathway for glucose catabolism that is encountered throughout the eukaryotic kingdom, as well as in many

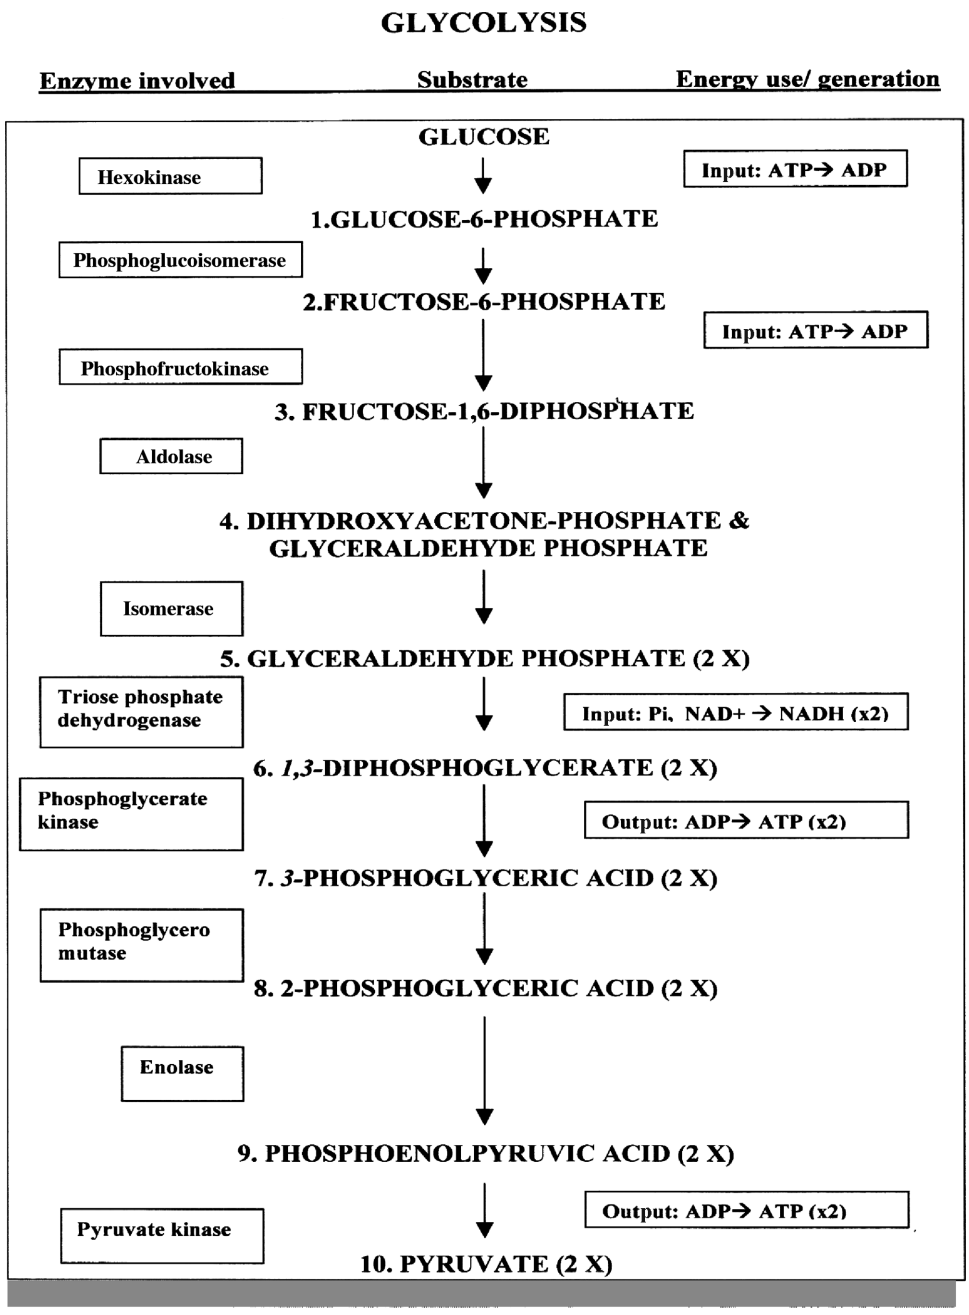

Figure 2.2.2 *An overview of the glycolytic pathway*

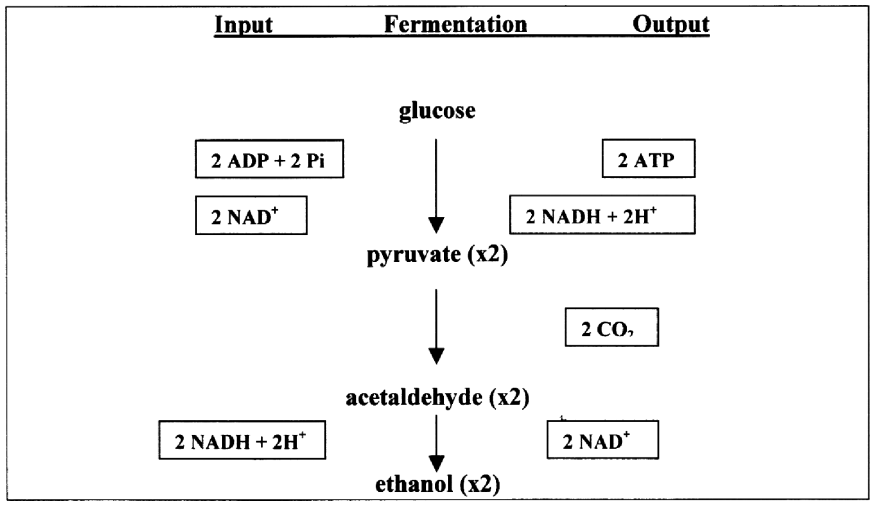

Figure 2.2.3 *An overview of alcoholic fermentation*

prokaryotes. This pathway is active under both fermentative and respiratory metabolism. Glycolysis consists of 10 steps, each catalyzed by a specific enzyme. The carbon skeleton of the sugar molecule is gradually dismembered during this process, and energy from the bond breaking is harvested in the form of ATP from ADP, and NADH from NAD^+. The first steps in glycolysis require an input of energy in the form of ATP, and serve to reorganize the sugar molecule. In fact, energy is invested in the first five reactions of glycolysis, and harvested in reactions 6, 7 and 10 (Jackson, 2000c). In step 4, the six-carbon sugar is split into two three-carbon moieties (glyceraldehydes and dihydroxyacetone) by the enzyme aldolase, and the preparatory reactions are complete. Thereafter, dihydroxyacetone is converted to glyceraldehydes and the two glyceraldehydes molecules are oxidized (hydrogen atoms with their electrons are removed), in the process reducing NAD^+ is to NADH. High energy bonds formed during glycolysis between phosphate groups and the substrate molecules are gradually broken, and the phosphate groups transferred to ADP molecules to form ATP.

During alcoholic fermentation (Figure 2.2.3), the pyruvate generated during glycolysis is converted to acetaldehyde, releasing carbon dioxide as a by-product. In *Saccharomyces*, the NADH from glycolysis acts as a reducing agent, and reduces acetaldehyde, which acts as the terminal electron acceptor, to ethanol. This process is necessary to maintain an acceptable redox balance within the cell (Jackson, 2000a). In the absence of oxygen, yeast cells are unable to transfer the energy stored in NADH to ADP and thus generate ATP other than through the reduction of acetaldehyde. Without this step, and the regeneration of NAD^+, the fermentation of glucose would cease altogether. In the early phases of fermentation, growth and cell division require considerable quantitities of reducing power (in short, the ability to get rid of excess electrons from within the cell). This is achieved through glycolysis, the diversion of sugar through the pentose phosphate pathway (to generate NADPH and precursors for nucleic acid synthesis), and the oxidation of pyruvic to acetic acid. The incorporation and reduction of compounds such as acetaldehyde and acetic acid that are initially released into the fermentation later on (Jackson, 2000c) helps to maintain the redox balance, and permit continuing fermentation. In contrast, during the declining phase of the fermentation, NADH and NADPH tend to accumulate.

Other organisms use other electron acceptors during fermentation and form, for example, reduced acids, such as the lactic acid bacteria. These organisms utilize pyruvate as a hydrogen acceptor during the reduction

to lactic acid, as do the cells of muscles in the human body during periods of strenuous activity (Purves *et al.*, 2001).

During respiration, which can be important in the earliest phases of the alcoholic fermentation and in all phases of commercial yeast production, most of the energy of the catabolism of carbon compounds is captured in the form of ATP. This is the result of the functioning of two metabolic pathways – the tricarboxylic or citric acid cycle and the electron transport chain. A further substrate level phosphorylation occurs during the succinyl-CoA-synthase reaction.

Fermentation and respiration are not mutually exclusive processes. If oxygen is available and glucose concentrations are low, *Saccharomyces* will switch to respiration for ATP production if fermentation cannot supply the ATP required for continued activity. This is not an instantaneous process, however, and yeasts need a period of adaptation to different growth conditions.

The next stage in respiratory metabolism is the citric acid cycle, also known as Kreb's cycle. Enzymes of this cycle and the electron transportation chain are situated in an endogenous organelle, the mitochondrion. Under anaerobic conditions, mature, fully functional mitochondria are not present in *Saccharomyces.* Since respiration is entirely dependent on oxygen, the enzymes required are only synthesized when needed, so in this respect, the availability of oxygen is a control mechanism for gene expression. In yeast, the expression of these enzymes is also controlled by the concentrations of glucose and other fermentable sugars in the medium. The expression is also suppressed by high concentrations of glucose and this regulatory phenomenon is known as glucose repression or the Crabtree effect (Boulton and Quain, 2001c). When the substrate is not limiting (i.e. present in high concentrations), yeasts depend entirely on fermentation or substrate level phosphorylation for the production of ATP. If the sugar concentration becomes limiting, the yeast need to convert to the respiratory metabolism in order to produce sufficient energy for continued growth and metabolism.

In the absence of oxygen, this metabolic shift will not take place. The citric acid cycle also provides the intermediaries that are required for amino acid and nucleotide biosynthesis. The enzymes, which are required for biosynthesis, are present in the cytoplasm in *Saccharomyces* under anaerobic conditions, as mitochondria are not functional. The mitochondrial and cytoplasmic forms are isozymes, i.e. similar in structure, but the product of different genes. The complete citric acid cycle does not exist in the cytoplasm under anaerobic conditions, but a form of the pathway serves to generate biosynthetic intermediates or end products of amino acid metabolism. Reverse flow along the pathway uses acetyl-CoA and helps form acetate esters. If the conversion of acetaldehyde to ethanol regenerates only limited NAD^+ from NADH, the reductive arm of the citric acid cycle can be used for this purpose with the associated production of malic and succinic acids. Otherwise, if reducing power in the form of nicotinamide adenine dinucleotide (NADH) is required, it can be generated via the oxidative arm of the citric acid cycle. Yeasts can utilize another metabolic process, the glyoxylate cycle (Walker 1998b), for the synthesis of sugars that are needed for cell wall structural components, glucans and mannans, and for growth substrates such as ethanol and acetate, but this pathway is only used if the cells grow in the absence of sugars. In the heterolactic malolactic acid bacteria, the pentose phosphate pathway is used for the metabolism of pentoses (five-carbon sugars) as carbon and energy sources, but *Saccharomyces* is not able to do this as the yeast requires this pathway for the formation of ribose-5-phosphate, a precursor of nucleotide biosynthesis (Jackson, 2000c). *Saccharomyces* also uses the pentose phosphate pathway for the formation of NADPH for biosynthetic purposes and erithrose-4-phosphate, which is required for the synthesis of aromatic amino acids. The pentose phosphate pathway therefore functions during both fermentative and respiratory growth.

In the cycle, pyruvate is decarboxylated and reacts with coenzyme A to form acetyl-CoA. The enzyme that catalyzes this reaction is pyruvate-dehydrogenase. Acetyl-CoA condenses with a four-carbon acid, oxalic acetate, to form citrate, a six-carbon acid, as well as a variety of other organic acid-intermediaries (Walker, 1998c). Under fermentative conditions, decarboxylation of pyruvate to acetyl CoA is inactive. One completed citric acid cycle generates two molecules of carbon dioxide and also regenerates oxalic acetate.

Three molecules of reduced (NADH) and one molecule of flavin adenine dinucleotide ($FADH_2$) are also generated.

Respiratory chain-linked NADH yields three molecules of ATP and two molecules of ATP from $FADH_2$, for a total of up to 14 molecules of ATP for each pyruvate that is metabolized. The generation of ATP during respiration is called oxidative phosphorylation; that which is formed during glycolysis is known as substrate level phosphorylation (Madigan *et al.*, 2003).

A further substrate level phosphorylation occurs at the succinyl-CoA-synthase reaction. Thus two molecules of pyruvate (equivalent to one glucose) moving through the citric acid cycle generate 30 molecules of ATP. Two molecules of ATP are produced during glycolysis giving a total of 32. If the pyruvate is completely oxidized to carbon dioxide, the two molecules of NADH that are produced during glycolysis can also be a source of ATP. This NADH molecule is cytoplasmic and not mitochondrial, and in order to be able to generate ATP the electrons must be transported to the mitochondria. Depending on the transportation mechanism that is utilized, two or three ATP molecules can be obtained for each NADH molecule that is oxidized. So, a single glucose molecule, when it is fully respired, will generate between 35 and 37 molecules ATP in total, of which 33 to 35 are from the oxidative phosphorylation and two from substrate level phosphorylation (Ribéreau-Gayon *et al.,* 2000h). The energy yield from the yeast metabolism is therefore around 15 times higher for aerobic sugar metabolism in comparison with anaerobic sugar metabolism.

To summarize then, under anaerobic conditions, or in a medium containing high levels of substrate, yeast will metabolize through fermentative pathways, rather than through respiration. Fermentation, despite producing so much less energy than respiration, still achieves two important metabolic goals. It uses NADH to reduce the pyruvate (or one of its metabolites) generated by glycolysis, and consequently NAD^+ is regenerated. This ion is used once more in glycolysis, so the cell can carry on metabolizing glucose. Also, fermentation allows the cell to produce a small amount of ATP through substrate level phosphorylation. Metabolic intermediates needed for cell growth will be supplied by glycolysis, the pentose phosphate pathway and the citric acid cycle.

Monitoring a fermentation allows the producer to ensure the fermentation is performing as required and allows prompt remedial action if any problems develop. The normal methods used are measurement of sugar (or, more accurately, dissolved solids) by hydrometry, measurement of temperature and sensory evaluation. One mole (180 g) of glucose yields about 103 kJ (24.5 kcal) as heat, and each percent of sugar (1° Brix) in the must generates enough heat during fermentation to raise its temperature by 1.3 °C/l, if no heat is lost. Hence, a wine must of 22° Brix would generate enough heat to raise its temperature by nearly 30 °C during the fermentation process, although some of this heat will be lost with the evolved CO_2 (Jackson, 2000b).

Important 'fermentation problem indicators' are high or low fermentation rate, temperature variations, turbulence and production of off odors such as H_2S. In difficult fermentations one of the first signs of a problem is the yeast settling as the fermentation slows down. It is thought that yeast cells die very quickly at the bottom of the tank due to sugar and nutrient depletion in that area, and that yeast that are in suspension are more likely to survive. Certainly, brewers know that suspended yeast cells provide the most efficient fermentation of beer wort (Section 2.6.4). Measures to rescue such 'sluggish' or 'stuck' fermentations include the increase of fermentation temperature, addition of vitamin supplements, limited aeration by pumping over and reinoculation (Pretorius, 2000).

Although alcohol is a major component of wine, there are many by-products of fermentation which will have a major impact on quality. Glycerol is not only produced by yeasts, but can also serve as carbon source in aerobically grown cultures. During wine fermentations, the main role of glycerol synthesis is to supply the yeast cell with an osmotic stress-responsive solute and to equilibrate the intracellular redox balance by converting the excess NADH generated during biomass formation to NAD^+ (Pretorius, 2000). Glycerol-3-phosphate, the precursor of glycerol, is an essential intermediate in the biosynthesis of membrane lipids.

Glycerol is viscous and has a slightly sweet taste (threshold 5.2 g/l in wine), giving smoothness, consistency and overall body to the product, so if it is produced abundantly during fermentation, it is usually seen as a positive contribution. The amount of glycerol produced by yeast during fermentation will vary according to nitrogen composition, sugar levels, sulfur levels and pH of the grape must, as well as fermentation temperature, aeration, choice of starter yeast strain and inoculation level. Typically, under controlled conditions, glycerol concentrations are higher in red wines than in white wines, varying from 1 to 15 g/l. About 4–10% of the carbon source is usually converted to glycerol, resulting in glycerol levels of 7–10% of that of ethanol. The overproduction of glycerol by yeast at the expense of ethanol could fulfil a growing need for table wine with lower levels of ethanol. Conversely, wine yeasts in which the glycerol pathway has been minimized would yield more alcohol, which would be of great value for the production of brandy and other distilled products (Pretorius, 2000) (Chapter 3.6).

The characteristic fruit flavors of wine are primarily due to a mixture of hexyl acetate, ethyl caproate, ethyl caprylate, isoamyl acetate and 2-phenylethyl acetate. Some of these aroma compounds have specific functions in the yeast cell, while others are still speculative (Pretorius and Lambrechts, 2000). Higher alcohols are produced during alcoholic fermentation through the conversion of the branched chain amino acids present in the medium (valine, leucine, isoleucine, threonine and phenylalanine), and are important precursors for the formation of esters, which are associated with pleasant aromas. They can also be produced *de novo* from a sugar substrate (Clemente-Jiminez *et al.,* 2005). Their exact function is unknown, but they may serve to detoxify any aldehydes produced during amino acid catabolism or be involved in the regulation of amino acid anabolism. Moreover, oxidative deamination provides the yeast with a mechanism for obtaining nitrogen. For this reason, amino acid metabolism to higher alcohols is restricted to the exponential growth phase. Tropical fruit notes are linked to acetates of higher alcohols, i.e. alcohols with carbon numbers greater than that of ethanol, such as isobutyl, isoamyl and active amyl alcohol. These compounds are produced by wine yeasts during alcoholic fermentation from intermediates in the branched chain amino acids pathway leading to production of isoleucine, leucine and valine by decarboxylation, transamination and reduction (Pretorius, 2000). At high concentrations, these higher alcohols have undesirable flavor and odor characteristics, but in wine they are usually present at levels below their threshold values and therefore they contribute favorably. Since higher alcohols are concentrated by the distilling process, they are not desired in wines that are to be distilled for brandy production (Chapter 3.6).

The effect of yeast on aroma and flavor development of the product is further discussed in Section 2.2.11.

The amount of alcohol produced by the fermentation depends, as previously stated, upon the initial sugar level and the strain of yeast used. Approximations can be made from the soluble solids level of the grapes, but the final alcohol level of the wine still needs to be measured for labeling purposes. As alcohol is a toxin as well as an intoxicant, there are strict regulations surrounding its production. Terminology for alcohol in winemaking is therefore complex, and can be confusing. Alcohol that could be made from the natural sugar in the wine is termed 'potential alcohol,' and needs to be determined before the fermentation process starts. Once this sugar has been converted to alcohol, it is termed the 'natural' alcohol of the wine. When alcohol is derived from added sugar (chaptalization), the wine is termed 'enriched' and this amount (according to UK legislation) has to be less than 3.5% (4.5% in poor years) (Morgan *et al.,* 2006). 'Actual' alcohol is that which is present in the wine after fermentation and chaptalization, and 'total' alcohol is determined by adding the contribution of potential alcohol from residual sugar in wine to the actual alcohol concentration. The way in which the alcohol content is displayed on the label is also subject to regulation, for example, the alcohol figure on a wine label must be accurate to within $\pm 0.5\%$ and prominently displayed. Duty is usually payable according to the alcoholic content of the wine. Alcohol is measured mainly by ebulliometry or distillation followed by hydrometry or pycnometry (Iland *et al.*, 2004), but there are many other methods (see Sections 4.3.2 and 4.6.3).

2.2.10 Flocculation

Yeast flocculation is a physical process and is of fundamental importance in most brewing and winemaking applications. During flocculation, yeast cells aggregate to form multicellular 'flocs' (or clumps) which sediment rapidly from the medium through precipitation, or are entrained by carbon dioxide and taken to the surface of the medium. The aggregation is brought on by interaction between lectin-like proteins on flocculent cell surfaces and mannose receptors on other cells. This interaction starts in early stationary phase, and it has been suggested that flocs form as a response of yeast cells to stress (Boulton and Quain, 2001d). Flocculation is critical to yeast recovery in a brewing context (Section 2.6.4) and to postfermentation clarification during winemaking. Yeasts can be removed through skimming the surface of the medium in open fermentors, or racking off (cropping) sediments in closed vessels. In-process changes in yeast flocculance are reflected in head formation during brewing. Although not usually quantified or monitored, yeast flocculation is a high profile fermentation parameter and is as important to a successful fermentation process as the rate and efficiency of conversion of sugar to alcohol.

If the fermentation is at the point where the producer wishes to finish it, a combination of refrigeration and/or accelerated clarification is normally used. The time taken to cool the ferment sufficiently should be taken into account and the ferment stopped earlier than the actual sugar level required. Clarification gets rid of the active yeast and allows other methods to work. The addition of SO_2 by itself to stop fermentation does not work in all cases, as the products formed during the fermentation (predominantly acetaldehyde) may bind and inactivate the SO_2 before it has had a chance to act against the yeast. If the number of suspended yeast cells has been lowered by clarification and activity reduced by cooling there is more chance it will be successful. It may still be necessary to add a larger than usual amount of SO_2 to ensure cessation of activity by the yeast. It is vital to keep a close check on the product towards the end of fermentation to see whether it is developing detectable levels of hydrogen sulfide. This is particularly true in the case of wines undergoing lees contact, which should be stirred through and, once the lees have settled, tasted. If there are high levels of hydrogen sulfide, the wine should be immediately racked and aerated or a copper treatment may be necessary, either by passing the wine over copper chips or by adding 0.2–0.4 mg/l copper sulfate (Morgan *et al*., 2006).

A wine chemist (Mulder, *ca.* 1857), working over a century ago, stated:

> 'A wine ferment ... is not essentially different from a beer ferment, for both consist of membranous cells which are formed out of gum or vegetable mucilage. Both possess albuminous contents, which exude through the walls of the cells, and when brought into contact with sugar, cause it to ferment. These contents are soluble in water, more so in vegetable acids, and peculiarly so in tartaric acid. So much of the albuminous substance as is soluble is decomposed during fermentation, and more or less of its products must be contained in the liquid.'

This quote is provided (with great respect to the author) to show how our knowledge of such a fundamental process has increased in detail, accuracy and magnitude over time. *S. cerevisiae* has enjoyed a long and distinguished history in the fermented food and beverage industries; it is without doubt the most important commercial microorganism with GRAS ('generally regarded as safe') status. With the emergence of modern molecular genetics, *S. cerevisiae* has again been harnessed to shift the frontiers of mankind's newest revolution, genetic engineering. *S. cerevisiae* was the first genetically modified organism (GMO), as distinguished from a genetically modified product (GMP), to be cleared for food use, as a baking and brewing strain (Pretorius, 2000).

2.2.11 Aroma Compounds and Fermentation

The aromatic potential inherent in grapes can either be realized or destroyed during the alcoholic fermentation. The yeast *S. cerevisiae* synthesizes a variety of volatile aroma compounds that form a very important part of the 'character' of the final wine and the task of choosing a yeast strain to produce desirable attributes in the final wine is significant. The preferable flavors of wine depend on a balance of volatile constituents such as acids, alcohols, aldehydes, ketones and esters, with yeast bouquet resulting largely from higher alcohols and esters (Swiegers *et al.,* 2005). Relative concentrations of the many by-products of fermentation can be influenced by the choice of yeast, the nutritional factors and the environmental conditions of the fermentation. Several studies suggest that the formation of varietal aroma is an integral part of yeast metabolism and not a simple cleavage of aromatic moieties from nonvolatile precursors (Loscos *et al.,* 2007; Koslitz *et al.*, 2008). The yeast chosen, given conditions in which it will ferment optimally, should produce the desired by-products, and few off odors such as hydrogen sulfide, mercaptans or acetic acid. It is generally accepted that these positive fermentation characters are easily lost during aging through oxidation and other chemical reactions in the bottle, so a wine that is dependent on yeast bouquet and/or primary aroma will be designed to be consumed early.

Some of the by-products of alcoholic fermentation are listed in Table 2.2.1, above. Glycerol provides sweetness and viscosity to the wine, affecting mouthfeel (body), but not aroma. The normal content in wine is 3–14 g/l but there is a higher concentration in 'noble rot' wines, as the fungus *Botrytis cinerea* produces glycerol in significant quantities. Specific yeast strains and high temperatures will also cause higher glycerol levels (Romano *et al.*, 1997). Levels of acetaldehyde, the major volatile carbonyl compound found in wine, vary between 10 and 75 mg/l. Wines exposed to air or to aerobic film-forming yeast will develop high levels of acetaldehyde as the oxidation of ethanol, through chemical or metabolic means, will produce it. It is characteristic of the aroma of oxidized or 'madeirized' wines like Madeira (Section 2.10.5) and also of flor wines like fino Sherry (Section 2.10.3), and can be detected sensorially at concentrations as low as 0.5 mg/l in aqueous ethanol (Francis and Newton, 2005), although the detection threshold would be significantly higher in wine (see Chapter 4.7 for discussion of sensory analysis). Acetaldehyde is frequently confused with ethyl acetate, which is a component of volatile acidity. The latter has the aroma of pear drops at lower concentrations, and is sharp and vinegary at higher concentrations. Ethyl acetate adds to complexity at lower concentrations, and is not considered to spoil a wine until levels become detectable (around 100–125 mg/l) (Francis and Newton, 2005). It is produced by yeast and bacterial metabolism, as well as through the chemical esterification of ethanol and acetic acid during wine aging. Acetic acid is formed by most yeast species during fermentation, but some strains produce more than others (Swiegers *et al.*, 2005). It has a sour, vinegary taste and aroma and is the major component of volatile acidity. It is produced by yeast as an intermediate in the pyruvate dehydrogenase pathway, but excessive concentrations are likely to be the result of metabolism of ethanol by acetic acid bacteria. It can also been seen as an indicator that the yeast is struggling to survive, as even *S. cerevisiae* strains that normally produce little acetic acid will show increases acetic acid production in musts with high sugar concentrations, low temperatures and marginal nutrition. Under normal circumstances, 0.25–0.35 g/l of acetic acid are produced during fermentation and concentrations of around 200 mg/l are detectable in aqueous ethanol (Francis and Newton, 2005). However, concentrations of acetic acid up to about 0.5 g/l do not have a detrimental effect on wine. The species *Hanseniaspora/ Kloeckera* is known to produce large amounts of acetic acid and ethyl acetate during fermentation. (Henick-Kling *et al.*, 1998). Research has also shown that it is a high producer of glycerol, esters and acetoin (Cadez *et al.*, 2002). Acetoin (3-hydroxybutanone) can be detected (organoleptically) at around 150 mg/l in aqueous ethanol and has a buttery or creamy aroma (Francis and Newton, 2005). Diacetyl and 2,3-butanediol, which are known to produce off flavors in higher concentrations, can be derived from acetoin, the former by chemical oxidation and the latter by yeast reduction. Generally, for wines fermented with pure cultures of apiculate yeasts,

Table 2.2.1 *Some odorous byproducts of fermentation*

Fermentation byproduct	Characteristic odor description
Acetic acid	Sour, vinegary
Acetone	Nail varnish
Acetoin	Buttery, creamy
Aldehydes (various)	Buttery, fruity, nutty
Butanediol	Sweet, sickly
Butyric acid	Rancid butter
Carbonyl sulfide	Ether, chemical
Diacetyl	Buttery, cloying
Dimethyl sulfide	Quince, truffle, stagnant water
Diethyl sulfide	Ether, pungent
Dimethyl disulfide	Quince, asparagus, garlic
Diethyl disulfide	Garlic, rubber
Ethanal (acetaldehyde)	Sherry-like, bruised apple, oxidized, unpleasant
Esters (various)	Fruity, floral
Ethyl mercaptan, ethanethiol	Onion, garlic
Formic acid	Tart, pungent
Fumaric acid	Smoky, pungent
Glycerol	Mouthfeel, sweetness
Higher alcohols (various)	Pleasant floral→ sickly fusel aromas
Hydrogen sulfide	Rotten egg
2-Mercaptoethanol	Burnt rubber
Methionol	Cooked cabbage, potato
Methyl mercaptan, methanethiol	Stagnant water, canned vegetable
Propionic acid	Cabbage, rancid

Source: Adapted from Swiegers *et al.* (2005)

high levels of acetoin are found in the final product, in contrast to mixed culture fermentations and pure *S. cerevisiae* fermentations, which have low levels (Romano *et al.*, 1993). This suggests acetoin may be utilized by *S. cerevisiae* to form 2,3-butanediol. Control of the production of diacetyl during fermentation is particularly important in the brewing of beer (Section 2.6.4). Higher alcohols (fusel oils) have agreeable odors at low concentrations and contribute to wine complexity, but at higher concentrations they are cloying and sickly. They are associated with fast, hot fermentations (Molina *et al.*, 2007) and are derived from amino acids via the Ehrlich pathway or synthesized as intermediates during sugar metabolism. Moreira and coworkers (1999) examined aroma production in *Hanseniaspora uvarum*, *H. guilliermondii* and *S. cerevisiae* in commercial culture media and grape musts, and found that media and wines fermented with *H. uvarum* present a low content of higher alcohols and sulfur compounds. As previously mentioned, esters are the products of reactions between alcohols and acids. They are very aromatic and provide aromas of banana, apple, peach and tastes of hazelnut or butter. *H. guilliermondii* produces relatively large quantities of esters (2-phenethyl acetate and isoamyl acetate in particular) and 2-phenylethanol, when inoculated as pure or mixed cultures in commercial media and grape must (Moreira *et al.*, 1999).

The effect on the aroma properties and chemical composition of coinoculating *S. cerevisiae* and *Candida stellata* in Chardonnay wine was studied by Soden and coworkers (2000). The fermentation did not progress to dryness and there was an increase in the concentration of glycerol and acetic acid. When the two species were fermented separately, as expected, sensory descriptive analysis showed a substantial difference in aroma

between the wines. The *C. stellata* produced significantly more intense 'honey,' 'apricot' and 'sauerkraut' aromas, and diminished the 'lime,' 'banana,' 'tropical fruit' and 'floral' aromas ascribed to *S. cerevisiae*. The authors suggested that a reliable mixed culture fermentation strategy may be a way of exploiting unconventional, fermentation-impaired yeasts for producing greater flavor diversity in wine.

Loscos and coworkers (2007) added an odorless flavor precursor fraction extracted from different nonfloral grape varietals to grape must and fermented it with three different yeast strains. The addition of the precursor fraction brought about a significant increase of the wine floral notes, irrespective of the yeast used. The levels of 51 wine aroma chemicals were found to depend on the precursor fraction addition and, in most cases, also on the yeast strain. Only β-damascenone, α-ionone and vinylphenols were produced at concentrations well above threshold. However, the concerted addition of groups of compounds has shown that lactones, cinnamates, vanillins and terpenes are together active contributors to the floral note.

Oxygen can affect the onset, progression and duration of the fermentation, favoring the growth of yeast cells and their fermentative activity (Ribćreau-Gayon *et al.*, 2000i). Yeasts require oxygen to synthesize and assimilate substances vital to their reproduction and if the must is not aerated sufficiently at the start of fermentation, oxygen will become the limiting factor for yeast numbers. The aeration of grape must prior to fermentation is usual in the winemaking process as a result of its transfers during the various processing stages. In the absence of oxygen, cell metabolism can be altered at the start of the fermentative process to favor the production of some aroma compounds, particularly esters and higher alcohols (Pretorius and Lambrechts, 2000). Exposure to oxygen in the initial stages of fermentation seems to increase survival for yeast during the declining phase of fermentation, leading to less residual sugar in the final wine. This may be explained by the partial removal of toxic medium length (C_8–C_{12}) fatty acid chains and accelerated synthesis of long chain (C_{16}–C_{18}) fatty acids and sterols, both factors contributing to a better sugar uptake through the cell membrane. The amino acid proline, which is not assimilable under anaerobic conditions, can be used as a supplementary nitrogen source in the presence of molecular oxygen. These effects seem to be more pronounced upon indigenous yeast than on active dry yeast multiplied under aerobic conditions (Ribereau-Gayon *et al.*, 2000i). The modern trend is towards the aeration in white wines to preserve greater aromatic complexity. This can be done using large doses of selected yeasts, which have been grown in hyperaerated media and so are rich in growth factors. Nevertheless, a slow onset of fermentation at normal temperatures indicates a lack of aeration (Zoecklein, 2006). If the fermentation medium is too reductive, yeast numbers may be too low, the fermentation will be slow and may end prematurely. Under these circumstances, there is a far greater chance that hydrogen sulfide will be formed. Therefore, early aeration of the must is recommended, particularly when using indigenous yeasts. Musts from rotted vintages, however, should be aerated as little as possible due to the risk of enzymic oxidation. Red musts can be aerated to a greater extent as the higher levels of phenolics present protect the must from oxidation to a certain extent. Rojas and coworkers (2001) found that highly aerobic conditions encouraged ester production by non-*Saccharomyces* yeast, whereas *S. cerevisiae* produced higher levels in minimally aerobic conditions. In an experiment regarding the effect of oxygen in the fermentative rate of different yeast strains, Valero *et al.* (2002) reported that the production of all higher alcohols monitored were dependant on the oxygenation conditions. The yeast strains studied (*S. cerevisiae* and *S. capensis*) produced lower concentrations of higher alcohols in musts in the absence of oxygen, which was attributed to the decreased growth of both yeast races under anaerobic conditions. The major esters studied showed a similar pattern, being produced in lesser quantities in the absence of aeration in both yeast races. Wines with higher ester/higher alcohol ratios possess an enhanced fruity flavor and better aroma quality, and there was a decrease in the ratio observed for the oxygenated wine compared to the nonoxygenated wine (Valero *et al.*, 2002). From these reports, it is therefore suggested that oxygen contact with the fermenting must should be kept to a minimum, in order for the resulting secondary compounds produced to have a positive impact on the sensory properties of the wine.

Sulfides in wine have distinctive aromas such as rubber, onion, garlic, cabbage, kerosene etc. Hydrogen sulfide in particular has a 'bad egg' aroma, and is a fault in wines that have had a stuck fermentation, or have been made and stored reductively. Hydrogen sulfide is a normal by-product of yeast metabolism, and the small quantities produced will escape with the carbon dioxide generated during fermentation. There can be several causes for abnormally high sulfur levels in wine, which include: spray residues, fermentation conditions such as low aeration, high temperatures and high solid levels, wild yeast strains, high concentrations of sulfur dioxide and long lees contact (Zoecklein, 2006). Yeast metabolism and chemical breakdown may lead to the production of volatile sulfur compounds from these sulfur sources, which can be very detrimental to the aroma. Any excess of hydrogen sulfide, if not removed immediately, will react with the alcohols in the wine to form other sulfides and mercaptans which have 'oniony,' 'rubbery,' 'cabbagey' or 'gasworks' aromas. Even exposing wines to a source of heat or to light can initiate chemical reactions involving methionine, which eventually lead to the production of methanethiol, which, on oxidation, forms dimethyl disulfide. Methionol (olfactory perception threshold of 1200 μg/l) is an unpleasant compound which is associated with atypical (premature) aging aroma in white wines. It is formed from an amino acid (methionine) in the grape juice, which undergoes successive deamination and decarboxylation reactions during yeast metabolism to produce methional and the alcohol.

Low levels of inorganic nitrogen may also cause hydrogen sulfide formation during fermentation. The optimal concentration of fermentable nitrogen depends on several factors, including yeast species and strain, and determining it is time consuming and expensive. Off odor formation in some yeast strains appears to be relatively independent of total fermentable nitrogen status over a fairly wide range, and may be more closely related to the ratio of certain amino acids in the must. However, yeast variability, with regard to reductive odor defect, is greatest under conditions of low levels of nitrogen or other stress factors. It is for this reason that most winemakers will automatically add diammonium phosphate (usually around 50 mg/l) to the must as a failsafe.

During fermentation, high levels of sulfur dioxide bind acetaldehyde, but if not enough of this compound is present, other juice components, such as sulfate, may be reduced instead, resulting in H_2S formation. One of the ways of avoiding this is to keep the concentration of sulfur dioxide before alcoholic fermentation below 8 g/hl (Zoecklein, 2006), or delaying sulfiting until after fermentation. It is important to act quickly if H_2S is detected during fermentation – wine should be aerated (briefly, so as to avoid oxidation of other components) and diammonium phosphate added, in case the production of H_2S is due to nutritional deficiencies. Hydrogen sulfide is oxidized by oxygen under these conditions ($2\ H_2S + O_2 \rightarrow 2\ H_2O + 2\ S$). The wine can then be racked, and the precipitated sulfur will be removed. One of the potential problems of using aeration to lower the concentration of some low boiling point volatiles, like H_2S and mercaptans, lies in the potential oxidation of mercaptans to disulfides (see above). To help avoid unwanted oxidation, especially in white wines, H_2S may be removed by sparging the must or wine with inert gas, such as nitrogen. However, this may take a significant quantity of gas, involve expense and manual labor, and may strip out positive aroma characteristics as well as the hydrogen sulfide.

The sulfur odor (reductive) defect may be an indication that a wine has a low oxidation–reduction (redox) potential, which can loosely be regarded as a measure of availability of oxygen (Zoecklein, 2006). The presence of off odor sulfur-containing compounds in a wine, and the corresponding smell, requires low oxygen concentrations (around –220 mV, compared to wine values of +220 mV to +450 mV, when wine is exposed to air). Reductive odor problems are not as great in barreled wines, due to the higher oxygen (redox potential) of barrel maturation. At the end of alcoholic fermentation, the addition of sulfur dioxide can represent a major cause of the formation of volatile sulfur compounds, mainly H_2S and methanethiol, in wines that have not been racked off the lees. Frequent barrel stirring to put the lees in suspension, and limited oxidation across the staves, inhibits the formation of postfermentation sulfur volatiles by increasing

the oxidation–reduction values. This occurs more rapidly in new barrels, as the oak contains more oxygen, and pores in the wood have not yet been blocked by phenolic and tartrates deposits. During barrel aging, volatile sulfur compounds generally decrease. All wines should undergo an odor screen for reductive-odor defect before bottling (Zoecklein *et al.*, 1995).

The temperature of fermentation has a considerable effect on the aromatic character of the wine. Low temperatures and slower fermentations are well known to help retain the fruit character of the juice. These aromatic compounds are lost at high temperatures. White wines should be fermented at low temperatures to preserve volatile aroma constituents that can be 'boiled off' with fast release of carbon dioxide. There is also a significant reduction in the levels of ethanol and glycerol produced at higher temperatures. Most authors agree that the optimum fermentation temperature for dry white and rosé wine production is about 15–20 °C and the maximum 23 °C, though the current trend is to ferment at temperatures below 15 °C. 'Noble rot' wines are usually fermented a couple of degrees higher than this. Red wines should be fermented at higher temperatures to maximize the extraction of color: the minimum recommended temperature for reds is 20 °C, the optimum 25–30 °C and the maximum 32 °C. In a study conducted by Molina *et al.* (2007), the influence of fermentation temperature on the production of yeast-derived aroma compounds at 15 °C and 28 °C was investigated. Higher concentrations of compounds related to fresh and fruity aromas were found at 15 °C, while higher concentrations of flowery related aroma compounds were found at 28 °C. The formation rates of volatile aroma compounds varied according to growth stage. In addition, linear correlations between the increases in concentration of higher alcohol and their corresponding acetates were obtained. These results demonstrate that the fermentation temperature plays an important role in the wine final aroma profile, and is therefore an important control parameter to fine tune wine quality during winemaking. In red wine fermentations the temperature also has an effect on the extraction of the phenolics and color. If the rate of fermentation is high, yeast growth and metabolism are encouraged, which then raises the temperature even further, leading to an even faster rate of fermentation. If this process is allowed to continue the heat produced may be sufficient to kill the yeast. This type of problem is more likely to occur in large volume fermentations with insufficient cooling at high ambient temperatures. In smaller fermentations it can occur if the cooling fails. Early recognition allows early intervention, which increases the chances of successfully increasing the fermentation rate so the ferment does not stop. On the other hand, fermentations that are too slow are inconvenient and give an increased probability of high acetic acid production. Lower temperature fermentations also favor estery characters in the bouquet that may not be desired in more full-bodied styles. The rate of fermentation and temperature should be chosen with the style of wine in mind, and both should be monitored constantly.

The formation of volatile compounds during alcoholic fermentation depends not only on the yeast species, but also on the particular strain (Pretorius and Lambrechts, 2000). It is important to know the potential differences in volatile production by yeast in order to select the best species, strain or mixture thereof, to produce a wine of a certain style and quality. Most cultured wine yeasts are not likely to produce off odors in large quantities. If a wild fermentation is carried out it must be watched carefully so that action can be taken if these faults develop. Some yeasts produce high ester concentrations (for example: strain QA 23) and these are used for neutral grapes as the yeast characters can add to the wine. Other yeasts such as VL3 are used with Sauvignon Blanc as they intensify the varietal aroma. In some cases yeasts such as CY 3079 are chosen for their influence on the body of the wine. In red winemaking, yeasts such as F10 are chosen for color and flavor extraction for early drinking reds. If fermentation difficulties are encountered, then EC1118 is a good strain to use. It can be used for restarting stuck ferments. In a study conducted by Patell and Shibamoto (2003), Symphony grapes were fermented with 20 different strains of the yeast *Saccharomyces*. Among 53 volatile compounds identified in the wines using gas chromatography/mass spectrometry, the major volatile compounds found were seven alcohols, seven esters and four acids. Isoamyl alcohol was the compound found in highest amounts with 19 yeast strains of Symphony wines. The amounts of isoamyl alcohol

ranged from 6.04 mg/l (A350/VL1/Fermiblanc) to 14.33 mg/l (Fermirouge). The other major compounds were 2-phenylethanol, ethyl-2-hydroxy propionate, monoethyl succinate, octanoic acid and hexanoic acid. Several esters, including ethyl-2-hydroxy propionate, may contribute to the fruity flavor of Symphony wines. Overall, 18 *S. cerevisiae* yeast strains (except A350/VL1/Fermiblanc and T73) used to ferment Symphony grapes produced the same major components, with certain variations in formation levels. The formation and composition of the volatiles produced by A350/VL1/Fermiblanc and T73 yeast strains were significantly different from the other strains.

2.3
Malolactic Fermentation

2.3.1 Introduction

For centuries, winemakers observed that wines released small bubbles of gas and formed a haze, sometimes months after the alcoholic fermentation had been completed, and even in the bottle. This often occurred in the spring, when temperatures in the winery began to increase. Louis Pasteur and Hermann Müller-Thurgau recognized the bacterial causes of malolactic fermentation over a century ago, but it was not until the mid 1960s that the organism responsible was isolated, characterized and named *Leuconostoc oenos* by Ellen Garvie (Bartowsky, 2005). This organism is now known as *Oenococcus oeni*.

Malolactic fermentation (MLF) is the bacterial-driven decarboxylation of diprotic (S)-(-)-malic acid (sharp green apple character) to monoprotic (S)-(+)- and/or (R)-(-)-lactic acid (softer, yoghurt character) and carbon dioxide. It usually occurs after alcoholic fermentation, but studies investigating advantages of cofermentation (inoculating yeast and lactic acid bacteria simultaneously) are ongoing (Jussier *et al.*, 2006) and in the production of traditional Spanish cider, alcoholic and malolactic fermentations proceed more or less concurrently (Section 2.8.5).

In winemaking, it is one of the most difficult processes to control and can affect the final aroma and taste balance of the product by modifying fruit derived aromas and producing aroma active compounds (Nielsen and Richelieu, 1999). One of the main effects of the malolactic fermentation is deacidification, which is particularly desirable for high acid wine produced in cool climate regions, such as New Zealand and the United Kingdom. Malolactic fermentation is often spontaneous and difficult to stop in red winemaking, possibly due to the higher temperatures involved and/or through the activities of indigenous lactic bacteria found in cooperage. Producers will allow it to proceed or actively encourage it early in the life of a wine in order to prevent it happening in the bottle. After undergoing a malolactic fermentation, and as long as residual sugar levels are low, the wine is relatively microbiologically stable.

In addition to its occurrence in wine, this fermentation occurs in other fermented beverages, such as cider (Lea and Drilleau, 2003) (Section 2.8.4). *Lactobacillus* and *Pediococcus* are amongst the important spoilage organisms isolated from beer, and Van Vuuren (1976) noted that there is no doubt that the presence of lactobacilli during brewing greatly influenced the quality of beer produced. *Streptoccoccus* and *Leuconostoc* were also observed by this author to produce diacetyl in beer. Certain beers, such as the 'spontaneous' lambic beers of Belgium (Section 2.6.7) and certain native beers and fermented drinks of Africa, Asia and South America (Chapter 2.7) rely on the activities of LAB to contribute special character to the product. Likewise,

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass

certain LAB can contribute positive characteristics to the fermented malted barley wort used for distillation into malt whisky, giving a product with greater complexity (Section 3.2.3). Nevertheless, in the production of both standard bottom-fermented (lager) beers and top-fermented ales, LAB are spoilage organisms, their presence being avoided at great lengths.

Lactic acid bacteria may also be present in significant numbers in base wine destined for brandy production (Chapter 3.6). In a study conducted by du Plessis in 2002, spontaneous malolactic fermentation was found to occur in around half the base wines studied, caused by populations of *Lactobacillus paracasei*, *Lb. plantarum* and *Oenococcus* spp. Concentrations of isoamyl acetate, ethyl acetate and 2-phenyl acetate were found to have decreased after the malolactic fermentation, but acetic acid, lactic acid and diethyl succinate increased. These changes had a significant effect on the quality of distillates from these wines, and most panellists preferred the distillates from wines that had not undergone MLF.

Many studies on the occurrence of malolactic fermentation in wine have indicated that lactic acid bacteria originate from grapes and winery equipment. Generally, the organisms occur on the surface of grapes and vine leaves (Wibowo e*t al.,* 1985) and as with acetic acid bacteria, the condition of the fruit has an influence. Their numbers are greatly reduced when working in new installations or in very clean conditions.

2.3.2 Malolactic Bacteria: Morphology and Physiology

Lactic acid bacteria are important in winemaking for two major reasons, they affect wine quality and they affect the economics of wine production (Wibowo e*t al.*, 1985). They are much smaller than yeasts, unicellular without a defined nucleus, are fermentative, aerotolerant, tolerant of high acidity and sensitive to sulfur dioxide in solution. The term 'malolactic bacteria' is usually used for those strains that prefer to metabolize malic acid over sugars and citric acid, and are more resistant to low pHs. The utilization of sugars as carbon and energy sources by lactic acid bacteria in wine has shown that there are species and strain differences in sugar utilization, but many species can metabolize pentoses, tartaric acid and glycerol.

Lactic acid bacteria are more exacting (fastidious) in their nutritional requirements than yeasts, and glucose and trehalose are generally preferred over other sugars (Liu, 2002). Morphology of the lactic bacteria found in wine is outlined in Table 2.3.1 below. They are broadly divided into two groups. Homofermentative

Table 2.3.1 *Comparison of major MLF bacteria in wine and cider*

Cell characteristic	*Oenococcus*	*Leuconostoc*	*Lactobacillus*	*Pediococcus*
Morphology	Spherical or lens-shaped cocci; occur in pairs and chains	Spherical or lens-shaped cocci; occur in pairs and chains	Long, slender rods, sometimes bent	Spherical cocci; occur in tetrads
Approx. size (μm)	0.6 × 1	0.6 × 1	0.8 × 5	0.4 ×1.4
Glucose fermentation	Heterolactic	Heterolactic	Both heterolactic and homolactic	Homolactic
Species found in wine and cider	*O. oeni*	*L. mesenteroides;*	About 16 species, including *Lb. brevis, Lb. buchneri, Lb. casei, Lb. cellobiosis, Lb. collinoides, Lb. hilgardii* and *Lb. plantarum*	*P. pentosaceus, P. damnosus, P. parvulus*

bacteria produce 80–90% lactic acid from glucose, and heterofermentative species produce between 30 and 50% lactic acid from glucose, also producing acetic and succinic acids, glycerol and ethanol (Jackson, 2000a). Heterofermentative bacteria also metabolize citric acid to acetic acid, lactic acid and carbon dioxide (Henick-Kling, 1995). In addition to being classed according to their products, they are also named according to their cell shape: 'coccus' for round and 'bacillus' for rods. Homofermentative cocci include *Pediococcus cerevisiae*, and heterofermentative cocci include the species *Oenococcus oeni*. *Lactobacillus casei* is an example of a homofermentative bacillus, whereas *Lactobacillus brevis* and *Lb. hilgardii* are heterofermentative. *Lactobacillus* and *Pediococcus* are capable of malolactic fermentation, but can produce undesirable characteristics – especially if the fermentation happens in the bottle. As with refermentations after bottling caused by the presence of yeasts, malolactic fermentations in the bottle can cause the production of carbon dioxide with off odors of vegetative, vinegar, mousy or geranium characteristics if sorbic acid is present.

With the introduction of molecular techniques, *Leuconostoc oenos* was reclassified as *Oenococcus oeni*, (Bartowsky, 2005). This species is generally preferred over other lactic acid bacteria in winemaking due to its acid tolerance and favorable flavor profile. It is microaerophilic, meaning that it grows best at low oxygen concentrations. *O. oeni* is heterofermentative and utilizes glucose via the phosphoketolase pathway, resulting in approximately one-sixth carbon dioxide, one-third ethanol, acetic acid or acetaldehyde and the remainder as lactic acid (Wibowo e*t al.,* 1985). However, if malic acid is present, this will be degraded before any glucose. Over centuries of selective pressure, *O. oeni* has become adapted to high ethanol concentrations ($<$15% v:v), low pH (as low as 2.9) and limited nutrient availability; conditions typical of a wine after alcoholic fermentation. Although *O. oeni* can tolerate this harsh environment, it can be a difficult and sometimes unreliable organism to work with. It is a fastidious organism and needs group B vitamins, an organic nitrogenous base and 11 amino acids, most of which can be derived from yeast autolysis. Lack of any one of these nutrients will inhibit growth.

2.3.3 Identification of Malolactic Bacteria

Lactic acid bacteria are Gram positive, catalase negative and fastidious. They require a medium rich in nutrients and will grow on glucose–yeast-extract agar and will be inhibited by penicillin. Isolation of lactic acid bacteria may also include the use of de Man Rogosa Sharpe agar (MRS) for the isolation of all three genera, *Leuconostoc*, *Pediococcus* and *Lactobacillus*, tomato juice agar and Irrmann agar. Wibowo and coworkers (1985) stated that no medium reliably recovers all of the malolactic species in a wine, and recommended the simultaneous plating of samples onto the three agars mentioned above. The incubation time and temperature are the same as that of acetic acid bacteria, but incubation of plates under an atmosphere enriched in carbon dioxide or nitrogen can encourage faster growth of the colonies of lactic acid bacteria (Fleet, 1994). Once isolated, a gram stain procedure can be performed and if the genera are all gram-positive, lactic acid bacteria can be rapidly and conveniently identified to species level with commercially available API 50 CH test galleries (Wibowo e*t al.,* 1985).

2.3.4 Factors Affecting the Growth of Malolactic Bacteria

The survival and growth of the bacteria are dependant on certain conditions, such as temperature, pH and sulfur dioxide levels. To encourage malolactic fermentation, the wine should have a pH of 3.3–3.5, no free SO_2, total SO_2 less than 50 mg/l and a temperature of 18–25 °C. Conditions that promote bacterial growth include extended skin contact, long lees contact with yeast autolysis and the inclusion of press fractions as the level of nutrients is increased. Carbonic maceration also favors growth. The yeast strain used should undergo

autolysis easily. When using indigenous bacteria (i.e. the population naturally present in the wine from grapes, barrels or lees), it is advisable to keep the wine temperature maintained at 18–20 °C. The presence of the bacteria can be very haphazard. Wineries vary greatly in the ease with which the MLF takes place. Often the fermentation is harder to start in newly established, clean or modern wineries. Once one tank has fermented, the lees may be used to inoculate other tanks if the wine showed no high increase in volatile acidity or other organoleptic defect. The bacteria also prefer an environment free of sorbic acid with low levels of glucose present (Morgan *et al.*, 2006). Factors affecting the growth of lactic acid bacteria are discussed in more detail below.

pH

Wibowo and coworkers (1985) stated that wine pH is one of the most important parameters that affect the behavior of lactic acid bacteria in wines and in wines above pH 3.5, spoilage flora of *Pediococcus* and *Lactobacillus* may grow. The pH of the medium needs to be considered in the selection of the bacterial strain as it affects the growth rate and yield, as well as the bacterial activity and the nature of the substrates involved. For most strains, minimal growth occurs at pH 3.0, and the lower the pH, the harder the malolactic fermentation is to start. At acidities between pH 3.0 and 4.0, *O. oeni* is the primary genus, different strains of which will dominate throughout MLF (Davis *et al.*, 1986). The optimum pH for the start of the fermentation is pH 3.5 to 3.8, and at pH 2.9 to 3.0 growth is possible, but slow. Inhibition of growth of *O.oeni* occurs above pH 4.5.

Sulfur Dioxide

The pH also affects the levels of sulfur dioxide, which influences both acetic and lactic acid bacteria. The higher the pH the lower the free sulfur dioxide, because the distribution of free or molecular sulfur dioxide in solution is a pH dependent equilibrium and it is the molecular form that is antimicrobial (for more detail on this see Chapter 2.5). Bacteria are more sensitive to SO_2 than yeasts, and so the wine is not sulfited after the alcoholic fermentation if malolactic fermentation is desired.

Although bound sulfur dioxide has little inhibitory activity against most yeast and acetic acid bacteria, at levels >50 mg/l it is believed to be inhibitory toward lactic acid bacteria (Fugelsang, 1997). Most lactic acid bacteria are sensitive to free SO_2 concentrations above 10 or 20 mg/l. Total SO_2 is usually kept below a maximum value of 70 mg/l (for reds) and 40 mg/l (for whites). Molecular levels of 0.6 mg/l are inhibitory, whereas levels of 1.2–1.8 mg/l are strongly inhibitory. Keeping molecular levels below 0.2 mg/l is desirable (Morgan *et al.*, 2006). It should be noted that *O. oeni* can degrade acetaldehyde. Thus, if SO_2 were previously added to the wine/must and subsequently became bound with acetaldehyde then the action of malolactic bacteria upon this bound complex will result in an increase in free SO_2. There is an interaction in effects of temperature and sulfur dioxide on bacterial growth. When no SO_2 is present in the wine the optimum temperature range for MLF is 23–25 °C (73–77 °F). However, this decreases with increasing concentrations of SO_2. Most strains of *O. oeni* either cease to grow or grow very slowly below 15 °C (59 °F). However, cells remain viable at low temperatures (Jackson, 2000a). Activity increases up to an optmum of 20–25 °C (Ribéreau-Gayon *et al.*, 2000), and bacteria start to die off above 30 °C (> 86 °F).

Contact with Yeast Lees

Lees provide nutrients for the bacteria, and by stirring the fine yeast lees, nutrients are released into solution even more effectively. Jackson (2000a) states that the polysaccharides released by yeast before and during the death phase at the end of fermentation stimulate growth. Substances that are toxic to the bacteria, such as

C10 and C12 fatty acids, which can be released during alcoholic fermentation, may inhibit growth if present in high enough concentrations, but this is unusual.

Temperature

This is the most easily monitored and controlled of the factors influencing the fermentation. Wines should be kept relatively warm if malolactic fermentation is required: the optimum temperature is between 20 and 37 °C in a laboratory culture. In wine (particularly when making white wine), it is not advisable to increase temperatures above 15 °C due to the risk of spoilage, but malolactic fermentation is unlikely to start below 20 °C (Morgan *et al.*, 2006). Depending on the temperature of the medium, the malolactic fermentation can take from a few days to several weeks. The fermentation may start with difficulty below 15 °C, but once started, it will carry on even if the temperature drops below 10 °C, but it may take several months to complete. As stated, temperature also has an effect on the resistance of the bacteria to sulfur dioxide.

Alcohol Concentration

The growth of lactic acid bacteria is also strongly influenced by the alcohol concentration, which appears to affect membrane function at higher concentrations. They are inhibited by levels above 13% v:v, and an 80% reduction in conversion of malic to lactic acid has been observed above this concentration (Jackson, 2000a). A few strains of lactic acid bacteria are able to grow in up to 15% v:v, but the higher the alcoholic strength, the longer the fermentation will take. Species differ in their tolerance, with *Lactobacillus* most resistant, and *O. oeni* most sensitive (Jackson, 2000a). Hence this must be taken into account when choosing a strain of bacteria. *O. oeni* appears to adapt to high alcohol environments over time, but loses this adaptation when returned to environments with lower alcohol concentrations.

Sorbic acid

This yeast inhibitor should not be added to a wine which is to (or may) undergo malolactic fermentation. The bacteria transform sorbate to 2,4-hexanediol, which reacts with ethanol to form an ester, 2-ethoxy-3,4-hexadiene. This has a strong smell of grass or geranium, and is the source of the 'geranium taint' (Jackson, 2000b).

2.3.5 Interactions Between Bacteria and Other Organisms

Interactions between coexisting yeast, usually *S. cerevisiae* and *O. oeni* (the most important MLF agent in wine) can cause problems with both fermentations (Lonvaud-Funel *et al*. 1988). *S. cerevisiae* releases ethanol, sulfur dioxide and medium chain fatty acids, which inhibit the bacteria. The utilization of complex nutrients such as amino acids by the yeast during the early stages of fermentation can complicate ensuing bacterial growth. Some authors recommend the addition of lactic nutrients to the wine if a coinoculation is to occur as yeasts tend to monopolize and consume most nutrients. Bacterial inhibition decreases towards the end of fermentation. This is probably connected with the death phase of yeast, as autolyzing cells release nutrients useful to the MLB. The growth of acetic acid bacteria during an alcoholic fermentation may favor *O. oeni*, as acetic acid is a known inhibitor of *S. cerevisiae*. Above pH 3.5, *Lactobacillus* spp. and *Pediococcus* spp. may have an advantage over *O. oeni*.

2.3.6 Spontaneous Malolactic Fermentation

Malolactic fermentation can occur before, during or after alcoholic fermentation. In traditional Spanish cider production, the two fermentations usually occur side by side (Section 2.8.5) (Blanco Gomis *et al.*, 2003), whereas in wine production, it is traditional for malolactic fermentation to occur after alcoholic fermentation, and frequently it happened automatically when wines were stored in barrels for ageing and maturation. However, using the natural bacterial population on the grapes and in the winery to conduct a spontaneous malolactic fermentation can be risky. The producer will not necessarily know which species is carrying out the fermentation, and the risks associated with this include degradation of glycerol to increase bitterness in the product, production of volatile phenols, production of pyridines, which lead to mousy odors, production of biogenic amines, degradation of arginine to ethyl carbamate and increased volatile acidity (du Toit, 2008).

Bacteria become resident in the wood or tartrate layer of cooperage, therefore a wine that has not been through, nor is intended to go through the malolactic fermentation cannot be made in a barrel which has previously been used for this purpose. Significant populations of bacteria are known to survive typical cleaning regimes that are applied to wooden casks or vats (see Section 2.8.5).

Lactic acid bacteria release enzymes that react with soluble substances in oak barrels, creating a wider range of flavors in a wine than would be produced in a sterile inert vessel. The MLF growth (lag) phase associated with spontaneous MLF (wild/uncultured strains) presents a time of increased risk from spoilage organisms due to the low SO_2 environment and the potential production of volatile acidity through the actions of other organisms or oxidation. Acetic acid is also produced during bacterial growth from sugar and organic acid degradation. Even under conditions chosen to stimulate development of the bacteria, the fermentation can take months to begin (Jackson, 2000a). Additionally, spontaneous malolactic fermentation in high pH and low SO_2 environments can be associated with unpleasant aromas and flavors, the source of which may be *Lactobacillus* and *Pediococcus* populations. The producer also runs the risk of introducing potential interference by bacteriophages (viral agents lethal to bacteria) present in a wild population.

When relying on wild bacteria, there can be no certainty of consistent results, but some producers feel that a spontaneous fermentation will add complexity and interest to their wines. Additionally, some areas in the world, which have been making wine in the same cellar (and region) for centuries, may have a resident population of spores and lactic acid bacteria, which produce consistent and favorable results for local producers. When using indigenous bacteria, it is advisable to keep the wine temperature maintained at 18–20 °C. The presence of the bacteria in wineries can be very variable, giving a wide variation in ease with which MLF takes place. Often the fermentation is harder to start in newly established, clean or modern wineries (for similar observations regarding traditional cider, see Swaffield *et al.* (1997) and Section 2.8.5).

2.3.7 Inoculation with MLB Starter Culture

In recent years, the introduction of commercial freeze dried bacterial cultures of *O. oeni* for direct inoculation into wine has ensured better control of the time of onset and the rate of MLF, reduced the potential for spoilage by other bacteria. Inoculating with a prepared culture avoids the problems associated with the bacterial lag phase by immediately providing the population necessary to conduct the fermentation. Commercially available preparations are normally freeze dried cultures of *O. oeni*, but some cultures contain more than one species of bacteria. Bacterial cultures are not easy to use as the bacteria are fastidious, but they are still more reliable than relying on natural populations (Morgan *et al.*, 2006). The winemaker also has more control over the flavor modifications. Inoculation of the bacteria is usually conducted after the wine has been fermented dry by yeast. This avoids the possibility of MLB metabolizing the sugar and producing unwanted products such as acetic acid. Some winemakers inoculate during or before the end of alcoholic fermentation, taking advantage

of the low alcohol, higher nutrient environment. In the event that the malolactic fermentation completes soon after alcoholic fermentation, sulfur dioxide can be added, and the wine is then protected from bacterial and oxidative attack.

It is important that the MLB have enough nutrients to develop. Fermenting yeast (*S. cerevisiae* var. '*bayanus*' in particular) can reduce the nutrients available to MLB considerably. Winemakers often add an MLB nutrient when inoculating with MLB to assist their development. When considering the timing of inoculation, the compatibility of yeast and LAB compatibility should also be considered. Inoculating grape musts with wine yeast and lactic acid bacteria concurrently in order to induce simultaneous alcoholic fermentation and malolactic fermentation can be an efficient alternative to overcome potential inhibition of bacteria in wines because of high ethanol concentrations and reduced nutrient content. The simultaneous inoculation of yeast and lactic acid bacteria was studied by Jussier *et al.* (2006) in cool climate Chardonnay must. Glucose, fructose, acetaldehyde, several organic acids and nitrogenous compounds were measured during the fermentations along with the final values of other key wine parameters. Sensory evaluation was done after 12 months of storage. No negative impacts of simultaneous AF/MLF on fermentation or sensory wine parameters were found. Acetic acid concentrations were slightly higher in wines after simultaneous AF/MLF, but the differences were not significant. Neither were any statistically significant differences found in pH or total acidity, nor in the concentrations of ethanol, acetaldehyde, glycerol, citric and lactic acids, and the nitrogen compounds arginine, ammonia, urea, citrulline and ornithine. Sensory evaluation by a semiexpert panel confirmed the similarity of the wines. Simultaneous inoculation of yeast and bacteria did, however, lead to considerable reductions in overall fermentation durations (Jussier *et al.*, 2006).

Another winemaking option is partial malolactic fermentation, which is used when the producer wishes to retain crisp acid and fruit character, but gain fullness and complexity from the bacterial metabolism. The volume of wine will be divided in a certain ratio, one portion goes through full MLF and the other no MLF. The two portions are then blended back together. The best method in providing bacterial stability therafter is to sterile filter the wine through a 0.45 μm (0.45 micron) membrane filter, as well as dosing with sulfur dioxide.

2.3.8 The Growth of Bacterial Populations

The growth of the lactic bacteria population may occur at the start of the alcoholic fermentation, during fermentation, at the end or later. The latent period in between is partly due to the formation of alcohol by the yeasts and can be prolonged by low temperatures after the alcoholic fermentation. Lactic acid bacteria require a certain population level (10^5 cells/ml) to be reached before they can begin malolactic fermentation, and inoculation will customarily achieve a million to 10 million cells per millitre (Jackson, 2000a). Due to the stress that inoculated bacteria undergo in adapting to the wine environment, inoculations of the bacteria may even be increased to population loads of at least 10^8 cells/ml. A bacterial population may simply be dormant and become active when conditions are more favorable. This explains the often seen delay of malolactic fermentation in bottled wines, as well as the increase in activity in cellared wines over the spring as cellar temperatures rise. Usually natural/indigenous MLF fermentations can have a lag phase of weeks to several months before they begin and this is prolonged at lower pH (Morgan *et al.*, 2006). The bacterial population will die back to 10^3–10^4 cfu/ml during alcoholic fermentation as cells lyse rapidly, but may rise to 10^6–10^8 cfu/ml once growth initiates substantially (Jackson, 2000a). After exponential growth, cell populations decline rapidly depending on the conditions (e.g. elevated temperatures or SO_2 will increase the rate). It is possible that the population of strains of *Lactobacillus* and *Pediococcus* may increase at this point. The malic acid breakdown usually occurs after the alcoholic fermentation when the bacterial population becomes greater than 10^7 cells/ml.

2.3.9 The Malolactic Fermentation Process

Malolactic fermentation is the conversion of (*S*)-(-)-malic acid to monocarboxylic (*S*)-(+)- or (*R*)-(-)-lactic acid and carbon dioxide, catalyzed by malate decarboxylase, and requiring the coenzyme NAD^+ and manganese (Mn^{2+}) (Du Toit, 2008). Only (*S*)-(-)-malic acid will be converted by MLB, but whether (*S*)-(+)- and/or (*R*)-(-)-lactic acid is produced depends on the bacterial strain and substrate involved. If *O. oeni* is the MLB, which is frequently the case, then the major product is (*S*)-(+)-lactic acid, as shown in Figure 2.3.1.

(*S*)-(-)-Malic acid concentration in grape juice varies depending upon the climatic regions from which the grapes are sourced; cool climate regions are often in the range 2–5 g/l, whereas in warm regions, grape juice often contains less than 2 g/l (Zoecklein *et al.*, 1995). Other substrates, such as residual sugars and citric acid are often broken down to obtain energy. Tartaric acid is only degraded in wines whose pH is above 4.

The malolactic fermentation is summarized in Figure 2.3.1. It consists of three steps:

- The uptake of malic acid from the external environment by a specific transporter, malate permease
- The decarboxylation of malic to lactic acid with an increase in internal pH of the cell
- The transport of lactic acid from the cell with one hydrogen ion, and an associated increase in proton motive force over the cell membrane.

The increase in proton motive force triggers the production of ATP within the cell (Du Toit, 2008). For every gram of malic acid metabolized, around two thirds is converted to lactic acid and a third to carbon dioxide, evidenced by the slight 'spritz' often found in wines undergoing the fermentation. The decarboxylation of malic acid (Figure 2.3.1) can reduce titratable acidity by between 1 and 4.6 g/l and increase pH by around 0.1–0.25.

Lactic acid bacteria are strictly fermentative. They have limited synthetic abilities, as stated previously, and are unable to produce heme proteins, cytochromes or catalase. Despite this, they are able to grow in the presence of limited amounts of oxygen, and detoxify oxygen radicals by accumulating large quantities of manganese ions, or by producing peroxidase enzymes. Manganese detoxifies superoxide by converting it to oxygen and peroxidase oxidizes peroxide to water (Section 5.8.4) (Jackson, 2000a). Although fermentative metabolism is inefficient in terms of energy production as discussed in Chapters 2.1 and 2.2, by metabolizing malic acid to lactic acid, acidity in the medium is reduced and the pH increased, which is beneficial for the bacteria.

Both malic acid and citric acid in the wine are metabolized by *O. oeni*. The cofermentation of citrate and glucose in *O. oeni* is physiologically important for this bacterium (Liu, 2002), and has been shown to enhance its growth rate and biomass yield, which result from increased ATP synthesis both by substrate level phosphorylation via acetate kinase and by a chemiosmotic mechanism (proton motive force). The growth stimulation of citrate–sugar cofermentation by the same mechanisms has also been reported in citrate-fermenting dairy bacteria (Nielsen and Richelieu, 1999). Malolactic bacteria follow a similar metabolic pathway to that of dairy lactic acid bacteria in the metabolism of citrate. Citrate is transformed to lactate, acetate, diacetyl, acetoin and 2,3-butanediol. A small amount of citrate is converted to aspartate via oxaloacetate and aspartate

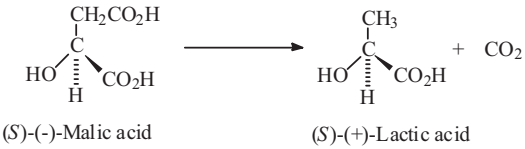

Figure 2.3.1 *Summary of MLF*

aminotransferase (Liu, 2002). From a winemaker's point of view, the cometabolism of citrate–sugar increases the formation of the volatile acid (acetate) in wine, which can affect the wine aroma detrimentally if present at excessive levels.

Ethyl carbamate (EC) is an animal carcinogen found in many fermented foods and beverages, including wine (Section 5.11.4). It is formed through the chemical reaction of ethanol and a precursor, such as citrulline, urea or carbamyl phosphate (Liu, 2002). Citrulline is an intermediate in the degradation of arginine by lactic acid bacteria. Arginine is a major amino acid present in wine: it is catabolized via the arginine deiminase pathway (ADI). Arginine degradation via the ADI pathway produces ATP, which is necessary for survival and growth of the bacteria. Carbamyl phosphate is also a precursor to pyrimidine and some bacteria can synthesize carbamyl phosphate from glutamine, bicarbonate and ATP, so this is potentially another source of ethyl carbamate. Factors affecting arginine degradation include LAB strain, pH, arginine concentration and sugar type. Citrulline excreted during arginine degradation, and ornithine, can also be catabolized by some wine LAB (Liu, 2002).

2.3.10 Production of Diacetyl

The most important enological significance associated with citrate fermentation is the production of diacetyl, an aroma compound with a buttery, nutty flavor note. It has been demonstrated that threshold values in different wines vary from 0.2 mg/l in Chardonnay wine to 0.9 mg/l in Pinot Noir and 2.8 mg/l in Cabernet Sauvignon wine. In general, wines that have undergone malolactic fermentation have higher concentrations of diacetyl (Martineau and Henick-Kling, 1995). The final level of diacetyl in wine is affected by a number of factors, such as bacterial strain, wine type, sulfur dioxide and oxygen (Nielsen and Richelieu, 1999). It should be pointed out that diacetyl is formed chemically from the oxidative decarboxylation of α-acetolactate, an unstable intermediary compound produced during citrate metabolism (Bartowsky *et al.,* 2002). *O. oeni*, as well as a number of other bacteria contain diacetyl reductase that converts the flavorful diacetyl to the much less flavorful acetoin and 2,3-butanediol. α-Acetolactic acid may decarboxylate spontaneously to acetoin and, in oxidizing conditions, also to diacetyl (Nielsen and Richelieu, 1999). In lactic bacteria-fermented dairy products, the latter reaction is now generally believed to be the only source of diacetyl.

After sulfiting, most wines are stored in tanks, barrels or bottles in a span ranging from a few months to several years. During this storage, SO_2 levels will gradually reduce as the molecule reacts reversibly or irreversibly with different compounds in the wine. Immediately after addition, some of the free SO_2 will combine with diacetyl. As the reaction is reversible, it can be the case that the diacetyl concentrations will increase later during storage as it is released once more into solution.

Oxygenation, high concentrations of citrate and sugars, lower temperature (18 °C), removal of yeast cells before malolactic fermentation and low inoculation rate all favor the production of diacetyl (Martineau and Henick-Kling, 1995). The presence of viable yeast cells during the fermentation, prolonged contact with bacteria and addition of SO_2 cause diacetyl reduction. Besides the microbial activity, the final diacetyl concentration in wine is also affected by the concentration of SO_2, which reduces it significantly. For example, addition of 80 mg of SO_2 per liter, which is within the range used in the wine industry, reduced the diacetyl concentration from initially 20 to as low as 5 mg/l, i.e. by 75% (Nielsen and Richelieu, 1999).

2.3.11 Microbial Stability

Under certain conditions, malolactic fermentation can increase the microbial stability of a wine. Some spoilage bacteria attack malic acid and by reducing its concentration, a more microbiologically stable wine will result.

Lactic acid bacteria also consume nutrients (amino acids, nitrogen bases, vitamins) and this reduction has been thought to increase microbial stability by limiting the potential growth of spoilage organisms. However, it has been shown that wines that have completed MLF can still support *O. oeni*, *Lactobacilus* spp. or *Pediococcus* spp., if SO_2 levels remain low (Morgan *et al.*, 2006). Malolactic fermentation can also raise the pH above 3.5, which provides a more favorable environment for spoilage organisms.

2.3.12 Monitoring Malolactic Fermentation

The progress of the malolactic fermentation can be monitored qualitatively in wines by tracking the decrease in malic acid and accompanying increase in lactic acid using paper or thin layer chromatography (Section 4.3.1). The usual criterion for completion of the malolactic fermentation, and subsequent addition of sulfur dioxide, is the exhaustion of malic acid. This may result in an incomplete citric acid degradation in the wine (Nielsen and Richelieu, 1999), leaving this as substrate for further bacterial activity if the wine is not sterile filtered. Other methods, for example chromatography (Sections 4.3.1 and 4.3.3), enzymatic/colorimetric analysis (Section 4.4.3) or infrared spectroscopy (Section 4.4.2) can also be used, but these are more complex and require capital investment into appropriate equipment. In the event that the producer is able to quantify the loss of malic acid, it is generally accepted that the MLF is complete when malic acid level falls below 0.1 g/l.

2.3.13 Finishing and/or Preventing Malolactic Fermentation

To prevent malolactic fermentation in wine, keeping maceration on skins and contact with yeast lees to a minimum, and maintaining relatively high levels of SO_2 at completion of the alcoholic fermentation, are required. Sterile filtration and pasteurization, if appropriate, are also good preventative measures, as this reduces bacterial load. Lowering pH (below 3.1 for whites, below 3.3 for reds) and storage temperatures (12 °C) will help prevent bacterial growth, as will sterile filtration to the 0.45 μm (micron) level. The use of a commercial antibacterial lysozyme (an enzyme that destroys the bacterial cell walls by catalyzing the hydrolysis of specific glucosidic links) can also help. In wine, an alcohol content of greater than 13% will inhibit malolactic fermentation.

Once malolactic fermentation is over, the wine should be racked, filtered and sulfited (40–50 mg/l to maintain the free levels at 20–30 mg/l). At this point, it is vital to clean all winemaking equipment thoroughly and maintain aseptic conditions in the winery.

Species associated with wine spoilage are generally members of *Lactobacillus* and *Pediococcus* genera. *Lactobacillus*, for example, can cause acescence (excessive acetic acid) by metabolizing residual sugar or tartaric acid. Both acetic acid and lactic acid bacteria are readily found in wines and the winery, but to minimize excessive growth leading to possible wine spoilage, measures should be taken to reduce contamination. Basic hygiene of winery equipment and the winery is essential and the proper storage of musts and wines will minimize spoilage. The removal of grape skins, a major source of bacteria coming into the winery, and the cleaning up of juice and wine spillages reduces the transfer of bacteria to the wine and equipment. Other then the winemaking conditions and the use of antimicrobial agents, a further method to minimize the growth of spoilage bacteria is the physical removal of such organisms by the way of filtration. The effectiveness of filtration depends on the correct set up being used, to ensure the filters are not compromised, and this is dependent on the wine style and the turbidity of the solution.

2.3.14 Production of Biogenic Amines by Malolactic Bacteria

Some lactic acid bacteria possess enzymes that decarboxylate amino acids to form the corresponding amines and carbon dioxide. Amines are toxic substances that have deleterious effects on human health if consumed in excessive amounts and some people can suffer severe allergic reactions from ingesting very low levels of amines in alcoholic beverages (Section 5.11.3). They are found in a range of fermented foods and beverages, such as fermented fish, cheeses, beer and meat products (Liu, 2002). *Lactobacilli*, *Lactococci* and *Leuconostoc* species isolated from beer, cheeses and meat starter cultures are known to produce histamine and tyramine via the decarboxylation of the corresponding amino acids, histidine and tyrosine. The major amines found in wine are histamine, tyramine, putrescine and phenylethylamine. The role of lactic bacteria and the malolactic fermentation in the biogenesis of amines has now been defined, since the decarboxylation of histidine to histamine and tyrosine to tyramine has been demonstrated with single strains of *Lactobacillus* and *Oenococcus* (Liu, 2002). Lactic bacteria vary in their ability to produce amines from amino acids, and in wine, it appears that the *Lactobacillus* and *Pediococcus* are the main producers. Histidine decarboxylase activity is also common in *Oenococcus*, which is primarily responsible for histamine formation.

Glyoxal and methylglyoxal found in wine are toxic compounds and also have implications for human health. It appears that *Oenococci* can produce glyoxal and methylglyoxal during malolactic fermentation. However, definitive studies are required to link the production of glyoxal and methylglyoxal with specific strains of *Oenococci* and other lactic bacteria.

2.3.15 Other Effects of MLF

It is generally accepted that the effect of the malolactic fermentation will vary according to the wine. It has a reputation as a destroyer of fruit character, red wine color and acid balance in low acid wines from warm areas. Also, MLF can be accompanied by by-products, sometimes of the sulfide or mercaptan type (cabbage, canned asparagus or green vegetable notes), or at other times diacetyl is formed, which has a buttery odor. Two consequences of deacidification during MLF are an increase in pH and a decrease in titratable acidity, which obviously affect taste, but have other, indirect consequences for the producer. As stated previously, an elevated wine pH can increase the susceptibility of wine to microbial spoilage. It can also decrease the efficacy of sulfur dioxide, and have implications for color and oxidative stability.

If a reduction in acidity is desired and the wine style is not driven by varietal aroma and flavors, malolactic fermentation may increase the quality of the wine. The malolactic fermentation is not encouraged in the making of wine from ‘aromatic’ varieties (those rich in terpenoid content) like Riesling, Gewürztraminer and the Muscat family or indeed any whites where primary (grape) aroma is important. Although malolactic fermentation traditionally occurred in red wine, some white wines, for example Chardonnay, can also benefit from the increased complexity. Base wines for sparkling wine production can be fairly acidic (pH 3.0), and most producers encourage malolactic fermentation in the base wine as it is impossible to remove bacteria during degorgement.

Malolactic fermentation can help to alleviate astringency in a number of ways. A decrease in acidity will decrease perceived astringency as the two sensations enhance each other. A raised pH may help polymerizing reactions to progress at a faster rate, and soften tannins and malolactic bacteria also metabolize a small percentage of the phenolics. A by-product of malolactic fermentation, ethyl lactate, often exceeds the sensory threshold of 150 mg/l giving fuller, enhanced mouthfeel.

Lactic acid bacteria are able to form exocellular polysaccharides (‘ropey’ wine) (for example, *Pediococcus* spp. produce a trimeric β-glucan, composed of three β-D-glucose units), but it seems to need a combination of factors including low sulfur dioxide and a mixed population of bacteria. In contrast to what is known

about the phenomenon in wine, a great deal of information is available on the exocellular polysaccharides in fermented dairy products. It appears that the bacteria in wine may be able to catabolize polysaccharides, which is one reason why 'ropey' wines are not common. *O. oeni* has been shown to possess extracellular β-(1-3)-glucanase activity and has the potential to degrade polysaccharides, such as β-glucans (Liu, 2002).

In conclusion, as Bartowski (2005) states:

> 'Living in wine can be very stressful for a cell; it requires a great deal of resilience to tolerate, amongst other things, high levels of ethanol and a low pH. What is required of O. oeni to survive and grow in such a hostile world? What distinguishes it biochemically and physiologically from most other bacteria, which struggle and perish in this habitat, and that includes the sturdiest of the other LAB? We do not have the answers yet, but we do have some ideas from research on other organisms, and work is well underway in several laboratories to address them for O. oeni.'

2.3.16 Malolactic Fermentation and Aroma

The impact of malolactic fermentation on the taste of wine as a result of deacidification is well recognized, but the effect on wine aroma and mouthfeel/body is ill-defined (Liu, 2002). Davis and coworkers (1985) reviewed the contribution of MLF to wine aroma and found no consistent impact of MLF on wine aroma. Nielsen and Richelieu (1999) cite studies (including that of Davis) that may be used to support the argument that malolactic fermentation does not significantly affect the flavor of wine other than to adjust the acidity. However, there are also those (e.g. McDaniel *et al.,* 1987) that state that similar wines which have undergone MLF can be distinguished fairly easily from those which have not. Swiegers and coworkers (2005) note that research in progress shows that bacteria can significantly modify components and sensory properties in wine. Since 1985, further work has been carried out to investigate the effect of MLF on sensory properties of wine using a more stringent panel training method, gas chromatography (GC)-olfactometry and GC-mass spectrometry (Liu, 2002). What is undeniable is that lactic acid bacteria produce a diverse range of products during their activities (including succinate, acetate, acetoin, lactate, diacetyl, mannitol, higher alcohols and a number of the biogenic amines) depending on available substrates and the strain of bacteria.

The compounds produced by lactic acid bacteria are claimed to modify or mask vegetal characters, and impart nutty, lactic and/or earthy aromas. It is probably safe to say that the process mellows the product and gives it complexity, but in some cases freshness, fruit and varietal aromas may be lost. The producer needs to consider these issues when deciding whether to carry out a malolactic fermentation, for example, where freshness and vivacity are important and in terpene-rich cultivars (like Riesling, Gewurztraminer and the Muscat types), the process is seldom recommended. In the case of barrel-fermented and aged Chardonnays (e.g. Burgundies) and red wines, where complexity is desirable, malolactic fermentation may enhance the quality and style of the wine considerably.

Diacetyl

Diacetyl (2,3-butanedione) is one of the major by-products of citric acid metabolism, which is closely linked to malolactic fermentation (du Toit, 2008). The compound imparts a buttery flavor to the wine, which benefits neutral cultivars, but is generally thought to have a negative impact on aromatic varieties. Threshold levels vary for different wines, depending on cultivar and style, as well as the personal preference of consumers. Jackson (2000a) states that 1–4 mg/l of diacetyl adds 'a desirable complexity' to the fragrance, but at more than 5 mg/l the aroma becomes overt and undesirable. On testing wines from 20 different regions, 28 different producers and eight vintages, Bartowsky *et al*. (2002) found that Chardonnay wines showed levels of diacetyl

between 0.3 to 0.6 mg/l, while reds (Cabernet Sauvignon, Merlot and Shiraz) showed 0.3 to 2.5 mg/l (mean value 1.1 mg/l). The extent of diacetyl formation strain also depends on strain (e.g. *Streptococci*), as well as oxygen and citric acid content.

Diacetyl appears to be a metabolic intermediary compound in the citric acid metabolism by *O. oeni* (Shimazu *et al.,* 1985). The higher the initial concentration of citric acid, the more diacetyl will be produced from MLF. Citric acid metabolism begins at the same time that malic acid degradation occurs, but the degradation of the citric acid is slower. Diacetyl concentration increases as citric acid is metabolized by the bacteria and decreases again when most of the citric acid has been consumed. Maximum diacetyl concentration tends to coincide with the exhaustion of malic acid during malolactic fermentation (Nielsen and Prahl, 1995). The amount produced depends on the bacterial strain and cell multiplication: the lower the cell multiplication, the lower the production of acetate and diacetyl. Under stressed slow growth conditions (where more diacetyl and less acetic acid are produced) the environmental conditions affecting LAB, the amount of citric acid available and the sulfur dioxide content, all influence the redox potential (oxygen content) of the wine. *S. cerevisiae* irreversibly reduces diacetyl, and sulfur dioxide binds reversibly with diacetyl. The addition of SO_2 will initially decrease the concentration of diacetyl, and increase the quantity of bound SO_2. When the diacetyl–SO_2 complex dissociates, however, the diacetyl and free SO_2 levels will increase. Semiaerobic (2–4 mg/l oxygen) malolactic fermentations yielded higher concentrations of diacetyl, whereas anaerobic ($<$0.2 mg/l oxygen) conditions yielded much lower concentrations. Also, it has been observed that the higher the pH, the lower the diacetyl production (Wibowo *et al.,* 1985).

Diacetyl is reduced irreversibly by lactic acid bacteria to acetoin and 2,3-butanediol, an odorless, but sweet-tasting higher alcohol. These two compounds have no influence on wine aroma when present in their normal concentrations in wine (de Revel *et al.,* 1989). For a high diacetyl concentration, the wine should be racked off the lees before inoculating with lactic acid bacteria and stabilized as soon as the malic acid is catabolized. Malolactic nutrients may be required in this case, since the necessary nutrients have been removed due to the racking/clarifying procedure. Since diacetyl is not considered desirable in red wines, malolactic fermentation is usually conducted on yeast lees, which results in the diacetyl being catabolized by the yeast (or the bacteria).

During malolactic fermentation in wine by *O. oeni*, the degradation of citric acid is delayed compared to the degradation of malic acid (Nielsen and Richelieu, 1999). The total production of diacetyl and acetoin during MLF by *O. oeni* is stimulated by increased citric acid concentrations in the wine. However, the production of the two compounds is strongly dependent on the redox potential and O_2 concentration of the wine (Nielsen and Richelieu, 1999). Maximum diacetyl concentration was found to occur when malic acid levels were exhausted. Once the maximum was reached, levels of diacetyl began to drop due to degradation of the compound by the bacteria. The authors noted that for control of the final diacetyl concentration in the wine, it is important to be aware of this coincidence of maximum diacetyl concentration and exhaustion of malic acid. If the wine is sulfited at this point, which is common at many wineries, all further microbiological activity stops. The irreversible reduction of the diacetyl will also then stop, because this can be accomplished only by living bacteria and yeast. If the buttery note from diacetyl is too overwhelming after exhaustion of the malic acid, the authors advise the delay of sulfuring until the diacetyl concentration has been reduced by the bacteria and yeast. Indeed, in the brewing of beer, it is usually necessary to allow a certain beer–yeast contact time after fermentation in order to remove excess diacetyl (Section 2.6.4). Sulfite added to wine reacts fast and rather strongly with diacetyl and also reduces the buttery flavor. However, in contrast to the microbiological reduction by bacteria and yeast, this reaction is reversible. If some of the SO_2 evaporates or combines with other compounds in the wine, the concentration of the flavor may later increase in the wine again. This should be kept in mind when the time of sulfitation after the MLF is decided and when the wine is stored in tanks or barrels and later bottled (Nielsen and Richelieu, 1999). The concentration of free diacetyl in wine containing SO_2 may also depend on the concentration of other SO_2-binding compounds,

such as acetaldehyde, α-ketoglutaric acid and pyruvic acid, which are substantially reduced during MLF. Several other factors can influence diacetyl formation and reduction. Low concentrations of sulfur dioxide, lower temperature (18 °C), and low inoculation rate favor the production of diacetyl (Swiegers *et al.*, 2005). Temperature also has a strong influence on the perception of the buttery aroma of diacetyl, and anything over 30 °C will lead to an overestimation of the actual diacetyl concentration. If one wishes to accentuate the buttery-nutty aroma of diacetyl in, say, a bottle of Chardonnay, it should be consumed at 20 °C rather than at 10 °C (Nielsen and Richelieu, 1999).

Hydrolysis of Grape Aroma Compounds

Detectable levels of β-glucosidase activity were found in 11 commercial preparations of wine *Oenococci* (Liu, 2002), suggesting that these bacteria have the potential to hydrolyse glycoconjugates to affect wine aroma and color. The sugar-bound monoterpenes are nonvolatile and flavorless. A glycosidase (e.g. β-glucosidase) hydrolyzes the sugar bound monoterpenes to release the volatile, aromatic monoterpenes as well as the sugar. The presence of glycosidase activity in lactic acid bacteria from sources other than wine is known. An α-glucosidase has been isolated in *Lactobacillus brevis* from beer, and a β-glucosidase was purified and characterized from *Leucenostoc mesenteroides* isolated from cassava. *Lb. plantarum* strains from cassava fermentation contain β-glucosidase that can degrade cyanogenic glycosides, which suggests that these enzymes may be used to detoxify food plants by way of enzymatic hydrolysis or fermentation. This area merits further study (Liu, 2002).

Increased levels of glycosidically bound grape-derived aroma norisoprenoids (α-ionone, for example) and monoterpenes, released through hydrolysis by bacterial endocellular β-glucosidase enzyme (du Toit, 2008) will contribute positively to wine aroma. Ugliano and coworkers (2003) studied the ability of four commercial preparations of *O. oeni* to hydrolyze wine aroma precursors by measuring the concentration of free and bound Muscat glycosides at the end of malolactic fermentation in model wines. They concluded that the *O. oeni* strains tested enhanced wine aroma through the hydrolysis of grape-derived bound secondary metabolites significantly. Another side effect of bacterial activity may be the modification of color in red wine. Anthocyanins are the main pigments of red grapes and young red wines, which are usually glycosidically bound to sugars, such as glucose (see, for example, Sections 2.9.2, 2.10.7, 2.11.2 and 5.8.6). A bacterial glycosidase (also referred to as anthocyanase) hydrolyzes the sugar bound anthocyanins to liberate the sugar and the corresponding anthocyanidin during malolactic fermentation, the latter spontaneously converting to brown or colorless compounds via condensation and other reactions (Liu, 2002).

Production of Volatile Phenols

Phenolic acids (mainly ferulic and *p*-coumaric acids) are natural constituents of grape juice and wine. These phenolic compounds can be decarboxylated microbially during fermentation into volatile phenols such as 4-ethylguaiacol and 4-ethylphenol (Liu, 2002). The volatile phenols can contribute to wine aroma positively or negatively, dependent on the concentration, due to their low detection thresholds and their distinctive flavors. It has been observed that the concentration of volatile phenols increased markedly during malolactic fermentation, suggesting that lactic acid bacteria might be involved. The metabolism of phenolic acids, *p*-coumaric acids, in particular by *Lb. plantarum* and *Brettanomyces* spp., have been well characterized, unlike the metabolism of phenolic acids by the more typical wine bacteria. *Lactobacilli* isolated from malt whisky fermentation can also decarboxylate phenolic acids into volatile phenols. However, phenolic compounds can favorably and unfavorably affect the physiology and growth of wine LAB, dependent on the concentration and type of phenolic compounds. (Liu, 2002).

Other By-products of Malolactic Fermentation

Esters, such as ethyl acetate and C_4 to C_{10} fatty acid ethyl esters, are largely, if not exclusively, responsible for the fruity aroma of wine. Yeasts are known to produce these esters during alcoholic fermentation (Jackson, 2000c), and there is some evidence to suggest that ethyl esters, such as ethyl acetate, ethyl lactate, ethyl hexanoate and ethyl octanoate, are formed by wine bacteria during malolactic fermentation. The ability of wine lactic acid bacteria to synthesize esters needs to be verified, but the bacteria and *Pseudomonas* of dairy origin are known to esterify alcohols and fatty acids. Dairy isolates of *Lactococci*, *Lactobacilli*, *Streptococci* and *Pseudomonas fragi* form ethyl butanoate and ethyl hexanoate from ethanol and butanoic and hexanoic acids (Liu, 2002). The concentrations of some esters decrease while others increase during storage of wines, presumably due to acid hydrolysis and chemical esterification.

Wine contains various volatile aldehydes that contribute important sensory properties, of which acetaldehyde is quantitatively the most abundant aroma compound present in wine (Jackson, 2000a). The aldehydes, including acetaldehyde, hexanal, *cis*-hexen-3-al and *trans*-hexen-2-al, cause the green, grassy and vegetative off aroma in wine, and can negatively impact on primary aroma from grapes. The removal of aldehydes in any wine except Sherry is beneficial to the quality of the product. Traditionally, sulfur dioxide is added to bind acetaldehyde when this compound is in excess, but it has been found that some lactic acid bacteria (specifically *O. oeni*) can catabolize acetaldehyde, converting it to ethanol and acetate (Liu, 2002), offering an alternative approach to sulfur addition. Lactic bacteria (for example, dairy *Lactococci* and *Lactobacilli)* may also produce acetaldehyde, but its production by *O. oeni* is still unclear (Liu, 2002).

Lactic acid bacteria can also metabolize glucose and fructose to acetic acid, lactic acid and mannitol, which may impart vinegary characteristics, and glycerol to acrolein, which is very bitter. Amino acids may be converted to the biogenic amines putrescine, cadaverine and histamine, which can cause allergic responses in some individuals, and at higher levels, have off-putting aromas (as their names suggest). Undesirable odors (cabbage, asparagus, canned vegetable) brought about by MLF are usually associated with the action of *Pediococci* or *Lactobacilli*, or with MLF occurring above pH 3.5, whereas malolactic fermentation by *O. oeni* below pH 3.5 is less likely to produce off odors (Jackson, 2000a).

Volatile sulfur compounds are produced via desulfuration of sulfur-containing amino acids, such as methionine and cysteine. The secondary reactions of amino acid catabolism involve the conversion of the above compounds (amines, α-keto acids and amino acids) to aldehydes. The reduction of the aldehydes to alcohols and/or their oxidation to acids constitutes the final reactions of amino acid transformation (Liu, 2002). Few studies have been conducted on the catabolism of amino acids other than arginine by lactic acid bacteria in wine, but this could have a significant impact on wine quality, given that a range of compounds can be produced.

In a study carried out by Zlotejablko and coworkers (2001), descriptive sensory profiles of Uruguayan Tannat wines after malolactic fermentation were compared with control wines where MLF was prevented. MLF led to a significant decrease ($P < 0.05$) in secondary descriptors such as 'berry fruit' and 'fresh vegetative,' as well as a decrease in related tertiary descriptors such as 'blackcurrant,' 'apricot,' 'cut green grass' and 'green pepper.' The main differences in the chemical composition found following MLF were an increase of the lactates (mainly ethyl lactate) over the sensory threshold, a significant decrease in ethyl esters and acetates, and a small increase of 4-vinylguaiacol and 4-vinylphenol (smoky aromas) with one of the MLF strains.

de Revel *et al.* (1999) studied lactic acid bacteria starter cultures in a white Sauvignon wine during partial malolactic fermentation in barrels and found carbonyl substances were formed during fast bacterial growth and metabolism of citric acid. Greater complexity was observed in the wood-matured wine after malolactic fermentation compared to a wine not having undergone bacterial development, especially regarding buttered, spiced, roasted, vanilla and smoked notes. The intensity of grape varietal character also decreased significantly.

2.3.17 Lactic Spoilage

As discussed earlier in this section, uncontrolled metabolism by lactic acid bacteria as well as other substrates may lead to the production of off odors within the wine. The fermentation of tartaric acid by bacteria occurs only in very high pH wines (above pH 3.5) with low free sulfite levels. Tartaric acid is converted into lactic acid, acetic acid and carbon dioxide, accompanied by a significant reduction in total acidity. This fault is known as '*tourne*,' and is primarily caused by *Lb. brevis*. The wine will appear cloudy with silky waves, gassy and dull in color, and red wine will gain a brownish tinge. The wine becomes very flabby and can appear 'mousy' in extreme cases (Jackson, 2000b).

Lactic acid bacteria may ferment glycerol in musts made from immature rotted grapes, with the effect being particularly noticeable in the press and lees wines, which have the lowest acidity. Glycerol is converted to lactic and acetic acid, causing the wine to taste thin and acidic. Acrolein, a bitter tasting compound, may also be formed, and putrid odors may develop. This spoilage (known as '*amertume*') was common in Burgundy at the end of the nineteenth century, but is now rare due to better pest control in the vineyard and the widespread use of sulfur dioxide. A fault known as 'lactic souring' occurs when sugars are attacked by any lactic acid bacteria, and on wines with stuck fermentations (particularly those which have overheated) or on high pH wines (over pH 3.3) with residual sugars on which the malolactic fermentation is attempted (Morgan *et al.*, 2006). The sugars are converted to lactic and acetic acids, giving the wine a sweet/sour taint. The risk of lactic souring can be reduced by good prefermentation clarification with sulfur dioxide addition and good fermentation control, fermenting the wine to dryness. Lactic souring often occurs after a normal alcoholic fermentation, as the nonfermentable sugars remaining are attacked. The resulting increase in acidity is slight, and the gain in volatile acidity is only 0.1–0.4 g/l. There is little clouding, so the spoilage often passes unnoticed, except for a slight loss of quality in the wine. To prevent this, wines of low acidity should be racked, clarified and sulfited as early as possible after the alcoholic fermentation (Morgan *et al.*, 2006).

During an apparently normal malolactic fermentation, the lactic bacteria surround themselves with a mucillaginous layer of polysaccharides (β-1,3-glucans) that connects them and makes the wine appear oily and flowing in a viscous fashion ('ropiness'). There is no increase in volatile acidity. This condition is rare in table wines, as it only occurs in wines with no sulfur dioxide (e.g. those destined for distillation). Strains of *O. oeni* and *Pediococcus* species have been isolated from ropey wines, but they are not always present (Jackson, 2000b). Sometimes a combination of microorganisms in combination with lactic bacteria may lead to a fault known as 'mousiness.' The sensitivity of individuals to this taste varies greatly, but it is most unpleasant to some people; often becoming apparent some time after the wine has left the mouth, and being very persistent. There is no known cure. The causative organisms are certain lactic bacteria including *Lb. brevis, Lb. cellobiose*, *Pediococcus* and/or *Brettanomyces* yeasts. These organisms are sensitive to free sulfur dioxide, and so this fault does not occur if wines are normally sulfited. The transformation of the antifungal agent sorbic acid by lactic acid bacteria to many other compounds may lead to the wine smelling of crushed geranium leaves. There is no cure for the 'geranium fault,' but it can be prevented by using sorbic acid only in the presence of 20–30 mg/l free sulfur dioxide (Morgan *et al.*, 2006). The sorbic acid will inhibit yeast development, and the sulfur dioxide will prevent lactic bacteria growth.

In conclusion, the current consensus would appear to be that malolactic fermentation can affect wine aroma, even if the effect is as subtle as giving greater complexity. It would also appear that the impact of MLF on wine flavor varies with wine LAB and wine type. It is certainly the case that further research is required to relate the wine attributes altered during MLF to the production and/or degradation of a specific chemical compounds by wine LAB (Liu, 2002). This information will help a producer to match the right strain of wine LAB to the right style of beverage being produced so as to maximize or minimize a particular flavor attribute.

2.4
Acetic and Other Fermentations

2.4.1 Introduction

The fermentation pathway, along with glycolysis, is one of the most ancient metabolic processes, as it appeared when the planetary environment was strictly anaerobic, and all life was prokaryotic The enzymes for these ancient pathways are located in the cytoplasm, and not in the mitochondria (Purves *et al.*, 2001). At some point in the very distant past, cells on Earth gained the ability to photosynthesize and molecular oxygen was added to the atmosphere, rendering most environments aerobic. Further evolution of cells in these new environments led to the incorporation of mitochondria through endosymbiosis, and the development of the citric acid cycle and the electron transport chain on and in the mitochondrial membranes. Respiration, therefore, is a relatively recent evolutionary development compared to fermentation.

The organisms that are likely to be encountered during a beverage production process will incorporate a wide variety of different metabolic styles, and many different fermentations are carried out by various bacteria and eukaryotic body cells distinguished in most cases by the end product. However, microorganisms that are not deliberately introduced to the fermentation medium by the producer will normally cause spoilage of the product or problems with the production process.

Microbial spoilage occurs when microorganisms break down desirable constituents in fermented beverages and produce undesirable substances. These changes may appear as turbidity, sediments, gassiness, color change and sensory changes (off odor and off taste). In almost all cases the damage is irreparable and so prevention, rather than cure, is the rule. Microorganisms causing spoilage during brewing and beer processing are limited to a few genera of bacteria, wild yeasts and molds. Beer is an unfavorable growth medium for most microorganisms due to the alcohol content, low pH and the presence of hop constituents, as well as the lack of nutrients, but a few species will survive, and have deleterious effects on flavor and shelf life (Goldammer, 2000). Wine, with an even higher alcohol content and similarly low pH is even less of an environment conducive to the growth of microorganisms. However, a number of specialized organisms are able to withstand the conditions, and complacency in the winemaking process will lead to high volatile (acetic) acidity or excessive acetaldehyde. It is not only the wine that can sustain the growth of unwanted microorganisms, but the equipment, including barrels, storage tanks, pumps, pipes and filters. Microorganisms which cause spoilage are either aerobes: (require the presence of oxygen in air to reproduce) e.g. acetic bacteria and yeasts; or facultative anaerobes: these can reproduce without the presence of oxygen, e.g. lactic bacteria.

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

The other factors that affect the growth of microorganisms in fermented beverages are the acidity in solution (only *Acetobacter* grow actively at pH 3.0–4.0), alcohol concentration, temperature and the use of preservatives such as sulfur dioxide. The existence of fermentable sugars (above 10g/l) in a medium facilitates the risk of spoilage – specifically by yeast. Growth factors, nutrients such as amino acids and vitamins, are important in determining the growth of microorganisms. In wine, there are many opportunities for microbial spoilage, but the winemaker has key controls at their disposal to ensure they are minimized. The conditions necessary for proliferation and spoilage in a winery can be avoided with good hygiene, the use of antiseptic agents like sulfur dioxide and management of storage conditions including higher temperatures and exposure to oxygen. These are discussed in more detail later on in this section.

2.4.2 Acetic Acid Bacteria

Although no known pathogenic bacteria can survive in wine media, many others can grow and flourish. Two of the most common bacteria found in the winery environment are acetic and lactic acid bacteria. There is an almost permanent presence of acetic acid bacteria during every stage of winemaking and a change in the type of bacteria present occurs during fermentation and storage. *Acetobacter* or acetic acid bacteria are able to oxidize ethanol to acetic acid, a process vital to vinegar production. It was thought originally that exposure to air was required for their growth, but it has been found they can use hydrogen acceptors other than oxygen so they can remain viable for years in anaerobic conditions such as barrels or bottled wine (Jackson, 2000). There are several genera of acetic acid bacteria, but the only one to jeopardize wine is *Acetobacter* (Ribéreau-Gayon *et al.*, 2000). This bacterium is capable of generating acetic acid in the absence of sulfur dioxide and in the presence of oxygen. In addition, it can esterify acetic acid and ethanol to ethyl acetate, which produces the unpleasant organoleptic characteristics of acescence (nail polish remover and vinegar odor). This organism is also responsible for elevated volatile acidity in wines exposed to air where it develops on the surface as a white layer (bloom).

The ability of acetic acid bacteria to metabolize sugar is atypical (Jackson, 2000). The pentose phosphate pathway is used by these organisms exclusively for the oxidation of sugar to pyruvate sugars may also be oxidized to gluconic and mono- and diketogluconic acids. In addition to oxidizing ethanol to acetic acid, acetic acid bacteria can also oxidize other alcohols to their corresponding acids, for example butanol to butanoic acid. In addition, polyols (molecules with more than one alcohol function, like glycerol) can be oxidized to ketones (dihydroxyacetone results from metabolism of glycerol). Members of the genus *Acetobacter* can further oxidize acetic acid to carbon dioxide and water, which is known as overoxidation.

Acetic bacteria can grow on the surface of the wine as a thin white film or as a thicker, more oily layer. It is a very serious problem, especially for red wines produced in warm regions. 'Mother of vinegar,' a thick, hard, viscous mass, is formed by an acetic bacteria which is rarely found in wine, but often found in wineries on dripping taps and leaking wine tank valves.

Acetic or ethanoic acid is the principal component of 'volatile acidity' or 'VA,' so called because its concentration is measured in wine by distillation followed by titration with a base. It is acrid and bitter to the palate and detectable at doses above 0.75 g/l as a vinegary taint, though lower concentrations will considerably 'thin' a wine. The maximum legal limit (UK) is 1.08 g/l in white and rosé wines, and 1.2 g/l in red wines (Robinson, 2006). The production of acetic acid is usually accompanied by its combination with alcohol to form ethyl acetate. This has a characteristic (pear drop) aroma, which is usually easier to detect in spoiled wines than the acetic acid itself (recognisable at 0.16 g/l). It is common for a wine to gain 0.1–0.2 g/l VA (as acetic acid) during the alcoholic fermentation, due to the action of wild yeasts, especially at high temperatures. Another 0.1g/l may be produced during the malolactic fermentation, particularly if the

temperature and pH of the wine are high. Any increase above 0.3 g/l indicates lactic or acetic spoilage. VA is detectable in white wines at around 0.4 g/l and in red wines at around 0.5 g/l (Morgan *et al.*, 2006).

It is recognized that the acetic acid bacteria form a distinct family of Gram-negative rod-shaped bacteria characterized by their ability to oxidize ethanol to acetic acid (Jackson, 2000). Acetic acid bacteria from the *Acetobacteraceae* family are divided into the genera *Acetobacter* and *Gluconobacter*. There are over 10 different species identified belonging to the genera, but *Gluconobacter oxydans, Acetobacter aceti* and *Acetobacter pasteurianus* are the most frequently encountered in enology (Ribéreau-Gayon *et al.*, 2000). Goldammer (2000) stated that for all practical purposes there are only seven common genera of bacterial contaminants in the brewery, and the Gram-negative spoilage bacteria in beer include *Acetobacter* spp*, Acetomonas* spp*, Zymomonas* spp*., Enterobacteriaceae* spp. and *Pectinatus* spp. The concentration and species of acetic acid bacteria introduced into the winery via the grapes can vary depending on the quality of the fruit. On good quality red or white grapes the main species found is usually that of *G. oxydans*, whereas on spoiled fruit, infected with *Botrytis cinerea,* the main bacteria species is that of *A. aceti* with the presence of *A. pasteurianus* in smaller quantities. *G. oxydans* prefers glucose for its growth and this species is not tolerant to alcohol, which explains why it is more readily found in the must and on good quality fruit, because once the fruit becomes spoiled and there is fermentation caused either by the presence of wild yeasts on the fruit or by controlled fermentation in the winery, alcohol levels rise. The other main area of acetic acid bacteria contamination, except for poor hygiene of equipment, is that of the barrel. Used barrels, due to the nature of the absorbency of the wood, retain wine and small quantities of bacteria. During maturation there is a small ingress of oxygen into the barrel (about 30 mg/l per year) which prevents the complete destruction of the population which would occur if conditions were strictly anaerobic, e.g. in bottles (Ribéreau-Gayon *et al.,* 2000). Insects such as fruit fly (*Drosophila*) will carry acetic bacteria onto damaged berries. Acetic bacteria are also present on all cellar surfaces, and even in normally sulfited wines. The numbers of acetic bacteria will often increase greatly in the pomace in red wines, particularly in open tanks where the pomace is not blanketed with carbon dioxide and is seldom immersed in fermenting must. Another factor increasing the risk of acetic spoilage is high temperature. Spoilage is twice as fast at 28 °C as at 23 °C and twice as fast at 23 °C as at 18 °C. The reproduction of acetic bacteria is greatly reduced at pH below 3.0 but rapid at pH above 3.2. Wines with high alcohol levels are less prone to spoilage (Morgan *et al.,* 2006).

Although acetic acid bacteria are classified as strictly aerobic, the ability of *Acetobacter* to grow under semianaerobic conditions and produce acetic acid emphasizes the importance of careful handling of the product during operations which may expose wine to air. Because of resistance to SO_2, control is by minimizing air contact at wine surfaces and keeping temperatures low.

Identification of microorgansims, particularly bacteria, is not easy and producers more often than not do not have access to the methods necessary for the task. The isolation of acetic acid bacteria requires an appropriate medium (glucose–yeast-extract agar with calcium carbonate is a common one), which is then incubated aerobically, usually for two to four days at a temperature of between 25 and 30 °C (Ribéreau-Gayon *et al.*, 2000). It is necessary to incorporate cycloheximide or pimaricin into the medium to inhibit the growth of yeasts, and the calcium carbonate neutralizes the acid resulting from the acetic acid bacteria. This also aids with identification, as the acid solubilizes the calcium carbonate leaving clear areas around each colony forming unit. Further additions can be made to the media to inhibit the growth of lactic acid bacteria making the isolation of acetic acid bacteria easier, and penicillin can be used for this purpose. Another addition that can be made to the media is that of ethanol and the strong aroma of acetic acid arising from ethanol oxidation is a good indication of the presence of acetic acid bacteria (Morgan *et al.*, 2006). If yeasts are not present, a simple Gram stain procedure can be performed on the isolate. The family of *Acetobacteraceae* are Gram-negative rods due to the constituents of their cell walls and this differentiates them from lactic acid bacteria, which are Gram-positive. Once isolated the acetic acid bacteria can be further identified to species level by their abilities to oxidize calcium D,L-lactate, overoxidize ethanol, form water soluble pigments, oxidize glycerol,

Table 2.4.1 *Characteristics of acetic acid bacteria and* Gluconobacter oxydans

	Acetobacter			*Gluconobacter*
Characteristic	*A. aceti*	*A. pasteuranus*	*A. hansenii*	*G. oxydans*
Overoxidation of ethanol	+	+	+	−
Growth on ethanol	+	some	+	−
Growth on sodium acetate	+	some	−	−
Ketogenesis from glycerol	+	−	+	+
Ketogenesis from sorbitol	+	−	+	
Ketogenesis from mannitol	some	−	+	
Oxidation of lactate to CO_2 and H_2O	+	+	+	−
2-Ketogluconic acid produced from glucose	+	some	some	+
5-Ketogluconic acid produced from glucose	+	−	some	+
2,5-Diketogluconic acid produced from glucose	−	−	−	some

produce 5-ketogluconic acid from glucose and the ability to grow on media containing ethanol and sodium acetate as sole carbon sources (see Table 2.4.1).

2.4.3 Lactic Acid Bacteria

Lactic acid bacteria, which affect both beer and wine as spoilage organisms, can be identified initially by using a Gram stain. *Lactobacillus* spp. and *Pediococcus* spp. are both Gram-positive. *Pediococcus* spp. metabolize a number of substrates including malic acid and/or sugars with different end products and consequences for wine quality. They are less likely to grow if substrates have been depleted by a previous malolactic fermentation. *Lactobacillus* is associated with wine spoilage, and is notorious for producing excessive acetic acid by metabolizing sugar or tartaric acid, which can cause yeast inhibition and lead to stuck fermentations. *Pediococcus* is one of the common lactic acid bacteria found in wine and its entire species are homofermentative (transform sugar exclusively into lactic acid). They may produce increased volatile acidity and polysaccharides that cause undesirable texture defects. Strains of *Pediococcus damnosus* produce histamine (a biogenic amine), which can pose a health hazard for individuals sensitive to the compound (see Section 5.11.3). Lactic souring, *tourne*, *amertume,* 'ropiness' and 'mousiness' are all wine faults caused, in whole or in part, by lactic acid bacteria (Jackson, 2000). These faults and other activities of lactic acid bacteria are discussed in detail in Section 2.3.1.

2.4.4 The Activities of Yeasts other than *Saccharomyces*

A spoilage yeast in a brewing context is defined as any yeast other than the pitching yeast (Goldammer, 2000). Spoilage yeasts can be isolated at all stages of the brewing process from raw materials, wort, pitching yeast and fermenting beer, through to the packaged product and the dispense system. They produce unintended flavors, including hydrogen sulfide, estery, acidic, fatty acid and phenolic or medicinal notes. Turbidity is another effect caused by growth of wild yeasts that remain after the culture yeast has been removed by filtering or fining. In the presence of air, some spoilage yeasts can grow rapidly and form a film on the surface of the beer, which can cause haze. Other effects may include primary yeast fermentation and separation difficulties,

significantly lower terminal gravities, and a higher alcohol content in the finished beer. The lower terminal gravities are due to the ability of wild yeast to ferment sugars (such as maltotetraose and dextrins) not used by the primary yeast. A spoilage yeast infection is usually more of a problem for brewers not having a pure culture yeast propagation system than for those who do. In a winemaking context, a spoilage yeast is any yeast (including *S. cerevisiae*) that ferments residual sugars once a wine has been bottled, as it will in all likelihood be spoiled. A number of different genera of yeast have been implicated in wine spoilage.

Pichia spp. are ascospore-producing yeasts which are capable of fermenting low levels of residual sugar, but are inhibited by alcohol levels of near 10% at lower temperatures. At higher temperatures, growth may be found in products of up to 13% alcohol. They are generally weak fermenters, but unrestricted growth imparts an aldehydic character to wine (Zoecklein *et al.*, 1995). The ascospores have a Saturn-shape and form pseudomycelium. *Hansenula* strains are reported to form large amounts of acetic acid, (around 1–2 g/l), and volatile esters, particularly ethyl acetate (up to 2 g/l) as well as isoamyl acetate (a pleasant, fruity banana odor at low concentrations) under aerobic conditions. In the early stages of fermentation, the formation of these volatile esters has been known to add limited flavor and bouquet to the wine. Boulton and Quain (2001) note that an infection by *Pichia* will be limited to the initial aerobic phase of fermentation, but the organisms can spoil unpasteurized draught beer, forming a haze and surface films. *P. membranifaciens* is known to give a 'sauerkraut' flavor.

Epiphytic yeasts, such as *Kloeckera apiculata* and *Metschnikowia pulcherrima*, are known to produce 2-aminoacetophenone as a result of their metabolism of sugars, as well as acetic acid, ethyl acetate and diacetyl (Jackson, 2000). The first compound has been implicated in the 'atypical aging aroma' in white wines, for which various descriptors exist, 'mothball' and 'wet wool' being amongst them. With *Hanseniaspora/ Kloeckera* known to add quantities of glycerol, esters and acetoin to the complexity of the final product, depending upon the strain present, a selection program with the aim of finding suitable apiculate yeast strains for use in fermentation would give the benefit of reduction of undesirable products to levels below the spoilage threshold and the increase of levels of desirable products not produced in sufficient levels by *S. cerevisiae.*

Zygosaccharomyces spp. are likely to be found in high sugar concentrations and are therefore commonly associated with grape juice concentrates that are often used to adjust color and sugar in final wine blends. It is far more common in white and rosé wines than red, for this reason, and because growth is somewhat suppressed by polyphenols. The species can grow in a large range of sugar levels, high alcohol concentrations and is resistant to yeast inhibitors like sulfur dioxide, sorbic acid and diethyl dicarbonate (Jackson, 2000). It generates floccular and granular deposits, which look a little like sand, if there is an infestation in a bottle. This spoilage yeast may produce carbon dioxide and turbidity once the wine has been bottled. Recent research has demonstrated that temperature is the principle factor affecting the development of *Zygosaccharomyces*, and as low a concentration as 1 cfu/10 l of wine is sufficient to induce spoilage (Jackson, 2000). Boulton and Quain (2001) state that this organism is infamous for spoiling soft drinks, fruit juices and high sugar products.

Brettanomyces species are notorious spoilage organisms on the one hand, but essential fermentative organisms for certain types of beers, on the other hand. *Brettanomyces bruxellensis (*synonym *Dekkera bruxellensis)* is an alcohol-tolerant asporogenic wild yeast isolated from British spontaneously fermented beer at the beginning of last century. It gives rise to an organoleptically disastrous condition known as 'brett' when it infects beers and wines, yet under different conditions it provides much of the sensory character associated with certain spontaneously fermented beers, such as the lambic beers of Belgium (Section 2.6.7). *Brettanomyces* species have been recognized as serious spoilage yeasts in wine for around 40 years, and depending on the species can produce either mousy taints, smoky, spicy, medicinal and woody taints, or apple cider odors, high levels of acetic acid and haziness. The influence of *Brettanomyces* and *Dekkera* on winemaking has been reviewed by Oelofse *et al.* (2008).

Brettanomyces spp. include nine different species of which those found in wine include *B. intermidius*, and *B. lambicus* (Jackson, 2000), both of which species produce 2-acetyltetrahydropyridines responsible for the

'mouse' taint. Boulton and Quain (2001) state that *Brettanomyces* is notable for causing off flavor in bottle-conditioned beers, and that the species succeeds *Saccharomyces* in the spontaneous fermentation of wort (lambic and gueuze: see Section 2.6.7). The name *Dekkera* refers to the ascospore-forming (sporogenous) form of this yeast, and *Brettanomyces* used for the non-spore-forming type. It is most well known for producing high concentrations of volatile acids, esters and the volatile phenols 4-ethylphenol, 4-vinylphenol and 4-ethylguaiacol, which are largely responsible for the infamous 'brett' characteristic. The yeast is capable of using many different carbon sources, including sugars extracted from wood and forming unpleasant secondary metabolites (Jackson, 2000), including the classic 4-ethylphenol (Band aid or Elastoplast), isovaleric acid (rancid/vomitous) and all three of 2-acetyl-1-pyrroline (ACPY), 2-acetlyltetrahydopyridine (ACTPY) and ethyltetrahydropyridine (ETPY), responsible for mousy off flavors (Herezstyn, 1986). It would seem that the yeast generally leads to a typical 'brett' aroma, with an associated degrading of varietal and fermentation character: that is a loss of typicity. However, low levels of 'brett' may also add complexity to certain robust styles of wines. *Brettanomyces*, however, is not easily controllable, and neither are the levels of products that result from its fermentative pathways. Jackson (2000) noted that the taint may also derive from synthesis of isobutyric, isovaleric and 2-methylbutyric acids. The organism is capable of growing in both red and white wines, but the polyphenol composition, higher pH and cooperage use seem to encourage development in red wine particularly. Populations of the yeast are ubiquitous in vineyards and wineries throughout the world, and the species was originally isolated from high strength 'stock' beer (see Section 2.6.13). Fruit flies (*Drosophila melanogaster*) can also be carriers of *Brettanomyces*.

The belief is that the main infection route in wine is through old barrels (Jackson, 2000), but it is just as likely to be from an original population on the grapes. Microbial analyses of older and recently bottled wines demonstrated the ability of certain wine microbial species to survive and grow in the bottle. Among them, *B. bruxellensis* was predominant, necessitating effective methods for removing these microorganisms before bottling (Renouf *et al.*, 2007). It is only during the wine ageing process that *Brettanomyces* cells slowly increase in number, which makes its presence difficult to detect before the sensory effects are noticed. Another factor that may enhance risk of infection is the presence of residual sugars left over at the end of fermentation as a result of high initial sugar levels at the start. Also, the addition of diammonium phosphate as a supplementary nitrogen source for yeasts has also become routine in winemaking, which means that amino acids are less likely to be metabolized, and may therefore form a nitrogen source for *Brettanomyces.*

2.4.5 Film Forming Yeasts

Yeasts can also ferment sugars, as well as other substrates, before a product has been bottled, during bulk storage, if the conditions are conducive to growth. Yeast can form films on the surface of wine, and other beverages, under aerobic conditions. The growth of any film forming yeast in wine is detrimental to quality (Loureiro and Malfeita-Ferreira, 2003). Film forming yeasts require oxygen for growth and include the genera *Hansenula*, *Kloeckera*, *Pichia*, *Metchnikowia* and *Debaryomyces*, as well as strains of *S. cerevisia*. They produce acetic acid, 2-phenylethanol and ethyl acetate under oxidative conditions, from ethanol as well as glycerol and organic acids. Uncontrolled growth results in decreased alcohol levels and total acidity/pH changes (Zoecklein *et al.*, 1995). The process of growth in a surface film is, of course, crucial to the production of certain sherries and other wines, where they are known as 'flor' and where they oxidize ethanol to produce acetaldehyde and at the same time protect the wine beneath the film from oxidation (Sections 2.10.3 and 2.10.4). Flor may be caused by several yeast species including strains of *S. cerevisiae* and *Zygosaccharomyces fermentati*, and species of *Candida*, *Hansenula* and *Pichia* can be associated harmlessly with flor films, but are a cause of spoilage when growing alone. Flor yeast growth in a production context is, of course, carefully monitored. Sherry production is discussed in more detail in Sections 2.10.1–2.10.3.

In wine, *Candida* spp. typically grow as surface yeasts, producing chalky white films on the surface of low alcohol wines. In the presence of oxygen they are fast growers, using ethyl alcohol in addition to wine acids as carbon sources, meaning *Candida* spp. have the potential to produce significant concentrations of volatile compounds, such as acetic acid, ethyl acetate and 2-phenylethanol in wines.

After the alcoholic fermentation, all the surfaces in the winery are covered with very large populations of yeasts. They should all be cleaned, if not disinfected, thoroughly. This is especially important if dealing with wines with residual sugar.

2.4.6 Molds

Molds are non-chlorophyll-bearing plants that range in size from a single spore to large cell aggregates. Commonly occurring types are species of *Mucor*, *Penicillium*, *Aspergillus*, *Cladosporium* and *Rhizopus*. Molds are normally aerobic organisms and can grow over a wide pH and temperature range, although most species prefer an acid pH (Goldammer, 2003) and higher temperatures.

In a study of tainted wines in the early 1990s, the most common off odor in wine was 2,4,6-trichloroanisole (TCA), notorious as the compound responsible for cork taint (Jackson, 2000). The moldy odor may originate from the growth of bacteria and filamentous fungi such as *Penicillium roqueforti*, *P. citrinum* and *Aspergillus versicolor* on corks. The role of *Penicillium* in the formation of TCA has been noted (Jackson, 2000). Further discussion on cork taint and its analytical assessment can be found in Section 4.2.4.

2.4.7 Prevention of Spoilage

The current trends in the wine industry are for wines with lower levels of sulfur dioxide and fewer processes such as sterile filtration. Although this is laudable if the goal of the producer is to aim for the most natural product possible, it is also risky, and should be coupled with increased hygiene controls and good manufacturing practices to minimize contamination.

It remains the case that one of the most effective methods of preventing growth of microorganisms relies on limiting microbial activity by addition of SO_2, to which both film yeasts and lactic acid bacteria are very susceptible (Sections 2.5.2 and 2.5.3). The main reason these groups are not as much of a problem in white wines compared to red wines is the higher concentration of free SO_2 in white wines. In red wine, a greater proportion of SO_2 is bound (e.g. to phenolic compounds) and is hence is less active. Maintaining low pH has a strong inhibitory effect on lactic acid bacteria, especially in the presence of SO_2. *Lactobacillus* and *Pediococcus* are more pH sensitive than *Leuconostoc*. SO_2 addition is not always effective against fermentative yeasts in sweet wines because of their higher tolerance to it and also because of the production of acetaldehyde, which then binds the free SO_2. Maintaining free SO_2 at moderate to high levels, and filtration to 0.45 μm is the only sure way of preventing refermentation of any sugar present in a bottled wine.

Filtration techniques (Sections 2.6.9 and 2.9.4) were evaluated over several years after bottling by microbial analysis and by volatile phenols measurements. The smaller the pore size, the more microbes were eliminated. Elimination of bacteria required a 0.3 μm filter, but a 1.0 μm filter was efficient for yeast elimination. It has been argued that filtration (especially tighter membrane filtrations) affect the quality of products. Renouf and coworkers (2007), for example, found that volatile phenol concentrations were lower in less tightly filtered wines and in unfiltered wines than in more tightly filtered wines.

Sorbic acid or its salts, such as potassium sorbate, are inhibitory to fermentative yeasts and are sometimes added to sweet wines at levels up to 200 mg/l. Sorbic acid should always be used in conjunction with sulfur

dioxide, and producers should note the possibility of formation of 2-ethoxy-3,4-hexadiene, which has a strong geranium smell, by lactic acid bacteria against which sorbic acid is ineffective (Section 2.5.4) (Jackson, 2000).

Excluding oxygen, especially in finished wines, is essential for maintaining the quality of the product. Film yeasts and acetic acid bacteria require atmospheric oxygen (apparently at low levels) so effective sealing of containers and inert gas cover are important strategies to control their growth. It is important to monitor the tops of tanks, especially if they are on ullage (air space) and do not have an inert gas cover. If a growth is detected prompt action should be taken. To further prevent the growth of acetic acid bacteria in a product, pasteurization or sterile filtering coupled with completely sterile conditions will eliminate them completely. Although a certain amount of acetic acid is formed by yeasts and lactic bacteria, acetic spoilage as such can only occur if the wine is in contact with oxygen for the duration of a few days, especially at low temperatures. Aeration on racking is not enough to make a substantial difference, as an increase of 0.1 g/l of acetic acid requires 0.24 l of air per liter of wine (Morgan *et al.*, 2006). Sulfiting is not totally effective, as the free sulfur dioxide on the surface of a partially filled tank will rapidly be combined or oxidized.

Temperature is an important factor affecting microbial activity. The activity of bacteria is very slow or nonexistent at temperatures below 15 °C, and yeast are inhibited, so storage of products at low temperatures is advisable. Pasteurization may also be used to sterilize products. In a winemaking context, heating to 60 °C for 5 mins or 70 °C for 6 s is sufficient. Short periods of heating at high temperatures are better than longer periods at lower temperatures due to the chemical and physical impacts of prolonged heating on the flavor and aroma of wine (Morgan *et al.*, 2006).

Timing and magnitude of sulfur dioxide additions are important in prevention of *Brettanomyces*, as small incremental doses of sulfur may encourage the selection of sulfur-resistant strains of *Brettanomyces*, which dominate during storage and aging. Sanitation has been shown to be an important factor in keeping wild spoilage yeasts from the final product, as reservoirs of wild yeast, bacteria and spores of both are found on production equipment. Wooden cooperage, which is fairly common in the production of quality red wines, is a well-known route for infection as *Brettanomyces.* The yeast produces β-glucosidase which allows it to metabolize cellobiose, a compound that results from the toasting process, present in both old and new barrels. The enzyme cleaves the disaccharide cellobiose to produce glucose molecules, which are then used for growth.

Many winemakers consider that the taint caused by powdery mildew in white wine results from the mycelium of the fungus itself, and thus minimizing taint is based on minimizing the quantity of the mycelium in the juice. The application of a high pressure, high volume water spray in the vineyard the day before harvest is reported to have a positive effect in minimizing mycelium levels. Juice from powdery mildew-affected fruit should be settled at the lowest temperature possible to achieve rapid settling, and pectolytic enzymes should be used (Morgan *et al.*, 2006).

2.5

Preservatives Used in the Production of Alcoholic Beverages

2.5.1 Introduction

Preservatives are added to beverages in order to protect them from microbial and oxidative effects, and to help retain their original quality as long as possible (in the case of wine, this may be decades). Generally, additives allowed in beverages and foodstuffs are strictly regulated, and anything added to a product in order to preserve it would be subject to exactly the same regulation. There are nonadditive methods, such as pasteurization, that will extend the shelf life of a product beyond a usual 'fresh period,' but generally speaking, these methods only work in the short term. It is also the case that heating can alter the organoleptic qualities of the product, which is usually undesirable. Other methods of removing microbial content include different forms of filtration, which are discussed in detail in Sections 2.4.7, 2.6.9, 2.8.5, 2.8.6 and 2.9.4. Cost of machinery, volume of product, packaging preferences, even distribution (climate/transport/storage and shelf-time/retail outlet type), all influence the method chosen to preserve the product.

2.5.2 Sulfur Dioxide (SO_2)

Sulfur dioxide has a long history of use in preservation of foods and beverages. It is formed by burning sulfur (32 g of sulfur reacts with 32 g of oxygen to give 64 g of sulfur dioxide), and dissolves in water and ethanol, depending on the temperature. In Europe, the permitted sulfur additives for wine are sulfur dioxide (E220), potassium bisulfite (E228) and potassium metabisulfite (E224) (Bird, 2005). Interestingly, SO_2 is produced in small quantities (between 12 and 64 mg/l) by yeast during fermentation (Jackson, 2000a). The formation of SO_2 by *S. cerevisiae* is a strain characteristic, with the majority of strains (80%) producing less than 10 mg/l of SO_2 and a few strains producing more than 30 mg/l, suggesting that completely sulfite-free wine is unlikely to be produced without some form of removal. The amount produced also depends on the wine environment and tends to be higher in highly clarified musts with low levels of suspended solids (Romano and Suzzi, 1993). Biological sulfite is always bound and is produced slowly so the effect on wine is difficult to assess, although there is some evidence to suggest that some of the sulfite-producing yeast strains act to stabilize the wines in a similar way to the addition of sulfur to the must. Sulfur dioxide per se can be produced by burning

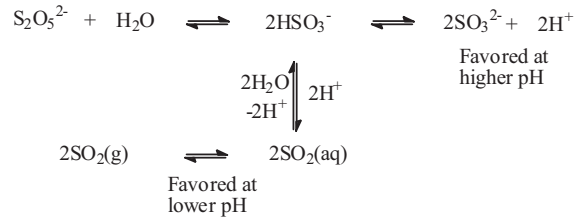

Figure 2.5.1 *Various forms of free sulfur dioxide in solution*

elemental sulfur in air, but nowadays is more likely to be obtained from a cylinder of compressed liquid (see Section 5.9.2). Sulfur dioxide exists in both 'free' and 'bound' forms in solution: the free forms are molecular SO_2 (SO_2), sulfite (SO_3^{2-}), and bisulfite (HSO_3^-) (Rotter, 2008) (Figure 2.5.1). Around 2% exists as the free dissolved gas in wine, with most of it occurring as bisulfite ions (Jackson, 2000). The bound forms include a range of compounds in which the molecule becomes associated with, or permanently bonded to, another molecule like an aldehyde or a polyphenol. The total sulfur dioxide content of a wine is the sum of the free and the bound concentrations.

Potassium metabisulfite dissociates in water to potassium ions (K^+) and singly ionized bisulfite (HSO_3^-). An equilibrium forms between the hydrogen ions present in the medium, sulfite, bisulfite and molecular sulfur dioxide, of which at wine pH around 2% exists as the free dissolved gas (Jackson, 2000a). The position of equilibrium and hence the concentration of each species depends the pH and to a lesser degree the temperature of the environment (Figures 2.5.1 and 2.5.2). Free molecular SO_2 is the form that is most active against microorganisms and it is present in greater concentrations at lower pH. Sulfur dioxide is thus far more effective as an antimicrobial if the environment is acidic (Jackson, 2000b), and a lowering of pH by even 0.1 units can greatly enhance the efficacy of its action.

Bound (combined) sulfur dioxide is bonded to sugars, phenolics, some minor wine acids and, especially, acetaldehyde (ethanal) (Figure 2.5.3). When sulfur dioxide combines with acetaldehyde, it is rendered

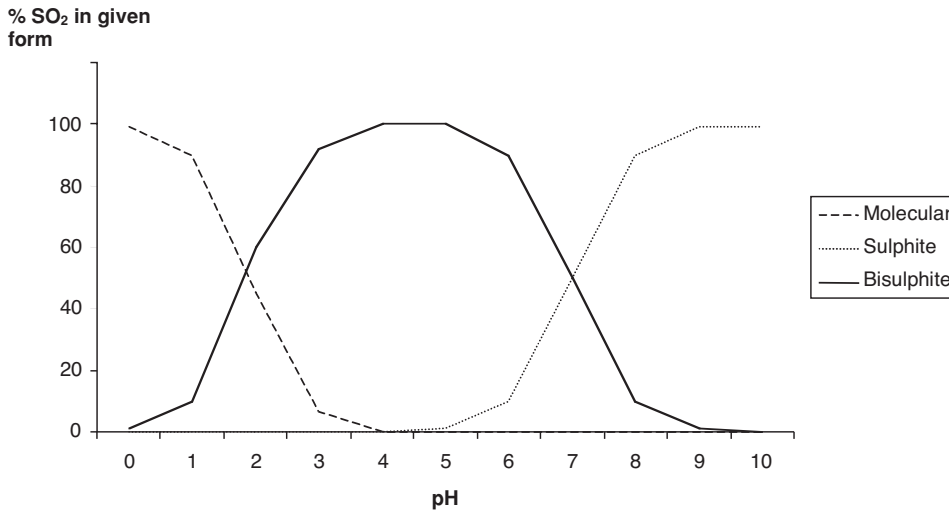

Figure 2.5.2 *Effect of pH on forms of free sulfur dioxide*

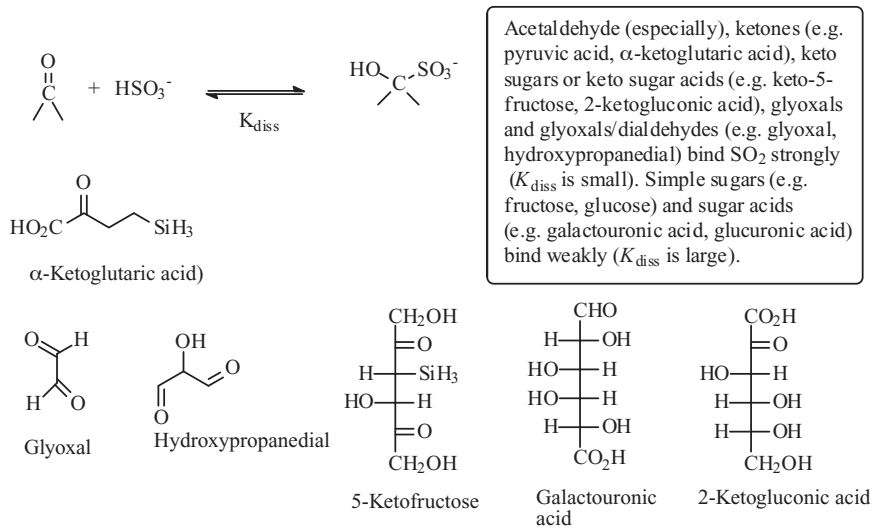

Figure 2.5.3 *Binding of SO_2 species by carbonyl compounds, with examples of carbonyl compounds found in grape must and wine*

permanently inactive because the bisulfite complex formed shows little tendency to dissociate (it has a high dissociation constant, K_{diss}). Most producers assume that around 50% of the SO_2 they add will become bound when the total SO_2 is below 100 mg/l. Ketonic acids (for example, α-ketoglutaric acid, pyruvic acid and galacturonic acid) also bind to SO_2 (Figure 2.5.3). Increased ketonic acid levels may be the result of nutritional deficiency or stress during fermentation, and different yeast strains also produce varying levels of these products. Keto sugars, keto sugar acids and glyoxals/dialdehydes (Figure 2.5.3) are found in higher concentrations in grapes infected by *Botrytis cinerea* (e.g. Sauternes, Tokay and Trockenbeerenauslese wines) and so these will may make a significant contribution to the binding of SO_2 species in the sweet wines, as some will survive fermentation. Low fermentation temperatures, anaerobic fermentations, addition of ammonium salts and use of nonketogenic yeast strains may all help minimize production of ketones and aldehydes, and therefore the bound fraction of sulfur dioxide.

2.5.3 The Roles of SO_2

Sulfur dioxide has a wide spectrum antimicrobial activity: about 1.5 mg/l concentration of molecular sulfur dioxide is enough to inhibit most yeast and spoilage bacteria (Jackson, 2000b). The toxic action of the molecule is thought to include inhibition of metabolism by reaction with coenzymes and by its reaction with disulfide bonds in protein, thus leading to denaturing and destruction of tertiary structure (Figure 2.5.4). The suphur dioxide in Figure 2.5.4 is depicted as bisulfite, which at biological pH is the most likely species. Some organisms are more susceptible than others: acetic bacteria are most sensitive, followed by lactic bacteria and so-called 'wild' yeasts, then cultured yeast (e.g. *S. cerevisiae*).

As an antimicrobial, sulfur dioxide has a strong effect when in the free form (hence the importance of constantly monitoring free SO_2 at all stages) which affects the majority of natural yeasts commonly found on grapes (Table 2.5.1). Sulfur dioxide is the only effective antimicrobial agent against lactic acid bacteria,

*Until inoculated

and greatly inhibits the growth of non-*Saccharomyces* yeasts, resulting in the variation of the aromatic characteristics of fermented media. *S. cerevisiae* has a very high resistance to SO_2, and dosing with this preservative allows this species to dominate the fermentation, thus SO_2 inhibits wild yeast growth and favors the added culture (Table 2.5.1) (Romano and Suzzi, 1993). Sulfur dioxide is also used to 'stun' wild yeasts before the alcoholic fermentation to allow enough time for static settling. It is used at higher doses after the alcoholic fermentation to protect wines from microbial spoilage. A 2% solution is often used to clean filters and for sanitation purposes in the production area (Morgan *et al.,* 2006).

Molecular SO_2 is most effective against lactic acid bacteria, but the ionic and bound forms also have an effect. Evidence suggests that while levels of free SO_2 between 1 and 10 mg/l are sufficient to inhibit lactic bacteria, in practice much depends on the specific species of bacteria, the pH and the amount of insoluble solids present in solution (Morgan *et al.*, 2006). Lower pH values and increasing ethanol concentrations work synergistically to enhance the inhibitory effect of SO_2. Evidence suggests that acetic acid bacteria are better controlled by ensuring an absence of oxygen rather than by the use of SO_2.

Sulfur dioxide also acts as an antioxidant, but does not react directly with O_2, rather with hydrogen peroxide (H_2O_2) and acetaldehyde formed during oxidation of phenolic compounds. During this process cinnamic acid derivatives, such as caffeic and caftaric acid, are enzymatically oxidized to their corresponding quinones (Section 5.8.7), which results in the browning (via the formation of polymers) of juice exposed to O_2. In wine the same reaction is possible, but alcohol inhibits oxidative enzymes and thus the oxidation that takes place is chemical in nature, and is a much slower process.

Acetaldehyde is the compound that binds to SO_2 most rapidly, and sulfur dioxide is said to 'freshen' the aroma by effectively removing it from solution. The main factors influencing acetaldehyde concentrations during fermentation are the yeast strain, the presence of other microorganisms and the juice thiamine content. If acetaldehyde (a yeast inhibitor) is produced early on in the alcoholic fermentation, sulfur dioxide will combine with it and allow the fermentation to proceed normally. After the fermentation, acetaldehyde can be produced by oxidation of ethanol or by spoilage microorganisms.

Oxidative enzymes are responsible for premature ageing reactions (like browning) in certain products, and the loss of aromas. As an antioxidant, sulfur dioxide rapidly inhibits catalytic action of tyrosinases (or polyphenoloxidases), which cause the browning of juices and musts. Catechol oxidase is a membrane-derived component of grapes, which can pass into juice following damage to berries at harvesting and crushing. Laccase is a strongly oxidizing enzyme secreted into the berry by *Botrytis cinerea*. SO_2 also decolorizes and stabilizes oxidation products against polymerization, by combining irreversibly with phenolic quinones (if present) to form colorless addition products. This makes these constituents unavailable as substrates for polyphenol oxidases.

Sulfur dioxide increases cell membrane permeability and helps substances (particularly phenolics) dissolve into the must. Sulfur dioxide is said to suppress tastes of rot, earth and mustiness, and accentuate aromatic qualities in wines, but if used incorrectly or in excess, it can be detected in the bouquet. It binds to anthocyanins, and temporarily bleaches them by neutralizing the positive charge on the central oxygen heterocycle (ring B – see Section 5.8.6, Figure 5.8.6), but this association is not permanent, and when free sulfur dioxide is removed from solution, the portion attached to the anthocyanidins will dissociate, and the juice or wine will regain its red color.

Liquid sulfur dioxide is sold as a gas compressed to liquid state. It is the cheapest way to buy sulfur dioxide and is easy to use, but presents a potential health hazard since high concentrations of SO_2 are toxic (Section 5.9.2) and dosing musts or wines this way can be inaccurate and wasteful. Sulfur dioxide from cylinders is often dissolved in water prior to utilization to give saturated 'sulfurous acid' solutions.

More commonly, sulfur dioxide is introduced to a medium as potassium or sodium metabisulfite ($K_2S_2O_5$ or $Na_2S_2O_5$), also known as 'Campden tablets' if sold in tablet form. It is a colorless powder and an almost universally used additive to wine. Potassium or sodium metabisulfite both give approximately 57% and 67%

(respectively) free SO_2 when dissolved, i.e. on dissolution, 1 kg metabisulfite will produce around 570 g sulfur dioxide (Bird, 2005). Metabisulfite can be used as a 2.5%, 5% or 10% solution.

Sulfur matches or candles can be burnt to produce sulfur dioxide, but this is only recommended for fumigating wooden barrels or casks; it should never be used with plastic or stainless steel vessels (Morgan *et al.*, 2006).

In white wine production, sulfur dioxide is usually added to the must as soon as it has been pressed. Sometimes sulfur dioxide is added to the vintage before pressing (e.g. in vintages which are very sensitive to oxidation), but it is recommended to destem first as phenolic extraction is increased. The amount of sulfur dioxide to be added before alcoholic fermentation depends on the ripeness, health and temperature of the vintage. Sulfur dioxide has a very low toxicity for humans if used at correct levels (Bird, 2005), however there has been an increasing consumer focus on the ingestion of SO_2 from foods/drinks. Between 10 and 20% of the population is hypersensitive to sulfur dioxide and some of these will develop headaches and gastric upsets even with wines containing normal doses (Section 5.9.2). Recommended doses vary a great deal, but due to health concerns (especially regarding asthmatics), the use of SO_2 is strictly controlled, with total additions being restricted by law to (for example) 160 mg/l for reds and 210 mg/l for dry whites (Section 5.9.5). Consideration should be given to the state of health of the crop, e.g. if levels of rot are high, more SO_2 will be needed to combat laccase activity. Addition of the sulfur dioxide should be homogeneous to ensure protection of all juice or wine fractions.

In winemaking, after alcoholic fermentation, unless a malolactic fermentation is required, 50–75 mg/l of sulfur dioxide is added on first racking (Morgan *et al.,* 2006). The free level is measured after a few days, and more sulfur dioxide may be added so as to maintain the free sulfur dioxide levels at 5 to 15 mg/l for red wines, 20–30 mg/l for dry whites and 60–80 mg/l for sweet whites. This dose depends on the temperature of storage and the pH of the wine. There is no maximum legal limit for the free sulfur dioxide content of wine, but the maximum total sulfur dioxide content in Europe is controlled by law (Section 5.9.5). The maximum total sulfur dioxide content in most countries for dry white and rosé wines is around 210 mg/l, whereas that for white or rosé wines with more than 5 g/l residual sugar is 260 mg/l (Morgan *et al.*, 2006) (see also Section 5.9.5). The addition of SO_2 is particularly important for wine being aged in wood as it is difficult to ensure complete air exclusion from all barrels with a resulting risk of film yeast growth.

As the sulfur dioxide content of wines must be below legal limits (Section 5.9.5), it is important to monitor levels of total SO_2 throughout the production of wine. Measurement of total SO_2 in wine is usually done by a modified Ripper method, in which the sulfur is titrated with iodine (Section 4.6.3). Once all the sulfur dioxide has reacted with the iodine, any more iodine added to the wine will turn a starch indicator solution blue. Sulfur dioxide can also be determined by aspiration and titration of aspirated, oxidized sulfur dioxide with sodium hydroxide (Section 4.6.3) (Iland, *et al.,* 2004).

2.5.4 Sorbic Acid

Sorbic acid is a short chain fatty acid used as a chemical preservative, primarily as a fungicide. Sorbic acid inhibits fermentative yeasts (but not oxidative film yeasts) so is useful as a fermentation control. It has little effect on lactic or acetic bacteria, and is relatively ineffective against *Zygosaccharomyces bailli* (Jackson, 2000c). The pure compound has a flavor similar to butter, but if impurities are present, it can seem rancid. It will reinforce the antimicrobial effects of sulfur dioxide, but has a low threshold value (135 mg/l), and some tasters perceive it at 50 mg/l, so should be used with care. pH affects the efficacy of this compound as a preservative. At pH 3.1, 150 mg/l is adequate for antimicrobial action, whereas at pH 3.5, the effective dose is more than 200 mg/l (Morgan *et al.*, 2006). Lactic acid bacteria can convert it to 2-ethoxyhexa-3,5-diene which has a ‘geranium leaf’ aroma (Jackson, 2000d) (Figure 2.5.5). It has no antioxidant action. It is sold

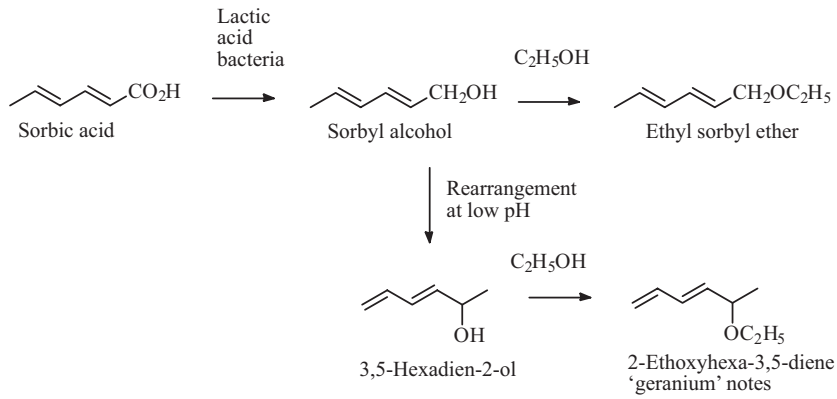

Figure 2.5.5 *Formation of malodorous products from sorbic acid*

either as sorbic acid, which is poorly soluble, or as potassium sorbate (270g KS ≡ 200g SA). Sorbic acid is only used in conjunction with SO_2, and in wines with residual sugar and a low yeast count (<100 cells/ml).

2.5.5 DMDC (Velcorin)

Diethyl dicarbonate, a preservative used in a number of beverages in the past, was formerly marketed as Baycovin. At higher pH and higher temperatures, this compound is hydrolyzed to ethanol and carbon dioxide. One of the breakdown byproducts is ethyl carbamate, which is carcinogenic (Section 5.11.5). Dimethyl dicarbonate (DMDC) was developed as a replacement for DEDC, and cannot form ethyl carbamate, but forms methyl carbamate on breakdown, which so far has not been found to be carcinogenic. It is a sterilant, which has been used with dealcoholized wines, and may have some application in sterile bottling without the use of membrane filters. Recent studies of the inhibitory effect of DMDC added to red wine media (12% ethanol v:v; pH ∼ 3.50) inoculated with cultured yeasts and bacterial populations showed that it was (at the maximum legally permitted dose: 200 mg/l) an efficient preservative against low contamination rates of yeasts (Costa *et al.*, 2008). DMDC at the 100 mg/l level was effective against initial inocula of 500 cfu/ml of *Dekkera bruxellensis*, *Lachanacea thermotolerans*, *Pichia guilliermondii*, *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Zygoascus hellenicus* and *Zygosaccharomyces bailii*, but not against all of them when inoculated at 10^6 cfu/ml. A combination of potassium metabisulfite (100 mg/l ≡ 1 mg/l of SO_2) and DMDC (100 mg/l) was effective against yeast populations of 10^6 cfu/ml, but did not fully kill *S. cerevisiae* or *S. pombe*. On the negative side, DMDC is ineffective against lactic acid and acetic acid bacteria (Costa *et al.*, 2008), is very corrosive, is not water soluble (Jackson, 2000c), and the equipment needed for using it is cost prohibitive for most small wineries.

2.5.6 Ascorbic Acid (Vitamin C)

Ascorbic acid or vitamin C is a monobasic acid with a lactone ring occurring between carbons 1 and 4 (Zoecklein *et al*., 1995). It has long been used in the wine industry as an antioxidant, the reason being the ability of the acid to rapidly remove molecular oxygen from juice or wine. Ascorbic acid has been licensed for use in winemaking in the USA since the mid 1950s and other 'new world' countries, where it

has been added to wine prebottling as a 'preservative.' The reaction between ascorbate and oxygen takes place almost 1700 times more rapidly than between sulfur dioxide (SO_2) and O_2. Ascorbic acid occurs in grapes at low concentrations (up to 50 mg/l) and it is rapidly oxidized during racking and crushing of grapes, but may be added to must or wine by the winemaker (maximum legal addition is 150 mg/l) (Morgan *et al.,* 2006). It serves to help preserve fragile aromas and prevent browning. It has no curative effect and no antimicrobial action. Ascorbic acid may reduce oxidized phenols (quinones) back again to phenols, but by-products of this reaction are dehydroascorbic acid and H_2O_2, the latter being a potent oxidizing agent (Jackson, 2000b).

The formation of H_2O_2 means that sufficient free SO_2 has to be present in the wine to react with it so as to prevent further oxidation. Zoecklein and cowriters (1995) suggests that ascorbic acid has no obvious antimicrobial or antioxidant benefit, and raises concerns that it may in fact have the opposite effects due to its reactivity with molecular oxygen. It has the ability to catalyze oxidation of SO_2 and should only be used where wines already have low levels of SO_2 (less than 100mg/l). It should not be used as an alternative to SO_2. Recent research certainly supports this view, showing that ascorbic acid seems at first to act as an antioxidant, but when its concentrations are low, it can enhance oxidation in an artificial wine medium (Bradshaw *et al.,* 2004). By-products other than dehydroascorbic acid and H_2O_2 have been identified and could lead to ascorbic acid enhancing the yellow color of white wine. This should prompt winemakers to reassess the use of ascorbic acid, as well as SO_2 levels in wine. It is usually recommended that ascorbic acid is used only in conjunction with free SO_2, which with H_2O_2 forms H_2SO_4 (sulfuric acid) (Bradshaw *et al.,* 2004). Ascorbic acid is mostly used for limiting oxidation before alcoholic fermentation (50 mg/l), protecting the wine against ferric haze, and protecting the wine from oxidation when bottling (the 'bottle sickness' period is reduced). Ascorbic acid is also widely used in fruit juices, beer and sparkling drinks. The concentration of ascorbic acid, even if moderately high, does not adversely affect quality.

2.5.7 Pimaricin (Natamycin)

Natamycin, also known as pimaricin, is a substance produced by the bacterium *Streptomyces natalensis* in order to prevent growth of competing yeasts and moulds. Pure natamycin has no color, odor or taste (http://www.dsm.com/en_US/downloads/dfs/Fact_sheet_Natamycin_v6.pdf).

Natamycin is widely used in the food industry in juices, wine and yoghurt, and may be used in South Africa in wine, but not in the EU as yet. It hydrolyzes after use, and loses its effect (Ribéreau-Gayon *et al.*, 2006). As natamycin is a 'natural ingredient,' it is also used in organic and biological cheeses. Natamycin binds to ergosterol, a building block in cell walls of yeasts and molds, causing breach of the cell wall. Bacteria do not contain ergosterol and are therefore not affected. Natamycin is effective in small quantities against most yeasts and molds that may occur on food products.

2.5.8 Other Preservatives

Stead (1993) assessed the potential of hydroxycinnamic acids (including caffeic, coumaric and ferulic acids) on the growth of three wine spoilage strains of *Lactobacillus collinoides* and one of *Lb. brevis* in tomato broth containing 5% ethanol at pH 4.8. At concentrations of 500 and 1000 mg/l, all three compounds markedly inhibited growth; coumaric and ferulic acids were more effective than caffeic acid. At a concentration of 100 mg/l, however, all compounds stimulated growth. In general, the strains of *Lb. collinoides* were more susceptible both to inhibition and stimulation than *Lb. brevis*.

2.6
Beer

A man who doesn't care about the beer he drinks may as well not care about the bread he eats.

—Michael Jackson, 1977

2.6.1 The Basic Brewing Processes

Nowadays, the term beer refers to any drink that is produced by the fermentation of sugars derived mostly or entirely from malted cereals (principal of which is barley) and flavored with hops. Other flavorings, such as cherries, citrus, coriander, juniper and spruce are also used for certain beer styles (see Section 2.6.13). Some staple drinks of Africa, Asia and South America: fermented beverages based on maize, rice or sorghum, and which do not involve flavoring with hops, are discussed in Chapter 2.7.

The basic source of fermentable sugars in the brewing of beer is malted barley grains, although other malted cereal grains, notably wheat and rye, may be used, but usually in conjunction with malted barley. Unmalted cereals, such as barley, wheat, torrified wheat, flaked maize, rice and others, are sometimes used as adjuncts (minor ingredients) in the brewing of certain types of beers or in others to effect particular characteristics in the finished product (Section 2.6.2). Also, some larger breweries use industrial enzymes to produce fermentable sugars directly from the starch of unmalted grains such as rice, thus avoiding the malting process for at least some of the mash (Section 2.6.2). Additionally, malt extracts, syrups and a variety of brewing sugars are used (along with malted barley) in some breweries (Section 2.6.3).

The basic stages of brewing are shown in Figure 2.6.1, which refers to batch (or 'gyle') brewing (see Section 2.6.5 for continuous fermentation). Malting and mashing can be considered as the first stages in brewing. Malting is the controlled germination of barley (and other cereal) seeds. It leads to 'modification' of the barley constituents: certain chemical changes, caused by the action of released enzymes, occur in the germinating grains (Section 2.6.2). Kilning (and/or roasting) then stops the modification processes and causes other effects (flavoring and coloring), depending on the temperatures (Section 2.6.2). Many breweries buy their barley already malted by large malting companies, such as Baird, Munton and Fison, Pauls and Simpson (all UK), Dewolf-Cosyns, Dingemans (Belgium), Meusdoerffer, Weyermann (Germany), Cargill (Australia), Gambrinus (Canada), Briess, Schreier (USA) and Malteries Franco-Belges (France). A few breweries still

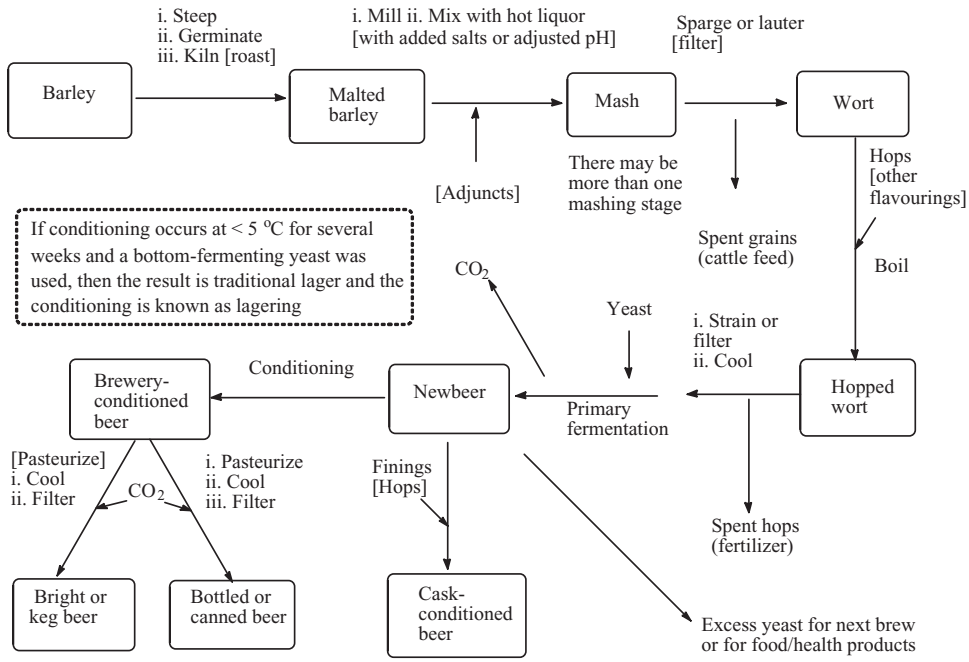

Figure 2.6.1 *The basic brewing processes (optional items are given in square brackets)*

malt their own barley, an example being Cooper's of Adelaide, Australia. However, the big majority of breweries buy malt from large malting companies or are supplied with malt from a malting company under the same ownership as the brewery.

Whatever the source of malt, the brewery will require the best quality barley, carefully malted to certain specifications, depending on the intended product. Quality control analysis of a malt sample will be carried out in order to ensure that these specifications are met (Bamforth, 2002a). Likewise, analysis of the brewery's water (liquor) supply, especially with regard to Ca^{2+}, SO_4^{2-} and HCO_3^- content, will be performed on a regular basis. This is to ensure that the mashing process occurs at the optimum pH (~5.2) and that the correct balance of salts is present for the type of beer being brewed (Section 2.6.2).

After mashing, the hot liquid (now called wort or gyle) is run off or pumped into a brewing kettle or 'copper.' The barley husks act as a filter bed, but the wort can be clarified by further filtration if necessary. The husks are then rinsed with a fine spray of a predetermined volume of hot liquor at a predetermined temperature. This is known as sparging or lautering; it optimizes the extraction of sugars from the malted grains. At this stage, the unhopped wort may be analyzed, at least for its original gravity (OG), so that the extraction efficiency can be determined (Section 2.6.2).

The wort is boiled with hops (and any other flavorings), filtered and then cooled rapidly, as it is transferred to the fermentation vessel. The boiling process not only stops enzyme action, sterilizes the wort and adds flavors, but also coagulates some proteins that might otherwise cause the beer to be cloudy (Section 2.6.3).

Yeast is added to the cool, hopped wort and fermentation is conducted at a temperature and for a period of time that depends on the type of beer being brewed (Section 2.6.4).

The fermentation progress can be monitored simply by measuring the drop in specific gravity (attenuation) (Section 2.6.4), but more specific tests can be performed, according to the circumstances. Excess yeast is

separated from the liquid as required; it can be compressed and used in a future brew, or can be used to make health products. After a period of primary fermentation, the young ('green') beer is run off or pumped into conditioning tanks where it continues fermentation; for traditional lager beers, this process can occur over several weeks at low temperatures (∼5 °C or 41 °F).

Alternatively, the young beer can be transferred directly to the casks for further fermentation ('cask-conditioning'). Finings and hops ('dry hopping') can be added at this stage. Extensive analytical and sensory tests may be carried out on the beer at any stage of the fermentation process, before and after the beer leaves the brewery. Most beers destined for can or bottle are pasteurized, chill filtered and then artificially carbonated, although many bottle-conditioned beers exist (Sections 2.6.10 and 2.6.13). Many brewery-conditioned beers intended for serving on draught are chill filtered, but not pasteurized (Section 2.6.9).

For detailed discussions on various aspects of beer production, the reader is referred to Hough *et al.* (1982), Fix (1999), Hornsey (1999), Hughes and Baxter (c06+bib+0006), Iserentant (2003) and Paterson *et al.* (2003).

2.6.2 Malting and Mashing

Barley is the most important of the many cereals that are used in brewing. *Hordeum vulgare* and *H. distichon* are the botanical names of the six-rowed and two-rowed species of the plant (respectively) producing the seeds (grains, corns or kernels) that are so valuable to the brewer. The superiority of barley over other cereals is a result of the higher starch to protein ratio and lower moisture content of its unmalted seed. Additionally, barley is rather easier to grow than wheat, rye or maize: it is more tolerant of inclement weather and is less liable to fungal infection. It is also easier to malt than other cereals.

Two-rowed barley is grown in areas with temperate growing seasons all around the world, from northern USA and Canada to central and western Europe, including England and Scotland. Six-rowed barley is grown in warmer climates, such as mid western USA. This produces grains with higher protein contents than two-rowed types. Six-rowed barley grains are used in brewing, but certain varieties of two-rowed barley (often winter sown varieties) form the mainstay of quality in the brewing industry. These include Harrington (USA), Maris Otter (UK), Scarlett (Germany), Alexis and Prisma (Belgium). Other popular two-rowed malting varieties include Chariot, Fanfare, Gallatin, Golden Promise, Halcyon, Merit, Optic, Pearl, Pipkin and Regina and two popular six-rowed varieties (USA and Canada) are Legacy and Robust. Some of these barley varieties (e.g. Optic and Pearl) are also used to produce malt whisky (Section 3.2.2). Many of these varieties are grown by farmers under contract from the large malting companies, who then malt the harvested crop according to specifications required by particular breweries, as described next.

Figure 2.6.2 shows a section through a typical barley grain. Such a grain contains 78–83% total carbohydrates (63–65% starch, 3–8% β-glucans, 4–7% pentosans and 4–5% cellulose), 10–12% proteins and amino acids, 2–3% lipids and 2% minerals. Apart from these, water and flavonoid phenols (including proanthocyanidins) and low concentrations of many organic compounds are present.

Brewers prefer their malted barley with a high starch, low protein and low moisture content. When the batches of harvested barley arrive at the malting plant, the maltster will immediately apply a number of tests to representative samples of the grains from different batches. These are:

1. Visual tests (for maturity, signs of disease or damage and identity)
2. Determination of protein and moisture content, by near infrared spectroscopy(Section 4.4.2)
3. Viability tests, such as the tetrazolium dye test.

The last-named test uses triphenyltetrazolium chloride (TTC) to determine the viability of cereal grain embryos. Intense, even staining of the aleurone layer is an indicator of viability; it predicts that the sample of

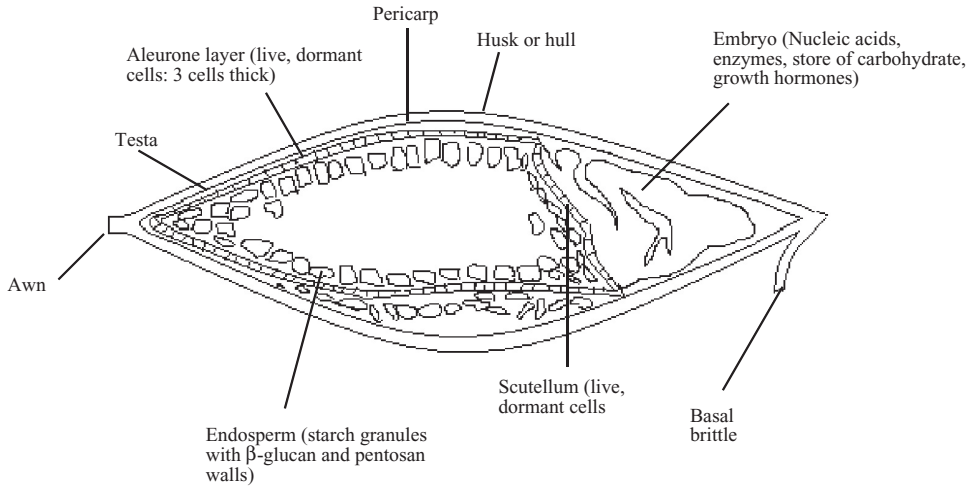

Figure 2.6.2 *Schematic cross section through a barley grain*

barley has good malting qualities and will undergo extensive modification during malting (Briggs *et al.*, 2009). Colorless, soluble TTC is reduced to a scarlet insoluble formazan product at sites on cereal cell mitochondria, including cytochrome oxidase, salicyl hydroxamic acid (SHAM)-sensitive oxidase and succinate oxidase. Barley with poor malting potential undergoes poor or patchy staining of the aleurone layer, because of faulty mitochondrial function, hence the intensity of tetrazolium staining of aleurone layers can be used as a guide to the breeding of barleys with superior malting qualities.

If these tests give satisfactory results, the barley will be accepted and will then be transferred to silos for storage. The maltster will then perform both physiological/anatomical tests and specific chemical tests on samples of grain. The former include germinative capacity, germinative vigor and germinative energy tests; these will be carried out periodically, so that the maltster can assess when seed dormancy is over and the grains are ready for malting. The results of these tests may indicate the type of malting regime that can be applied. Specific tests include moisture assessment, nitrogen content determination (Section 4.6.3), β-glucan assessment (Section 4.4.3) and analysis for fungal toxins (especially deoxynivalenal, DON, from infection by *Fusarium* species) (Section 5.11.4) and pesticide residues (Section 5.10.2).

The concentrations of fungal toxins and pesticide residues must be below regulatory limits: levels of DON may be decreased by spraying the barley grains with sodium bisulfite solution prior to malting (Lake *et al.*, 2007). Apart from the above analyses, pale ale brewers require low levels of the dimethyl sulfide (DMS) precursor *S*-methyl methionine (SSM) (Section 2.6.4) in the malt and may request its assessment. Once satisfied, the maltster will carry out a pilot (small scale) malting before committing larger quantities. A typical barley specification prior to malting is given below:

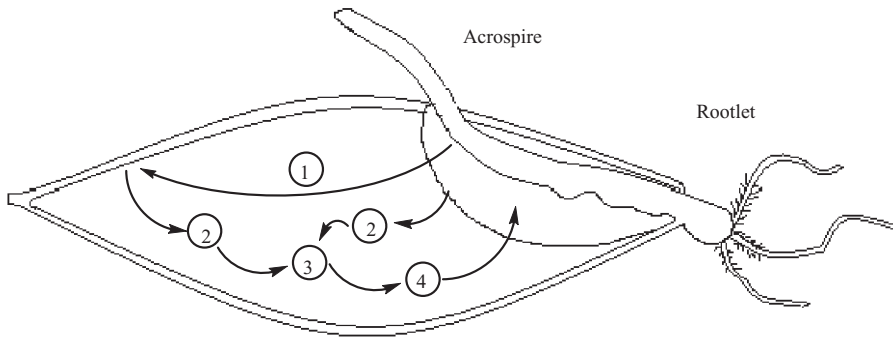
Germinative capacity >96% after 72 h
Germinative energy 95% after 72 h
Water content 12.0–13.0%
Protein content 9.0–11.5%
β-glucan content < 4%
Pesticide and fungal toxin residues within statutory limits

Purity of barley variety >99%
The malting process consists of the following basic steps:

- washing
- soaking/aerating
- germinating
- drying (and/or roasting for brewing dark beers)

There are many ways in which each of these steps can be performed, and indeed a particular malting plant may use different combinations of methods for particular kinds of malt. Modern malting plants, apart from being partially or fully automated and generally working with hundreds of tonnes of grain at a time, are designed to occupy minimal space, to waste less energy and water, to promote maximum hygiene and ease of cleaning and to produce uniformly high quality malt. Traditional malting houses, which include a germination floor (they are often known as 'floor maltings') are now quite scarce, but include small scale operations associated with a small number of Scotch malt whisky distilleries (see Chapter 3.2, Figures 3.2.2 and 3.2.5; see also this section, Figure 2.6.5). They are much more labor intensive than modern malting houses and are probably more wasteful on energy and water, but they do produce excellent malt and they have an unmistakably romantic aura attached to them. The first two stages of malting, washing/steeping and germination, along with a description of the biochemical and physiological changes that occur during these stages, are outlined next for both traditional and modern malting plants. This is followed by an outline of the final malting stages of drying (kilning) and roasting.

In the steeping vessel, the washed grains are subjected to a cycle of spraying and aeration. After about 24 h, the water content of the grains reaches 45% or so and small roots ('chits') appear as first signs of germination. In traditional malting plants, the grains are transferred to the malting floor to a depth of about 25 cm in order to continue germination for 5–8 days, depending on the degree of modification required. Germination causes profound biochemical changes to the barley grains, as summarized in Figure 2.6.3. During germination, the first scene of action is the embryo. Influx of water promotes respiration of the embryo carbohydrates, which provides energy for growth. As these carbohydrates are depleted, the scutellum cells produce hormones called



1. Gibberellin release from embryo on steeping in water. 2. Release of hydrolytic enzymes from a leurone layer and scutellum. 3. Hydrolysis of cell wall carbohydrates, proteins and some starch (to maltose and glucose) 4. Transport of sugars to embryo for metabolism (respiration) and growth.

Figure 2.6.3 *Barley germination: summary of events*

gibberellins, which are released into the endosperm, where they stimulate the aleurone cells to produce a variety of enzymes, as summarized below:

- Cytolytic enzymes: β-glucanases and cytases, for degrading the endosperm starch cell walls (composed of ~75% β-glucans, 20% pentosans (arabinoxylans) and 5% proteins)
- Carbohydrases: α- and β-amylases mainly, for degrading starch into maltose and other sugars such as dextrins (α-glucans)
- Proteolytic enzymes (proteases): proteinases and peptidases, for degrading proteins into α-amino acids and small peptides
- Oxidoreductase enzymes: thioredoxin (actually a thioredoxin-thioredoxin reductase-NADPH complex) for reducing disulfide bridges of proteins (e.g. hordeins, α-amylase subtilisin inhibitor), thereby destroying their tertiary structures and making them more susceptible to hydrolysis by proteases.
- Acidity regulating enzymes: phosphatase.

The actions of these enzymes during germination cause 'modification' of the barley: β-glucan polymers, proteins and a little starch are degraded to soluble products of lower molecular weights. On the other hand, the maltster takes care to avoid overmodification: the aim is not to produce new barley plants.

Excessive quantities of soluble β-glucan oligomers (smaller polymers) in the wort can cause processing problems and can also lead to haze problems in the finished beer (Section 2.6.9). In view of this it would seem desirable that degradation of β-glucan polymers and release of soluble β-glucans is minimized and/or extensive soluble β-glucan degradation (to β-D-glucose) is promoted during malting and mashing.

In practice, during malting, degradation of β-glucans in the cell wall to soluble oligomers is limited, whereas degradation of pentosans (arabinoxylans) is much more extensive. Experiments mimicking the action of hydrolytic enzymes on cell wall constituents support this observation. Addition of purified enzymes to purified barley cell walls have indicated that the action of β-glucanase enzymes on β-glucan polymers is hampered by the presence of pentosan polymers, and especially because of the numbers of acetyl and feruloyl sidechains in these polymers (Kanauchi and Bamforth, 2002). In fact, xylanases were the most effective releasers of β-glucans, presumably because these enzymes were able to release all of the pentosan from the cell walls. Also, esterases that hydrolyze acetyl and feruloyl groups released some β-glucan (but not pentosan), suggesting that these side chains play an important role in the inaccessibility of the β-glucans. No more than 15% of total glucan present in the purified cell walls was released by various enzymes, under these conditions.

Up to 40% of barley proteins are degraded during germination. Again, excess protein content in the beer can lead to hazes, especially if the polyphenol content (Section 2.6.9) is also high. On the other hand, starch degradation is only slight – a typical malt has 59% starch and 8% sugars, compared with 65% and 2%, respectively, in unmalted barley. This is despite the fact that α-amylase and associated enzymes are synthesized in malted barley; the α-amylase activity of raw barley is typically less than 10% that of malted barley. The major degradation of starch occurs during mashing, hence the hydrolytic reactions will be dealt with there (see Figure 2.6.10). Structural characteristics α- and β-D-glucose, of α-glucans, β-glucans and starch are illustrated in Figure 2.6.4.

Germination time depends on barley characteristics, temperature and aeration of the malt bed, but is usually around five days. Regular turning of the malt grains during germination ensures uniform modification. In a traditional floor malting plant, this is known as 'grubbing' and is performed manually using a large wooden fork (Figure 2.6.5).

Some of the more modern malting houses use the saladin box type (or rectangular enclosed floor type) (Figure 2.6.5) for germination or the revolving drum type for both germination and kilning (see Section 3.2.3). Uniform germination is achieved by regular use of mechanical screws or rotation, respectively. The

Figure 2.6.4 *Glucose based carbohydrates in barley and malt*

main advantages of these types of malting techniques are that they demand less space than traditional floor malting, require less labor and use less energy and water.

Tower malting is an even more modern technique, best described by consideration of the malting plant owned by the Bavaria Brewery (Lieshout, the Netherlands) at Eemshaven on the Dutch coast. The malting process (which went into operation in 2005) is performed in steel sectionalized towers. The grains are steeped in the top section (which can accommodate batches of 440 tonnes of barley), known as the 'Ecosteep' (Figure 2.6.5) because of its economical use of water. The section below is comprised of three rotatory germination units, each capable of taking 440 tonnes of grains. Rotation is reckoned to result in uniform germination and modification of the grains. The bottom section is a single floor rotating kiln deck for hot air kilning. Malt houses like this are able to produce almost 140 000 tonnes of malt a year, the malt being of very uniform high quality because of the rotating floors and gentle screw conveyors that discharge and spread the grains. Major advantages of lower water usage (30% less than floor maltings) and better sanitation are claimed.

The least modified malt is preferred for traditional Pilsner style beers, whereas rather more highly modified malts are used for pale ales. The extent of modification of malt grains can be assessed using a friabilimeter, consisting of a rubber roller and a rotating sieve drum, through which the grains are passed. Satisfactorily modified malt will break into small pieces and filter through the sieve, the percentage by weight that does this being regarded as a measure of proper modification. The expectation is 90% friability or better. Alternatively, the brewer can take a representative sample of malt grains and boil them in water for 30 min. This loosens

the husks and allows inspection of the length of the acrospires of, say, 100 grains; the longer the acrospire in relation to the grain length, the greater the modification. This gives the brewer a general picture of extent of modification and may also indicate cases of overmodification, where the acrospire is longer than the grain.

Germination stops when the malted barley grains are moved to the kiln and dried, usually in a stream of hot air. This mild heating (85–90 °C) shrivels the rootlets (which fall off the grains) and partially inactivates

some of the enzymes that promoted modification during germination. It also produces a very small amount of coloring substances, so the resulting beer brewed from these malts alone will be a pale to full gold. These are the base malts; not only are they used to brew pale beers, but they also form the main cereal ingredient of most other beers (Section 2.6.1). During mashing, most of the enzymes are supplied by these malts.

Whilst malting necessarily results in the formation of acrospires and rootlets, growth of large rootlets leads to significant loss (*ca.* 4%) of barley weight upon kilning, known as 'malting loss.' At the present time, potassium bromate is used by some maltsters to inhibit excessive rootlet growth during malting. A pilot plant screening experiment using *Lactobacillus plantarum* 15GR as rootlet inhibitor resulted in a 50% reduction in malting loss, but produced malted barley of similar quality to untreated barley (Schehl *et al.*, 2007). The *L. pantarum* strain performed significantly better than potassium bromate under these conditions (and is probably considerably safer).

Stronger kilning, or roasting at higher temperatures, often in a slotted, rotating drum, produces colored malts for brewing darker beers. The heat causes production of highly colored substances, caramelization and the formation of flavor compounds, via the 'Maillard reaction' (Figure 2.6.6). Caramelization of sugars causes the production of yellow-brown polymers and pleasantly aroma active furans, isomaltol and maltol. However, most of the color (called 'nonenzymic browning') and flavor of dark malts arise from the Maillard reaction, which is actually a complex multitude of reactions that begin with sugars and α-amino acids, amines or peptides. Products include those similar to caramelization, plus strongly antioxidant 'reductones,' Strecker aldehydes, nitrogen heterocycles and mellanoidins, brown pigments that are also antioxidants (Coghe *et al.*, 2004).

Many of these compounds are flavor active, some being more attractive than others (Figure 2.6.6). To minimize burnt flavors, some breweries, such as Diebels Altbier Brauerei of Issum, Germany, have requested dehusking of the barley grains after malting, but before roasting. Prolonged exposure to high temperatures disables more of the enzymes, so that the diastatic power (ability to hydrolyze starch molecules via amylases), measured in °Lintner (°L) (Section 4.6.3), of most colored malts is low: zero for the darkest malts. A typical pale malt would be expected to have around 130 °L of diastatic power (Bamforth, 2002b). Consequently, the highly colored malts must be used in conjunction with base malts.

Amber, mild ale, Münchner and Wiener malts are the palest of the colored malts. These still have considerable diastatic power, typically 40–70 °L (Fix, 1999b), and may be used as the major cereal in the 'grain bill' of certain beers (Section 2.6.13). They are produced from green malt by ramping the kiln temperature from 65 °C (when the moisture content has reached ∼10%) to 85 °C, the depth of color depending on the ramping programme and the time spent at higher temperatures.

Next are the caramel and crystal malts: these have a wide range of colors and other characteristics depending on the roasting temperatures and the humidity and duration of heating. They are made by sending the green malt directly to the roaster, where firstly the surface moisture is dried off at ∼50 °C for a few minutes, then a temperature of 65–75 °C is applied for 45 minutes to stimulate saccharification and crystallization. Next, the temperature is increased to 80 °C for about the same period of time in order to dry the grains to about 5% moisture and to start color/flavor reactions. Finally, the latter processes are continued at temperatures of 120–160 °C for a period of time, depending on the depth of color and caramelization required. Two hours at 135 °C is typical for crystal malt.

Chocolate and black malts are the most highly colored of all malts, although roast (unmalted) barley gives the strongest color of any adjunct (Section 2.6.13). Brown, chocolate and black malts are all produced by roasting pale malts from the kiln. A gradual increase in the roaster temperature up to 230 °C is applied; the higher the final temperature or the longer the time spent in the higher temperature range, the greater the carbonization and the darker the malt will be.

The degree of malt coloration can be estimated by visible spectrophotometry or colorimetry (Section 4.4.3) and is expressed on scales devised by the American Society of Brewing Chemists (Standard Research

Method, SRM, similar to the old Lovibond scale) or the European Brewing Convention (EBC). Table 2.6.1 displays typical characteristics of common malts. It should be kept in mind that these characteristics will differ somewhat between maltsters and from season to season.

In recent years, there has been considerable interest in the malting of cereals other than barley and wheat, such as sorghum or millett (*Sorghum bicolor* L. (Moench) and buckwheat (*Fagopyrum esculentum*), which are infrequent components of European beers, but are commonly used to make indigenous brews of Africa and Asia (Section 2.7.2). It has been found that a five day malting period at 26 °C led to an optimum sorghum malt regarding starch modification, protein degradation and lipid degradation. Addition of such malt to a sorghum flour porridge (which is often the way indigenous African brews are mashed and fermented) resulted in an overall sixfold increase in carbohydrate digestibility and a fourfold increase in free amino acid content (Correia *et al.*, 2008). Malted indigenous Botswana surghum varieties were shown to have β-amylase as the major contributor of diastatic power, ranging from 55% to 88% (Letsididi *et al.*, 2008). Limit dextrinase was also high: up to 231 U/g for the variety Sefofu. The malted grains of several varieties showed desirable amylolytic properties, indicating their potential use in the production of lager type beers.

Common buckwheat (with or without hulls), when malted at 16.5–20.2 °C showed similar free amino acid and soluble nitrogen contents to those of malted barley. At 20.2 °C germination, the major diastatic power contributor was again β-amylase (∼127 U/g wet weight): optimum α-amylase activity was ∼48 U/g (wet weight) using hull-less buckwheat at 16.5 °C germination. Maximum apparent fermentability was 56% with buckwheat germinated at 20.2 °C. Although fermentability and amylolytic levels were

generally low compared with malted barley, buckwheat malt is considered to have potential as a brewing ingredient (Wijngaard *et al.*, 2004), particularly with regard to gluten-free beers (Section 5.11.3).

The next stage in brewing is mashing: the malted barley grains are put through a screening machine (to remove stones and other debris) before being crushed ('milled') and the resulting grist is mixed with hot brewing liquor. This mash is left for a period of time at a fixed temperature, or is taken through a number of temperature stages ('rests') by a temperature ramping process (Figure 2.6.7). Cereal adjuncts can be added at the mixing stage and the acidity and mineral content of the liquor can be adjusted prior to mixing.

During mashing, starch is hydrolyzed by α- and β-amylase to soluble sugars (mainly maltose and α-glucans or dextrins). Proteins and β-glucans are hydrolyzed to soluble products by proteinases and β-glucanases, respectively. Additionally, there is believed to be some reaction between proteins and carbohydrates to give glycoproteins, useful for haze stability and foam stability ('head retention'). It has been observed that the native barley hydrophobic protein, lipid transfer protein 1 (LPT1), which is a poor foam promoter, is transformed during malting and mashing to a modified structure, which is a good foam promoter (Leisengang and Stahl, 2005).

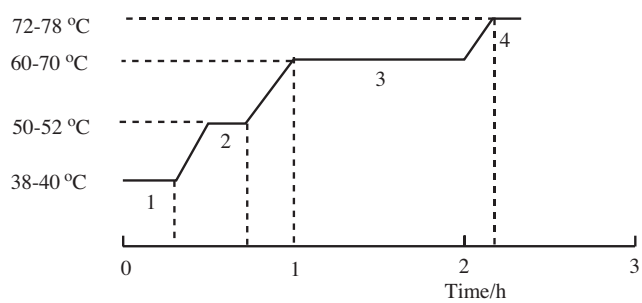

Figure 2.6.7 *Typical stepwise infusion mashing program*

Mashing lasts for about an hour or more depending on the regime, after which time, the sweet liquor (wort) is run off through the grains into the brewing kettle, ready for the boiling stage. The spent grains are rinsed through with hot liquor ('sparging') in order to maximize sugar extraction. Most of the above factors are discussed in more detail in the next paragraphs.

Coarse milling tends to be favored by smaller breweries: the grains are cracked, but the hulls are left intact to act as a filter bed for the wort. Some malting companies are able to supply microbreweries with small bags (10 kg) of crushed pale malt. Adjuncts such as flaked maize and rice hulls can aid this filtration process. Figure 2.6.8

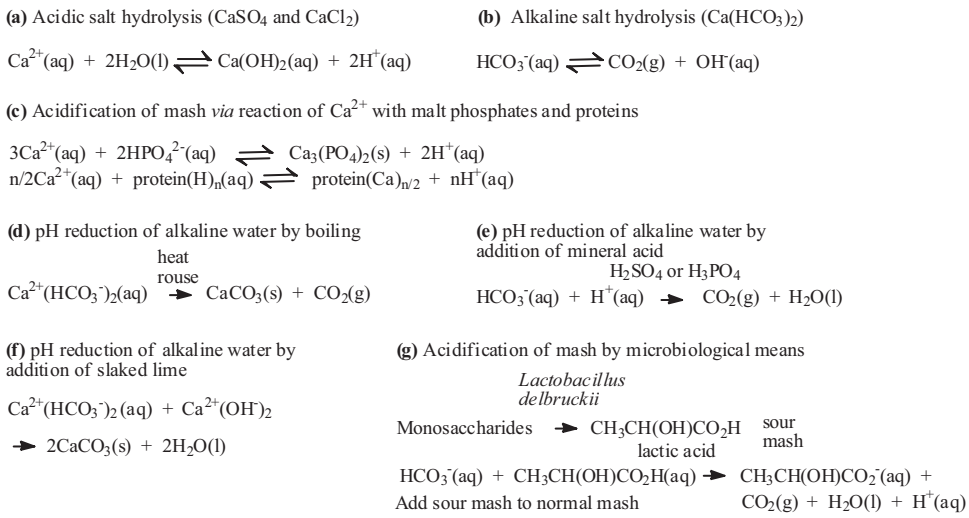

Figure 2.6.9 *Salt hydrolysis, effect of Ca^{2+} on mash acidity and methods for reducing liquor or mash pH*

shows malt mills, mash tuns and related equipment at a number of breweries. Many larger breweries prefer to mill the malt grains into a fine powder. Because of the larger surface area, this results in a more effective conversion of starch to sugars. Following this, a more efficient extraction of the sugars from the insoluble residue can then be obtained by mash or membrane filtration (Kunze, 1996; Schneider and Weisser, 2004).

The mineral content and pH of the mashing liquor are of prime importance, not only because of the influence that these have on the mashing process itself, but also because this liquid will be the medium for all subsequent brewing stages. The hydrolytic enzymes in the mash require a medium pH of between 4.5 and 5.0 for maximum activity, and it is generally held that the maximum mash pH should be 5.4 (Fix, 1999). Because of salt hydrolysis, the presence of significant concentrations of minerals (dissolved salts) in the liquor can cause the mash pH to deviate either way from the optimum range (Figure 2.6.9). Now, a mash of pale malts only and distilled water will have a pH close to 6.0, whereas a mash with substantial quantities of colored or roast malts in its grain bill may have a pH of less than 5.0. Consequently, acidic salts in the liquor will be beneficial in the brewing of pale beers, whereas alkaline salts will be more suitable for dark beers. Acidic salts (in permanently hard water) include $CaSO_4$, $CaCl_2$ and $MgSO_4$; alkaline salts (in temporarily hard water) include $Ca(HCO_3)_2$, $Mg(HCO_3)_2$ and $CaCO_3$. The mineral content of brewing liquor will depend on the local geology and, if obtained from the local water company, on the water treatment implemented by that company.

Experience has shown that certain locations produce their best beer styles in accord with the mineral profile of the local water, as outlined in Table 2.6.2 However, 'incompatible' beer styles have been brewed in such areas for many years (or even centuries) by adjustment of mineral content and pH; indeed some of the best pale ales are brewed in London and some of the best Pilsners in Dortmund, despite the high HCO_3^- content of the local water in these two cities.

The most important salts are $CaSO_4$ and $Ca(HCO_3)_2$, although salts of Mg^{2+}, Na^+ and Cl^- may also be significant. Calcium ions in the brewing liquor are of benefit to brewers for many reasons:

- Reaction with malt phosphates and nonhydrolytic proteins lowers mash pH, which in turn enhances hydrolytic enzyme activity
- Reaction with nonhydrolytic proteins causes precipitation, thereby enhancing clarity
- Calcium ions protect α-amylase from inhibition (denaturation) by heat

Table 2.6.2 *Approximate mineral composition (in mg/l or ppm) of famous brewing liquors (major ionic species only)*

Location	$[Ca^{2+}]$	$[SO_4^{2-}]$	$[HCO_3^-]$	$[Mg^{2+}]$	$[Cl^-]$	Most famous beer style

*Applies to much of the English Midlands
§Also contains ~60 mg/l of Na

- Oxalates are precipitated by Ca^{2+}, hence minimizing hazes
- Reduced pH reduces extraction of undesirable polyphenols and silicates from the malt grains
- Reduced pH gives the wort and subsequent beer greater resistance to microbiological infection
- The production of colored substances during the boiling stage (see Figure 2.6.6) is inhibited by Ca^{2+} ions
- Calcium ions aid yeast flocculation, thereby enhancing clarity.

Calcium deficient brewing liquors intended for pale beers are adjusted by addition of gypsum ($CaSO_4.2H_2O$) or calcium chloride dihydrate ($CaCl_2.2H_2O$), whereas liquors intended for dark beers are adjusted with chalk ($CaCO_3$). A total Ca^{2+} concentration of around 150 mg/l (ppm) is the usual aim. Countering the effect of calcium ions, high concentrations of bicarbonate are responsible for high pH brewing liquors. If such untreated liquors are used to brew pale beers, several problems can arise. Firstly, hydrolytic enzyme action is impaired in mashes of high pH, giving wort with lower sugar content and higher protein content, which can lead to haze problems. Secondly, hop character is more pronounced – often to the point of astringency – in the finished beer. Other problems may arise, but these are the main two.

Some of the more common methods used by brewers to lower liquor pH, by removal of HCO_3^-, are outlined in Figure 2.6.9 (d–g). On the positive side, high pH water is suitable for the brewing of dark beers. During mashing, the alkalinity of the liquor is partially offset by the higher acidity of the dark malts. Also, the presence of bicarbonate in the medium seems to decrease the astringency of some of the Maillard products that are necessarily present in dark beers. This gives a certain mellowness of flavor, provided that the 'hop rate' is low.

At the start of mashing ('mashing in'), the liquor and the grist are often mixed in the proportion of around 2.5 l of liquor to each kg of grist (~1 gal/3 lb), although the extremes are from ~3.5 l/kg (thin mash) to ~1.5 l/kg (thick mash). Cereal adjuncts that possess gelatinized starch (flaked maize, torrified barley or torrified wheat, for example) can be included in the grist at mashing in. Others, such as rice, unmalted barley or wheat and sorghum need to be treated in the cereal cooker before mixing with the mash – see 'double infusion.'

There are many mashing regimes, but all of them use temperatures in excess of 60 °C for a period of time, in order to enable the saccharification enzymes (the amylases and limit dextrinase) to hydrolyze starch to soluble sugars. The most common mashing methods are:

- Stepwise infusion
- Infusion
- Decoction
- Double infusion.

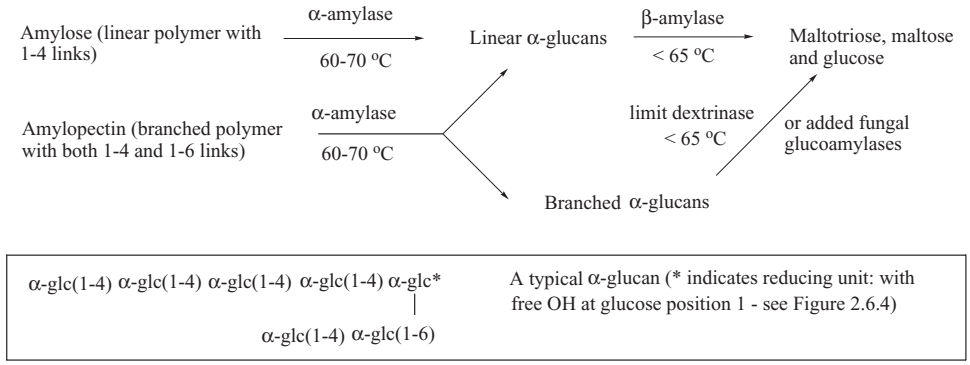

Figure 2.6.10 *Scheme for saccharification of starch during mashing, showing a typical branched α-glucan (dextran)*

In practice, there are many variations within these methods, but their basic characteristics are discussed next.

Stepwise infusion takes the mash through a series of temperature controlled stages, with ramping and rest periods that are designed to optimize sequentially the conditions for different enzymes. Figure 2.6.7 shows a typical program, although some breweries may skip one or more rest and temperature ramps and times will vary between breweries or between different beer styles. Equilibration of pH occurs during stage 1, along with cell wall and protein hydrolysis, catalyzed by β-glucanases and xylanases, and carboxypeptidases and endopeptidases, respectively. This continues into stage 2, where proteolytic activity reaches a maximum. The α-amino acids produced here will provide nutrition for the yeast during fermentation, and some of the peptides will contribute to head retention in the finished beer. Stage 2 is also responsible for a certain degree of starch cell gelatinization, and saccharification begins here.

A further increase in temperature to stage 3 inactivates the proteolytic enzymes and provides the most favorable conditions for the saccharification enzymes α-amylase, β-amylase and limit dextrinase. The enzyme α-amylase works best at temperatures close to 65 °C, but is relatively heat tolerant and is still viable at 70 °C or higher. It hydrolyzes the polymeric starch molecules randomly at (1→4) links to produce oligomeric (medium sized molecules) α-glucans (dextrins), which cannot be fermented by normal brewing yeasts (Figure 2.6.10). The enzyme β-amylase is much more heat sensitive and is inactivated at temperatures above 65 °C. It hydrolyses the α-glucans at alternative (1→4) links, but cannot hydrolyze (1→6) links; it thus produces maltotriose, maltose and glucose, and residual branched α-glucans ('limit dextrins') containing from seven up to 25 glucose units (Figure 2.6.9). The third enzyme, limit dextrinase (LD), is normally present in much lower concentrations than either of the two amylases (McCaffery *et al.*, 2004). Hence its action is limited, so that typically ~20 % of the starch in the mash remains as nonfermentable dextrins.

Performing stage 3 at 60 °C allows β-amylase and limit dextrinase maximum efficiency and leads to highly fermentable low dextrin worts, used for the brewing of 'light' (lite) beers and 'diet Pils' (Section 5.7.2), especially if the pH of the mash is initially lowered (e.g. by the addition of $CaCl_2$), and then readjusted. Addition of certain reducing agents (e.g. dithiothreitol) also leads to inceased LD activity. Some brewers add glucoamylase or pullulanase (of fungal origin) to the mash in order to accentuate the hydrolysis of branched α-glucans (Section 5.7.2). At the other extreme, performing stage 3 at 70 °C (or higher) disables both β-amylase and limit dextrinase and produces a high dextrin wort, suitable for brewing certain low alcohol beers (Chapter 2.13).

Finally, the temperature can be raised to stage 4, where some of the α-glucans react with residual proteins to give glycoproteins, substances that are known to increase beer foam stability (Ishibashi *et al.*, 1997) (Section 2.6.9).

In practice, it has been found that for well-modified malt at 62 °C, the saccharification stage 3 requires only 20 min rest time for production of maximum sugars and free amino nitrogen (FAN) (Mitzscherling *et al.*, 2007). Indeed, a longer rest time at this temperature results in a mash with unnecessarily high levels of soluble β-glucans, which may lead to filtration and haze problems further on in the brewing process (Kühlbeck *et al.*, 2005).

Infusion mashing is the traditional method for ales. The mash is held at a fixed temperature (∼65 °C) for 1–2 h, thus giving the amylases optimum conditions for starch hydrolysis. This method is especially good with low protein malts (from two-rowed barley), traditionally used in the brewing of pale ales. However, nowadays the infusion mash is also used in the brewing of many lagers, where more modified, low protein malts are used in place of the traditional undermodified, higher protein malts.

Decoction mashing, however, is the traditional method for lager beers; it involves heating a part of the mash to boiling point (>100 °C) and mixing this back into the mash bulk, so that a predetermined temperature is achieved, typically ∼50 °C, for protein degradation. This process can be carried out twice (double decoction) or three times (triple decoction), achieving a different rest temperature, by varying the bulk mash:boiled mash ratio. As mentioned already, decoction is the traditional method for lagers, where undermodified, high protein and enzymatically weak malts were once the norm. Decoction mashes are still used in many breweries in southern Germany and Central Europe.

Double infusion mashing is used in the production of high adjunct beers, where the adjuncts are unmalted (ungelatinized) cereals, such as rice, maize (corn) or sorghum. These adjuncts provide cheaper and low flavor extracts, but they must be subjected to a cereal cooker to gelatinize the starch cells before use. This adjunct wort is then mixed with a high diastatic malt wort (often produced from six-row barley), which has sufficient enzymes for saccharification of the whole mixture. High adjunct beers are a common product of many breweries on the North American continent.

On completion of the mashing process (by whatever method), the wort is separated from the grains, leaving a considerable extract as residue on the small particles. Sparging is the name for the process of rinsing the grains through with hot liquor (74–78 °C, but no higher) in order to maximize extraction. Lautering is the name for the whole process, filtering plus rinsing. The sparge liquor should be about the same volume as the mash liquor, too much (especially if pH >5.5) extracts polyphenols, lipids and other undesirable substances, which can cause astringency, haze and staling problems (Section 2.6.12) in the finished beer.

Many brewers simply filter the wort and sparge washings through the bed of broken hulls and particles, ready for the next stage, boiling. Rice hulls, added at the start of mashing, may help in the lautering of wheat mash grains, because these do not possess their own hulls. Brewers in larger breweries will often use mash filtration, having milled the malted barley into a powder for the mash (Schneider and Weisser, 2004); this gives clear wort. Brewers are undecided on the influence of wort clarity on the characteristics of the finished beer, but clear wort may benefit pale beers, whereas turbid wort may be better for full-bodied dark beers. Recent research has shown that beers brewed from clear and turbid worts show little difference in quality (Kühlbeck *et al.*, 2006). However, linoleic acid levels were higher in beer brewed from turbid wort, a condition that may cause a premature onset of staling in the packaged beer if a long shelf life product is desired (Section 2.6.12).

2.6.3 Boiling the Wort

Boiling of the wort is an important part of the brewing process; only some local brews of certain countries around the Baltic Sea (see Sahti, Section 2.6.13) and some beverages based on rice or sorghum

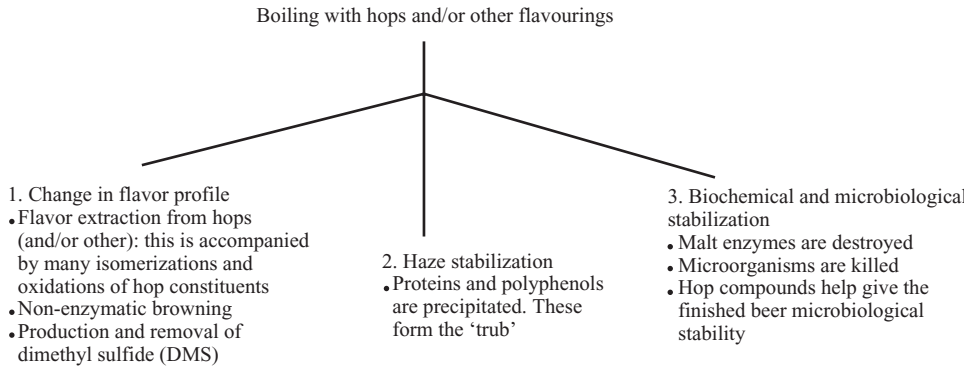

Figure 2.6.11 *Effects of boiling the wort*

(Sections 2.7.1 and 2.7.2) do not use boiled wort. The major ways in which boiling affects the wort are shown in Figure 2.6.11; these will be discussed in greater detail in the next paragraphs, but much the greatest emphasis will be placed upon flavor profile, bitterness, protein coagulation and clarity.

The brewing vessel in which boiling is carried out is known as the kettle, the wort boiler or the copper. The last term pays homage to the fact that for many years copper was the metal of choice for construction of such vessels, because of its superior heat conduction and malleability. Nowadays, stainless kettles are popular; they are less easily corroded ('pitted') than copper and are easier to clean, but have inferior thermal conductivity. There is also a tendency for insulating layers of air bubbles to form at the wort/steel interface and for wort solids to bake onto the steel surface at the air/wort/steel interface. Both of these problems can be minimized by the inclusion of impellers in the kettle, for agitation of the boiling wort. Direct heating of the kettle, using natural gas or electrical heating elements, tends to be limited to craft breweries and microbreweries. If too great a thermal load is applied without sufficient agitation, there is the likelihood of some charring and the formation of unwanted bitter Maillard products (Section 2.6.2, Figure 2.6.6). Kettles in most breweries are heated by either high pressure hot water or steam conducted from an external heating system known as a callandria. This is done via an external jacket at the base of the kettle or by way of internal pipes or central radiating panels ('star heaters'). Many kettles are supplied with impellers or other forms of wort agitators, such as fountain devices. Other kettles are designed to produce a 'whirlpool' action (discussed later). Some examples of kettles can be seen in Figure 2.6.8.

Whatever the design of the kettle, it is essential that the wort is boiled vigorously, for maximum extraction of bittering substances from the hops, for maximum formation of 'hot trub' (a precipitate of proteins and polyphenols, mostly) and to drive off unwanted volatile compounds, especially sulfur compounds. The kettle should also be energy efficient, with low operating and maintenance costs. It should be easy to clean. High pressure kettles are probably the most energy efficient, but undesirable volatile compounds cannot escape unless the kettle possesses a condensate trap in the stack.

In recent years, many European brewers have replaced or supplemented their conventional externally heated copper whirlpool systems with energy saving systems. These include Merlin, Schoko and Ziemann systems (Mitter *et al.*, 2007). In the first system, the wort is boiled, transferred to a whirlpool and then boiled again before cooling, etc. In the second two systems, the wort is boiled, transferred to a whirlpool and then to either a flash evaporator (Schoko) or vacuum evaporator (Ziemann) prior to cooling, etc. These systems give worts with very similar bittering units and iso-α-acid concentrations as conventional systems, although levels of aroma substances can be lower, a situation that can be rectified by incremental addition of hops, as in conventional boiling.

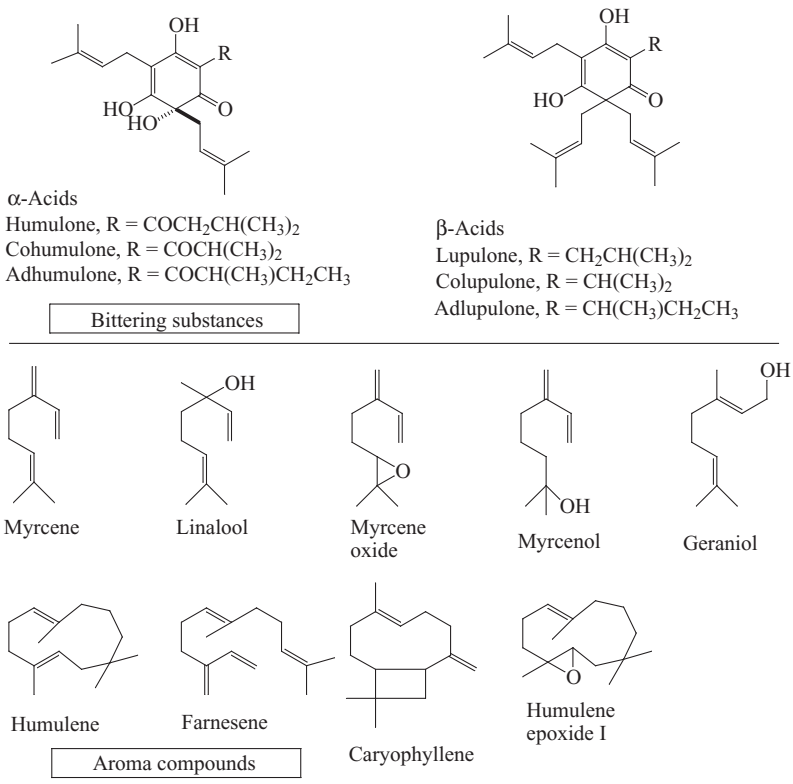

Figure 2.6.12 *Some bittering and aroma constituents of hops*

An important aspect of boiling is the extraction of bittering substances and aroma compounds from the flavoring agent, by far the most important of which is the hop flower or cone, which comes from the female hop plant (*Humulus lupulus*). The hop flowers contain substantial amounts of resins (for bitterness) and essential oils (for aroma and flavor). Both the resin and oil are composed of numerous compounds, many of which belong to the terpenoid or norisoprenoid families of natural products (Figure 2.6.12). The phenolic norisoprenoids, known collectively as α-acids and β-acids, are the principle source of bitterness, whereas monoterpene and sesquiterpene hydrocarbons and their oxygenated derivatives are the main source of aroma (Figure 2.6.12).

The hop is a perennial climbing plant that thrives in temperate climates. It is grown throughout the world, the largest producers being Germany, USA, Russian Federation, Czech Republic, UK, Slovenia and Poland. There are many varieties, but these can be divided into categories according to their α-acid content. Low (∼5%) α-acid varieties are often known as aroma or noble varieties and include Cascade (USA), Crystal (USA), East Kent Goldings (UK), Fuggles (UK), Hallertau (Germany), Lubelski (Poland), Saaz (Czech Republic, Germany) and Styrian Goldings (Slovenia). Moderate to high α-acid (8–15%) varieties, known as bittering hops, include Brewer's Gold (UK), Columbus (USA), Galena (USA), Northern Brewer (Germany, UK) and Wye Target (UK).

Typical α-acid and β-acid compositions, as well as aroma compound compositions, are given for some common hop varieties in Table 2.6.3. Cohumulone (Figure 2.6.12) is reckoned to be the most aggressive bittering agent of the three main α-acids, especially if the hop cones are added late in the boiling stage.

Table 2.6.3 *Bittering and aroma constituents of hops Data from Haunold (1998)*

Variety	Origin	α–Acids/% of total acids	α/βAcid ratio	Cohumulene/ % of total α–acids	Myrcene	Humulene	Farnesene	Caryophyllene
					/% total essential oil			
Cascade	USA	5.8	1.0	38	52	13	10	4
Crystal	USA	4.2	0.8	22	45	25	0	6
East Kent Goldings	UK	4.8	2.0	20	50	30	0	5
Fuggles	UK	5.0	1.5	20	30	35	2?	10
Galena	USA	13	1.8	43	58	13	0	5
Hallertau	Germany	4.0	1.0	25	35	37	0	10
Northern Brewer	UK/ Germany	9.0	2.2	33	33	27	0	9
Saaz	Czech Rep/ Germany	4.0	1.0	25	30	25	12	6
Wye Target	UK	12	2.2	38	63	13	0	5

This is why the percentage cohumulone data is included in Table 2.6.3. Myrcene is one of the most pungent of the aroma compounds, whereas humulene is much more subtle, but each compound will make its own contribution and together they make up the aroma profile of a particular hop variety.

During boiling and fermentation, large quantities of aroma compounds are lost, through evaporation and by numerous chemical transformations. However, given a particular hop variety and a fixed brewing regime, the hop character of the finished beer should be reasonably constant from brew to brew. Many beers are produced using a single hop variety, but others are brewed with two or more varieties, for a particular hop character. It is quite common for high α-acid hops to be added at the start of boiling ('first wort hops'), with aroma hops being added toward the end of boiling, or for aroma hop only brews, hops being added at the start and toward the end of the boiling. The aim here is to achieve an acceptable bitterness, whilst preserving an attractive aroma. This aim can also be realized by the use of isomerized hop oils, produced by low pressure steam distillation, at the conditioning stage, or by the dry hopping of cask-conditioned beers.

After harvesting, hops are dried and compressed packed into pockets or bags; many breweries use only hop cones to produce their beers, although relatively small bags of vacuum packed hops, with longer shelf lives, are available for small scale or home brewers.

However, because the compression packing ruptures many of the lupulin glands in the hop cones, oxidative degradations and other transformations occur during prolonged storage. Loss of α-acids, in particular, can be extensive (∼50%) after 12 months storage, even at low temperatures. In the extreme, the carbonyl side chains of α-acids (Figure 2.6.12) are oxidized to short chain carboxylic acids, which have definite cheesy notes. The loss of α-acids during storage, may be partially compensated by the survival of β-acids, in varieties with low α-acid:β-acid ratios (especially the aroma hops). Also, many of the hydrocarbon aroma compounds are oxidized on storage to oxygenated derivatives (Figure 2.6.12).

The appearance of hops flowers changes markedly with time. Aged hops lose much of their fresh green character and take on a much more yellow appearance; bags of such hops will often be found to have deposits of yellow or even orange-brown powder at the bottom. In general, for ordinary beer, the quality will not be as good as fresh hops, although lambic beer (Section 2.6.7) is traditionally brewed with old hops.

Recently, it has been discovered, using reversed phase HPLC with tandem mass spectrometric detection to determine stilbene phenols in six American hop varieties, that *cis*-resveratrol can be found only in aged hops, whereas *cis*- and *trans*-piceids, as well as *trans*-resveratrol were found in both fresh and aged (leaf and pelleted) hops (Jerkovic and Collin, 2009). Thus, the concentration of *cis*-resveratrol can be used as an indicator of hop freshness.

Some brewers use hop powders, pellets or extracts to supplement, or to replace entirely, hop cones in the kettle. Hop pellets do not deteriorate so rapidly as cones, especially if kept at 0–5°C. They give a higher degree of α-acid extraction/isomerization than cones and also simplify the use of a whirlpool in place of a hopback. Some hop pellets are made from mechanically enriched powder: these are especially useful in the dry hopping of cask-conditioned ales. Also, some pellets are made from hop powder containing ∼1% (w:w) of $Mg(OH)_2$ or $Ca(OH)_2$. They are known as stabilized hop pellets because a substantial α- and β-acids are converted to their anions, which are more resistant to oxidation. Hop extracts are also used by some breweries to supplement or replace hop cones in the kettle; this also aids whirlpool separation. Nowadays, many hop extracts are made by using supercritical carbon dioxide (at *ca.* 10 °C and 50 atm. pressure) as the extraction fluid, rather than organic solvents. These extractions can be fractionated: aroma compounds extract first, followed by β-acids and finally α-acids. The first (essential oil) fraction is a useful (and much faster) alternative to cones or pellets in dry hopping. Hop oil, produced by the low pressure (∼0.02 mm Hg) steam distillation of hop powder at 25 °C, can be added to bright beer in conditioning tanks and can also be used for the dry hopping of cask-conditioned beers.

During boiling, many of the resin and essential oil constituents decrease in concentration, presumably because of loss in vapors to the atmosphere, but some may also undergo isomerization or decomposition;

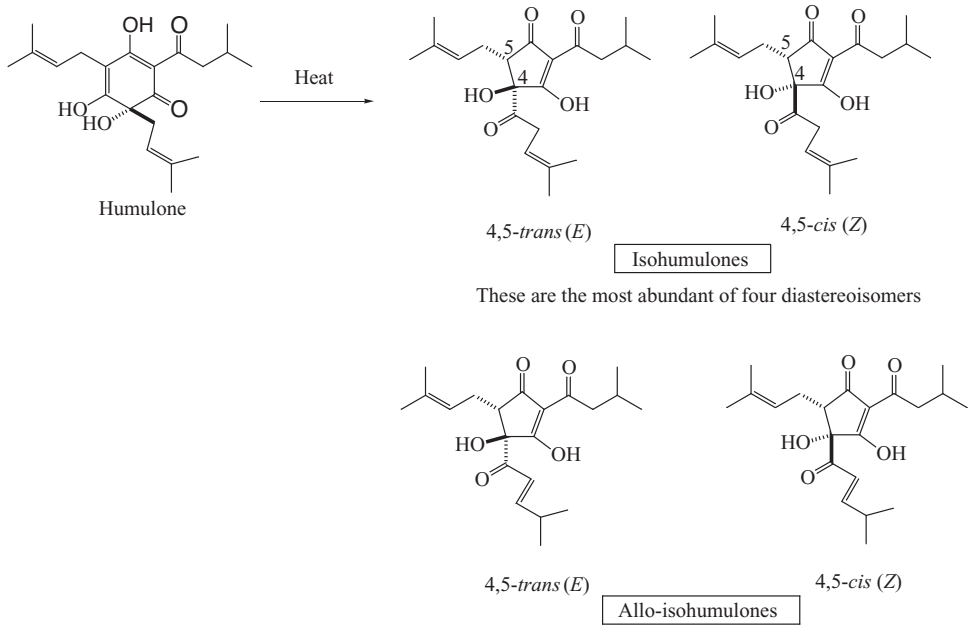

Figure 2.6.13 *Isomerization of humulone during boiling of hopped wort*

terpenoids and norisoprenoids are generally prone to rearrangement when heated under mildly acidic conditions. β-myrcene and linalool undergo a quadratic-like drop in concentration with boiling time, whereas the decrease in concentration of many others (such as β-caryophyllene, β-eudesmol, β-farnesene, geraniol, α-humulene, humulene oxide I and humulenol) with time follows a more linear curve (Kishimoto *et al.*, 2005). The norisoprenoid β-damascenone, on the other hand, was found to increase its concentration slightly during boiling and then markedly during the whirlpool step.

The principle isomerization is the conversion of α-acids to the much more soluble (and hence more potent flavoring) iso-α-acids, by a ring contracting rearrangement, as illustrated for humulone-isohumulone, in Figure 2.6.13. Many other isomerization products are formed (see Figure 2.6.13 for two examples) and other reactions, such as hydrolysis and oxidation occur in abundance (Hough *et al.*, 1982). Many of these conversions are incomplete at the end of the boil (∼1.5 h), particularly with respect to the formation of iso-α-acids, so that % utilization (≡ [quantity of iso-α-acids formed/quantity of α-acids used] × 100) is rarely greater than 40% when hop cones are used. Much higher utilizations are possible when isomerized hop extracts are added to fermented wort.

Consistent bitterness is an important commercial factor in brewing, especially for larger breweries with global markets. Bitterness may be expressed as International Bittering Units (IBU) and may be determined by standard solvent extraction/colorimetric methods (Section 4.4.3) of the European Brewing Convention (EBC) or American Society of Brewing Chemists (ASBC). Small scale brewers can estimate bitterness by calculating α-acid units from the mass of hop cones used in the brew and assuming 10% utilization, after 5 min boil, 20% after 30 min and 30% after boiling for 1 h. The final isomerized α-acid units can be converted to IBUs by multiplying by 75. Although this is only approximate, it is probably sufficiently close for most brews. Sensory analysis does not always relate to bitterness units in blind tastings and certainly the quality of hop flavor bears no relationship to IBUs (Fix, 1999c). Other flavoring agents, such as coriander (Section 2.6.13), can be added at the boiling stage, as can brewing sugars, syrups and caramel.

The second important aspect of boiling is the precipitation of proteins, polyphenols and lipids, such as long chain fatty acids and esters. Removal of proteins and polyphenols is important for haze stability in the finished beer (Section 2.6.9), whereas removal of lipids will reduce the risk of premature 'staling' (Section 2.6.12).

Very soon after application of heat, a brown scum forms on the surface of the wort. Once boiling starts, this scum breaks up into lumps that circulate within the boiling wort. It is known as 'hot trub.' The general opinion is that it is important to rid the hopped wort of the hot trub before the fermentation step. The three major methods for doing this are the hopback, the coolship and the whirlpool.

The hopback is a vessel with a perforated false bottom (rather like a mash or lauter tun), such that when the hopped wort is discharged into the vessel, the spent hop cones provide a filter bed (thickness ~15–60 cm), filtering both the hops and the trub. Some brewers provide a bed of fresh hops on the false bottom before discharge of the hot wort, thus aiding filtration and enhancing hop aroma. The hopback should not allow hop material through (this may block the plate heat exchanger during cooling) and filtration of a whole batch ('gyle') should take only 30 minutes or so, including a final rinse or sparge with hot liquor. Many larger breweries use hop separators that incorporate screw conveyers to compress the sparged hops before expulsion. A typical hopback is shown in Figure 2.6.8; it is located below the kettles.

The coolship is the simplest vessel for the removal of trub, and it (at least partially) cools the wort prior to fermentation. It is a long, wide, shallow vessel, usually of stainless steel. Typically hot wort is left in the coolship for about 3 h and is then pumped off the settled trub through plate heat exchangers. Less commonly, the wort is left to cool fully in the coolship (~12 h), before being transferred to fermentation vessels. Here, the risk of infection may be minimized by the use of sterile air ventilators. Coolships are still used in a very few UK breweries and some breweries in Belgium (see Section 2.6.7 and Figure 2.6.18) and southern Germany.

The whirlpool tank, pioneered by Molson Breweries in Canada, is now the most widely used vessel for the removal of hot trub, especially in breweries that use hop powder, pellets or extracts in the boil. Whirlpool tanks are insulated stainless steel vessels with a vent or stack. They are cylindrical vessels with floors that are flat, conical or inverted conical. The standard height to diameter ratio is between 0.3:1 and 1.5:1, with the most popular being around 0.7:1. The hot wort enters the tank at an angle of about 25° to the vertical wall, usually about one third tank height, at a speed of between *ca.* 3.6 and 15 m/s (~12–50 ft/s). The complex circulatory fluid movements ultimately impose a centrifugal force on the trub particles, which are deposited at the center of the tank floor. Larger breweries incorporate whirlpool tanks with vibrating screen filters and wort return pumps in order to minimize an otherwise substantial product loss; other breweries use combined kettle/whirlpools. These usually involve pumping the hot wort from the bottom of the kettle to just above the surface of the wort, tangentially. Alternatively, an impeller, driven by a high speed motor with a clutched gear drive, can be used to create the whirlpool.

Hot trub is composed mostly of proteins (derived from the malt), but it also contains some polyphenols (from hops and malt), lipids and minerals, such as Zn^{2+}. The presence of some of these substances in the wort can lead to haze and premature staling problems in the finished beer. In order to reduce the amount of potential haze forming substances in beer, some brewers add certain fining agents ('kettle finings') to the boiling wort. The most common of these is Irish Moss, dried fronds of the red marine alga, *Chondrus crispus*. Carrageenan, a polysaccharide consisting of α-D-galactose and other monosaccharides, with alternating 1→3 and 1→4 links, is responsible for the precipitating action of Irish Moss. Purified carrageenan can be used in place of Irish Moss. A substantial number of monosaccharide side chain OH groups are esterified with sulfate groups, hence carrageenan molecules are negatively charged. Haze active proteins carry an excess of positively charged sites (side chains of the α-amino acids arginine and lysine, mainly) at wort pH (~5), so when mixed with carrageenan, the protein colloidal sol flocculates. A danger of using Irish Moss or carrageenan is the possibility of removing foam stabilizing glycoproteins, along with the haze active proteins.

More recently, silica xerogel, polyvinylpolypyrrolidone (PVPP) and polyvinylpyrrolidone have been shown to be shown to be more or less specific in their interaction with polyphenols, thus removing, at the boiling stage, crucial haze forming agents, without affecting glycoprotein concentrations too much (Mitchell *et al.*, 2005; Leiper *et al.*, 2002).

The third benefit of boiling is the removal of unwanted volatile compounds, including organic sulfur compounds, many of which have low odor threshold values (OTV) (Section 4.7.3) and are unpleasant. A good many organosulfur compounds can be found in hop oils (Hough *et al.*, 1982b) and many others are degradation products of these and possibly of organosulfur pesticide residues (Section 5.10.2). A normal, vigorous and well ventilated boiling procedure should dispel most of these into the atmosphere. High protein malts (e.g. from six-row barley) can contain relatively high levels of *S*-methyl methionine (SMM), a nonvolatile α-aminoacid derivative. This compound undergoes thermal decomposition to the volatile dimethyl sulfide (DMS) (Figure 2.6.14), which has an unpleasant odor in all but the lowest concentrations. DMS is produced during the kilning of malt (Section 2.6.2), where most of it is vaporized. This is why the more highly kilned pale malts and darker roasted malts contain the least SMM and DMS. Similarly, during boiling, DMS formed from SSM is vaporized and, in well ventilated kettles, is dissipated into the atmosphere. Residual SSM can decompose to DMS after boiling has finished, if the cooling rate is low (as in coolships), thus allowing organoleptically detectable levels of DMS to remain in the beer, even after fermentation (which reduces DMS content). This is more likely if high SSM malts are used. In the brewing of pale ales, this is rarely a problem, as low SSM malts (e.g. from Maris Otter barley) are usually the choice. Also, a certain concentration of DMS in the beer is considered desirable for many pale lagers, which otherwise may taste rather insipid. Wort is relatively rich in flavor active Strecker aldehydes, such as 2-methylpropanal, 3-methylbutanal, 2-methylbutanal, benzaldehyde, phenylactetaldehyde and other compounds, such as methional, that can produce off flavors in stored beer (De Schutter *et al.*, 2008). A 60 min boiling period can reduce significantly the concentrations of many of these volatile components, although some, such as acetylfuran, β-damascenone (desirable for white wine, but not for beer), methional and phenylacetaldehyde, tend to persist at high levels after boiling (De Schutter *et al.*, 2008).

Cooling the hot wort is necessary before the yeast is added ('pitched'). For top fermentation (ales), pitching temperature should be >15 °C, whereas for bottom fermentation (lager) a temperature of around 8–10 °C is normally desirable. The original method was to transfer the wort to coolships. These are still used in a number of breweries, but usually in conjunction with heat exchange type wort coolers, which are much more rapid and much smaller cooling systems. The major disadvantages of coolships are the possibility of infection and the large space required. The main idea behind heat exchangers is the rapid cooling of wort caused by the transfer of heat, though a highly conducting wall, to a coolant fluid, often cold water. The resulting hot water (∼70 °C) can be used for the next mash or for cleaning purposes. Vertical shell type heat exchangers and tube coolers are still in use, but plate heat exchangers are by far the most common (Figure 2.6.8). Using cold water coolant, the wort will emerge from the exchanger at about 15 °C, suitable for top fermentation. A two stage cooling process, using firstly cold water and then water–ethylene glycol, is needed to bring the wort temperature down to 8 °C, ready for bottom fermentation.

During cooling of wort, further precipitation occurs; this is known as 'cold trub' or 'cold break.' It occurs throughout the yeast of the brewing process and consists of coagulated particles of protein–polyphenol complexes, which would otherwise cause haze (Section 2.6.9) in the finished beer. Some North American breweries encourage a good formation of cold trub, by running off the newly fermenting wort a day or so after pitching the yeast. Others cool the wort to ∼2 °C so that it forms slush ice. The temperature is then raised to 8–10 °C and the wort is run off the sediment into a fermenting vessel before pitching. However, recent research suggests that the presence of a small amount of trub particles has a beneficial effect on fermentation: trub-containing worts were observed to ferment more rapidly to lower final gravity, lower pH and higher

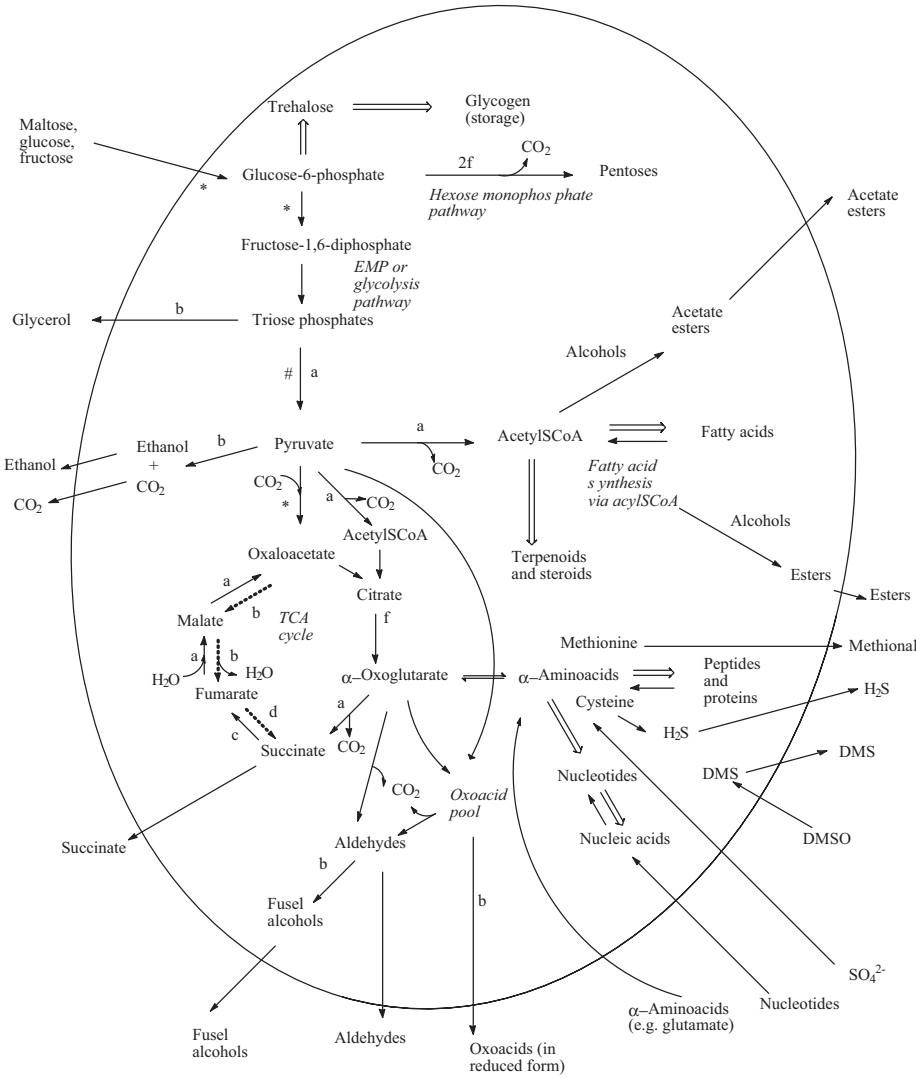

Figure 2.6.14 *Summary of anaerobic carbohydrate metabolism in yeast cell*

f $NADP^+ \rightarrow NADPH + H^+$

ethanol content compared with clarified worts under similar conditions (Kühlbeck *et al.*, 2007). It appears that the particulate nature of trub improved suspended yeast cell concentrations, allowing optimum fermentation efficiency and at the same time improved the evolution of CO_2 from the fermenting wort, thereby minimizing the inhibitory effect of CO_2 on yeast metabolism. The presence of lipid and mineral nutrients in trub may also play a part.

2.6.4 Fermentation

The classification of yeast and a general discussion of alcoholic fermentation performed by the various *Saccharomyces* species (including *S. cerevisiae* and *S. uvarum*) can be found in Section 2.2.1. Other fermentations – desirable and undesirable – are discussed briefly in Chapter 2.4, along with microorganisms that promote them. Consequently, the discussion here will focus on aspects of fermentation that are directly relevant to the brewer. Good accounts of the fermentation of beer wort can be found in other sources (e.g. Hornsey, 1999).

The two most widely used yeasts, ale and lager, belong to the same genus, but different species. Ale yeasts are classified as *S. cerevisiae* and are related to baker's yeast – indeed some of the indigenous beers of the Baltic Sea countries are still brewed with baker's yeast. Lager yeasts are described as *S. uvarum*, but until recently they were classified as *S. carlsbergensis*, since they were first isolated and characterized by E. C. Hansen of Carlsberg Brewery in the 1880s. Within these broad classifications are many strains (varieties) that have different physiological and biochemical characteristics, often differing in subtle ways. Brewers strive to maintain their own healthy stocks of yeast for consistent brewing and many breweries have colonies of their yeasts propagated and preserved at yeast depositories (yeast banks), such as the National Collection of Yeast Cultures, at Norwich, UK.

Yeast strains easily mutate and the brewer is wise to carry out various tests on yeast stocks and to generally keep a watchful eye on yeast performance (such as attenuation behavior) and on certain physical characteristics (such as flocculation and sedimentation). Flocculation of yeast cells during fermentation of wort is a genetic characteristic that can be used to monitor yeast performance.

Brewing yeasts fall into three broad categories, although some authorities (Hough *et al.*, 1982c) quote no less than seven. The categories are strongly flocculating (sedimentary), powdery and nonflocculating and all three types are used in brewing. These terms describe the yeast's sedimentation tendencies: strongly flocculating yeasts form sediments at an early stage in the alcoholic fermentation whilst nonflocculating types remain largely in suspension, even toward the end of fermentation.

Yeast flocculation occurs via cell surface interactions involving mannans (poly-D-α-mannose), sugar-binding proteins (known as flocculins or lectins, or more specifically zymolectins) and Ca^{2+} ions. The mannans are present on the cell surface at all times, but it is believed that in flocculent yeast strains, zymolectins are expressed by the FLO genes when these are activated by lack of nutrients toward the end of fermentative activity.

The mechanism is not fully understood, but is believed to involve zymolectins binding to mannans on the surface of neighboring cells, leading ultimately to the formation of flocs of aggregated cells. Because of reduced surface to volume ratio, the flocs sediment more rapidly than individual cells. A study of cell surface hydrophobicity, charge density and zymolectin density of flocculent and nonflocculent strains of *S. cerevisiae* showed a positive correlation between cell surface hydrophobicity and flocculation ability (Jin *et al.*, 2001). The role played by Ca^{2+} ions is unclear, though it has been shown that Pb^{2+} competes reversibly with Ca^{2+} and inhibits flocculation. Using a fluorescent avidinfluorescein isothiocyanate (Avidin-FTC) microscopy probe, it was observed that zymolectins were not fixed to the cell walls in the presence of Pb^{2+} (Gouveia and Soares, 2004). This suggests that although the Pb^{2+} ions (much larger than Ca^{2+}) bind to the calcium ion binding sites of the lectin molecules, the resulting protein conformations are unable to bind to the cell surface mannans.

More recently, yeast mitochondrial activity was shown to be higher in flocculent yeast strains than in nonflocculent types (Strauss *et al.*, 2007). The same authors also showed, for the first time, cell surface protuberances to be composed of hydrophobic '3-OH oxylipins,' produced in mitochondria by incomplete β-oxidation of long chain fatty acid lipids. Scanning electron microscopy showed oxylipin binding sites and protruding osmiophilic layers, sometimes extending from one cell wall to another. Thus yeast flocculation may be mediated by oxylipin interactions as well as mannan–lectin–Ca^{2+} interactions.

A change in a brewery's yeast flocculation behavior may be a sign that the strain is mutating or that cropping is not being performed properly. For example, some brewery yeasts are composed of several strains with varying degrees of flocculation behavior. Repeated 'bottom cropping' and repitching can rapidly lead to domination by sedimentary strains and hence to a change in the brewery's yeast characteristics (see also Section 2.6.6). The brewer has unintentionally selected the sedimentary strains. Suspended yeast cells give the best attenuation and the lowest levels of undesirable by-products (Fix, 1999d), so brewers who use strongly flocculating or sedimentary strains regularly rouse the fermenting wort. The subjects of flocculation and sedimentation will be considered once more, in terms of top- and bottom-fermentation (Section 2.6.5 and 2.6.6).

Attenuation is the drop in the wort specific gravity caused by fermentation, as sugars are converted to ethanol, carbon dioxide and other products. The specific gravity (SG) or relative density of wort is the density (in g/ml) of the wort divided by the density of water, which is taken as 1.000 g/ml at 17.5 °C. Thus, wort with a specific gravity of 1.044 is 4.4% heavier than an equal volume of water. The temperature must always be specified when quoting specific gravities and if it is not the same as the reference temperature of 17.5 °C, then a correction must be applied, although this is very small if the temperature difference is less than 5 °C. A convenient and widely used way of expressing this is the 'gravity' scale – the above wort is said to have a gravity of 1044 (relative density $\times 10^3$). Another widely used scale, based upon the correlation of the wort specific gravity with those of sucrose solutions of accurately known % (w:w) concentrations, is known as the °Plato (°P) scale. This scale thus expresses extract as the percentage of sugar in the wort by weight. The corresponding scale for wine is °Brix. Other scales, such as °Beaumé scale exist, but the gravity and Plato scales will be used here. Specific gravity and °Plato can be measured by a hydrometer that is calibrated in both scales: single scale hydrometers are also used, in which case the °Plato instrument is known as a saccharometer. Digital density meters have become popular in recent years; they are robust, inexpensive, easy to use and accurate (Section 4.6.3).

Although fermentable sugars make a big contribution to the specific gravity of wort, a contribution also comes from nonfermentable solutes, such as certain carbohydrates, amino acids, proteins, minerals and others, hence the majority of beers possess final gravities above 1000 (typically 1004–1008). Apparent attenuation depends on the drop in gravity that occurs during fermentation and is given by Equation 2.6.1.

$$\%\ \text{apparent attenuation} = \frac{(\text{OG} - \text{FG})}{(\text{OG} - 1000)} \times 100 \tag{2.6.1}$$

where OG is the original gravity and FG the final gravity.

Bottom fermenting (lager) yeasts are generally high attenuators (~80%), whereas top fermenting (ale) yeasts tend to be moderate attenuators (~77%), although there is some overlap in performance of the two species. If attenuation is below 75%, then the yeast may be considered to be underperforming and some attention may be necessary. More detail on attenuation can be found in Sections 2.6.5 and 2.6.6.

The ethanol content of beers is expressed as % ethanol v:v (≡ % alcohol by volume or %ABV) or less commonly as % ethanol w:w. The apparent concentration of ethanol produced by the fermentation of hexose sugars can be calculated from the stoichiometry of the Gay Lussac equation, $C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2$. However, the actual concentration of ethanol will be a little less than the calculated concentration because of 'losses'; some of the sugars are used in metabolic pathways that do not produce ethanol (Chapter 2.2). Hence, relating % ethanol content (w:w) (A) of a beer to the original and final gravities must take this into account.

Both the EBC and ASBC provide methods for brewers and customs officials to relate A to both the original extract (OE) and the residual extract (RE), expressed in °Plato. The methods involve distillation of the beer: A is determined from the specific gravity of the distillate and RE from the specific gravity of the residue (Section 4.6.3). Thus OE and RE relate to original and final gravities, respectively. The ASBC formula is

given by Equation 2.6.2.

$$OE = (2A + RE) - F \tag{2.6.2}$$

where F is a correction factor that can be found from tables supplied by the ASBC.

Provided fermentation performance is satisfactory and 'true to type,' a brewer will recover and store substantial quantities of yeast from a current brew for fermentation of future brews. For this, a reliable recovery method and storage system is required, one that collects a representative sample of the yeast colony and maintains it in a viable state for a period of time, without contamination by wild yeasts or bacteria. This important aspect of brewing will be dealt in more detail separately for top and bottom fermentations (Sections 2.6.5 and 2.6.6 respectively). Here, the major characteristics of wort fermentation will be discussed, starting with the mixing of wort and yeast.

Pitching the yeast is the act of adding yeast to the wort, often as a slurry in water or fresh wort. In the early stages of fermentation (but not in later stages), yeast cells need oxygen, so the wort and/or the yeast should be aerated. Pitching should result in wort with about 16×10^6 live yeast cells per ml, after thorough mixing. This corresponds to a pitching rate of about 0.2 kg per hl ($\equiv$100 l). Higher pitching rates may lead to yeast autolysis (Section 2.2.1) and the production of off flavors (Cahill *et al.*, 1999). In some breweries, notably in the USA and Canada, the wort is run off the cold trub into another vessel, some 24 h after pitching. In this case, the initial fermentation vessel is known as a settling tank or starter tank. The majority of breweries, however, carry out the fermentation of a batch of wort in a single vessel.

The early part of fermentation is characterized by a relatively gentle evolution of CO_2 and the formation of a fine, white or cream foam on the surface of the wort. Attenuation is very slow at this stage, as the yeast cells are more involved in various preparatory functions than in alcoholic fermentation itself. Initially, yeast cells synthesize various steroids (such as ergosterol and zymosterol), using their own reserves of glycogen to provide the energy for such syntheses. These sterols increase the permeability of the cell walls and plasma membranes, allowing transport of nutrients from the wort that will be required for alcoholic fermentation. These nutrients include certain sugars, NH_4^+, α-amino acids, phosphates, metal ions and various growth factors, such as biotin. Transport in the opposite direction also occurs and certain permease enzymes can carry specific solutes (sugars, α-amino acids and ionic species, such as NH_4^+, K^+, phosphates and SO_4^{2-}) through the membrane in both directions. This is called active transport. Some permeases are constitutive (they have a permanent presence), whereas others are induced only in the presence of a specific substrate. On the other hand, proteins, sterols and carbohydrates embedded in the plasma membrane aid the diffusion of certain other solutes, such as fatty acids; this is called aided transport. Simple diffusion may account for the transport of other solutes.

The major sugar of wort is maltose, followed by maltotriose and glucose. The presence of maltose induces yeast cells to synthesize a maltose specific permease enzyme, maltopermease and a corresponding hydrolytic enzyme, maltase. When all the maltose is used up, synthesis of both these enzymes ceases and hence they are known as induced enzymes or proteins. If the wort possesses substantial levels of D-glucose and D-fructose (e.g. from sucrose adjunct), as well as maltose (from malt), then synthesis of maltopermease and maltase is repressed or inactivated. Hence glucose and fructose are selectively transported by constitutive (permanent) permeases into the yeast cells to be metabolized in preference to maltose. Induced permeases are synthesized toward the end of a cascade process that starts with interactions between the inducing substrate (e.g. maltose) and molecules on the outer membrane surface. This probably signals the synthesis of more cyclic adenosine-5′-monophosphate (cAMP) and the production of a cAMP-protein complex that interacts with the yeast genome and signals the DNA transcription to produce the enzymes (e.g. maltopermease and maltase).

Yeast cells utilize the glycolysis or Embden–Meyerhof–Parnas (EMP) pathway (Section 2.2.9) to convert hexoses to pyruvate, acetyl-coenzyme A (acetyl-SCoA or $CH_3COSCoA$), CO_2 and other products.

Acetyl-SCoA enters the TCA cycle, where the acetyl unit is oxidized completely to carbon dioxide. Some of the energy released by these catabolic processes is used to constitute ATP (from ADP), NAD^+ (from NADH) and other coenzymes from their reduced forms. Likewise, some energy goes into the synthesis of essential molecules, including proteins, fatty acids and nucleic acids. Thus, the initial fermentation stage is characterized by yeast cell growth and reproduction.

Wort normally contains a plentiful supply of nitrogenous nutrients in the form of small peptides, α-amino acids and ammonium salts, the second of which is known as the free amino nitrogen (FAN) content of the wort. About 40% of the peptides are hydrolyzed to amino acids that are then metabolized, the remainder survive and may contribute to either haze formation or foam stability. Amino acids are transported through the yeast cell membranes by specific permeases that act in a specific order. Amino acids with acidic side chains (ASP, GLU), amide side chains (ASN, GLN), basic side chains (ARG, LYS), hydroxy side chains (SER, THR), plus MET are absorbed first and largely consumed within the first 24 h of fermentation. Amino acids with aromatic side chains (PHE, TRY, TYR) plus ALA, ammonia and GLY are generally absorbed most slowly, and the hydrophobic amino acids (HIS, ILEU, LEU, VAL) are absorbed at intermediate speeds. Proline, one of the most abundant amino acids of wort, is absorbed and secreted during fermentation, with no net absorption.

Both the nature and concentration of amino acids present in the wort can have a strong influence on yeast metabolism, affecting the speed of fermentation and the levels of by-products, such as diacetyl and 2,3-pentanedione (Lekkas *et al.*, 2007). Thus, added methionine prevented absorption of hydrophobic aminoacids, slowing down fermentation. Also, diacetyl and 2,3-pentanedione concentrations were lower than in control fermentations. On the other hand, supplementation of the wort with lysine enhanced the fermentation rate by stimulating absorption of amino acids and ammonia. Higher levels of diacetyl and 2,3-pentanedione were also evident after fermentation, probably because of much less time being available for natural yeast removal of these compounds (see Figure 2.6.15).

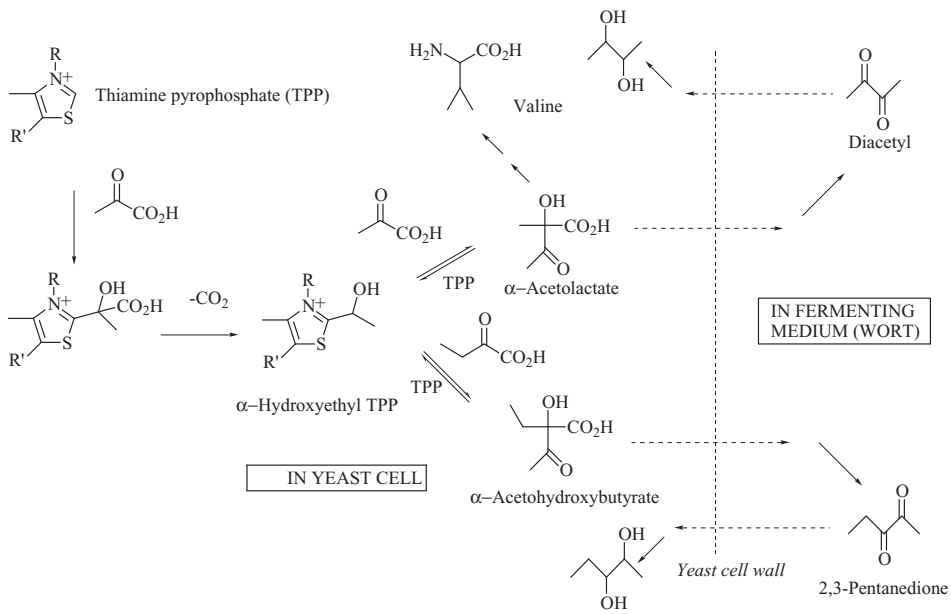

Figure 2.6.15 *Formation of α,β—diketones, competitive valine formation and reabsorption. Reactions are given by →, transport by ⇢*

The second stage of fermentation is the anaerobic carbohydrate metabolism stage (Section 2.2.9), in which sugars are converted to ethanol and carbon dioxide. It is characterized physically by a more rapid attenuation, vigorous evolution of CO_2 and formation of thick creamy white foam on the surface of the wort. The growing mass of yeast cells faced with limited oxygen supplies, switch their main metabolism to the anaerobic alcoholic fermentation pathway. Instead of converting pyruvate to acetyl-SCoA ready for entry into the TCA cycle, the bulk of the pyruvate is now used to produce acetaldehyde and ethanol; a much shorter route that gives a more rapid return of energy when oxygen supplies are low. The TCA cycle works only partially during anaerobic fermentation – as far as succinate and α-ketoglutarate, both of which are fermentation end products, like ethanol. In the earlier part of alcoholic fermentation, when the yeast is still growing and reproducing vigorously, the synthesis of essential biomolecules is still important. The consequent excess of NADH is used up, in part, by the reduction of dihydroxyacetone phosphate to glycerol phosphate. The latter is dephosphorylated to glycerol, which is excreted as another end product. The major features of the anaerobic metabolism of hexoses and other substrates are shown in Figure 2.6.14. For clarity, some steps and intermediates have been omitted. Also, the many relationships that exist between this pathway and others, both degradative and synthetic, are given in outline only. The other fermentation end products, such as aldehydes, carboxylic acids, esters, ketones (including 1,2- or α,β-diketones, like diacetyl) and sulfur compounds are considered next.

All the organic acids of the TCA cycle are excreted by yeast cells, the oxoacids pyruvic acid and α-oxoglutaric acid (from the 'oxoacid pool') being excreted as their reduced forms, lactic acid and 2-hydroxyglutaric acid, respectively. In beers brewed principally with *S. cerevisiae* or *S. uvarum* (the great majority), succinic acid is the major organic acid end product, but others, such as citric acid and malic acid, may contribute to the overall taste and/or flavor. The aforementioned acids are all hydroxy acids; simple carboxylic acids, such as acetic acid and higher fatty acids, probably arise from hydrolysis of acetyl-SCoA and higher analogs of the fatty acid synthesis pathway. Also from the oxoacid pool are the α,β-diketones, diacetyl and 2,3-pentanedione, produced from pyruvate and oxobutyrate, respectively, by reaction with hydroxyethyl thiamine pyrophosphate, in the presence of acetohydroxy acid synthetase. The acetohydroxy acids are excreted into the beer where they are oxidatively (nonenzymatically) decarboxylated to α,β-diketones (Figure 2.6.15).

Both these diketones have low OTVs, giving buttery or butterscotch aromas that, like many aroma compounds, can be unpleasant if too concentrated, yet attractive at low levels. Both diketones can be reabsorbed by the yeast, where they are reduced to nonodorous 1,2-diols (glycols). However, yeast strains differ in their abilities to both produce acetohydroxy acids (and hence α,β-diketones) and to reabsorb and reduce the diketones (Fix, 1999e). Also, fermentation conditions are important: rapid fermentation at higher temperatures and overexposure to air favor conversion of acetohydroxy acids to diketones, but a relatively warm resting time after fermentation favors reabsorption and reduction of the diketones (Fix, 1999e).

The oxoacid pool is also the source of many aldehydes (by decarboxylation) and fusel alcohols (by reduction of aldehydes). Esters mostly appear to be derived from the fatty acid synthesis pathway: acetyl-SCoA gives acetate esters with alcohols produced from the oxoacid pool, and other acylSCoA molecules (differing by two CH_2 units) give higher esters.

Yeast cells need sources of sulfur for the synthesis of proteins (i.e. using the sulfur containing amino acids CYS and MET) and certain coenzymes, such as biotin, coenzyme A, glutathione, lipoic acid and thiamine. The preferred source is methionine (MET), but even SO_4^{2-}, sulfate, tends to be metabolized (reduced) to S^{2-} via HSO_3^-, whence it is converted to CYS and MET. Many of the sulfur compounds found in beer are derived from malt and hops rather from alcoholic fermentation. Thus DMS, important in lager brewing, but not in ale brewing, comes mostly from SSM in malt (Section 2.6.2), but a certain amount originates from the enzymatic reduction of dimethyl sulfoxide (DMSO), also from malt sources. Hydrogen sulfide (H_2S) is produced by dehydrosulfuration of cysteine by the enzyme cysteine desulfydrase.

Examples of brewery fermentation and yeast propagation equipment can be seen in Figure 2.6.16.

After the primary fermentation, yeast activity can continue at a subdued level in unpasteurized and unfiltered or aseptically filtered beers being matured in tanks or casks, in preparation for serving on draught. The same applies to maturing bottle-conditioned beers. Metabolism of certain oligosaccharides occurs, increasing the quantity of CO_2 produced and hence increasing the foaming ability. However, yeasts also excrete proteinase A, which degrades some of the foam enhancing beer proteins and thus is thought to compromise foam stability after an extended maturation time (Shengli *et al.*, 2009). At the same time, the presence of β-glucans in the beer can compromise haze stability. Although there is today much consumer resistance towards the use of genetically modified materials in brewing (see Section 1.3.13 for one example), Shengli *et al.* (2009) have produced a recombinant *S. cerevisiae* strain that exhibits reduced proteinase A activity and increased production of β-glucanase. The strain was prepared by insertion of gene bg1S into the PEP4 locus by homologous recombination, and the resulting beer fermented by this strain showed greater foam stability and lower β-glucan levels than beers brewed with control strains.

2.6.5 Top Fermentation

Not so very long ago top fermentation reigned supreme. Today, bottom fermentation dominates brewing, but top fermentation is still used to brew a very wide range of beers in the UK, Ireland, Belgium, Germany, the USA and some other countries (Section 2.6.13). Top fermentation yeasts are often called ale yeasts and the beers that are produced using them are known as ales. Top fermentation is characterized by the substantial crop of yeast that collects at the head as fermentation proceeds.

Well aerated wort at about 15 °C is pitched with yeast, usually as a slurry with wort. If the yeast strain is of the highly flocculating type, further aeration and regular agitation will be necessary during the course of fermentation. This can be done using paddles, or more likely these days by pumping fermenting wort from the bulk and discharging it as a spray over the surface (see Figure 2.6.16 for examples).

During fermentation, at the height of the yeast's metabolic activities, the temperature of the wort may rise to 20 °C or higher. In order to control this temperature rise, fermentations vessels are fitted with internal tubes or coils (attemperator coils) through which cold water is circulated. Toward the end of fermentation, it is common practice to lower the temperature of the wort to 14 °C, or even as low as 11 °C in some breweries, for certain beers. Some ale breweries use a refrigeration unit to lower the temperature of the newly fermented beer to around 5 °C lower temperatures in order to encourage yeast suspension and help clarification.

In ale breweries, removal and preservation of some of the yeast from the head is an important part of the brewer's job. Provided fermentation is proceeding normally, yeast removal may be carried out several times, by skimming, using paddles or 'parachute' devices or by suction. Most brewers use the crop from toward the end of fermentation for repitching, as this tends to have the best attenuation ability. The yeast crop is transferred to a holding vessel (a 'yeast back'), from where it can be used directly in the next brew or it can be pumped and collected on a sheet filter press.

The yeast-entrained ale ('barm ale') – a substantial volume in large scale fermenters – can be added back to the main batch, sometimes after pasteurization, in order to minimize infection. The yeast mass is discharged from the filter into trays which are kept in the refrigerator at 2–4 °C. Repitching can be performed using either the pressed yeast alone or as a slurry with water or wort.

The course of a typical fermentation is shown in Figure 2.6.17(a), for ale wort with an original gravity of 1040. The final gravity will depend on both the attenuation characteristics of the yeast and the ratio of fermentable to nonfermentable sugars, which is determined largely by the mashing regime (Section 2.6.2). For the example in Figure 2.6.17, the fermentation temperature may be controlled from 15 °C at pitching, through 20 °C at the height of activity, to 11–14 °C toward the end of fermentation. Production of esters and

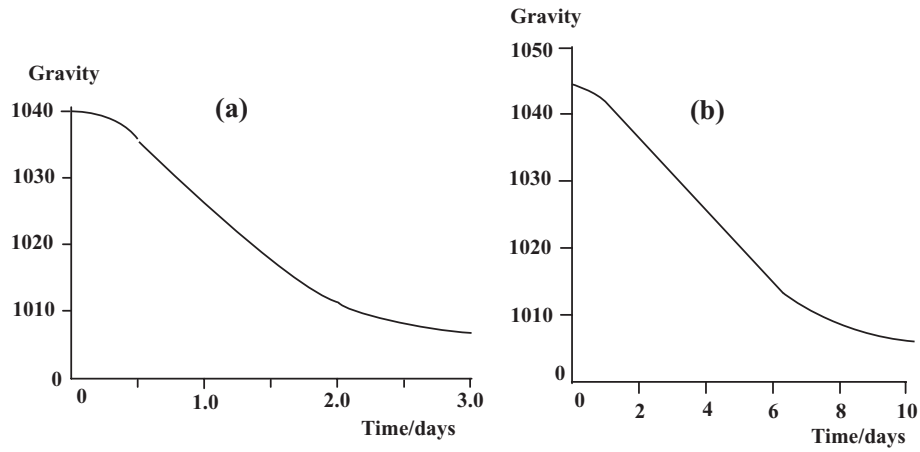

Figure 2.6.17 *Course of typical beer fermentations: (a) top fermentation at 16 °C; (b) bottom fermentation at 9 °C*

fusel alcohols reach maximum values and pH reaches a minimum value after about four days of fermentation (Hough *et al.*, 1982c).

Many top yeasts possess the phenylacrylic acid decarboxylase (Pad 1) enzyme that is able to decarboxylate phenolic acids of the hydrocinnamic acid type (such as *p*-coumaric acid, ferulic acid and sinapic acid) during fermentation (Vanbeneden *et al.*, 2008). These compounds with high odor threshold values (OTV; Section 4.7.3) are thus converted to the much more flavor active phenols (4-vinylphenol, 4-vinylguaiacol and 4-vinylsyringol, respectively), which contribute much to the aroma and flavor of many top-fermented beers, including German wheat beers, Belgian white beers, saison beers and other ales (Section 2.6.13). These volatile phenolic flavor compounds are also produced in much smaller quantities during high temperature brewing operations such as boiling and pasteurization.

Typical final gravity is around 1008 (2 °Plato), of which there will be about three degrees of gravity (∼0.7 °Plato) is still fermentable. Most of the fermentable sugar at this stage is maltotriose, which is only slowly and partially fermented by ale yeasts (Section 2.6.6). Hence, beers destined for cask conditioning are normally racked at this stage, so that a slow secondary fermentation can occur in the cask, concurrently with maturation and clarification. At the point of racking, there will still be about 0.5 million viable yeast cells per ml of beer, quite enough for secondary fermentation. To accelerate clarification, isinglass finings (Section 2.6.9) are added at the time of racking and dry hopping (Section 2.6.3) may also be carried out. The casks are bunged and may be kept at the brewery for a few days before dispatch to the trade, where several more days will pass before tapping and serving. Thus, it is not unusual for cask-conditioned ales (especially those of low OG, say < 1040) to be consumed within three weeks after pitching. However, many cask ales of medium to high OG (say 1045–1085) benefit from much longer maturation/secondary fermentation periods and some breweries perform initial conditioning in tanks before racking into casks. Some larger breweries, especially those that use powdery yeast strains, subject their new or 'green' beer to discharge centrifugation whilst racking into casks. This gives sufficient numbers of viable yeast cells (∼0.5 million per ml) to perform a secondary fermentation in cask, but insufficient to cause haze problems.

Most breweries rack a certain volume (in many breweries the major volume) of new beer into conditioning tanks, where maturation/conditioning occurs at 10 °C (or even lower temperatures) for many days or even weeks, depending on the OG and style of beer. This beer is usually destined for pressure casks (kegs), bottles or cans (Sections 2.6.9 and 2.6.10) and is known as brewery-conditioned beer.

Traditional ale fermentation vessels are usually square and sometimes circular in plan view and, in small to medium breweries, range from 2 to 4 m deep, typical capacities being between 150 and 400 hl (~90–240 barrels or ~3240–8640 gallons). Microbreweries and brewpubs may have vessels of only 4–40 hl capacity and of course larger breweries need much larger vessels. Many ale breweries still have open fermentation vessels, but many others use closed vessels (see the examples in Figure 2.6.16). The main advantages of closed vessels are lower risk of microbiological (and other) contamination and ease of cleaning with in-place cleaning systems. On the other hand, they are more expensive than open vessels and are not so easily cleaned manually. All vessels possess attemperator tubes or outer jackets for control of temperature and some older vessels were fitted with a skimming device known as a 'parachute.'

Modern top fermentation tanks tend to be less shallow than traditional ones and are conical based, rather than flat bottomed. The extremes of these are the cylindroconical vessels, whose heights are typically 3–4 times their diameters. They can be purchased in capacities from 1 hl (or less) to well over 1000 hl – suitable for the smallest and largest breweries. Typically, they are made of cold rolled stainless steel and the medium to large size vessels are lagged and fitted with height adjustable jackets for temperature control. Several advantages are claimed for cylindroconical vessels, including reduced costs, economy of space, increased throughput, excellent drainage, (and hence good yeast separation and minimum beer loss), improved (and more consistent) beer quality, better yeast hygiene and ease of in place cleaning. The largest vessels are located outside the brewery walls, although these are more likely to be used for bottom fermentation (Section 2.6.6); such vessels can be seen at Budweiser plants in the USA, Coors plants in the USA and UK and the Hite plant in South Korea, amongst others (see Figure 2.6.18). The very strong circulatory flow that occurs in fermenting wort when contained in cylindroconical vessels ensures effective yeast suspension, thus maximizing attenuation. Cylindroconical vessels are especially useful for breweries whose yeasts are of either highly flocculant or sedimentary types, although powdery yeasts can be used, especially if centrifuges are available during racking.

Other modes of top fermentation exist which have highly specialized vessels. Probably the best known of these is the Burton Union system, originally practiced at many breweries in Burton-on-Trent itself and at some others in the English Midlands. At the time of writing (2008) only the Marston, Thompson and Evershed brewery in Burton-on-Trent still operates the Burton Union system, although the Firestone Walker brewery in California also uses an adaptation of this system for some of its beers (Figure 2.6.16), on a smaller scale. The Burton Union system is basically a cask fermentation method with an ingenious way of removing excess yeast. It is especially useful with nonflocculating yeast, which were once the norm with Burton brewers. Two sets of 12 casks are arranged back-to-back on a framework fitted with upper and lower troughs and attemperator tubes. Traditionally, these are oak casks of about 7 hl (5 barrel) capacity, and each of these is connected by a pipe to its two nearest neighbors. Each cask has a swan-necked tube attached to its upper bung hole. Wort is fermented in a conventional vessel for 24–26 h, after which time it is transferred to each cask of the Union. As fermentation continues, excess yeast (with some beer) is discharged through the swan-necked tube into a slightly inclined trough situated above the rows of casks. The trough is held at a lower temperature than the casks and so the yeast tends to sediment in there, whilst the beer runs down the incline into a collecting vessel or 'feeder,' where it is returned to the casks via 'side rods.' At the end of fermentation, nearly all the yeast has been transferred to the top trough and the clear green beer is run via the bottom trough into a 'racking back' vessel, ready for racking into casks.

The Burton Union system maintains excellent yeast stocks and gives clear beer – it probably played a big part in the once unique character and high consistency of Burton beers. Against this, the system is expensive to install and maintain, it uses considerable space and is not easy to clean.

Another specialist vessel for top fermentation is the Yorkshire Square, originally made of stone (Yorkshire Stone Square), but nowadays constructed of slate or stainless steel. Unlike the Burton Union system, the Yorkshire Square works best with highly flocculating strains of yeast. The vessel has a lower and upper

compartment, separated by an overhanging deck (Figures 2.6.16 and 2.6.19). The deck connects the two compartments by a central flanged hole (∼60 cm in diameter) and by off centrally situated thin unflanged pipes ('organ pipes'). The bottom compartment is filled with wort and the yeast is pitched (as a slurry) into the top compartment. As fermentation proceeds, yeast with beer rises through the central hole. The yeast tends to deposit on the deck, whilst the beer drains through the 'organ pipes' into the bottom compartment. Frequent rousing is needed, often by pumping (Figures 2.6.16 and 2.6.19). At the end of fermentation, the yeast can be skimmed off the deck and the beer is racked from the bottom compartment.

2.6.6 Bottom Fermentation

The big majority of the world's beers are produced by bottom fermentation and the family name for the beers thus produced is lager. The greatest differences between top and bottom fermentation are the yeast species, fermentation temperatures and length of maturation/conditioning, although there is much variation in both types of fermentation from brewery to brewery and also between different beer styles produced in the same brewery. Bottom fermentation is carried out by *Saccharomyces uvarum*, which gives much less of a yeast crop in the head and readily forms a sediment, especially toward the end of fermentation and at the low temperatures that are generally used for bottom fermentation.

In the brewing of traditional lagers, well-aerated wort at 7–14 °C is pitched with yeast (as a slurry) at much the same rate as in the brewing of ales. To keep the temperature within the above limits throughout the primary fermentation, an efficient cooling system is required, supplied by a single refrigeration unit serving all, or by several smaller units serving a smaller number of fermentation vessels, or even a single vessel. The brewer of bottom-fermented beers, like his ale counterpart, needs to collect and store viable and representative crops of yeast for repitching. Yeast from bottom fermentation tends to be collected from the middle layers of the sediment. The wort/yeast slurry is subjected to treatment using an oscillating sieve and is then washed with cold water to remove less dense debris and bacteria. The yeast is stored under water at 2 °C in refrigerated rooms, but only a portion is used for repitching. It is usually pitched as a slurry with water or wort.

The course of a typical bottom fermentation is shown in Figure 2.6.17(b), for a lager wort of OG 1045. Compared with a typical top fermentation (Figure 2.6.17(a)), it is of longer duration, with the major activity ('high krausen') occurring around four days after pitching, as opposed to 1–2 days for ale. Ester formation is

about the same as for top fermentation, but fusel alcohol formation is much less. Also, bottom yeasts lack the phenylacrylic acid decarboxylase (Pad 1) enzyme (Section 2.6.5) and so only very small amounts of flavor active phenols, such as 4-vinylphenol, are formed. Indeed, such flavors although highly prized in certain top-fermented beers, are regarded as off flavors when they occur in Pilsner and other pale lagers.

In traditional lager brewing, the beer is racked into lagering tanks whilst some 4 degrees of gravity (1° Plato) of fermentable extract remains and there is in suspension at least 1 million viable yeast cells per ml of beer. Lagering is often carried out for several weeks at 4 °C in traditional breweries, especially if the brewery uses a powdery yeast strain. This is to ensure that the yeast sedimentation is extensive and that secondary fermentation occurs slowly and incompletely, leaving some unfermented extract as residual sweetness. Alternatives to this involve the use of a centrifuge as in top fermentation (Section 2.6.5) or the use of 'krausening' techniques. In the latter, a powdery yeast is allowed to ferment the wort right out and then freshly fermenting wort (at the 'krausen stage' and brewed with flocculating yeast) is added at 5–10% of the volume of the lagering beer. Agitation is used here to make sure that no more than about 1° Plato of fermentable extract remains at the end of the lagering process. Closed fermentation vessels are the norm for lager brewing, but rectangular open vessels are still used in a number of Bavarian, Czech and Slovak breweries. In order to maintain low fermentation temperatures, traditional vessels are fitted with cooling jackets on the walls, or with internal attemperator tubes (or panels), depending on the vessel dimensions. Smaller rectangular vessels of, say, up to 500 hl capacity (~5 m × 5 m × 2.75 m depth) need only cooling jackets. Closed vessels are generally favored because of more efficient refrigeration: about 15% less energy is needed to cool a closed vessel, with respect to an open vessel of the same dimensions.

The largest breweries, such as Budweiser and Coors, use large outdoor vessels that have elaborate cooling, pressure relief and in place cleaning systems (Figure 2.6.18). A single tank, known as a 'Unitank,' is often used for both primary fermentation and postfermentation treatment, whether this is lagering (secondary fermentation/maturation) or 'accelerated ageing' (see next). A common procedure is to allow secondary fermentation in a number of tanks at 4 °C and then when almost complete, the beer is given a coarse filtration before being transferred to a second set of tanks held at 0 °C. Some breweries use tall cylindroconical vessels (Section 2.6.5), which can also be used for lagering, because a strongly sedimenting yeast in the base cone is well compressed and can be run off, leaving comparatively clear beer above. However, many breweries that have powdery yeasts use two such vessels per batch – one for primary fermentation, the other for lagering – with a chiller and centrifuge device connecting the two.

Fermentation characteristics of yeast cropped from the cones of two large (2000 hl) cylindroconical fermentation vessels showed variability according to how the yeast was cropped, indicating extensive heterogeneity within the crop (Powell *et al.*, 2004). Environmental conditions (ethanol, gravity, pH and temperature) within the cone were found to vary widely. It was considered that successive cropping and pitching with a specific portion of the cone may lead to selection and possibly to fermentation inconsistency.

For several decades now, lager brewers worldwide have sought to cut the primary fermentation and particularly the lagering time for batch fermented beers. This, of course, is in response to increasing economic pressures for increased throughput (see also Continuous Fermentation, Section 2.6.8). Indeed, by fermenting the wort completely (e.g. by using a powdery yeast) at the higher end of the bottom fermentation temperature scale (~14 °C), removing the yeast by filtration and then lowering the temperature to 0 °C (either slowly or rapidly), the beer undergoes stabilization and ageing (with no secondary fermentation) over a period of 3–21 days. This is sometimes called 'accelerated ageing.' Lagers can thus be produced on the same time scale as ales.

After lagering or ageing, most lagers are filtered (Section 2.6.9) and some (especially those destined for bottle or can) are pasteurized, either in bulk ('flash pasteurization') or in bottle ('tunnel pasteurization') (Section 2.6.9).

It is important for the brewer to be sure of the identity of the yeast: is it a bottom yeast or is it really a top yeast that has been accidentally supplied to brew the next batch of lager? DNA fingerprinting techniques will give

the answer, but there are many other simpler and more accessible methods that the brewer or brewery analyst can apply to the yeast himself. The simplest method is incubation: ale yeasts will grow on an agar medium at both 25 °C and 37 °C, whereas a lager yeast will grow only at the lower temperature. Similarly, bottom yeasts will ferment a liquid medium containing the disaccharide melibiose (α-Gal(1-4)α-Glc) (as witnessed by evolution of CO_2 and drop in pH, monitored by methyl orange indicator), whereas top yeasts will not.

2.6.7 Other Fermentations

Here, an account is given of the fermentations that are used to produce some specialized, but traditional styles of beer. Although the focus is on features of fermentation, other aspects of brewing, such as the grains used, mashing and boiling will also be considered, in order to give a balanced account.

Lambic is one of the most distinctive styles of beer. It originates in Pajottenland, a small area to the southwest of Brussels – although versions of it are brewed in other countries (Section 2.6.13). Lambic beer is brewed from grist of about 70% malted barley and 30% unmalted wheat. A decoction mashing method (Section 2.6.2) is used to take the wort through a series of temperature rests, ranging from 45 °C to 85 °C. Such a regime gives a cloudy, highly nutritious wort that is suitable for the wide variety of microorganisms that will ferment it. In the boiling stage (which at 6 h is exceptionally long), aged, dried hops (never fresh ones) are used. This is to give low iso-α-acid levels, so that antimicrobial activity is limited and the desired proliferation of a number of yeasts and bacteria can occur. Also, high concentrations of polyphenols from these old hops give the finished beer a certain astringency and the presence of short chain fatty acids (from the degradation of α-acids in old hops – see Section 2.6.3) may give some cheesy notes to the finished beer. Typical ingredients of lambic beer from Lindemans Brewery can be seen Figure 2.6.20.

The 'hopped' wort (pH ~5.3) is transferred to shallow wooden or steel coolships (see Figure 2.6.18) that are open to the atmosphere. Here, sufficient microorganisms are able to grow as the wort cools, so that a 'spontaneous fermentation' begins when the wort is transferred to fermentation vessels, often wooden casks that have been used previously for lambic beer production. The microorganisms are abundant in the whole fabric of the brewery, as well as in the air above the coolships. Fermentation is dominated initially by various *Enterobacter* species – *Escherichia coli*, *Klebsiella aerogenes* and several others (Hornsey, 1999b).

Figure 2.6.20 *Lambic beer ingredients at Lindemans Brewery. Malted barley, unmalted wheat, aged hops and microbes. Photo taken by LucBohez and used with kind permission of Lindemans Brewery*

Here, a slow fermentation of glucose and other sugars to a range of acids (including lactic acid), ethanol and carbon dioxide causes a drop in pH and (after about four weeks) makes the wort more suitable for the growth of various *Saccharomyces* species, especially *S. cerevisiae*, whereupon a slow alcoholic fermentation commences. This lasts for up to 12 weeks and produces a range of products already discussed in Section 2.6.4.

Toward the end of alcoholic fermentation, acetic acid bacteria become active, thus lowering pH further by the production of a small quantity of acetic acid. At roughly the same time, *Lactobacillus* and *Pediococcus* species begin to proliferate, their fermentations producing lactic acid, diacetyl, acetoin and various esters, with further lowering of pH (now less than 4). Following this, fermentation is taken over by *Brettanomyces bruxellensis* (initially) and *B. lambicus* (later) for about 6 months. These fungi produce a range of short chain fatty acids (cheesy notes) and a number of esters. On the other hand, certain unwanted odorous compounds, notably isoamyl acetate, diacetyl and DMS, produced in earlier fermentations, are reduced to lower levels during the *Brettanomyces* period of fermentation.

A 'young' lambic beer is around one year old, whereas pure ('old') lambic beers are three years old and are usually served on draught. They are flat, hazy and often rather tart drinks (pH $\sim$3.3), with ester-like and cheesy aromas. Much lambic beer is used to make a blend (Gueuze) and flavored beers (Faro and fruit lambics). Gueuze is a blend of young lambic and old lambic in a 2:1 ratio. It is normally bottled, whence it undergoes a secondary fermentation (bottle conditioning). Dextrinase enzymes, of microbiological origin, in the old lambic hydrolyze unfermented α-glucans (dextrins, Section 2.6.2) of the young lambic and the resulting sugars are fermented by the *Saccharomyces* species from the young lambic, thus producing CO_2 in the bottle. Faro is old lambic with brown sugar added. The many fruit lambics (lambic beer with fruit pulp or syrup added) are produced as bottle-conditioned beers. After sufficient ageing, the bottle-conditioned lambic beers possess a fine mousse, more like Champagne than typical beer foam.

Steam beer, now sometimes known as Californian common beer, is a hybrid beer, neither ale nor lager. Steam beer wort is fermented with lager yeasts at temperatures more typical of top fermentation ($>$12 °C) in shallow stainless steel vessels that more resemble coolships than conventional fermentation vessels. The large surface to volume ratio encourages dissipation of the heat of fermentation into the air and at the same time facilitates settling of the yeast when fermentation begins to subside. Because the lager yeast does not produce a thick head that protects the beer from airborne contaminants, fermentation is best carried out in rooms that possess a positive air pressure from an input of sterile filtered air at ambient temperature.

Formerly, constant skimming of the surface was needed to remove contaminants, but nowadays in a modern sterile fermentation room, only limited skimming is necessary, mainly to remove cold trub. The bottom-fermenting yeasts for the production of steam beer require special properties: in particular, they need to remain in suspension during the course of fermentation, form a sediment rapidly when fermentation is coming to an end and produce acceptable flavors at temperatures far in excess of those used in normal lager fermentations. Not all lager yeasts are suitable for this, but competent strains can be obtained from companies such as Wyeast, yeast depositories or by cultivation of the yeast deposit in bottle-conditioned steam beer. Largely because of the hybrid nature of the fermentation, modern steam beers display characteristics of both ale and lager: some fruity ester notes, but with a clean finish. For further description and a brief account of the history of steam beer, see Section 2.6.13.

Just as modern steam beer takes its name from a process that died out in the 1950s, German Dampfbier is a revival of a style that was of minor but significant importance in mainly the southeastern part of Bavaria (in a region called der Bayerischer Wald) but which disappeared in the early twentieth century. Unlike Californian steam beer, Dampfbier is a true top-fermented beer, where traditionally, wheat beer (Weizen) yeasts perform the fermentation of the all barley malt wort at high temperatures, even for ale ($>$21 °C). This gives the beers a strong, fruity-spicy, phenolic character, not unlike wheat beers and some Belgian saison ales (Section 2.6.13). The word Dampf (steam, in English) comes from the observation of a continuous plume of mist above the surface of the wort at the height of fermentation, caused by vigorous yeast action at such high temperatures.

2.6.8 Modern Methods of Fermentation

High gravity brewing is practiced in a number of large breweries in the USA and Canada, originally to save space and to brew large volumes of beer using fewer vessels. In theory, dilution to normal gravities ('breaking down') can be carried out anywhere between the end of boiling and packaging, but the most usual time is after fermentation, before lagering or maturation, because this demands least extra space and vessels, except for maturation vessels. Typically, worts of OG 1072 (18 °Plato) are prepared and fermented with special high alcohol tolerant yeasts. The resulting beer will have an alcohol content similar to a Moselle wine (~8% v:v). The beer is then diluted with pH adjusted, deoxygenated, sterile filtered water to the required percentage ethanol level and is then treated in a similar way to standard beers (Sections 2.6.5 and 2.6.6). Apart from more economical use of space and vessels, high gravity brewing has several advantages: it has lower energy consumption, lower liquor, water (for washing) and effluent costs, and gives a more efficient production of ethanol. Additionally, by dint of different dilution ratios, use of brewing colorants, and use of isomerized hop extracts and other flavor agents, it is possible to produce widely differing beer styles from a single batch of high gravity wort.

High gravity brewing also allows a higher proportion of unmalted gelatinized adjuncts from the cereal cooker to be included in the mash, which is an important consideration for the North American beer market. In any case, it has been known for many years that all-malted barley high gravity brewing is difficult because of lautering problems, decreased yeast performance (high initial osmotic pressure and later, high alcohol levels) and poor head retention (Section 2.6.9). With respect to yeast performance, pilot scale fermentations of very high gravity wort have shown that increased yeast inoculum size, increased free rise timing and temperature, and optimized oxygenation reduced fermentation time by 34% (Jones *et al.*, 2007). This improved fermentation profile was consistent over three successive inoculations. A key factor is oxygen supply: 25 ppm of oxygen delivered to the wort 12 h after inoculation reduced fermentation time by 33%.

All the beer production processes discussed so far are of the batch fermentation type: indeed batch fermentation still dominates the brewing industry. However, in the 1950s, Morton Coutts of the (now) DB Breweries in New Zealand developed a continuous fermentation method to produce normal strength beers. It is still in use today (2008) and is probably the only large-scale continuous fermentation process in full operation.

The method, of the 'cascade' type, involves a continuous supply of wort to a series of fermentation vessels, with continuous recycling of yeast and fermented beer back to the fresh wort. A continuous flow of 'green' beer is thus produced at the opposite end of the process (Figure 2.6.21). The boiled wort is chilled to 0 °C and is continuously fed into the holding vessel (HV) where, on its way, it is aerated and warmed to about 10 °C. In the holding vessel, it is mixed with already fermenting wort from fermentation tank 1 (FT1). As fermentation proceeds, some yeast from FT2 and the separating tank (ST) is also recycled to HV. FT1 is the major (larger) fermentation vessel, with a residence time of over 30 h. By the time the beer reaches FT2, fermentation vigor is diminishing and a significant degree of attenuation has been achieved.

The fermenting beer in both tanks is stirred, keeping much of the yeast in suspension and thus maximizing attenuation and minimizing production of off flavors. Residence time in FT2 is at least 12 h. Next, the beer passes to ST, where the yeast forms a sediment in the conical base. The beer is run off the sediment into warm (~14 °C) maturation tanks, where it stands for two days. This is essentially a 'diacetyl rest': at this temperature and pH (~4.2), α-acetolactate is secreted by the yeast cells into the beer, where it is converted to diacetyl (Section 2.6.4). Diacetyl is then absorbed by the yeast cells and converted to the flavorless 2,3-butanediol.

The yeast from ST is partially recycled and partially washed (with recovery of beer washings) and then sold to health companies. As in any closed fermentation system, excess CO_2 can be collected, purified and then either sold to gas suppliers or returned to the matured beer to increase the level of carbonation. The advantages of this continuous fermentation process are related to more efficient use of space and vessels, high

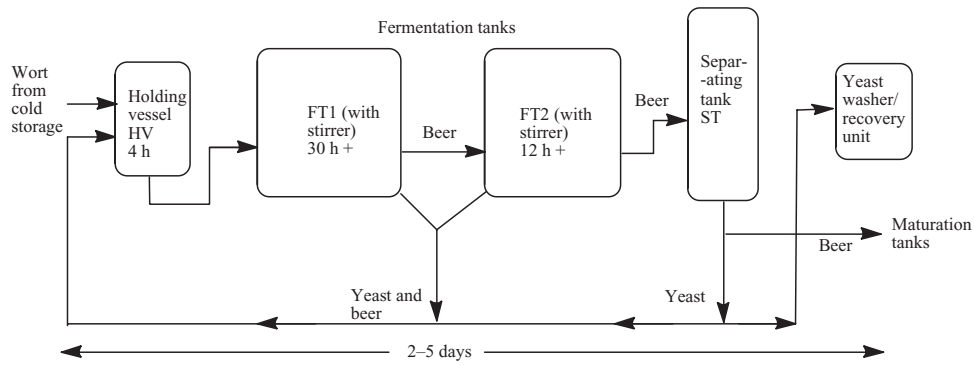

Figure 2.6.21 *Plan of cascade type of continuous fermentation process (based on Dominion Breweries (DB) system, New Zealand). Not drawn to scale*

(but variable) throughput via a rapid fermentation, lower costs and higher beer consistency. Also, it is fully automated and there is reduced wastage due to the lack of stop-start operations. The major disadvantage is that the highest hygiene standards are needed to prevent microbial infection; the CF system can be run for months and during this time it is impossible to carry out any cleaning of vessels.

Continuous fermentation methods using 'bioreactors' that contain colonies of immobilized yeast cells have been adapted to beer production on both pilot and industrial scales (Iserentant, 2003; Brányik *et al.*, 2004). These processes differ from the DB CF system in that a continuous flow of wort is exposed to yeast cells entrained or immobilized on some solid support, instead of continuous recycling of yeast and continuous injection of fresh wort. The solid support ('carrier') includes spent barley grains, sintered glass rings, wooden chips, biopolymers and synthetic polymer gels. Designs of bioreactors vary considerably – from packed bed reactors, through gas lift types to fluidized bed reactors. So far (2008), the application of immobilized cell CF to the regular production of standard beer types has been quite limited, because of a number of problems. These include operational problems (CO_2 removal, excess yeast production, irregular flow and clogging), problems with yeast performance (changed cell physiology, cell ageing and excess diacetyl production) and unexpected additional costs (usually due to unstable operation and breakdown). Also, the lack of a suitable continuous wort production process (Section 2.6.2) has held back this type of CF; wort needs to be supplied in batches, thus increasing the risk of infection. Contamination by *Obescumbacterium proteus* and *Pantoa agglomerans* (both of which produce high levels of DMS) have been the most problematic for immobilized yeast CF. Nevertheless, versions of these processes have been used in continuous beer fermentation, continuous maturation and alcohol-free beer production (Branyik *et al.*, 2004) (see Chapter 2.13). A gas lift type of reactor for continuous fermentation is shown in Figure 2.6.22. Such a reactor would contain yeast immobilized on spent grains, fermenting wort and gases, and is designed to run smoothly with high solid (biocatalyst) loading, with low shear rate and low mass transfer resistance (Brányik *et al.*, 2004; 2005).

Immobilized yeast reactors find greater application to rapid conditioning of beer, especially with respect to yeast mediated reduction of diacetyl to concentrations below its OTV. Green beer, produced in cylindroconical vessels or by a continuous process, is first heated (under anaerobic conditions) to 90 °C for 5–10 minutes to ensure all α-acetolactate is converted to diacetyl. After cooling to ~15 °C, the beer is passed through several reactors, so that during a contact time of around 2 h, all diacetyl is transformed to acetoin and other flavorless products (see Figure 2.6.15). Such a process has been used for nearly 20 years by Synebrychoff (Finland). The yeast is supported on Spezyme GDC® (Cultor, Finland), which is essentially diethylaminoethyl cellulose on a cross linked polystyrene support particles, with TiO_2 incorporated to increase the particle density. It is

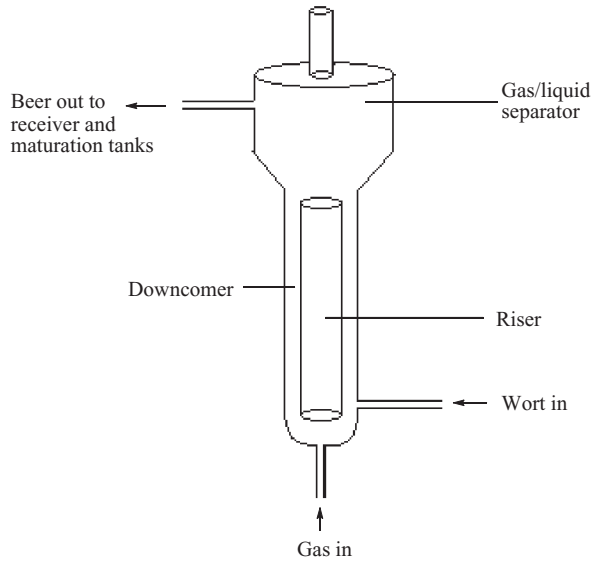

Figure 2.6.22 *Simplified diagram of a gas lift reactor for continuous fermentation of beer using immobilized yeast cells. Not drawn to scale. Based on Brányik* et al. *(2004) and reproduced with permission from the American Society of Brewing Chemists*

claimed that a good quality beer can be produced by this method in just 24 h. The heat treatment confers no flavor or color changes and indeed denatures proteins that might interfere with foaming characteristics of the finished beer (Hornsey, 2003).

It is of interest to note that a combination of a high gravity wort and a continuous ethanol fermentation on a multistage packed column bioreactor system can be used to produce liquors with over 15% ABV for conversion to industrial ethanol, by distillation or other techniques (Bai *et al.*, 2004).

2.6.9 Beer Treatment: Fining, Filtration and Pasteurization

Beer treatment is aimed at achieving and maintaining the perceived commercially attractive characteristics of a beer from the time it leaves the brewery to the point of dispensing and consumption. The main qualities of concern are flavor, clarity, foam quality and lack of microbial contamination, so beer treatments seek to provide flavor stability, haze stability, foam retention stability and microbiological stability. The major reasons for nonbiological beer instability have been discussed by Stewart (2004).

Apart from certain wheat beers (Section 2.6.13) and some other speciality products, like Lambic beers (Sections 2.6.7 and 2.6.13), commercial brewing is heavily orientated toward the production of clear, haze-free beers. There is also a bias toward brewing beers that display a substantial and persistent foam (or 'head') when served. Since proteins are involved in both haze formation and the production of foam, these two topics will be treated together in this section.

There are two basic kinds of beer hazes: temporary and permanent hazes. Beers that have a low tendency to throw hazes are known as 'haze stable' and the processes that are used to minimize hazes are called 'beer haze stabilization.' The various steps that the brewer can take to minimize hazes have been discussed

(Sections 2.6.2 and 2.6.3). At least one authority (Fix, 1999f) maintains that beer brewed properly from the best ingredients should clear spontaneously, given sufficient time, and that permanent beer hazes are caused by brewing faults. Nevertheless, in reality, hazes do occur and the clarification methods of fining and filtration are important aspects of commercial brewing. Haze is expressed in terms of ASBC 'formazin turbidity units' (FTUs), with 0–100 indicating brilliant clarity, 100–200 slightly tarnished clarity, 200–300 translucent haze and >400 turbidity. The corresponding EBC ranges are 0–1.5, 1.5–3.0, 3.0–4.5 and >6, similar to the nephelometric turbidity units (NTU) used to express wine clarity (Section 4.6.3).

Chill haze is the most common type in beer; it is temporary in the sense that the haze appears on cooling the beer, but disappears again on warming. The greater the haze stability, the closer to 0 °C the beer can be brought before chill haze appears. Chill haze is formed by interactions between proteins and polyphenols; the former are derived mostly from malt, whereas the latter come from both malt and hops. Polyphenols are molecules that possess several phenolic OH groups. They can be simple phenolic acids (like gallic acid and ferulic acid) flavonoid phenols (like catechin) monomers (like ferulic acid and catechin) and oligomers (like proanthocyanins) (see Section 5.8.6, Figure 5.8.6). Many monomeric phenols, especially anthocyanins and catechins, polymerize at beer pH to give high molecular weight oligomers (dimers, trimers, etc.) that are variously known as proanthocyanidins and tannins (tannoids), depending on their monomer make up and degree of polymerization. Polyphenols of the catechin family (see Section 5.8.6, Figure 5.8.7), and various oligomers are particularly active in forming colloidal complexes with proteins from malted cereals, especially hordein (barley) and gliadin (wheat).

These proteins are rich in proline (PRO) residues, which are α-helix and β-sheet disruptors and are thus more likely to be found in 'random coils' – relatively flexible polypeptide chains in the proteins. Although these proteins are denatured (unfolded) during the early parts of the brewing process, they will refold to some extent, though probably never retrieving their native structures. The bonding holding the complexes together is probably mostly weak hydrogen bonding (~10–20 kJ/mol per bond) that can be broken at higher temperatures (say, ~25 °C), thus explaining the disappearance of chill haze on raising the temperature.

This kind of model also explains why chill haze formation is maximized when polyphenol and protein concentrations are roughly equal; reducing either polyphenol or protein content (but not both) therefore reduces haze formation. However, chill haze appears to be a frequent precursor of permanent haze, the transformation occurring over a period of time. It is possible that oxidation of catechol (1,2-dihydroxybenzene) units of polyphenols, catalyzed by an enzyme of the polyphenol oxidase family, occurs to give *o*-benzoquinone (1,2-benzoquinone) units which can then react with amino acid residues of proteins to give much stronger covalent bonds, bonds that cannot be broken by raising the temperature by 20 °C. Certainly, 4-methyl-1,2-benzoquinone has been shown to react with proline methyl ester to give 4-(2′-carboxymethyl-1′-pyrrolidinyl)-5-methyl-1,2-benzoquinone (Rizzi, 2006) (Figure 2.6.23). Beers that have been produced by strict low oxygen regimes (Sections 2.6.4 and 2.6.10) suffer least from this problem.

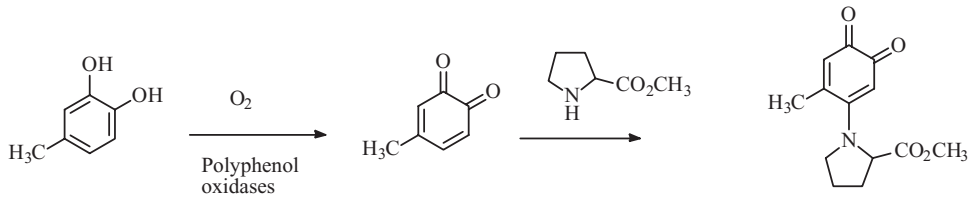

Figure 2.6.23 *Reaction of 4-methyl-1,2-benzoquinone (4-methylcatechol) with proline methyl ester as a model for formation of covalent polyphenol-protein bonds in permanent haze formation. Rizzi (2006)*

Table 2.6.4 *Beer hazes, their causes and some possible remedies*

Haze type	Causes	Remedies and Comments
β-Glucan	Poor malt, unsympathetic mashing and high sparging temperature	Improve malt and mashing/sparging programme. Use of GM malt. Add β-glucanases
Starch	Insufficient mashing and/or oversparging	Modify mashing/sparging regime
Bacterial	Infection	Discard. Find source of infection and improve hygiene
Yeast	Low flocculating yeast strain	Centrifugation, fining, filtration
Protein/polyphenol (including oxidation)	Colloidal complexes of proteins and polyphenols. Made permanent if polyphenols are oxidized by by O_2 and oxidases	Temporary chill haze: fining with PVPP or silica materials, filtration. Permanent haze after oxidation: no remedy. Minimize O_2 uptake at all stages post-fermentation. Lower sparge temperatures minimize extraction of polyphenols. Use of GM modified barley eliminates polyphenols.

Permanent hazes are essentially caused by brewing faults, as outlined in Table 2.6.4. All the haze types displayed here can be avoided in the brewery by using sound, hygienic brewing techniques, along with good quality materials and in the absence of 'market abuse' (rough handling, storage at high temperatures, etc.). In the last case, poor treatment of the beer by the trade can lead to hazes in otherwise sound beer.

Foam is an important attribute of most beers and it plays no small part in consumer acceptance of beers. Many beer drinkers prefer a thick, stable 'head' on their beer that clings to the glass (known as 'lacing') as they drink the beer. Hence, foam production, retention and lacing are all important features by which foams can be characterized. Foam formation indicates the actual quantity of foam (thickness of the head) that is present on the surface of the beer. For beers brewed with high cereal worts, there should be no trouble in producing adequate foam. Retention is a measure of the ability of the foam to take up a stable network of bubbles, thus allowing an extended lifetime. Lacing is a measure of the foam's ability to stick to the walls of a clean glass. Deficiencies in foaming characteristics can be rectified by the use of additives (e.g. hydrolyzed albumen or propylene glycol alginates) in the later stages of brewing.

Large glycoproteins (or protein–carbohydrate complexes) are thought to play a major role in the foaming characteristics of beer. They are composed of hydrophobic high molecular weight proteins, to which are attached long hydrophilic carbohydrated chains. Bubbles are formed as gas is released from solution in the beer. These interact with glycoproteins to form spherical micelles, in which the protein part of the molecules are found at the gas/liquid interface, whereas the carbohydrate chains point outwards and are essentially associated with solvent and solute molecules (Figure 2.6.24). The carbohydrate chains form hydrogen bonds to large numbers of water molecules and other hydrophilic molecules, which are carried to the surface as the bubbles rise. This results in a thick, moist head. If the carbohydrate chains are long enough (just how long has yet to be determined), the viscosity of the liquid between the bubbles is high enough to keep the liquid within the foam matrix, resulting in a moist, stable foam that clings to the surface of the glass.

Other foam enhancing molecules (that is, apart from high molecular weight glycoproteins) include dextrins (α-glucans), β-glucans, iso-α-acids and melanoidins. They probably work by increasing the liquid viscosity or by forming more extensive hydrogen bonded networks amongst the hydrophilic chains.

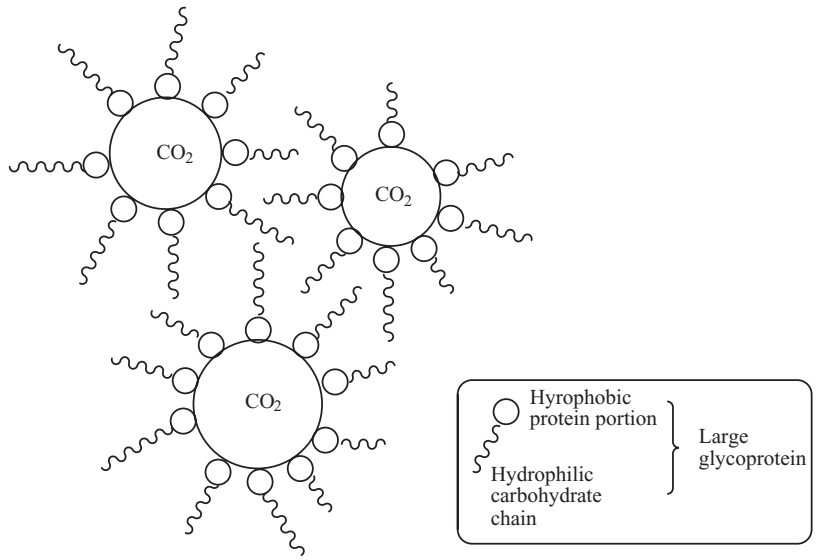

Figure 2.6.24 *Spherical protein micelles at the gas-beer interface (two-dimensional section). Water and other polar molecules are retained in the hydrophilic regions between the carbohydrate chains*

Molecules that compete with large glycoproteins for micelle formation, but which do not have extensive hydrophilic chains, adversely affect foam retention, because lack of hydrogen bonding lowers the viscosity of the entrained liquid between the bubbles. Such molecules include hordeins, lipids (oils and fats), like triglyceride esters, steroids and phospholipids, small glycoproteins and most detergents. This explains why the foam on beer may collapse if the drinker is eating oily or greasy food at the same time. Also, detergent molecules compete for micelle formation, which explains why the use of improperly rinsed glasses (containing detergent residues) leads to poor head retention. Similarly, at the brewery, washing of all equipment needs careful and thorough rinsing. Certain cereals, such as oats, possess relatively large amounts of lipids, explaining why beers brewed with a high oat cereal bill often lack head retention. At the other extreme, wheat contains comparatively high contents of large glycoproteins and β-glucans, which give wheat beers, or beers with a high wheat content, good head retentive properties.

Ethanol has a marked effect on the foaming properties of beers: too little ($< 1\%$ ABV) and too much ($>10\%$ ABV) tend to give beers with low foaming abilities. The optimum positive effect appears to be between 3% and 6% ABV. The role of ethanol here is a complex one and is probably related to hydrogen bonding, viscosity and solubility of CO_2. For example, in beers of ABV $>10\%$, there is enough ethanol to both decrease the viscosity of the liquid entrained between the bubbles and to reduce the solubility of CO_2, thus leading to early release of the gas and drier, low retention foam.

Chill hazes can be eliminated (or at least minimized) by the use of fining agents (discussed next) and /or ice stabilization, whereas yeast hazes can be removed by fining agents, centrifugation or filtration, and often by a combination of these. Since chill hazes are caused by colloidal protein–polyphenol complex formation, the addition of fining agents that selectively adsorb either proteins (protein-active agents) or polyphenols (polyphenol-active agents), will actively restrict the formation of these hazes. Fining agents (often called flocculants) act by adsorbing (chemically bonding) haze forming molecules onto their particle surfaces, thus removing them from the beer (or wort, in the case of kettle finings). Brewers are undecided on whether haze active proteins and foam active proteins are the same or different entities. Hence, it is possible that

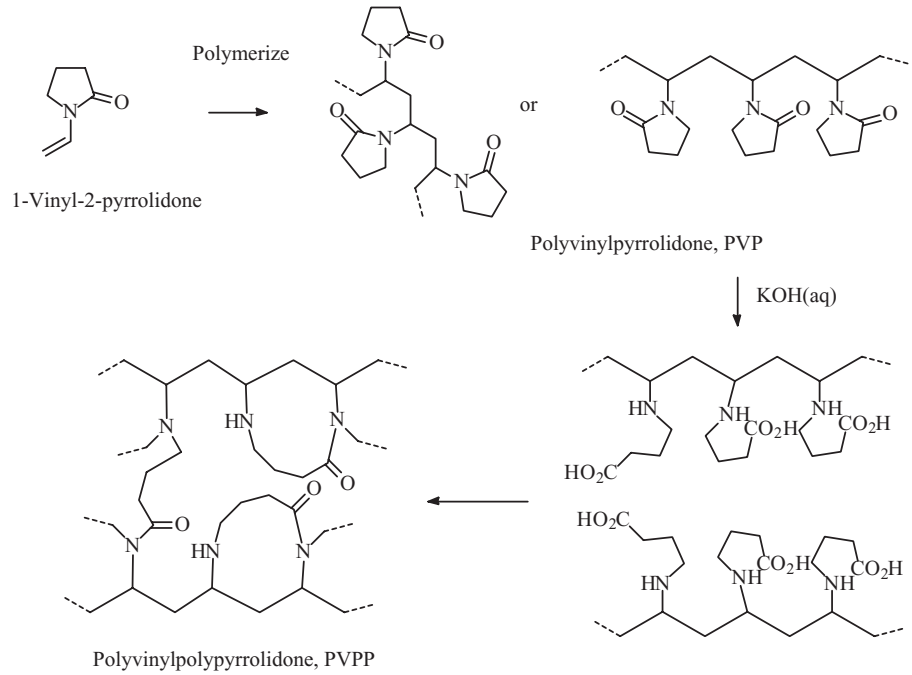

Figure 2.6.25 *Simplified scheme for formation of PVP and PVPP from their monomer*

the use of protein active fining agents (such as bentonite, carageenan and tannin) may reduce the foaming capability of the beer; this would be regarded by many consumers as a serious mark against quality. Certainly, overuse of kettle finings based upon Irish moss is known to adversely affect the foaming characteristics of beer (Fix, 1999g). Hence, a better approach to haze removal may be to use polyphenol active agents. These include polyvinylpolypyrrolidone (PVPP), polyvinylpyrrolidone (PVP) and various silica-based materials, such as hydrogels and xerogels. The consensus of opinion appears to be that removal of polyphenols (whose concentrations are too low to influence flavor) is more desirable than the removal of proteins (which may adversely affect foaming ability) (Mitchell *et al.*, 2005). Two of the most widely used polyphenol active agents are PVPP and silica bound PVP (or PVP–silica composite), typically added at a rate of 50 g/hl. These are more polyphenol specific than silica materials alone, with PVPP being somewhat the more effective of the two (Mitchell *et al.*, 2005). PVPP exists under a large number of trade names or pseudonyms, including Albigen A, Kollidon, Plasdone, Polyclar, PVP-K60, Subtosan and Vinisil. Figure 2.6.25 illustrates representative structures of PVP and PVPP, and their chemical formation from monomers. It can be seen that both polymers (PVP being essentially linear and PVPP being cross linked) possess numerous hydrogen bonding groups: NH (donor) and C=O (acceptor). It appears that these polymers form stronger hydrogen bonds and other attractive interactions with polyphenols rather than with proteins, especially foam active proteins. Silica-based adsorbents predate PVPP and PVP as fining agents by a number of years. They are selective toward haze active proteins, leaving foam active proteins largely unaffected. The surface of silica gel particles is covered with silanol (Si-OH) groups that are sensitive, with regard to ionization, to the pH of the medium. This, in turn, influences the extent (or even type) of silica–haze active protein interaction. Thus, removal of chill haze using silica adsorbents has been found to be greater at pH 3.8 and less at pH 4.4 (Siebert and Lynn, 2007).

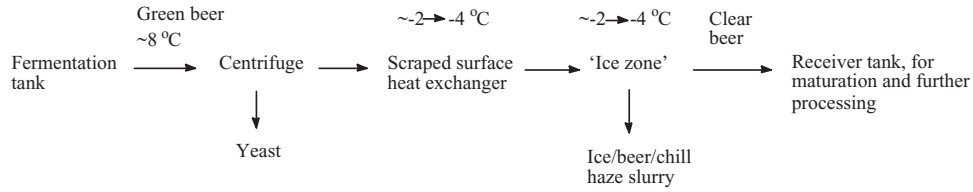

Figure 2.6.26 *Outline of ice stabilization process. Based on the Ice Process of Labatt Breweries, Canada*

Filtration of the beer from the fining residues (the 'floc') is often carried out using silica gel or diatomaceous earth (kieselguhr) cake filters to trap the residue particles.

Ice stabilization has become popular in recent years, as a nonadditive type of beer clarification method, especially when used in conjunction with filtration and/or centrifugation. The ice beer process is typified by the régime used by Labatt Brewing Co. of Canada (Figure 2.6.26). Very small ice crystals (<5% of the total volume) are formed at –2 to –4 °C. The haze active proteins are entrained in and between these crystals and are eventually left behind when, after settling, the cold beer is pumped off the ice/beer slurry in the receiving tank. A similar method can be used to enhance the alcoholic content of beer (or any other alcoholic drink; it is really a form of distillation) as in certain German strong lagers (Eisbock) (Section 2.6.13).

Yeast haze is a natural consequence of the production of traditional unfiltered new ('green') beer. Suspended yeast cells provide a reducing environment for beer, which endows it with high flavor stability, by protecting it against oxidation (Section 2.6.12). Consequently, clarification (especially the total removal of yeast cells) tends to be carried out when the beer is almost ready for packaging. A well made beer should clarify itself of yeast haze during conditioning and maturation, given sufficient time, a method that is used by many European breweries, some American microbreweries and even some British microbreweries, but most brewers in the UK use finings. Isinglass finings are made from the dried swim bladders of certain fishes, nowadays mostly species of catfish or drumfish from subtropical waters. They are shredded, flocked or ribboned and then soaked in dilute solutions of tartaric acid and sulfites for several weeks before use. Isinglass preparations must be kept at low temperatures (~4 °C), as many lose their fining ability above 15 °C and all fail to work if kept above 20 °C. The cloudy viscous liquid contains solubilized collagen, gelatin and insoluble materials, the first of which is largely responsible for the fining action. At beer pH, collagen molecules carry an overall positive charge, so they interact with yeast cells that carry an overall negative charge. It also takes up lipids, antifoaming agents and, to a certain extent, positively charged proteins. A simplified scheme for the action of isinglass finings is shown in Figure 2.6.27. Collagens are supercoiled fibrous proteins with an unusual abundance of the amino acids glycine, hydroxylysine, hydroxyproline, lysine and proline. The collagen in fish swim bladders is of the type I class (Walker *et al.*, 2007) and is composed of triple helical structures of about 300 nm in length and 1.5 nm in diameter, organized into fibrils, which in turn often aggregate into larger structures called fibers. The procedure for the preparation of isinglass finings probably results in the degradation of most of the fibers into fibrils or even triple helix 'monomer' structures. Figure 2.6.27 shows a schematic representation of a triple helix structure, although in reality, much larger collagen structures may account for the fining action. Until recently, the use of isinglass finings was almost entirely limited to the UK, but some brewers in a number of other countries (notably the USA) are realizing its advantages as an aid to filtration and as a foam enhancer. For cask-conditioned ales, isinglass finings are usually added at the time of racking, at 0.4–1.0 l/hl. They can be added to the bulk beer in the racking back or to individual casks, at the brewery, or to the cask at the location of dispensing. Settling of finings and yeast normally takes 2–24 h at 10–16 °C, depending on the yeast strain. More recently, optimum effectiveness of fining with isinglass has been achieved by the use of an inline mixing process (Freeman *et al.*, 2003).

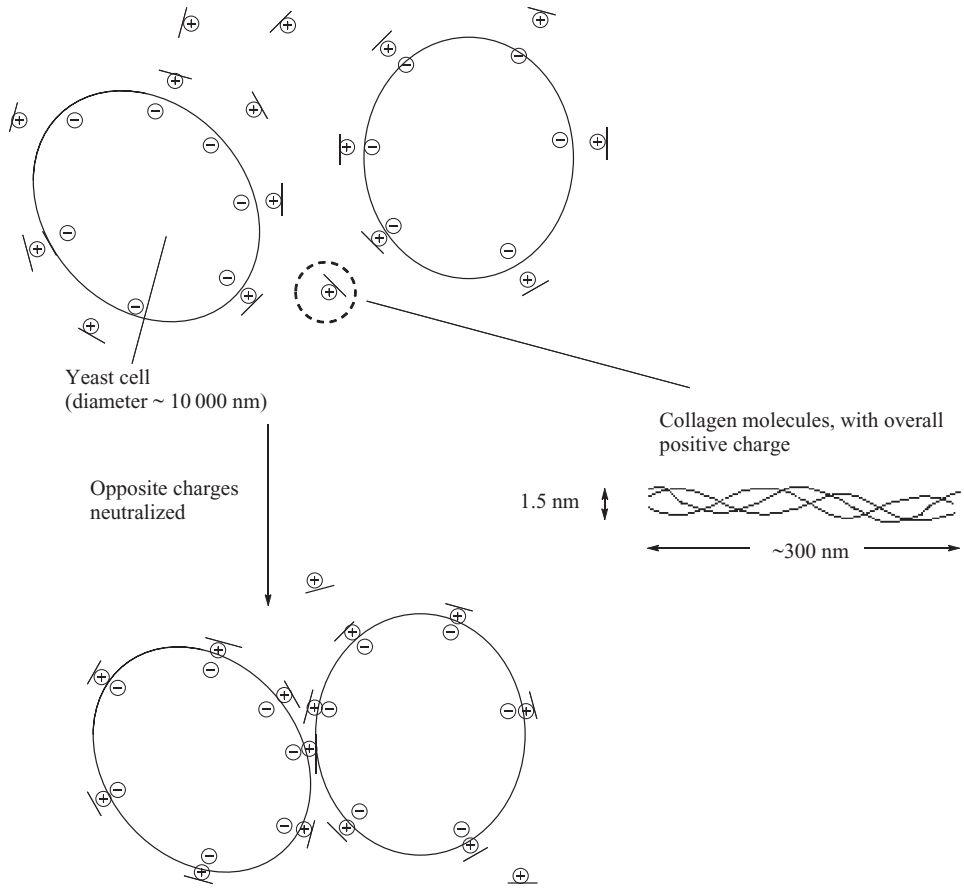

Figure 2.6.27 *Simplified scheme for the action of isinglass finings. Electrostatic (ionic attractions are emphasized here; other attraction types (like hydrogen bonding) will exist. Counterions (Ca^{2+}, SO_4^{2-}, phosphates, etc.) are not shown, for clarity. Not drawn to scale: the collagen molecules maybe much larger polymers or fibrils*

As isinglass is effectively an additive, it is not looked upon favorably by most European brewers, particularly German brewers, whose *Rheinheitsgebot* forbids its use. In the UK and USA, beers produced without the use of isinglass finings (often bottled-conditioned beers) are sometimes labeled 'suitable for vegans' (Section 5.9.5). Alternative collagen containing finings for beer, derived from chicken skins and yellow split peas, have been investigated recently (Walker *et al.*, 2007). On a small scale, both of these worked as well as isinglass and the latter may provide a useful alternative fining agent, particularly as mandatory allergen labeling is required for food by the European Union and the USA. This is despite the fact that isinglass residues in beer are usually very low and the evidence for collagen itself (which is the major organic component of isinglass) causing allergenic reactions is questionable (Baxter *et al.*, 2007) (see also Section 5.9.3). Other agents are used to clear yeast hazes, notably gelatin of animal origin and beechwood chips, both in the USA.

Filtration has been used for decades in the clarification of beer, but nowadays it is frequently applied after fining and/or centrifugation steps, which remove the bulk of insoluble substances that would otherwise quickly clog the filtration system. In this way, it becomes a final 'polishing' step to produce a brilliantly clear and

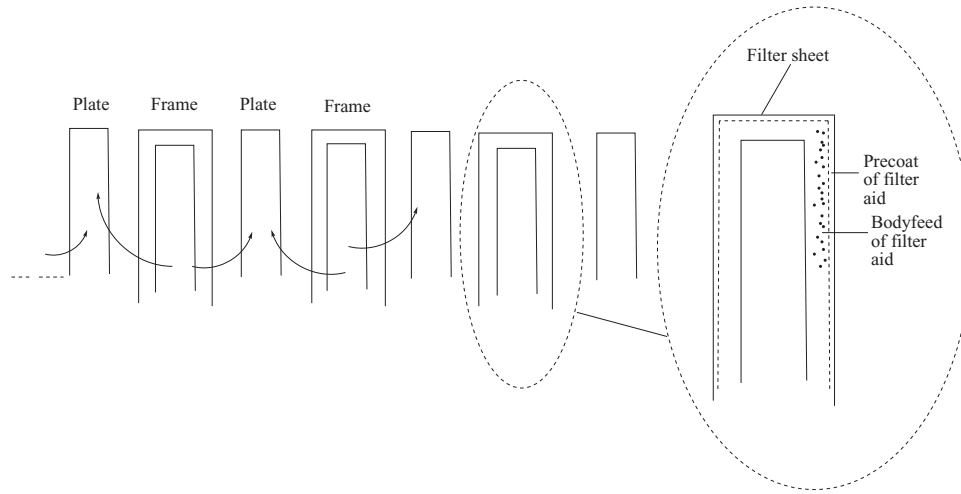

Figure 2.6.28 *Arrangement of plates and frames (vertical section) in a plate and frame filter machine*

microbiologically stable beer. Nevertheless, filtration is still used in varying degrees of severity, depending on the type of beer being produced. See also Section 2.9.4 for filtration of wine. For removal of most yeast cells and other suspended matter, depth filters are used, whereas much finer membrane filters will be needed for absolute filtration – that is, sterilization of the beer by removal of all yeasts and bacteria. Filtration is used to maximum effect on chilled beer (0–2 °C, depending on the beer gravity), where formation of cold trub and chill haze are maximized. Depth filtration is mainly carried out these days using either sheet filter or plate and frame (and related) filter equipment. The former uses sheets of fibrous materials of varying porosities (coarse, fine or sterile), usually made of cellulose and/or kieselguhr, although PVPP can be incorporated for the removal of polyphenols. Filter sheets are obtainable in sizes of up to 1 m^2 (1 m × 1 m) and frame presses are available in sizes that hold up to 200 sheets, thus allowing a throughput of up to 240 hl/h. Plate and frame filtration uses filter frames that are made of fibrous (cellulose) cloth impregnated and layered with the filter aid, usually kieselguhr. For optimum operation of such filters, a slurry of filter aid (called 'body feed') is added to the beer being filtered at intervals of time and in such concentrations that are suggested by the filter manufacturer or that have been found from experience. A typical body feed is 100 g of filter aid per hectolitre of beer and it may also contain PVPP for polyphenol removal. Other filter aids, such as perlite (a material of volcanic origin) and silica hydrogel, are used by some breweries. In a plate and frame filter, the filter frames are held alternately with blank frames in the filter machine (Figure 2.6.28). Variants of this kind of depth filtration include vertical leaf, horizontal leaf and candle (filter stick) systems. In all cases, chilled beer is pumped through the filters under pressure, such that the outflow rate does not exceed 4 or 5 hl/m^2. Pore sizes of filter frames (or leaves or candle elements) vary from a few μm up to about 90 μm, enabling sterile fine to coarse filtration. In all cases of depth filtration, the filter materials not only sieve out particles that are larger than the pore sizes but also adsorb a considerable amount of much smaller particles (see Section 2.9.4, Figure 2.9.26). This is because the particles of filter materials such as kieselguhr carry an overall positive charge, whilst yeast and bacteria cells carry an overall negative charge. Thus, even coarse filters are able to remove some (but not all) of the suspended yeast and bacteria cells. In order to remove all microorganisms, the brewer must resort to sterile fine filtration, for which purpose cellulose acetate membrane filters (pore size ≤ 0.45 μm) probably give the best results. However, it is essential that beer filtered in this way has been previously extensively clarified, for example by a régime consisting of a combination of sedimentation,

centrifugation, fining and filtration. Membrane filtered beer is microbiologically stable and can be sterile packaged (tanked, kegged, bottled or canned) (Section 2.6.10) – suitably chilled and carbonated – immediately, whereas less rigorously filtered beer will require pasteurization (Section 2.6.10) to kill unfiltered microorganisms.

Centrifugation is really an aid to the settling of solids from beer. According to Stokes' Law, the settling rate v is given by Equation 2.6.3, where r_p is the particle radius, s_p the particle density, s_m the medium density, g the gravitational constant and η the medium viscosity constant.

$$v = \frac{2r_p^2(s_p - s_m)g}{9\eta} \tag{2.6.3}$$

Thus by increasing g by rotating the sample, the rate of sedimentation may be increased. Note also that finer particles (smaller r_p) in a high density medium (large s_m), such as powdery yeast in a high gravity beer, will sediment relatively slowly.

Centrifuges in breweries tend to be used in three major ways: as wort clarifiers, as inline clarification devices for beer en route to maturation vessels (or casks) and as devices for the recovery of beer from sediments at the bottom of fermenters or tanks. The last use is important for larger breweries, where considerable losses can arise from beer being entrained in sedimentary material. However, the use of centrifuged yeast for repitching is open to question, since shear stress causes a drop in yeast viability, vitality, foam stability and general beer quality (Chlup and Stewart, 2007). The most widely used centrifuges are of the disk stack, cylindrical bowl, self-clarifying and decanter types. They are hermetically sealed, so that neither oxygen is taken up nor carbon dioxide lost, and they are capable of 5–600 hl/h throughput rate. Although they take up little space, are easy to sterilize (and to keep sterile) and require no filter aids, centrifuges are costly both to purchase and to operate and they tend to be noisy. Also the stresses imposed upon yeast cells under centrifugation can cause cell wall damage, thereby releasing cell wall mannans, extracellular proteinase A and other materials, resulting in hazes and reduced foam stability (Chlup *et al.*, 2008). Proteinase A is known to hydrolyze beer lipid transfer protein 1 (LPT1), one of the proteins that are associated with beer foam formation and stability (Leisengang and Stahl, 2005).

For beers that require a long shelf life (kegged, bottled and canned beers), pasteurization will be required if full sterilization has not been achieved, as noted previously. There are two kinds of pasteurization that are used in breweries: flash pasteurization of bulk beer, mainly destined for tanks or kegs, and tunnel pasteurization, used for bottled and canned beers. Flash pasteurization is carried out in plate heat exchangers, where hot and cold beers are in counter flow. More detail regarding both flash and tunnel pasteurization is given in Section 2.6.10. The degree of pasteurization is given by the pasteurization unit (PU), which is arbitrarily defined as the lethal effect on microorganisms obtained by holding the beer at 60 °C for 1 minute. Increase in lethality caused by increase in temperature (over 60 °C) is given by Equation 2.6.4, where T is the pasteurization temperature in °C.

$$\text{PU}(/\text{min}) = 1.393^{(T-60)} \tag{2.6.4}$$

Typically, bottled beers are given are given between 20 and 30 PUs, but sometimes as little as 5 PUs, when the quality of the filtration is high. The greater the number of PUs applied to a beer, the more pronounced is the cooked flavor. For bottled beers, pasteurization at 20 or more PUs tends to be favored in the UK, whereas in Europe and the USA, a lower degree of pasteurization is often used. Pasteurization can be applied to noncarbonated bulk beer (e.g. in a tank) or already highly carbonated beer (e.g. in bottles or cans). The brewery microbiological contaminants that are most resistant to pasteurization are lactic acid bacteria and *Saccharomyces pastorians*.

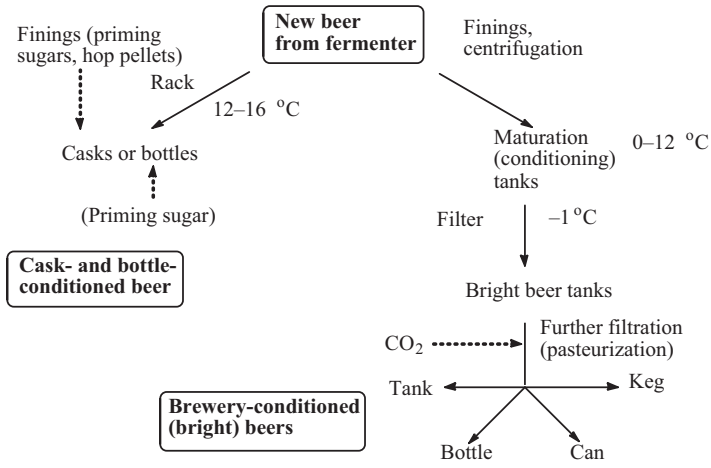

Figure 2.6.29 *Simplified schemes for packaging beer at the brewery*

2.6.10 Packaging of Beer: Casking, Kegging, Bottling and Canning

The beer treatments described in Section 2.6.9 are dependent upon the type of beer being produced, its desired shelf life and how it will be packaged and dispensed. This is summarized in Figure 2.6.29. The simplest, cheapest and most natural mode of packaging beer is bottle or cask conditioning, both most commonly used for top-fermented beers. Here, the beer is served directly from the container in which it has conditioned and matured. Bottle-conditioned beers, although less common than their brewery-conditioned and processed cousins, are available worldwide and include the darkest Irish and UK stouts and porters, through Belgian Gueuze beers, to the palest German Weizenbiere. Like bottle-conditioned beer, beer that is conditioning in cask is a living product: suspended yeast cells are responsible for secondary fermentation, so producing CO_2 that gives the beer its sparkle and foaming head when served. If the number of yeast cells falls below about 3×10^5 per ml, carbonation will be on the low side and the beer may be rather 'flat,' but if much above 4×10^6 per ml, carbonation may be too high and the beer may gush when the cask is tapped, especially at higher temperatures (say >16 °C). Breweries aim for the optimum, but many would argue that overcarbonation is better than undercarbonation, because the excess CO_2 pressure can at least be vented.

When the fermentation progress (see Figure 2.6.17) and level of suspended yeast cells are judged to be correct, casks are filled with beer either directly from the fermenter or from a racking back, using a counter pressure racking equipment to prevent frothing or 'fobbing.' Priming sugars (typically as a 34 °Plato syrup) can be added at 0.4–1.8 l/hl. Many cask beers are not primed, but the big majority are fined with isinglass suspension at 0.4–1.1 l/hl. Many are also dry hopped, often nowadays with pellets rather than cones at rates of 9–50 g/hl. Pellets and isomerized extracts, when used in dry hopping, greatly decrease the risk of clogging beer lines and the cleaning of returned empty casks is far easier at the brewery. The beer in cask may rest at the brewery for a number of days (up to over a week) before being dispatched to the trade, where it may have a week or so rest before being tapped. The maximum shelf life of cask beer is considered to be four weeks, but this depends on a number factors, including alcoholic strength and storage temperatures. Beer casks were once all wooden, but these require skill and care in cleaning and maintenance, especially if they are not in use for some time. They also have a tendency to leak, both through the pores of the wood and at the joints between the staves. Hence, many are lined with brewers' pitch; some lager at the Urquell Brewery

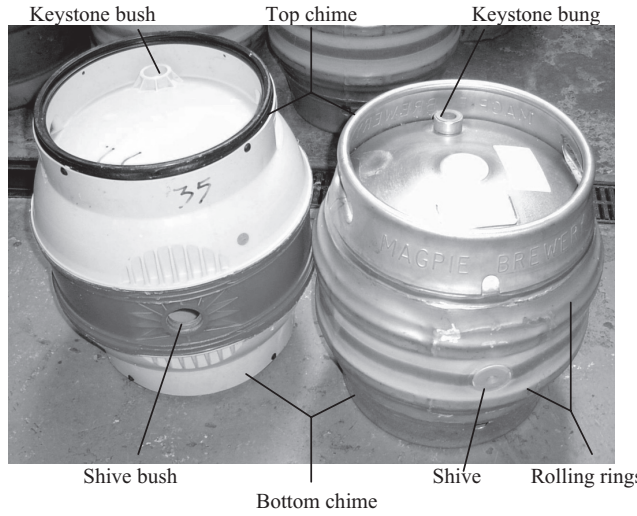

Figure 2.6.30 *Stainless steel and plastic casks at the Magpie Brewery, Nottingham, UK. Note the brewerycolour coding and embossed label*

in Plzeň (Pilsen) was until fairly recently stored for a time in large casks of this type. Even today, a number of UK breweries still supply the trade with some of their beers in wooden casks (e.g. Banks, Theakston and Wadworth), as do some brewers of Altbier and Kölsch in Germany. Wooden maturation vessels and other process vessels are still used for certain beers in a few breweries in the UK (e.g. at Greene King brewery for a strong ale), in Belgian Lambic breweries, such as Lindemans (Figure 2.6.18) (Section 2.6.7) and in a few traditional German breweries. However, the big majority of vats and casks these days are made of stainless steel, aluminium (for casks) or plastic (for casks). Figure 2.6.30 shows a stainless steel and a plastic cask, both of 41 l (9 gallon) capacity; cask sizes in the UK are still nonmetric. Important parts of the cask are also illustrated in Figure 2.6.30 – in particular, casks always have two holes, one for the outlet of beer and the other for the inlet of gas (either air or a blanketing gas: CO_2 and/or N_2). Since casks are regularly returned to the brewery for reuse, the cleaning and washing program is of prime importance. Cask washing systems come in many forms, depending on the size of the brewery and its cask beer output: larger concerns have automated, computer controlled cask washers. Washing cycles vary between breweries, but are normally comprised of an external wash, bung and shive removal, an ullage wash, a hot water rise, one or two detergent washes, one or two hot water rinses, a steam clean and finishing with manual or microbiological inspection (Hornsey, 1999c). Adequate drainage time must be allowed between washing stages and some of the water is recycled between stages to cut down waste. The water washes and rinses may involve water feeds at 6 bar pressure (∼90 l/min) at 90 °C, usually for 1 min each. The detergent wash feed may be at 6 bar at 70 °C and the steam feed is typically at 3 bar (∼80 kh/h). Older casks have often accumulated a deposit of 'beer stone' – basically calcium oxalate, which is derived from calcium salts in the liquor and oxalates from malt. This must be removed with either acidic detergents (based on phosphoric acid) or sequestering detergents.

Brewery-conditioned beer (often called bright or processed beer) is beer that has been matured, conditioned, fined, possibly centrifuged, filtered and possibly pasteurized in the brewery. It is thus microbiologically dead, since all microorganisms, including yeast, have either been removed or killed. Consequently, this type of beer (which represents the big majority of beers worldwide) must be packaged in sterile containers such as

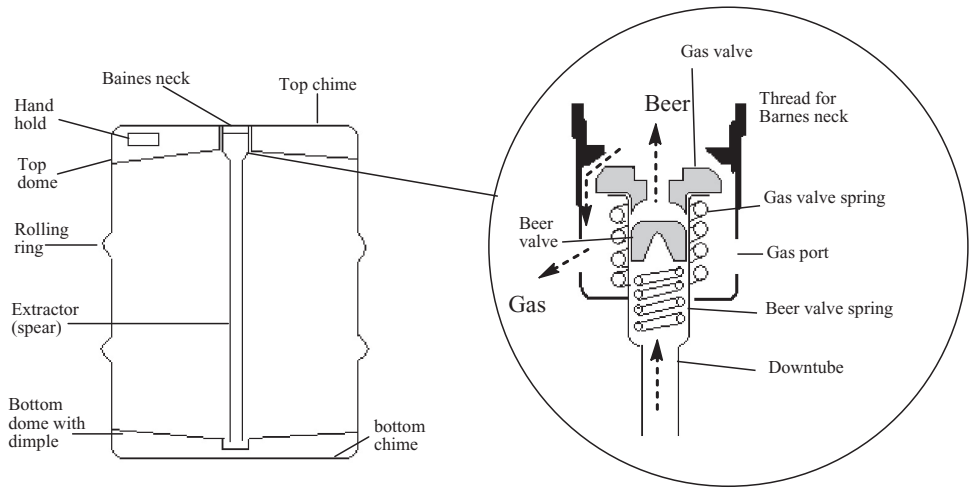

Figure 2.6.31 *Simplified section through a typical beer keg, showingamplification of extractor head, in dispense mode. In filling mode, the kegis inverted; beer enters by the gas ports and excess gas leaves by the downtube*

tanks, or more usually kegs, bottles and cans, where at least some artificial (and often much) gasification (CO_2 and/or N_2) will be used.

High quality traditional lagers, such as some from the Czech Republic, Slovakia and Germany, are likely to have spent many weeks undergoing secondary fermentation and maturation, at gradually diminishing temperatures. At the end of this period, cold break, chill haze and yeast precipitations will be almost complete, the beer will be very nearly bright and will require only a final gentle or polishing filtration before packaging. Some of these lagers are unpasteurized and some are fed (unfiltered) directly from their lagering tanks into casks or kegs for draught dispense, although nearly all are given some artificial carbonation. However, the majority of brewery-conditioned beers are highly filtered and pasteurized and never see the inside of a cask – they are put into kegs for draught dispensing.

Unlike casks, kegs have only a single hole (Figure 2.6.31), which is used for both filling with beer at the brewery and dispensing the beer at the point of sale. Kegs are usually made of aluminium (with oxidized or epoxy resin lined interior surfaces) or stainless steel and contain an extractor system (a 'spear') that screws into the 'Barnes neck.' This extractor system stays in place (more or less) during the keg's lifetime. When filling with beer (and during washing) the keg is inverted, whence beer enters the keg through the ports in the spear head and excess gas is voided through the extractor tube. When dispensing beer, the reverse applies (Figure 2.6.31). Like casks, kegs have to be thoroughly cleaned before refilling with beer, but most breweries carry out both cleaning and filling using a single automated computer controlled machine. These systems consist of two rotating carousels – one for washing and the other for filling – and kegs are passed from the former to the latter via a conveyor. These days, the whole operation uses automated depalletization (for incoming empty kegs) and palletization (for outgoing filled kegs) procedures. At the washing carousels, there are four manifolds: one for deullaging, one for detergent wash (with its attendant rinses and drainage $\sim$1 min per keg), one for steam sterilization (e.g. steam at 120 °C for 1 min) and one for counter pressuring with CO_2 and/or N_2. The last process purges out steam condensate and gives a counter pressure of gas that reduces fobbing when the casks are filled (at the next stage). The kegs are then conveyed to the filling carousel where they are filled with cold, bright carbonated beer (filtered and often pasteurized), slowly at first and then more

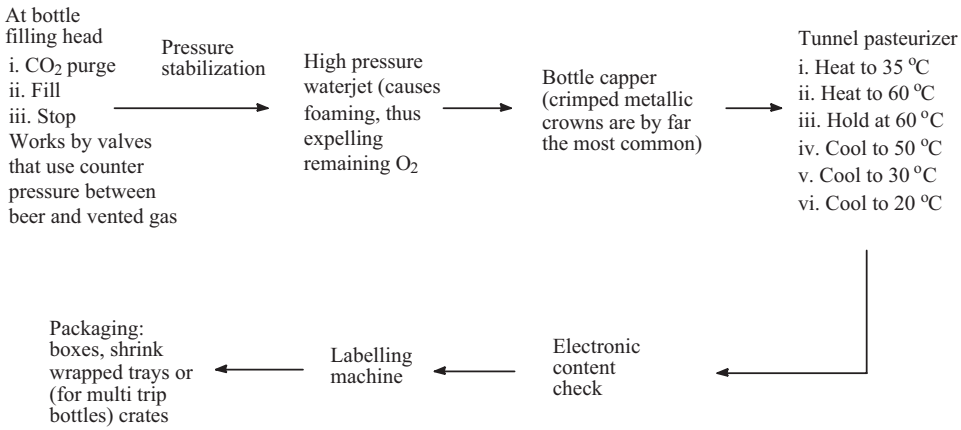

Figure 2.6.32 *Typical bottle filling scheme. This is focused on single trip bottles*

rapidly. Filled kegs are then given an external wash, dried, weighed and labeled. A modern washing/filling machine can deal with 1000 kegs/h.

Like kegging lines, bottling lines tend to be highly automated and computer controlled, but vary according to whether the bottles are returnable ('multitrip'), and hence need cleaning, or nonreturnable ('single trip'), in which case they essentially require filling only, since they arrive at the brewery in virtually sterile condition. A typical bottle filling operation is summarized in Figure 2.6.32 and a typical bottle washing programme is outlined in Figure 2.6.33. It will be noticed from Figure 2.6.33 that a very vigorous washing regime is essential, not only to ensure thorough internal cleansing, but also to remove old labels. It is easy to appreciate that single trip bottling lines are much easier to run than multitrip washing and bottling lines, there being no outlet and inlet end to coordinate.

Canning lines are similar in many ways to single trip bottling lines. Beer cans are constructed of either tin layered low carbon steel or aluminium (actually an aluminium–silicon–magnesium–manganese alloy) for greater strength. They arrive at the brewery (already printed with the brewery logo, etc.) in two parts: the (bottom) body, to be filled with beer, and the top (which contains the opening mechanism, nearly always of

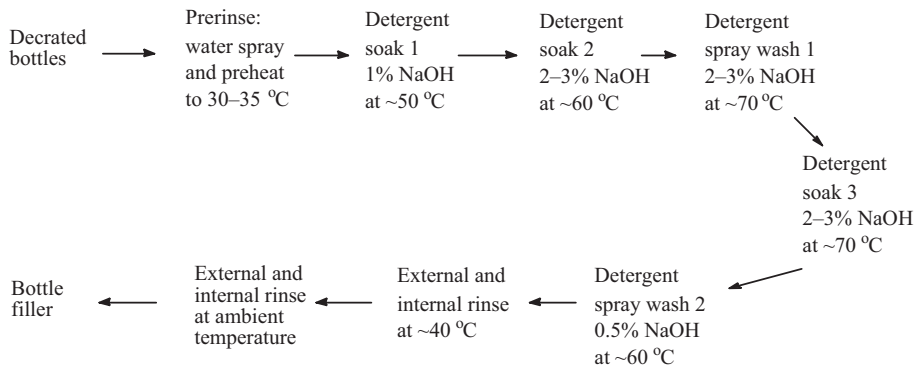

Figure 2.6.33 *Typical multitrip bottle washing regime. Adequate drainage times are allowed between each stage. Washings are often recycled to save water*

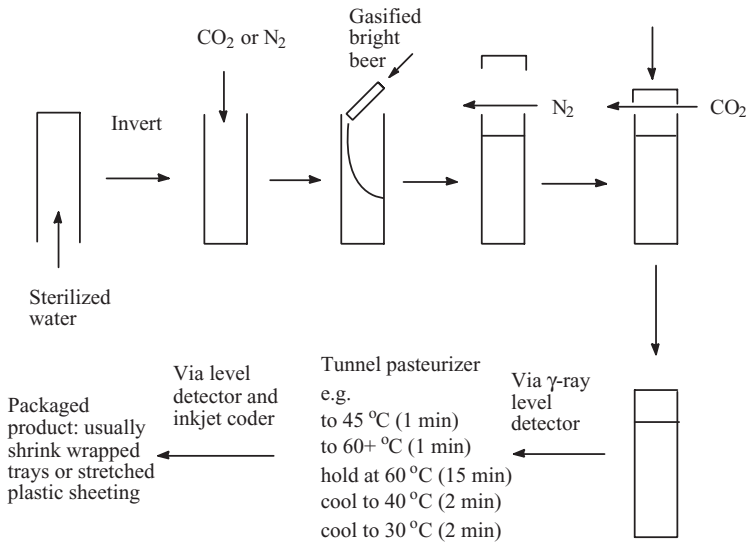

Figure 2.6.34 *Simplified scheme for typical brewery canning program*

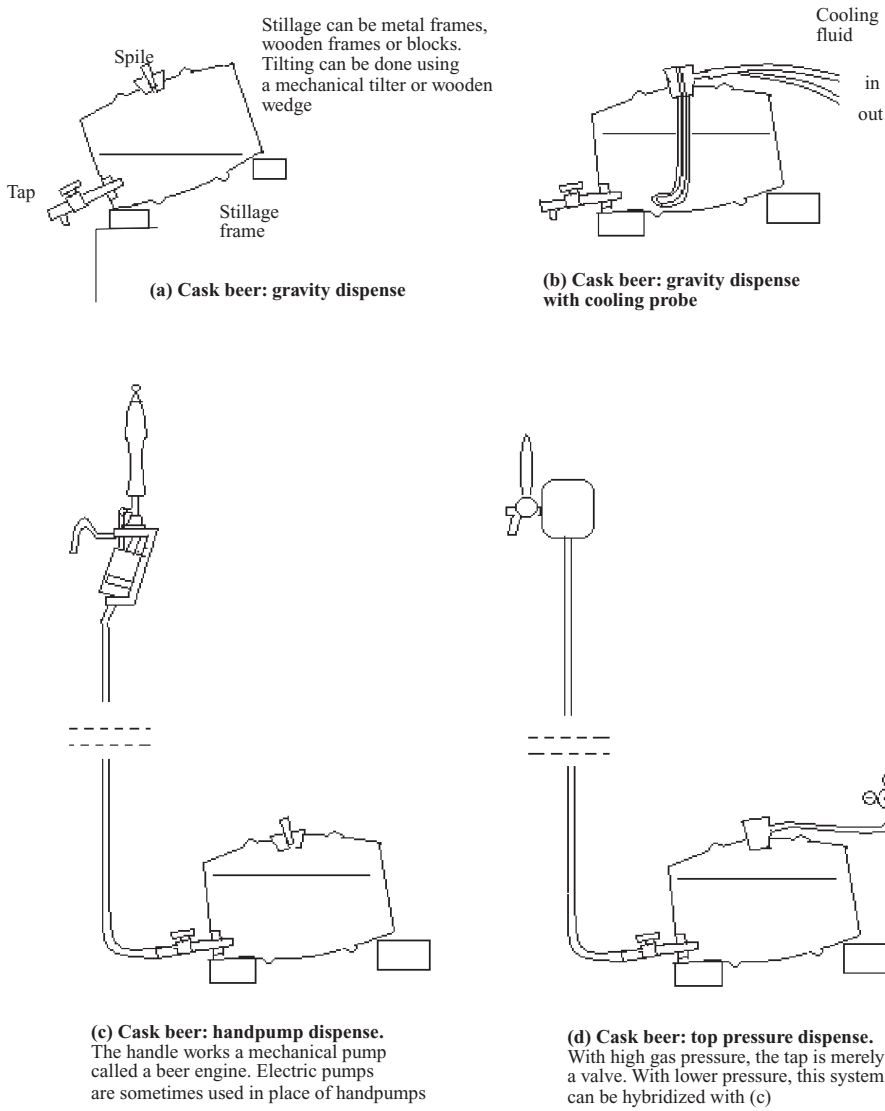
the 'ring pull' type), to be joined to the filled body at the brewery. A typical sequence of events in a brewery canning line is outlined in Figure 2.6.34. Canned beers, like bottled and kegged beers are supersaturated with gas (either CO_2 or a mixture of CO_2 and N_2 – often 60:40); that is, they contain more dissolved gases than is theoretically possible at room temperature and pressure. This is typically equivalent to 4.0–4.5 g/l of dissolved CO_2, or 2.5 volumes of CO_2. In recent years, interest has grown in the use of N_2 as both a gasification agent for canned, bottled and keg beers and as a dispensing gas for cask and keg beers (see Section 2.6.11). Not only is nitrogen much less soluble in beer than carbon dioxide, but it produces smaller bubbles which result in a compact, creamy head that resembles that of well conditioned cask beers, especially if a 'sparkler' is used on the dispensing tap (see Section 2.6.11). As far as can be ascertained, N_2 makes no contribution to beer taste, whereas it is generally agreed that high volumes of dissolved CO_2 give beer an acidic taste and prickly mouthfeel. In some canned beers (and a few bottled beers) the use of a plastic device known as a widget and dissolved N_2 (*ca.* 20 ppm) gives a thick, compact head resembling that of draught beer. Upon opening the can, the rapid shearing action of the widget (due to the suddenly reduced pressure) induces the formation of very small bubbles than are seen in normal canned beers, provided that the temperature is low enough ($< 5\ ^\circ$C), so that the maximum volume of N_2 is released from solution.

2.6.11 Dispensing of Draught Beers

This section deals mainly with the methods of dispensing various forms of draught beer, both of the cask-conditioned type and of the bright (keg or tank) type. Also discussed here is the behavior of gases (CO_2, N_2, O_2) and how they influence tank and bottle headspaces and beer dispensed by a top pressure system.

Figure 2.6.35 shows a numbers of ways in which it is possible to serve cask-conditioned beers, although in practice there are many other methods that are not illustrated here.

There can be no doubt that the simplest and most natural way of dispensing draught beer is by gravity, straight from the cask, without the use of external gas pressure (Figure 2.6.35(a)). Of course, this applies to



(a) Cask beer: gravity dispense

(b) Cask beer: gravity dispense with cooling probe

(c) Cask beer: handpump dispense. The handle works a mechanical pump called a beer engine. Electric pumps are sometimes used in place of handpumps

(d) Cask beer: top pressure dispense. With high gas pressure, the tap is merely a valve. With lower pressure, this system can be hybridized with (c)

Figure 2.6.35 *Methods for the dispense of cask conditioned beer. There are many variations on these themes. Spiles are removed when the beer is being served. Cask breathers, which supply CO_2 at atmospheric pressure, are sometimes used in place of spiles*

cask-conditioned beers, which generate their own CO_2 from secondary fermentation in the cask. As the cask is emptied, air is drawn through the spile or shive hole. Oxygen in the air is a potential enemy of beers, but initially it will be held above the blanket of CO_2 above the beer in cask. Soon, oxygen will either diffuse or circulate to the surface of the beers, where it will dissolve and begin to promote oxidation reactions. Many believe that a short contact with limited quantities of O_2 actually improves the flavor of cask-conditioned beer, and indeed, if the beer is all dispensed in one or two days, no deleterious effects of oxidation will be detected.

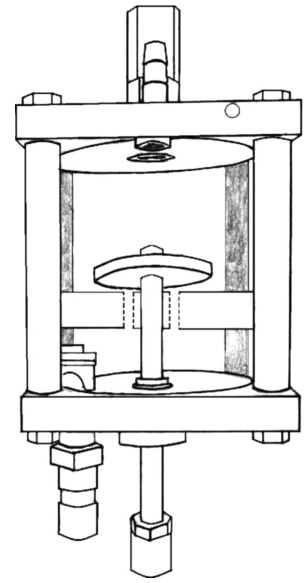


Figure 2.6.36 *Sketch of cylinder part of beer engine, with section through piston showing breather holes and piston shaft. Note floating top is raised as piston moves down, thus allowing beer to fill the cylinder*

The problems arise when turnover of the beer is slow or if the half empty cask has been stored overnight without a hard spile. Beer drawn by gravity is especially impressive if the casks are installed in public view in the bar area, but some kind of cooling system is required, like the probe illustrated in Figure 2.6.35(b). Much more likely, cask-conditioned beer will be drawn from casks that are stored in a cellar beneath the bar and this is a laborious job if done by gravity. For this reason, beer engines operated by (often ornate) hand pumps are a common feature of bars in the UK, especially England (Figure 2.6.36).

A beer engine consists of cylinder of borosilicate glass containing a plunger made of acetal, nylon or other inert polymer that is connected to the pulling handle by connecting rods and a pivot. Figure 2.6.36 shows the basic working parts of a beer engine – in particular the inlet valve, the plunger with 'breather' holes and the floating top. At the commencement of serving beer from a newly tapped cask, the pump handle is upright, the plunger is at the bottom of the cylinder and the inlet valve is closed. When the pump handle is pulled forward, the plunger moves up the cylinder, creating a vacuum below, which causes the inlet valve to open and fill the cylinder with beer. This stroke is often called the priming stroke. The pump handle is now forward and the cylinder is full of beer.

The handle is next returned to the upright position. On doing so, the plunger moves down the cylinder without much resistance because the downward motion raises the floating top, revealing four 'breather' holes, through which the beer easily flows. The plunger is now at the bottom of the cylinder with beer above it. Upon the second forward pull of the handle (and on all subsequent forward pulls, called dispensing strokes) the plunger moves up the cylinder and the force of the beer above keeps the floating top tight against the breather holes, thus pushing the beer out of the cylinder, through the beer tap into a glass. At the same time, a vacuum is once again created in the cylinder below the plunger, opening the inlet valve, through which more beer flows. With the handle now forward and a measure of beer in the glass, the plunger is at the top of the cylinder, which is again full of beer. On returning the handle to the upright position, the sequence of events described above is repeated, ready for the next dispensing stroke.

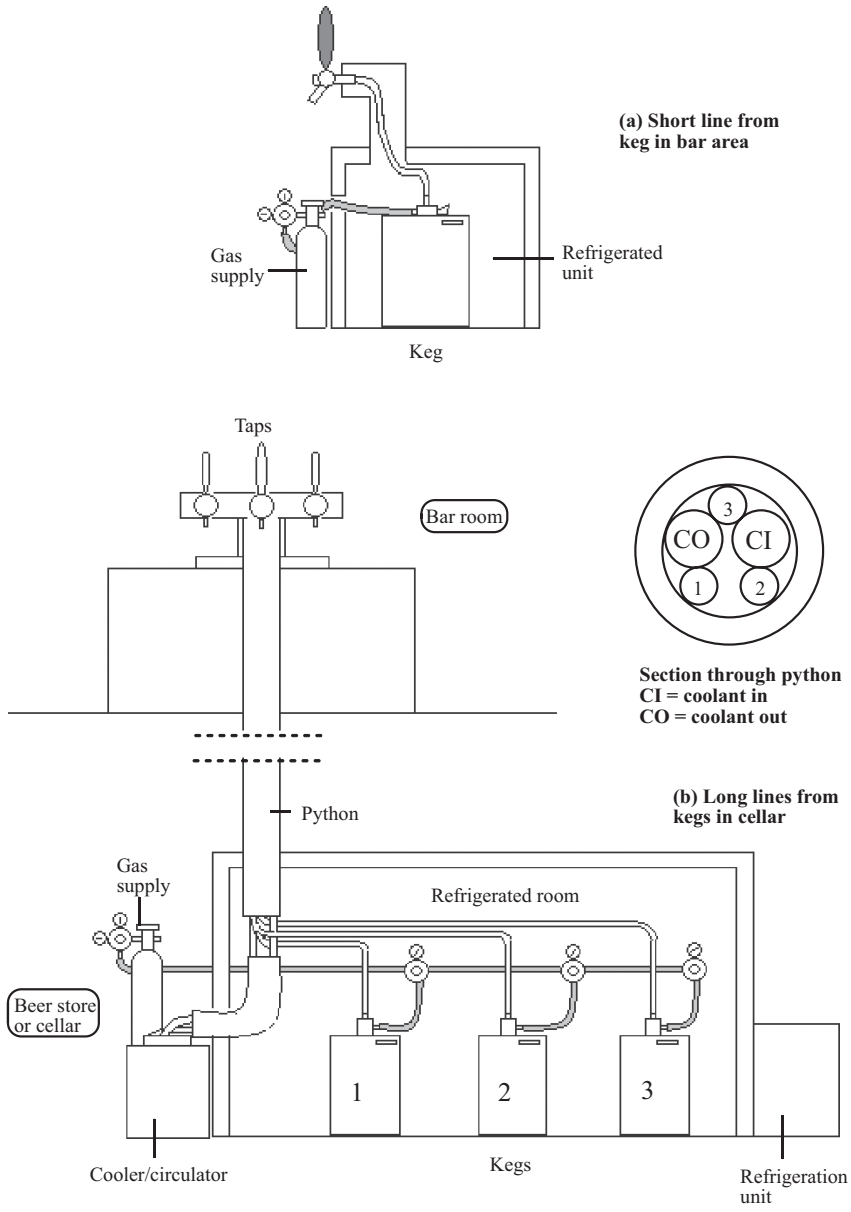

Figure 2.6.37 *Dispensing keg beer. Not drawn to scale*

The measure of dispense from a single pull depends on the cylinder volume, but is usually $^1/_2$ pint. The cellar temperature can be controlled (at, say 10–15 °C) by an air conditioning unit, and if several casks are being used at any one time on a regular basis, the beer lines can be bound up with ethylene glycol chill lines in an insulating plastic sheath (the whole thing is called a 'python'), leading to individual hand pumps. This ensures that the beer is served close to a predetermined 'cellar temperature.'

A similar arrangement (but at lower temperatures) is used for keg beers (see Figure 2.6.37).

Table 2.6.5 *Carbon dioxide headspace pressure (atm) as a function of the concentration of dissolved gas (volume of CO_2 per volume of beer) and temperature*

Temp/°C \ Vol. CO_2	1.4	1.8	2.0	2.5	3.0
4	–	0.25	0.45	0.81	1.17
6	0.08	0.38	0.61	0.96	1.34
10	0.25	0.61	0.81	1.34	1.73
12	0.33	0.67	0.93	1.40	1.96

Beer served from a cask using extraneous CO_2 (or other) gas pressure from a cylinder to push the beer to a tap on the bar counter above the cellar, is known as top pressure beer (Figure 2.6.36(d)). Beer that is conveyed from the cask using a beer engine and gas is used merely to re-establish equilibrium pressure within the cask is known as blanket pressure beer. In both top pressure and blanket pressure, it is difficult to prevent extraneous uptake of gas by the beer, especially if CO_2 is used.

Keg beers are served using CO_2 (or a CO_2/N_2 mixture) from cylinders, as shown in Figure 2.6.37(a) (short lines) and Figure 2.6.37(b) (long lines). Generally these beers are served at 4–6 °C, as opposed to the normal 10–15 °C for cask beers. The amount of dissolved CO_2 in a beer is quoted in units of volume (vol), where/volume = 1 liter of CO_2 per liter of beer. Cask-conditioned beers contain 1.0–1.5 vol, keg beers 2.2–2.8 vol and bottled beers 2.4–3.0 vol of CO_2.

The relationship between quantity of CO_2 in the headspace above a beer (as given by its partial pressure, P) is proportional to the concentration of CO_2 in the beer, provided that equilibrium conditions are in operation. This is Henry's Law and is best expressed by Equation 2.6.5.

$$P(CO_2) = kX(CO_2) \tag{2.6.5}$$

Henry's Law constant, k, is temperature dependent and X is the mole fraction of CO_2 in the beer (= number of moles of CO_2/total number of moles). The relationships between the volume of dissolved CO_2 and the corresponding headspace gas pressure at different temperatures are summarized in Table 2.6.5.

Two other laws that are useful in calculations involving pressure of CO_2 and other gases in both beer and the headspace above beer are Dalton's Law of partial pressures and the ideal gas law (Equations 2.6.6 and 2.6.7, respectively).

$$P(\text{total}) = P(CO_2) + P(N_2) + P(O_2) \tag{2.6.6}$$

$$P(CO_2)V = n(CO_2)RT \tag{2.6.7}$$

Dalton's Law states that the total pressure in a headspace is the sum of the partial pressures of the gases present. Equation 2.6.6 relates, say, to a bottled beer with some air in the headspace. The ideal gas law relates pressure P (in atm), volume V (in liters), temperature T (in K which is defined as °C + 273.15) and molar quantity (n) (= mass/molar mass) of an ideal gas. The constant R is the gas constant, and with the units for P, V, T and n described above, it has the value 0.0802 l atm/mol/K. Under the conditions involved in contained beer (tank, bottle, cask or keg), the gases (CO_2, N_2 mainly) approximate to ideal gases. For carbon

dioxide, where the density at standard temperature and pressure (273 K, 1 atm) is 1.96g/l and molar mass is 44.01 g/mol

$$\begin{aligned}\frac{n(\text{mol})}{V(\text{l})} &= \text{vol}\left(\frac{\text{density(g/l)}}{\text{molarmass(g/mol}}\right)\\ &= \frac{\text{vol}}{22.45(\text{l/mol})}\\ \text{or vol} &= 22.45(\text{l/mol})\left(\frac{n(\text{mol})}{V(\text{l})}\right)\\ &= 22.45(\text{l/mol})\left(\frac{P(\text{atm})}{R(\text{latm/mol/K})T(\text{K})}\right)\end{aligned} \tag{2.6.8}$$

These laws can be used in various calculations involving gases, taking into consideration a number of factors that have been determined as a result of experience. The first example involves carbonation of a storage tank of 1500 l capacity, containing 1200 l of beer so that CO_2 content of the beer is 2.5 vol. Firstly, the 20% headspace in this example is typical. Secondly, it can be assured that 0.2 vol of CO_2 will be lost in processing, so carbonation should be conducted to 2.7 vol. Now, the calculation of the mass of CO_2 to be added can be started.

At equilibrium, 2.5 vol of CO_2
$= 2.5$ (l/l) $\times$ 1.96 g/l
$= 4.9$ g/l
or 5.88 kg in 1200 l

If the tank temperature is 4 °C, then from Table 2.6.5 (based upon Henry's Law), this will require 0.81 atm of headspace CO_2 pressure for equilibium.

Next, the volume of CO_2 in the tank can be calculated using Equation 2.6.8.

$$\begin{aligned}\text{i.e.vol} &= 22.45\left(\frac{P}{RT}\right)\\ &= \frac{22.45 \times 0.81}{0.0821 \times 277}\\ &= 0.80\text{vol}\\ &= 1.57 \text{ g/l or } 1.88 \text{ kg in } 1200 \text{ l}\end{aligned}$$

Hence the total mass of CO_2 needed is $5.88 + 1.88 = 7.76$ kg.

The second example involves the dispensing pressure. Three pressures need to be considered, as shown in Equation 2.6.9.

$$P_{\text{eff}} = P_{\text{E}} - P_{\text{H}} - P_{\text{LR}} \tag{2.6.9}$$

P_{eff} is the effective pressure. When P_{eff} is zero, there will be no beer flow and $P_E = P_H + P_{LR}$. In practice, P_E, the equilibrium pressure, is chosen to be 0.14 atm higher than that calculated from Equation 2.6.9, to give a flow rate of 4.5–-5.5 l/min. P_E is essentially the pressure required (via CO_2 cylinder) to preserve the beer's CO_2 contact during serving. P_H is the gravity head, the pressure needed to push the beer against gravity from tank or keg to tap. A widely used value is 0.11 atm/m (height).

Finally, P_{LR} is the line resistance, the pressure needed to overcome resistance (friction, capillary attraction, etc.) in the beer lin;, it is taken as 0.022 atm for 9.5 mm i.d. (internal diameter) tubing, 0.134 atm for 6.4 mm i.d. tubing and 0.49 atm for 4.8 mm i.d. tubing.

Suppose beer with 2.5 vol of CO_2 is to be dispensed at 4 °C to a tap 5 m above the keg or tank, via a 9.5 mm i.d. tube. From Table 2.6.5, 2.5 vol of CO_2 at 4 °C is equivalent to 0.81 atm of headspace gas (= P_E). $P_H = 0.11 \times 5 = 0.55$ atm. Now, $P_{LR} = P_E - P_H = 0.81 - 0.55 = 0.26$ atm. The length of tubing thus required is given by $0.26/0.022 = 11.8$ m, rather longer than the 5 m of height. Thus, a better choice might be tubing of 8.0 mm i,d. for this particular example. The dispensing pressure would actually be $0.81 + 0.14 = 0.95$ atm, as noted previously.

The use of N_2 or an N_2/CO_2 mixture for top pressure beer dispensing has been gaining popularity for a number of years now. The main aim is to have sufficient CO_2 to balance the equilibrium pressure of the beer, so that the N_2 pressure overcomes the gravity head and line resistance. Typically, a 75% N_2, 25% CO_2 mix may be used with a beer kept at 4 °C, with a total headspace pressure of 1.11 atm (∞ 0.84 atm N_2 and 0.28 atm CO_2, from Dalton's Law). The partial pressures of the gases in the bubble are much closer to atmospheric partial pressures ($\sim$0 for CO_2, $\sim$0.8 atm for N_2), than in a bubble of CO_2 from a 2.5 vol beer (at 4 °C) : 0.81 atm in the bubble and $\sim$0 in the atmosphere. Gas loss (by collapse of the bubble) is thus less for N_2/CO_2 bubbles, leading to a tighter, more stable foam.

2.6.12 Oxidation and the Staling of Beer

Many beers are brewed for distribution to many points of trade (often at significant distances from the brewery) and are required to have long shelf lives – that is, they should be able to survive in peak condition for a considerable time, so that at the point of consumption they are still lively and 'fresh,' with no 'stale' odors or flavors. This applies most strongly to brewery-conditioned beers that are destined for keg, bottle or can. These beers have undergone extensive brewery processing, particularly with regard to filtration and in many cases pasteurization. Generally, keg beers are expected to last about four months in peak condition, whereas bottled and canned beers are often given shelf lives of over a year. However, sooner or later the flavors of these beers gradually change (in a sequence of steps or phases) from typical fresh profiles to what is perceived as stale. The process is called staling and arises largely as the result of oxidation of certain beer constituents by molecular oxygen or by various oxidized species that have been formed at various stages of the brewing procedure. Superimposed on this are various oxygen independent aging processes, such as the formation of heterocyclic compounds (via the Maillard reaction), carbonyl compounds and esters, and other reactions that can lead to undesirable flavors in aged beer (Kuchel *et al.*, 2006; Vanderhaegen *et al.*, 2006). Depending on the beer and stage or phase of staling, the flavors have been described variously as 'currant,' 'metallic,' 'paper' and 'cardboard,' and are often linked to an increase in astringent or bitter taste and also sometimes to permanent haze formation.

Many breweries operate a 'minimum oxygen' regime for the brewing of brewery-conditioned beers. Here, oxygen uptake is minimized in both the prefermentation stage (mashing and boiling/cooling), called 'hot side aeration' and also from fermentation onwards, called 'cold side aeration.' A 'zero oxygen' process is impossible, but a minimization program should at least ensure that the packaged beer undergoes staling later, rather than sooner. The steps that can be taken include gentle 'mashing in' (with minimum

splashing), mashing in an enclosed vessel, mash filtration, proper separation of hot and cold trub and removal of air from the headspace of the packaged beers, To this we can add the choice of malt with low lipid levels.

Classical beer production involves either aeration of wort or yeast preoxygenation, since oxygen is required for yeast biosynthesis of unsaturated fatty acids and ergosterol for initial growth and subsequent good fermentation performance. It is widely believed that wort aeration, although a helpful prefermentation process, may ultimately be detrimental to beer quality, because of more rapid beer staling. However, recent work has demonstrated that normal aeration (8 mg/l) of both ale and lager worts did not determine flavor stability in a direct way (Depraetere *et al.*, 2008). No significant differences were found in either the natural or forced aged beers produced from aerated worts or by use of preoxygenated yeast. On the other hand, it has been found that beers produced in a working brewery from nonaerated wort and yeast that had been mixed with olive oil during storage had greater flavor stability over those brewed by the traditional wort aeration method (Hull, 2007). These beers had similar flavor, but with higher ester (fruity) profiles, and similar foam retention to the traditional beers.

Staling of a bottled beer may occur prematurely, despite all reasonable efforts to minimize oxidation during the brewing and subsequent processes, as described above. This is often caused by oxygen ingress through the stopper of conventional glass bottles or through the fabric of polyethylene terephthalate (PET) bottles. So-called 'crown corks' have been used on bottled beers for decades. They are crimped metal caps that originally had cork sealing liner material, but nowadays this has been replaced synthetic polymer materials, sometimes incorporating a chemical oxygen scavenger. Also, many modern crown stoppers are also designed as screw stoppers, being fixed to bottles that have a few grooves engraved in the glass at the top of the bottle neck. The drinker has the option of levering off the stopper (as per conventional crown stopper), but he or she is much more likely to unscrew it. It is the perceived lack of a reliable barrier to oxygen ingress that has resulted in several brewers in the USA, led by Sierra Nevada Brewing Co. (Chico, California), to switch from the modern kind of crown stopper to a much more dense stopper that has to be levered off. This is sometimes known (rather grandly) as barrier crown technology.

PET, having been used for some time to produce fruit juice, soda and other bottles is becoming an important bottle material for beers, despite earlier problems of premature staling and loss of condition as a result of both oxygen ingress and carbon dioxide egress. Nowadays, PET beer bottles are manufactured with multilayer, coated or monolayer structures, an oxygen absorbing or blocking substance being used in each case. In the former, at least one layer of oxygen barrier/scavenger, often a nylon nanocomposite (e.g. clay or H_2 rich carbon) is sandwiched between inner and outer layers of PET. The second type involves the coating of a super-thin layer of barrier material to one surface of a monolayer PET bottle. In the third option, now being developed, the oxygen absorber or barrier material is incorporated into the body of the single layer of PET material. This method does away with the need for multilayer or coating equipment, but is not yet widely feasible because of the high cost of materials.

The brewing of cask-conditioned beers does not require such elaborate precautions against oxygen absorption, since these beers are normally consumed within a few weeks, and the presence of yeast has a number of stabilizing effects, provided consumption occurs within one or two days once the cask is breached. Even so, the brewer will be careful not to expose the wort and subsequent beers to unnecessary amounts of air. An exception to this can be found in lambic beers (Section 2.6.7), where parts of the brewing and maturation processes deliberately promote a certain amount of oxidation.

Oxidations of wort or beer components can be divided into two broad groups – those that occur in the absence of enzymes (nonenzymic oxidations) and those that require enzyme catalysis (enzymic oxidations). These categories can be further subdivided according to whether molecular oxygen is involved or not. With this in mind, some typical oxidations that cause staling of beer are summarized in Figure 2.6.38. Oxidation of iso-α-acid side chains by headspace oxygen (Figure 2.6.38(a)) leads to a change in hop aroma and is

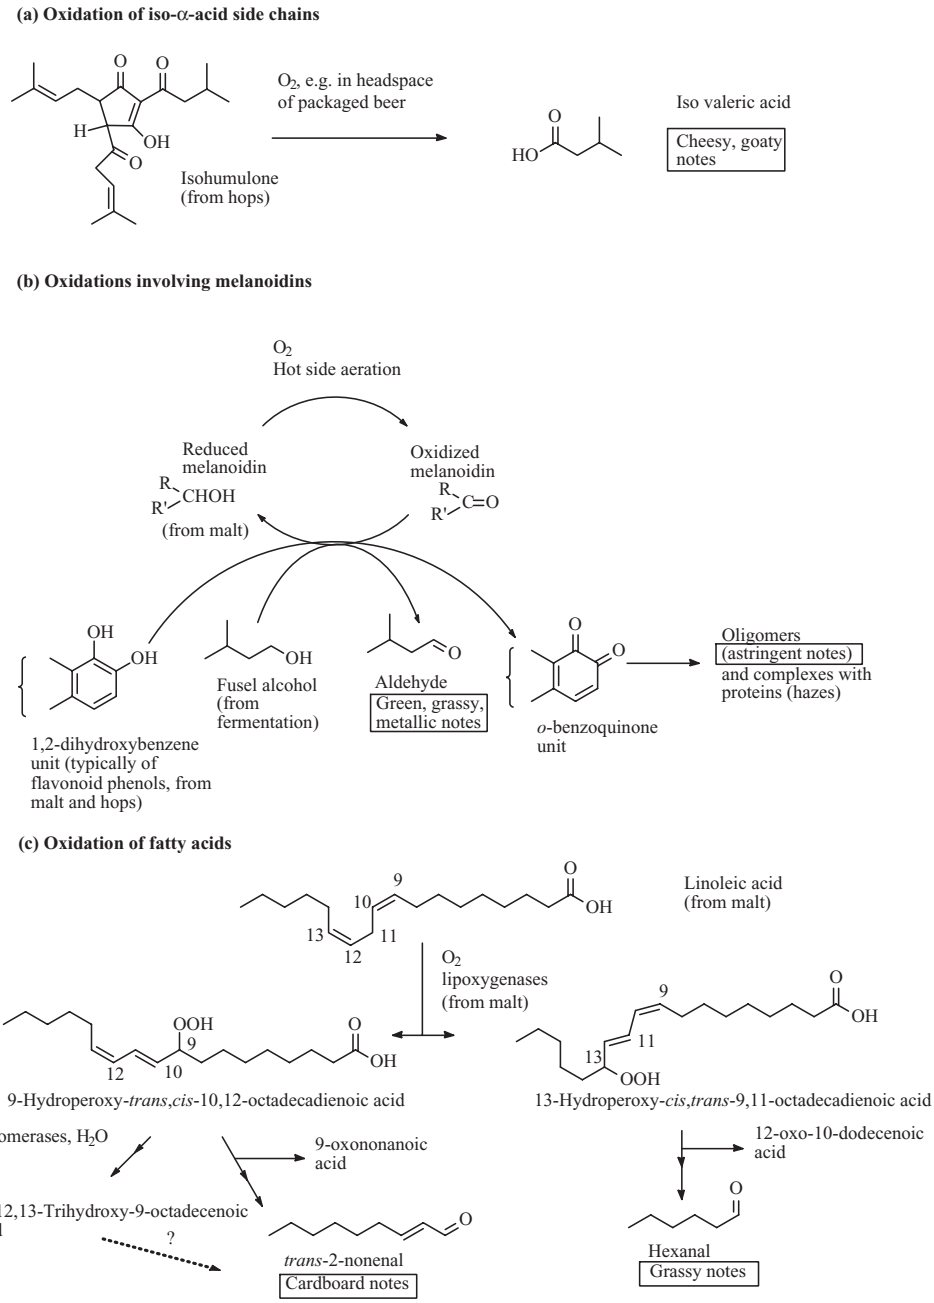

Figure 2.6.38 *Some oxidation reactions that cause staling of packaged beer*

generally taken to herald the onset of staling. Melanoidins appear to play a key role in staling oxidations (Figure 2.6.38(b)). These are produced in parts of the brewing process that involve higher temperatures: kilning, mashing (Section 2.6.2) and boiling (Section 2.6.3). Oxidation of melanoidins seems to require higher temperatures, so it is thought it occurs only during hot side aeration. The oxidized melanoidins are oxidizing agents that are capable of oxidizing fatty acids (not shown), fusel alcohols and polyphenols. In the latter case 1,2-hydroxybenzene units are oxidized to 1,2-benzoquinone units; these products are not only astringent, but cause permanent hazes by forming stable complexes with proteins (see Section 2.6.9 for enzyme catalyzed oxidation of phenols). On the positive side, dark beers with high (reduced) melanoidin content and that have been brewed with low hot side aeration are generally more resistant to staling compared with pale beers, because of the protecting (antioxidant) effect of the melanoidins. Oxidation of unsaturated fatty acids, from malt lipids, can lead to *trans*-2-nonenal (Figure 2.6.38(c)) and other aldehydes (C6 and higher). Excess lipids in the beer may also partly be the cause of the presence of Strecker aldehydes (Section 2.6.2, Figure 2.6.6) in staling beer. It has been shown that lipid oxidation products, like 4,5-epoxy-2-alkenols are able to form Strecker aldehydes (such as phenylacetaldehyde) from amino acids (such as phenylalanine) in model systems (Hidalgo *et al.*, 2005). *Trans*-2-nonenal is regarded by many as the most serious staling agent of all, because of its low odor threshold value (OTV; see Section 4.7.3) of 0.1 mg/l. This means it will make a marked organoleptic impact (cardboard notes) even though it is produced in very small quantities. Probably the best way of minimizing formation of *trans*-2-nonenal is to curtail the amount of lipids and fatty acid oxidizing enzymes (lipoxygenases) that get into the wort. Choice of low lipid malts, use of more highly kilned malts (with less lipoxygenase content), mash filtration, and good hot and cold trub separation are all reckoned to be beneficial in this respect, especially if coupled with a minimum oxygen program, because it is thought that *trans*-2-nonenal may also be formed by the aldol condensation of smaller aldehydes that probably originate from oxidation of alcohols formed during fermentation.

Recently, Saison *et al.* (2010) have shown that it is possible to remove aged aromas (e.g. black-currant (Ribes), cardboard, Madeira, Maillard notes) by refermenting the aged beer with fresh brewing yeast. During the new fermentation, certain molecules responsible for the offending aromas (diacetyl, 5-hydroxymethylfurfural, (*E*)-2-nonenal and Strecker aldehydes) are reduced to odorless products by yeast metabolic processes. Although some malodorous compounds, such as 2-furfuryl ethyl ether (and other ethers) are not affected and aldehydes are not entirely reduced by fermenting yeast (and indeed, other aldehydes are formed during fermentation), several aged aromas disappeared entirely as a result of refermentation. There may be a parallel here with bottle-conditioned beers, where the beer is in contact with its yeast for the whole of its 'shelf life.' The reducing ability of yeast may offer the beer some protection against oxygen or other species that promote beer aging. Certainly, it is common for bottle-conditioned beers to have a considerably longer shelf life than filtered (and maybe pasteurized) carbonated beers.

It has long been known that the presence of metal ions (especially Fe^{2+}/Fe^{3+} and Cu^{2+}) in beer promotes staling via the production of hydroxyl radicals from the Fenton and Haber–Weiss reactions (Figure 2.6.39), the hydrogen peroxide having been formed from molecular oxygen in packaged beer by a variety of reactions (Uchida and Ono, 1996). It is thought that hydroxyl radicals are the most potent producers of flavor changes in staling beer (Bamforth and Parsons, 1985). The origins of these metal ions in beer include raw materials, brewing equipment and filtration aids, such as diatomaceous earth, although it is known that their general levels fall during the brewing process, so that maturing beers often have only 50% of the wort concentrations of these ions (Zufall and Tyrell, 2008). More recently, it has been demonstrated that Mn^{2+} contributes significantly to beer staling both by forming hydroxyl radicals from H_2O_2 and by forming unsaturated fatty acid radicals directly (Figure 2.6.39) (Zufall and Tyrell, 2008). The Mn^{2+} ions emanate from brewing cereals and persist to a greater extent than either Fe^{2+} or Cu^{2+} throughout the brewing process, so that maturing beer has concentrations of Mn^{2+} typically three and five times those of Fe^{2+} and Cu^{2+}, respectively.

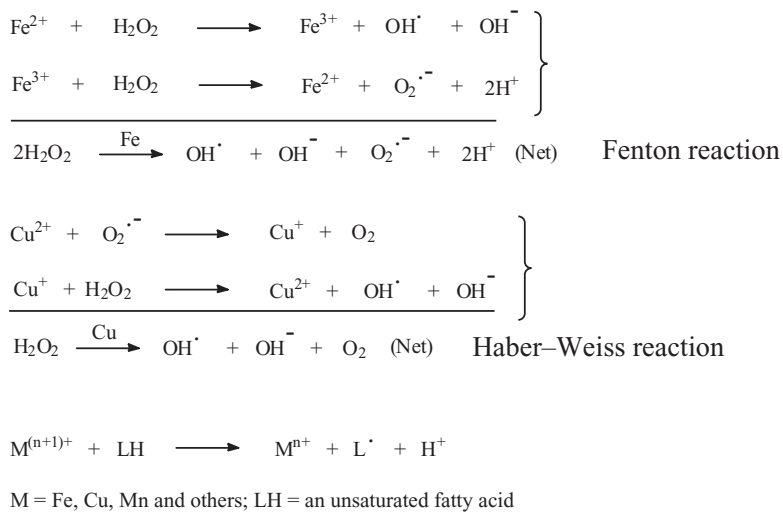

Figure 2.6.39 *Metal ions in the generation of radical intermediates involved in beer staling. Based on Zufall and Tyrell (2008)*

2.6.13 Beer styles

This section gives a description of both the more common and the more specialist styles of beer, in terms of original gravities, % ABV, color, flavor and other characteristics that are related to technical aspects of their production. It should be noted that in several cases there is overlap between styles, and divisions between certain beer types can be rather arbitrary. For example, where do strong ales end and barley wines begin, with respect to, say, % ABV? For some styles a short history is given and in most cases, notable examples are quoted. The styles are discussed in alphabetical order. Light (or lite) and diet (or diät) beers are discussed in Section 5.7.2.

Abbey Beers

This is a name that is reserved for beers brewed in abbeys, or by outside breweries by arrangement with the abbeys, principally in Belgium, but also in Holland and northern France. They are nearly all top fermented (ales), but the best known (and considered by many to be the best) are those brewed in Cistercian Trappist monasteries. According to EU law, only the five Trappist abbeys that still brew on the premises are allowed to use the description 'Trappiste' for their beers. These are Chimay (the original), Orval, Rochefort, Westvleteren (all near the French border) and Westmalle (near the Dutch border). Other abbeys, of the same or different religious orders, have licensing arrangements with outside breweries to brew beers bearing their names. Examples of these are Leffe (probably the best known and owned by the giant Anheuser-Busch InBev group), Floreffe, St. Sixtus and St. Feuillon (all Belgian). Dutch and northern French examples include Raaf and Rimaux, respectively. The Trappiste beers of Belgium are commonly regarded as masterpieces of the brewing art. They vary in alcoholic strength from 6 % to10 % ABV. Likewise the color varies between full gold/amber (∼6/10 °SRM) through copper to full brown (∼20 °SRM). The color is no guide to alcoholic strength (e.g. Westmalle's 6 % ABV beer is darker than its 8% ABV beer), instead alcoholic strength is indicated by the use of colored bottle caps (e.g. Chimay red (6 % ABV), white (7% ABV) and blue (8% ABV)) or by the

words 'Dubbel' and 'Triple' (e.g. for the two stronger Westmalle beers). Although certain Abbey beers are available on draught at or near the abbey, they are best known as their bottle-conditioned versions.

Altbier

This top-fermented beer is found on draught or in bottle in certain cities and towns of the Niederrhein/Westfalen area of Germany. The principle centres are Düsseldorf, Issum, Mönchengladbach and Münster. The term 'Alt' refers to the style of beer that existed everywhere in Germany before beers of the Pilsener type became almost ubiquitous. They are normally copper or pale brown beers (color: 13–20 °SRM) with a creamy white head and are brewed from pale malts, with caramel and other roast malts (but see Pinkus Müller Alt, below). The hop rate is usually rather light (~25 IBU) and alcoholic strengths are around 4.5% by volume. Notable examples include the beers of Düsseldorf old city (Altstadt) home breweries of Schumacher and Uerige. The larger producers include Diebels (Issum) and Hannen (Mönchengladbach). Pinkus Müller Alt (Münster) is much paler than the norm, being produced from Pilsener malt and, until recently, wheat malts. Altbier is given at least four weeks cold maturation (3–5°C) after about a week's primary fermentation. They are usually given a light filtration, although Diebels Alt is also pasteurized.

Barley Wine

This style is basically English in origin and is probably derived from the special strength March and October beers of the eighteenth and earlier centuries. They are top-fermented beers of between 8 % and 12 % ABV, the original gravities of the worts often being over 1100 (24 °P). In color, they range from full gold (Whitbread Gold Label and Harvey's Elizabethan Ale) to mid brown (Robinson's Old Tom). They are often highly hopped (~70/75 IBU) to balance the maltiness and high alcohol content. Many microbreweries and smaller breweries outside the UK have taken to brewing very good versions of the style: Nils Oscar Barley Wine (Sweden), van Steenberg Dragon (Belgium), Monster Ale (Booklyn Brewery, USA), Bigfoot Ale (Sierra Nevada Brewing Co, USA), Old Crustacean (Rogue Brewing Co, USA), St-Ambroise Vintage Ale (McAuslan Brewing Co., Canada) and Old Foghorn (Anchor Brewing Co, USA) are just a few examples.

Bière de Garde

A translation of this phrase is beer for keeping (or laying down). It should refer to bottle-conditioned (= sur lie) top-fermented beer of 4.5–7.5 % ABV from small breweries in northern France. Unfortunately, the same name is sometimes given to a number of pasteurized, artificially carbonated bottom-fermented beers. Color varies from pale gold (blonde: ~6 °SRM) through full gold (amber: ~9 °SRM) to brown (brune: >15 °SRM). Prime examples are produced by the breweries of d'Annoeullin, Castelaine, La Choulette (who give their beers rousing revolutionary names, like 'Sans Culotte' and 'Robespierre'), Duyck (famous for Jenlain beer), Monceau St.-Waast, St. Arnold, St. Leonard and Terken.

Bitter

This is Great Britain's basic draught beer (although there are bottled versions); it is top-fermented and many regard it as the draught version of pale ale. Indeed, some are known as pale ale or India pale ale (IPA) (often erroneously – see Pale Ale and India Pale Ale). Nowadays, bitter beers vary in color from mid gold/light amber (e.g. Boddington's Bitter, Holden's Golden Glow, Magpie Early Bird and Young's Bitter of color ~6–10 °SRM) to mid brown (e.g. Jennings Bitter and Nethergate Suffolk of color ~15 °SRM). However, the most common color range is from light amber to copper (e.g. Fuller's London Pride, Jennings Cumbria,

Blacksheep Bitter, Belhaven Best, Belhaven 80/- and Holden's Bitter). Alcoholic strength varies from just over 3.5% to well over 5% by volume. Likewise, malt character and hop bitterness show a wide variation, the latter generally being anywhere between 20 and 40 IBUs. Dry hopped versions have fine, spicy aromas. As far as alcoholic strength and drinkability (i.e. quantity) go, bitter beers can be divided into three categories: session (ordinary) bitter ($<$ 4% ABV), premium (best) bitter ($\sim$4.5% ABV) and strong (special) ($>$5% ABV). Outside Great Britain and Ireland, there are fine beers of this style, most notably in Australia (Cooper's Sparking Ale), New Zealand (Galbraith's Bitter and Twisted) and Belgium (de Koninck of Antwerp). An outstanding example from the USA (where the style is becoming popular with some microbreweries) is Firestone Walker's Double Barrel, which is brewed using an oak cask union system, similar but not identical to the old Burton Union system (Section 2.6.5). It should be mentioned that bitter as a style of draught beer has its origins in the early twentieth century; previously mild ale and old ale were the main draught styles in England.

Bock, Doppelbock and Related Styles

These are strong bottom-fermented beers that were originally a German speciality, but are now much imitated throughout the world. Bock and Doppelbock beers must have in excess of 6.3% ABV and 7.5% ABV, respectively. Bock beer colors range from pale gold ('blonder Bock') through full gold/amber ('heller Bock') to brown ('dunkler Bock'). The prefix Ur-, or the word 'Urtyp'are often used in the names of Bock beers, to signify purity and originality.

Some noteworthy Bock beers from Germany include Einbecker Urbock Dunkel, Forschungs Blonder Bock and Spaten Franziskus Heller Bock. It is possible that the word 'Bock' in derived from Einbeck, a town in Lower Saxony (Niedersachsen), where the Einbecker brewery is thought to have first brewed this style of beer. Bock style beers are brewed all over the world, some good examples being those from Lindeboom brewery (Holland), Faxe Brewery (Denmark) and Great Lakes Brewing Co. (USA).

Maibockbier is basically a pale Bockbier brewed in the spring. Well respected examples come from Ayinger Brauerei, Einbecker Braühaus and the Hofbraühaus (München). Doppelbock is an even more revered style of beer than Bock. The names of German Doppelbock beers usually end in -ator, as in Celebrator (Ayinger Brauerei), Delicator (Hofbraühaus), Kulminator (EKU) and Salvator (Paulaner Brauerei). Strictly, Kulminator of EKU belongs to a smaller subgroup of Doppelbock, called Eisbock, because of the freezing process that is used to increase its alcoholic content. At 13.5% ABV, it is the second strongest beer in the world. The accolade of strongest beer goes to the Utopia beers (21–25% ABV), produced by the Samuel Adams Brewing Co. (USA).

Brown Ale

Although the color of many beers may be described as 'brown,' only top-fermented beers that use the word 'brown' (in whatever language) in their names should be included in this style. In Britain, brown ale can be considered as the bottled version of mild ale, with generally low alcohol content (typically $<$ 4.0% ABV), mild hop bitterness ($<$ 24 IBUs), relatively high residual sugar ($>$3.0 $^{\circ}$P) and color in excess of 15 SRM. This was not always the case and there are exceptions today: Newcastle Brown Ale is a dry, copper-colored beer of 4.7% ABV. The Brown Ales of Belgium (Bruinnen) are classics of the style: many are over 6.0% ABV and are bottle conditioned. Probably the best known (and very highly regarded) are the Oudenaarde brown ales of the Liefmans and Roman breweries, and also that of the Crombé brewery in Zottegem. The 'brune' versions of bière de garde from across the border in northern France, are not dissimilar in style. There are

notable American brown ales, from such breweries as Brooklyn Brewing Co. and Great Lakes Brewing Co. (Cleveland Brown Ale). These tend to be stronger and hoppier than their UK equivalents.

Cream Ale

This is an American style of beer that was introduced by ale brewers as an attempt to counter the growing popularity of Pilsener style beers in the late nineteenth and early twentieth centuries. Modern cream ales are still mostly top fermented, but like Kölsch, they undergo cold maturation after primary fermentation. Alcohol content is around 5% by volume, color pale-medium gold (3–5 °SRM), with light hoppiness (<20 IBU). Examples of the style include Genesee (High Falls Brewing), Dave's Original (Molson) and Whitetail (Wisconsin Brewing).

Flavored Beers

This rather broad title covers a wide range of very different beers that have been flavored at the brewery with ingredients other than or as well as hops. Flavoring can be carried out at the boiling stage, but is more likely performed during the fermentation or maturation/conditioning period. Ingredients include whole fruits (or concentrates), beans and pods, spices, leaves, needles and oak. Probably the best known flavored beers are the fruit beers of Belgium, especially cherry ales ('krieken') from breweries such as Liefmans in Oudenaarde. Brown ale from the previous year is infused with fresh whole cherries and undergoes a gentle fermentation for a year, whence it is bottled and maturated further before sale. See also Lambic Beers for description of krieken-lambic. Other fruits, such as raspberries (framboise) or peaches are sometimes used as flavorings. On a bigger scale, Coors Brewing Co. (USA) produces Blue Moon Pumpkin Ale in the autumn, for consumption during the winter months. Citrus peel (zest), especially of orange, is a common beer flavoring ingredient, but is often used alongside spices, such as coriander, cardamom and cloves. A prime example is Hoegaardse wit bier (see Wheat Beers). Coriander is a frequently used spice for flavoring beer, as in the Umbel Ale of Nethergate Brewery (UK). A range of strongly flavored spices is used in beers such as Birrificio Troll's Shangrila Ale (8.5% ABV) and in the extreme, Brasserie des Franches-Montagnes' La Dragonne (Switzerland) is uncarbonated and is intended to be drunk while hot. During the past few years, new oak has featured as a beer flavoring; this is not to be confused with normal oak cask-conditioned beers, where the casks are not new and their internal surfaces are often lined with brewer's tar, so that little or no oak flavor is extracted by the beer. Anheuser Busch's Winter's Bourbon Limited Edition Seasonal Brew is not only aged in new Bourbon casks, but over whole vanilla beans as well. Innis and Gunn's IPA is an ale, brewed at the Glenfiddich Distillery in Scotland. It is matured in new oak casks for one month, blended and matured further before being bottled. The emptied casks are never again used for brewing – instead they are used to mature whisky. This was the original intention of the distillery, but the beer brewed in the new casks proved to be so good it was matured as a new style.

Chocolate beers have gained note in the USA during the past few years. Michelob (part of Anheuser Busch) produce Celebrate Chocolate Beer of 8.5% ABV, that is matured on cocoa beans. There are several 'chocolate stouts' such as Brooklyn Black Chocolate Stout (Brooklyn Brewery) and Rogue Brewery's (Newport, Oregon) Chocolate Stout, the latter being brewed with natural chocolate flavor.

Herbs and berries are also used to flavor beers; many of these beers are based on ancient recipes, since herbal beers predate hopped beers. Gruit (gruyt or grut) ale was brewed in Northern Europe using mixtures of herbs, but usually including juniper, heather, may wort, sweet gale and yarrow. Some modern microbreweries have recreated this style of beer in recent years, some using only one or two herb flavorings, along with hops. Included here are Spruce Goose (Steamwork Brewing Co., Colorado), Alaskan Brewery Co.'s Winter

Ale (some spruce) Fraoch (Williams Brothers, Scotland), containing heather flowers, sweet gale and ginger, Rogue Brewery Co.'s Juniper Ale and Birrificio Troll's Febbre Alta. Buds, needles, leaves or twigs tend to be added at the boiling stage, as with spruce, but more delicate flowers (e.g. heather, sweet gale) and berries (e.g. juniper) may be added at the maturation stage. Essence can be added at this stage, too. See also Sahti for use of juniper in brewing.

Nuts also have a place as beer flavorings, as witnessed by Birrificcio Troll's Palanfrina (9% ABV, with chestnuts) and Rogue Brewing Co's Hazlenut Brown Nectar (made with hazlenut extract). Many of the flavorings mentioned here are important ingredients of liqueurs and related beverages – they are discussed in more detail in Chapter 3.8.

Honey Beers

These are mainly top fermented, honey usually being added at the 'rocky head' ('high krausen') stage of fermentation. The honey supplies extra sugars (fructose and glucose mainly) and also aroma compounds; more delicate honeys (those with more subdued aroma profiles) tend to be used in pale beers (the majority of honey beers) for better balance. A well known example of honey ale in the UK is ex-Vaux brewery's Waggledance (now – 2009 – brewed by Charles Wells-Young, Bedford), named after the communication dance of honey bees. Other examples include several from American craft breweries, such as Rogue Brewing Company's Honey Cream Ale and Milwaukee Ale House's Downtown Lites Honey Ale. In Europe, the Brasserie Lefebvre (Belgium) provides Barbar Honey Ale.

Kölsch

In the cities and environs of Köln (Cologne) and Bonn, a pale, refreshing top-fermented beer is brewed at several breweries. It is called Kölsch and, by law, can only be brewed in Köln and Bonn. It is invariably pale (color: 4–5 °SRM), fairly well hopped (20–30 IBUs) and has around 4.5% ABV. Kölsch is brewed at typical ale temperatures, but is then matured for several weeks at low temperatures (3–5 °C), like Altbier. Also, like Altbier, most are filtered and are often served from small wooden casks. Probably the best known examples of Kölsch are those of Sion and P.J. Fruh (Köln). A similar style is brewed by Goose Island Brewing Co. ('Summertime'), in the USA.

Lambic Beer

This is the 'wild beer' of Belgium and is unlike almost all other brewing styles. It is brewed from pale malted barley and unmalted wheat, with old hops. No yeast is added, instead the fermentation takes place in lengthy stages that involve a number of wild yeasts and bacteria that are present in the air and in the very fabric of the brewery. See Section 2.6.7 for a more detailed description of lambic brewing. Lambic styles include young ($\sim$1 year old), old ($>$3 years old), Faro (sweetened old), Gueuze (a young-old blend) and fruit Lambics. Blending is an important aspect of many Lambic beers: Gueuze is a blend of young Lambic refermented with old Lambic (ratio $\sim$2:1); it is found mainly as a bottle-conditioned beer. Likewise, fruit lambics (blended lambics matured and conditioned with added fruit pulp or syrup) are found in bottle-conditioned form. Lambic beers all have a refreshing degree of sourness (even tartness) and some have cheesy or resinous overtones. The sourness is mostly attributed to the presence of lactic acid, arising from the brewing process (Section 2.6.7). Its concentration can be anywhere between 0.1% and 1%, depending on the brewer. They are brewed in Payottenland, to the west of Brussels. The best known breweries are those of, Belle Vue, Boon (famous for its 'Marriage Parfait'), Cantillon (famous for its 'Grand Cru'), De Neve, De Troch, Girardin, Lindemans, Timmermans and Vandevelden (especially for its 'Oud Bearsel').

Malzbier

This is a rich, dark, but low alcohol (<1% ABV) beer that is brewed in Germany, originally as a nutritious beverage for sailors about to embark on a long journey and later for people recovering from illness. Traditionally, it is often the first beer children drink as they grow up. Roast malts give it the dark color and the low alcohol content comes from the high initial gravity and high mashing temperatures and/or very low fermentation temperatures. In recent years, the style has gained some extra popularity as result of increasing health awareness (Chapter 2.13), probably the best known example is Henninger (Frankfurt) 'Karamalz.'

Märzenbier

Traditionally, in the days before the refrigerator, brewing in southern Germany had to be concentrated in autumn to spring, since the warm summers caused fermentation problems. The last brew was in March and this was given a somewhat higher alcohol content to preserve it through the summer months until the autumn. This became known as Märzenbier (March beer) and was served ceremoniously in the autumn, then later at the Oktoberfest in München. The tradition is continued to this day, despite the fact that refrigeration has long made summer brewing a facile process. Modern Märzenbier is pale (color ~5 SRM) and has about 6% ABV; the best-known are those of the Munich breweries – Hacker-Pschorr, Hofbrauhaus, Paulaner and Spaten.

Mild

Modern mild ale is a British style of top-fermented beer, generally of low gravity (OG <40), lightly hopped (<20 IBUs) and of low alcohol content (<4% by volume). Residual sweetness varies, but all in all draught mild ales, especially cask conditioned, are ideal session beers. The best are a living demonstration that volume of alcohol does not necessarily reflect volume of flavor, as anyone who has tasted Bateman's Dark Mild (Wainfleet) or Jennings Dark Mild (both ~3% ABV) will realize. Most mild ales are dark (color 15–25 °SRM), but there are some pale versions (e.g. Mc Mullen's AK (Hertford) and Taylor's Golden Best (Keighley)). The popularity of mild beers in the UK has declined tragically since the 1960s in the favor of bitter beers and lagers, but the past few years have seen something of a comeback, or at least a stabilization, thanks largely to the consumer group CAMRA (Campaign for Real Ale). A number of breweries still produce copybook dark mild ales, Banks (Wolverhampton), Brains (Cardiff), Elgood (Wisbech), Holden (Woodsetton) and Holt (Manchester) being just five examples, apart from those named above. The Dark Ruby Mild of the Sarah Hughes Brewery (Dudley, UK) is probably the best known example of a Strong Mild (6% ABV). The mild style is uncommon in Scotland, although Scotch Ales possess many of the mild ale characteristics, apart from being much stronger in alcohol. In pre-nineteenth century England, 'mild' was used to describe fresh (unaged) beers, all dark and with a fair range of alcoholic strengths. They had an X-rated naming system: X for the weakest (~4–5% ABV) and XXXX for the strongest (>7% ABV). These beers were often blended with aged beers (old ales) in proportions depending on requirements and taste (see Old Ale, Strong Ale and Stock Ale, and also Porter).

Münchner (or Münchener)

This name originally referred to the dark, malty bottom-fermented beers of the city of Munich (München), and as such, this style is imitated in other countries and the moderately roasted malts that are used in these and other brews are still known as Münchner malts. The modern beer equivalent is simply known as Dunkel and is produced by all the Munich breweries, along with their more popular Helles (Pale) and Pilsener beers. Its color varies between dark copper and dark brown (14–28 SRM), alcohol content is around 5% by

volume and it is light to moderately hopped (18–28 IBUs). Notable examples from Munich include Paulanes Dunkel, Augustiner Dunkel Volbier and Spaten Export Dunkel. Good examples of the style are produced by other German breweries (e.g. Kaltenberg, Kulmbacher and Tucher breweries) and in other parts of the world (e.g. Capital Munich Dark (USA) and Harpoon Munich-type Dark Beer (USA)).

Old Ale, Strong Ale and Stock Ale

These are similar styles of English top-fermented beers of moderate to high alcoholic strength. In pre-nineteenth century England, old ales were known as keeping ales, referring to the fact that they were matured in wooden casks or vats for at least a year, and often for considerably longer. These beers varied in color from copper to dark brown and alcohol content was usually in excess of 6% by volume and could be as high as 12%; they were named X to XXXX to signify alcoholic strength. Because of their extended maturation, most old ales had significant sour notes due to the production of acids by *B. lambicus*, as in Lambic beers (Section 2.6.7). At the turn of the nineteenth and twentieth centuries, some strong ales possessed ∼0.3% lactic acid or higher (lambic beer typically has ∼1% lactic acid). Consequently the tendency was to blend them with young (mild) beers. Today, a classic and very agreeable example is provided by Greene King's Old Suffolk Vintage Ale, produced by blending an XXXX Old Ale (12% ABV) with a fruity, fresh beer (BPA).

Nowadays, stock ales are uncommon, but the Samuel Adams Brewing Co. (USA) describes its Boston Ale as a stock ale. Old ales and strong ales, on the other hand, are well represented in England and others countries, notably the USA and Canada, and with good strong ales coming from Belgium. Perhaps the best known strong ale is Thomas Hardy's Ale, which at ∼11.5%ABV is probably the world's strongest beer that is produced without freeze distillation. It was originally brewed by Eldridge Pope of Dorchester, but following the demise of that brewery, it is now brewed at O'Hanlon's Brewing in Devon. Also of high repute are Gale's Prize Old Ale (now brewed at Fuller's brewery in London), Fuller's 1845 Celebration Ale, Theakston's Old Peculier and Usher's 1824 Particular. It is not easy to make a distinction between old ale, strong ale and barley wine, especially as their alcoholic strengths overlap. In some old ales and strong ales there is perhaps more of an emphasis on roasted flavors, coming from the inclusion of modest amounts of roasted malts is their grain bills; dark malts are not usually included in the brewing of barley wines. Outside England, other classics include Scotland's Traquair House and McEwan's Champion Ale, Belgium's Duvel (Moortgat Brewery), Bush (Dubisson Brewery), Goude Carolus (Anker Brewery) and Piraat (van Steenberge Brewery).

Pale Ale

This style of top-fermented beer was essentially developed in Burton-upon-Trent and surrounding areas during the first half of the nineteenth century, when darker beers were much more common. They were heavily hopped, but malty beers of 5–6% ABV and typically of medium gold to amber color (6–10 °SRM). A subvariety, rather stronger and hoppier was India Pale Ale (IPA), first brewed in quantity by Allsopp's Burton Brewery for shipping (in cask) to India. To survive the long sea and land journey, the beer had to be of a very strong constitution. Modern pale ale is often regarded as the bottled version of bitter and tends to have the same range of colors (6–10 °SRM), alcoholic strengths (4–6% ABV) and they are usually well hopped (25–45 IBUs). However, there are draught pale ales (Nottingham Brewery's Extra Pale Ale is a notable example) and draught IPAs, although the latter (usually of 3.5–4.5% ABV) often bear little resemblance to the original style (6–8% ABV). The best known bottled English pale ale is probably Worthington White Shield (∼5.6% ABV), brewed at the White Shield Brewery on the brewing museum site (now owned by Coors Brewing Co.) in Burton-upon-Trent. Also of high reputation, and also bottle conditioned (some have draught versions) are Hop Back Summer Lightning, Freeminer Trafalgar IPA, Kelham Island Pale Rider, Hampshire Brewery 1066 SPA and Young's London Ale. The craft brewers of Canada and the USA (especially) have gone for pale ale

and IPA in a big way and produce some excellent examples, many bottle conditioned, as witnessed by Liberty Ale (Anchor Brewery Co.), Pale Ale (Firestone Walker Brewing Co.), and others produced by Bridge Port Brewing Co. (Oregon), Sierra Nevada Brewing Co., Tankhouse (Toronto) and Keith (Nova Scotia).

Pilsener

This style is without doubt the most emulated and the most widely available of all styles. The first beers of this type (pale, bottom fermented) were brewed in the Bohemian town of Plzeň (Pilsen in German) in 1842, in response to the continued unsatisfactory quality of the town's top-fermented beers at that time. Although the first lager beers (i.e. bottom fermented) were probably brewed in Germany or Austria, the pale, malty and delicately hoppy Pilsen lager style quickly began to compete with (and even oust) the established regional styles (whether top or bottom fermented) in larger cities throughout Europe and (later) in the 'New World.' Nowadays, there are hundreds of pale lager brands (∼2–4 °SRM) throughout the world that have been inspired by the Pilsener style, even though many of the brand names do not include the words 'Pilsener' or 'Pils.' Many that do call themselves by these names bear only a passing resemblance to the real thing, although others are its equal in quality. Many other similar styles emerged at about the same time or shortly after Pilsener, the most noteworthy of which are probably those of Českе Budějovice and Dortmund. The German name for the former is Budweis – Budweiser, the major product of Anheuser Busch, is named after that town. The most famous brewery of Pilsen is that of Plzeňský Prazdroj (Urquell). Like the somewhat newer Pilsen brewery, Gambrinus, it became famous for its beer produced only from Pilsener malt, Saaz hops, bottom-fermenting yeast and ultra-soft Pilsen water. These factors, combined with traditional bottom-fermenting practices (e.g. double decoction mashing and long, cool lagering) resulted in a finely balanced brew. Elsewhere, the Pilsener style can be maltier as in some of the Dortmund beers or hoppier, as in Jever Pils (Embden, Germany) and some of the Belgian Pils brands. Kellerbier, Zoigelbier and Zwickerbier are all cask-conditioned forms of lager, often served cloudy, directly from the cask, although tank, keg and bottled versions exist. They are a speciality of Bavaria and Franconia, Germany. Probably the best known is the bottled Kellerbier of the St. Georgen brewery in Franconia.

Porter

This style originated in London in the early eighteenth century, acquiring its name from its popularity amongst the river and street porters. It was very dark being brewed with 'brown malts' (possibly similar to today's lighter crystal malts) and had an OG of around 1070, with about 6.5% ABV. Over the next 100 years, the style underwent a number of changes, as a result of changing brewing practices that occurred alongside population and brewing expansion during the Industrial Revolution. It became brewed with pale malts and a small portion of patent black malt (instead of all brown malt), in a variety of strengths and ages. The weakest were called single or plain porters, whereas the strongest were known as double or extra stout porters (see Stout). Young ('mild') and old porter (often two years aged) were often blended (e.g. 2:1) at the point of sale. As tastes and economic circumstances changed, porter was increasingly sold in 'mild' from, gradually declining in alcohol content and hop bitterness. Eventually (in the 1930s) the name disappeared, being replaced by 'stout,' until it was revived in England by microbreweries in the 1980s. Modern porter (apart from Baltic Porter) is top-fermented of OG 1040-65, 4-6% ABV, color: 20–35+ SRM and hop bitterness: 20–50+ IBUs. Prime examples from the UK include Flag Porter (Elgood, Wisbech), Old Growler (Nethergate Brewery), and Original Porter (Shepherd Neame) and from the USA there are those of the Anchor, Great Lakes, Yeungling and other brewery companies. The brewing of porter beer was taken up by breweries in countries around the Baltic Sea, as a result of the influence of imported porter and Russian Imperial Stout (see Stout) from England. Porter is still produced there today, although usually bottom-fermented and of 7–9% ABV, color:

17–30 SRM and hop bitterness: 20–40 IBUs. Examples include Sinebrychoff Porter (Finland), Zywiec Porter (Poland), Alderis Porteris (Latvia) and Stepan Razin Porter (Russia).

Rauchbier

These beers, a speciality of Franconia (Germany), are characterized by smoky aromas and flavors derived from the use of smoked malts. Before the advent of hot air kilns, much malted barley was kilned or roasted using wood fires, so that a degree of smoky character would be present in all beers. Nowadays, it is a speciality style, with beech wood being the major fuel. Smoked beers are usually copper colored, the most famous examples being Bürgerbräu Kaiserdom and Schlenkerla Spezial (both from Bamberg). Other breweries producing smoked beers include Budels (Holland), Poretti (Italy) and Alaskan (USA).

Red Beer

There are many beers that can be described as 'red,' but the term here refers only to those beers that have acquired the name or were originally called red beers. On that basis there are two main types. Firstly, the Irish Red Ales are standard top-fermented beers, the most famous of which is Killian's, brewed under license from Lett's (Enniscorthy, Wexford) by Pelforth in France (Bière Rousse). The second style, much more distinctive, comes from Western Belgium, produced by breweries such as Rodenbach. These beers are based on blends of two year old matured ale that has acquired some degree of sourness, and younger ales; Rodenbach Grand Cru is pure two year old Ale.

Roggenbier

This term refers to beers that are produced from worts with at least 50% malted rye in their grain bills. This style of beer was revived in Germany in the 1980s. Formerly, rye was grown exclusively to bake bread, but before the Rheinheitsgebot, rye malt was a common ingredient of beer (in Germany, up to the end of the fifteenth century). Most modern versions (e.g. Paulaner – ex-Thurn und Taxis/Schierlinger) are top fermented. Malted rye gives a fruity, spicy character and modern Roggenbier is bottle conditioned and turbid. Hop bitterness is lowish ($<$ 20 IBU), color is 15–20 SRM and alcohol content around 5.5% by vol.

Sahti and Koduölu

These are strong traditional beers from the Baltic countries of Finland (Sahti), Estonia (Saaremaa Island – Koduölu) and Sweden (Gotland –Gotlandsdricke). They are brewed using baker's yeast and worts made with both malted and unmalted grains, including barley, oats, rye and wheat. The mash is filtered though a thin bed of juniper twigs. Juniper berries, as well as, or in place of hops are used for flavoring. Dried hop cones are sometimes used, along with juniper twigs, as the filter bed. The wort is not usually boiled, but the mash, when contained in wooden vessels, is sometimes heated by hot stones and some sahti wort is given a brisk, short boil. Both ramped and isothermal mashes are used. The dominant flavors are estery, banana and phenolic notes, derived mainly from yeast action. There are also juniper notes in the flavor. There may be some hop aroma, if hops were used, but no hop bitterness. Alcoholic strength varies between 7% and 11% by volume and color is around 15 SRM, due to use of crystal or Münchner type malts. There are several sahti breweries in Finland, some of them microbreweries. Finlandia, Huvila, Joutsen and Lammia are just four examples.

Saison

This is the name given to pale gold to copper top-fermented beers brewed in southern Belgium. They were once seasonal beers (hence the name), brewed in autumn or winter for drinking at the next harvest. Now, they are brewed all the year around by small breweries and are mostly bottle conditioned, having an alcohol content of 5–8% by volume, color of 5–12 SRM and hop bitterness of 25–45 IBU. Saison wort is fermented at high temperatures (>30 °C), which gives the beer peppery, spicy and floral notes. Notable Belgian examples include those of Brasseries Dupont, Frantôme, Lefèbvre, de Silly and à Vapeur. The style is known in the USA; examples include Samuel Adams Saison and Dans Saison (Dogfish Head Brewing Co.)

Scotch Ales

Strictly, this name is reserved for Scottish strong ales, of at least 6.5% ABV. Amber (rather than pale) malts form the basis of the grain bill, which can also include brown malts, or even roasted barley, and hence Scotch Ales vary in color from amber to dark brown. Compared with English strong ales, the hop character of Scotch ales is muted: maltiness (and sometimes smokiness) being more to the fore. The yeasts, though top fermenting, are often sedimentary in character and are low attenuators, thus leaving significant residual sweetness. Typical examples include Belhaven Wee Heavy, McEwan's Scotch Ale and Skullsplitter Ale (Orkney Brewery). Fine beers in this style are also produced in Belgium (e.g. Scotch de Silly and Achouffe McChouffe) and the USA (e.g. Kilt Lifter from Moylan's Brewing, California).

Sourish Shchi

This is a traditional Russian unhopped 'wild' beer, brewed with six ingredients (Shchi is the old Russian for 'six'): malted barley, rye and wheat; wheat or rye flour; unmalted buckwheat and honey. No hops are used and the wort is unboiled (like old English ales), being fermented by the yeasts and bacteria on the ingredients and brewing equipment, followed by sediment from the previous brew. Traditionally bottle conditioned in Champagne bottles, thus give a sourish, winey, spicy effervescent drink – unlike Kvas (brewed from rye bread), which is served 'flat' (Dankovtsev *et al.*, 2002).

Steam Beer

This is a hybrid beer brewed using lager (bottom-fermenting) yeasts to ferment the wort at ale temperatures (Section 2.6.8). The style has become associated specifically with California, but was quite widely spread throughout the USA in the ninteenth century. Steam beer was rescued from extinction in the 1960s with the revitalization of the Anchor Steam Brewery in San Fransisco. The original style probably arose as an attempt to brew cheaper lager beer without refrigeration. Its name probably comes from the high carbonation of the original cask-conditioned beer. Modern steam beers tend to be based on the Anchor revived prototype; they are amber beers (color: 10–15 SRM) of moderate bitterness (∼35 IBU). They have a malty/fruity palate, but with a clean finish. Apart from the Anchor Brewing Co.'s definitive steam beer, examples of the style include Old Dominium Victory Amber, Southampton West Coast Steam Beer and Sleeman Steam Beer (Canada). In Germany, there is Dampfbier (= steam beer), a top-fermented brew named after the steamy mist above the vigorously fermenting wort at temperatures in excess of 21 °C. It was a speciality of southeastern Bavaria (der Bayerischer Wald, near the Czech border), dying out in the early twentieth century, to be revived by Erste Dampfbierbrauerei (Zwiesel) in 1989. Other examples are those of Maisel (Bayreuth) and Borbeck (Essen). Like the original Dampfbier, the modern version is brewed with wheat beer yeast (even though the grain bill is exclusively malted barley), so it has spicy, clove notes over the malt and hop character. High temperature fermentation also gives it phenolic notes.

Steinbier

This ancient style was revived by the Rauchenfels brewery in Germany a few years ago. In the days before large metal kettles, big stones were baked in wood fires and then used to boil the wort, then contained in a wooden vessel. The intense heat of the stones caused localized caramelization of the wort sugars, some of which stuck to the stones' surfaces. After cooling and fermentation, the stones were added back to the beer so that the caramelized sugars could infuse the beer. Modern Steinbier (= stone beer) is a bottom-fermented, copper-colored brew with a smoky, caramelized aftertaste.

Stout

The history and development of stout is intricately connected with that of porter.

Porter's home base was London, but imports of the brew into Ireland caused Arthur Guinness and other Irish brewers to brew their own versions of porter, alongside their other ales. The style rapidly displaced the paler styles. The stronger types of porter were called stout porter and extra stout porter (etc.) and eventually, the term porter was dropped, but Guinness continued to brew porter until the 1960s. The same happened in England, except that changes in taste and economic circumstances, resulted in dominance of the stout beer market by the Irish breweries. Still the most prominent form of stout is bitter stout, as typified by those of Guinness, Murphy, and Beamish and Crawford, the last two of which companies are located in Cork. These beers are characterized by a deep (black) color ($\sim$35 °SRM), with thick white (or off white) head and bitter, but smooth taste. Guinness Extra Stout is available in bottle-conditioned form as well as brewery-conditioned forms in cans and bottles. The dark color and a certain bitter flavor are derived largely from the use of roast barley (black roasted unmalted grain). Their alcohol contents tend to be around 4.5% by volume, but export types have higher than 7% ABV. English stouts tend to be both less bitter and sweeter, though nowadays there are many variations – from the sweet Mackeson ($\sim$3% ABV) to Freeminer Deep Shaft (6.2% ABV). Milk stout is brewed with added lactose for sweetness – lactose is not fermented by *S. cerevisiae*. Oatmeal stout is brewed with a small proportion of oats (5–15%) in the grain bill (too much oats give an astringent taste). By the 1970s English breweries had ceased brewing oatmeal stout, but the style was revived a few years ago by Sam Smith's Tadcaster Brewery (5% ABV). Oyster stout probably refers to the long association of eating oysters with a glass of stout, although some stouts have allegedly been matured over oysters. Highly roasted malts such as chocolate malt and black malt often produce beers with chocolate and/or coffee notes in their flavors. This led some brewers to name their stouts as chocolate or coffee stout; some are even brewed with added chocolate (or cocoa beans) or coffee (see Flavored Beer). The most potent subcategory of stout is Imperial Russian Stout, probably the best known of which was that of Scottish Courage (previously Simonds, Barclay and Perkins, and before that, Thrales). Beers of this kind evolved from stout porters that were exported to the Tsarist Court and to the Baltic countries. They are invariably rich and malty with spicy, chocolate notes and are usually around 10% ABV. Modern versions include Sam Smith's Imperial Russian Stout (7% ABV) and Harvey's Imperial Extra Double Stout (9% ABV). Stouts of all types are now brewed all over the world, notable examples (apart from those already mentioned) being St. Amboise Oatmeal Stout (McAuslans Brewing, Canada), Best Extra Stout (Cooper's Brewery, Adelaide), Øl (Ølfabrikken brewery, Denmark), Hook Norton Double Stout (U.K.) and Wilson Mild Stout (van Steenberge brewery, Belgium).

Wheat Beer

After barley, wheat is the most important brewing cereal and many beers are brewed from wort with some malted wheat in the grain bill. However, the term wheat beer is used here to indicate only those beers that have sufficient malted wheat to give recognizable wheat character (say $>$40%). Malted wheat is higher in protein

content than malted barley (13% compared with 10%) and has a different flavor profile: wheat beers are often distinguisted by biscuity, fruity and spicy notes. Germany is the leading exponent of wheat beer, which falls into two major categories: Weizenbier (or Weisse), prominent in Bavaria and Franconia, and Weisse, from the north, especially Berlin. The latter are brewed from about 30% wheat malt and are light in alcohol (~3.5% by volume), whereas the former are usually brewed with over 50% malted wheat and have over 5% ABV. All are top fermented and many are available in bottle-conditioned form, whence they are known as Hefeweizen. Many are cloudy and are meant to be drunk as such. Classic wheat beers from southern Germany include Spaten Franziskaner, Hofbräuhaus Edel Weizen, Schneider (many brands) and Riedenburger Weisse. From the north come Schultheiss Berliner Weisse, Berliner Kindl Weisse and Haake-Beck Bremer Weisse. Apart from those pale brews, there are Dunkel Weizen, Weizenbock and Weizendoppelbock, notable examples being Schneider Dunkel Weiss, Erdinger Pikantus and Schneider Aventinus, respectively. Additionally, there are German wheat beers that are brewed from the genetic forerunners of modern wheat (*Triticum aestivum*), such as Emmer (*T. monococcum*) and Dinkel (*T. spelta*), a cross between Emmer and wild grasses. These wheats have even higher protein contents (up to 17% for Dinkel) and also high phenolic compound contents, which means that they are either dehusked before mashing or are limited to less than 50% of the grain bill. Prominent examples are Riedenburger Emmer Bier and Neumarkter Lammsbräu Dinkel. Belgium is also a producer of fine wheat beers (Wit Bier or Witte), including Hoegaarden, Lefebvre Blanches Bruxelles and Gouden Boom Brugs Tarwebier. Wheat beer has become popular worldwide during the past few years, being brewed in all major brewing countries, in all styles. Examples include Blue Moon (Coors Brewing, USA), Oakham White Dwarf (UK), and Lion Nathion Breweries Mac's Great White (New Zealand).

2.7

Cereal-based and Other Fermented Drinks of Asia, Africa and Central/South America

The numerous indigenous nondistilled alcoholic beverages of the continents of Africa, Asia and Central/South America are discussed in this chapter. Most of these drinks are based on cereal crops, including barley, maize, sorghum, rice and wheat, although others are derived from tree sap, cassava and other roots, and plantains.

The production of many of these drinks is via natural ('spontaneous') fermentation and with little in the way of refinement, except simple filtration. Others, such as Asian rice wines are brewed using special starters containing colonies of particular microorganisms. They are mostly consumed fresh (often while still fermenting) and cloudy (sometimes of the consistency of porridge) and hence they often have comparatively high levels of protein, carbohydrate, fiber and unfermented sugar, as well as yeast and other microorganisms, such as lactic acid bacteria (LAB). Consequently, they are usually far more nutritious than the highly refined European style beers that are brewed in the same countries, often by breweries owned by multinational brewing or drinks companies. Indeed, in many countries the indigenous alcoholic drinks, such as pulque in Mexico (Section 2.7.2) and the sorghum beers of Africa (Section 2.7.2) make an important contribution to the diet, particularly of lower paid workers. Additionally, because they are consumed 'live' (i.e. containing large populations of microorganisms like yeasts and LAB), they possess a greater prebiotic potential than the microbiologically dead European style beers brewed in the same countries. On the downside, brewery hygiene and quality control is very variable and there have been concerns about safety, particularly relating to the use of pathogenic mold infected materials (Odhav and Naicker, 2002). The majority of these drinks are produced by home brewers (artisanal brewers), for local consumption, but some, such as rice wines, pulque and African sorghum beers, are also brewed and distributed by small-scale industrial outfits and can be obtained in cans (pulque) or bottles (rice wines).

Although many of these beverages have been produced up to the last few years with minimal commercial exploitation and little supervision from governments and other legislative bodies, there is now growing interest in the regulation of some of these drinks, as in the case of Mexican pulque. The main purpose of this is to ensure good production practice, with an acceptable standard of hygiene, so that a safe, nutritious product of consistent quality can be brewed on a regular basis. Concurrent with this are modern programs of research, especially regarding the microbiological profile of the fermentations and its relation to the organoleptic character of the beverage. Research of this kind is important in determining the combination of

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

microorganisms and the production conditions that give the highest quality product, while maintaining its traditional character.

The rice wines of Asia are discussed in Section 2.7.1, whereas the maize and sorghum beers of Africa, chica and pulque of Central/South America, the palm wines of Africa and the other beverages produced from cassava and plantains are discussed in Section 2.7.2.

2.7.1 The Rice 'Wines' of Asia

Rice 'wine' is produced all over eastern Asia. Unlike wine, which is made by fermentation of naturally sweet grapes and (stretching the definition) other fruit, rice 'wine' results from the fermentation of rice starch converted to sugars. This process is more akin to that used to produce beer; however, beer production employs a mashing process to convert starch to mainly fermentable sugars whereas rice wine uses different amylolytic processes. Both nonglutinous rice (*Oryza sativa* L.) and glutinous ('sticky') rice are used and in Vietnam, purple glutinous rice (*Oryza sativa* var. *glutinosa*) makes rice wines that are often described as having a 'Sherry character.'

A characteristic feature of Asian rice wines is the use of a starter that supplies fungi and bacteria that have been grown on a solid medium: wheat grains in Korea (see below), barley, pea or wheat in China (Fan and Qian, 2006), rice and/or cassava powder in Vietnam (Dung *et al.*, 2006) and cooked rice in Japan (see below). Sometimes, a different starter is used to brew wines destined for distillation; for example in Japan, barley shochu is distilled from wine brewed with a koji made from pearled barley (Iwami *et al.*, 2005).

Some major types of rice wine in northeast Asia (Korea, Japan and China) are listed in Table 2.7.1.

The less refined, cloudy beverages are outlined first, followed by the more refined, filtered versions.

Cloudy Rice Wines

Choujiu is a type of Chinese fermented alcoholic beverage brewed from glutinous rice. It is very thick and has a milky white color, which is sometimes compared to jade. Choujiu is an ancient variety of Chinese wine, and is possibly the original Chinese wine. It can be traced back to the Tang Dynasty, where it was praised by the poet Li Bai. In ancient times, choujiu was referred to as yùjiāng. Today, the city of Xi'an is known particularly for its choujiu. Doburoku is the Japanese equivalent of choujiu, and in Korea gamju and makkoli are similar (Belleme and Belleme, 2007).

Table 2.7.1 *Summary of the major rice-based nondistilled alcoholic beverages of China, Japan and Korea*

Crude or cloudy rice wine	Clear (filtered) rice wine
Makkoli - a milky traditional rice wine indigenous to Korea	*Cheongju* - Korean rice wine *Beopju* - a variety of cheongju
Gamju - A milky, sweet rice wine from Korea	
Amazake - low-alcohol Japanese rice drink	*Sake* (*Nihonshu*) - Japanese rice wine
Doburoku - the Japanese equivalent of makkoli	
Choujiu - A milky glutinous rice wine popular in Xi'an, China	*Mijiu* or *Lao-zao* - a clear, sweet Chinese rice wine/liqueur, made from fermented glutinous rice

Figure 2.7.1 *Typical presentation of Korean makkoli*

Makkoli (or makgeolli), also known as takju, is a traditional alcoholic beverage native to Korea and is used during ancestral rites in Korea. It has a milky, off white color, and a cereal winey taste, with some sweetness. It is made by fermenting a mixture of boiled rice and water, and is about 6.5–7% alcohol by volume. It was originally quite popular among farmers, earning it the name nongju, which means 'farmer's liquor.' A regional variant, originally from Gyeonggi-do, is called dongdongju. Another variety, called ihwaju (literally 'pear blossom wine') was so named because it was brewed from rice with rice malt that had fermented during the pear blossom season. Ihwaju is often so thick that it must be eaten with a spoon.

Commercially, makkoli is most commonly available in plastic bottles or aseptic box containers (Figure 2.7.1). As it is an unfiltered beverage, it is generally shaken before consuming, as the cloudy white portion tends to settle to the bottom, leaving a pale yellow clear liquid on top.

Gamju or dansul is a traditional Korean alcoholic beverage, made from rice fermented with yeast cake. Because its fermentation is incomplete, its alcohol content is relatively low. It is made from steamed rice, to which water and yeast cake are added.

Although production of makkoli and similar drinks in Korea is many centuries old, both the production and demand for traditional Korean wines and liquors declined sharply during the Japanese colonial period (1905–1945). In 1986, in an effort to remedy this situation, the Cultural Heritage Administration of South Korea selected 86 varieties of traditionally brewed alcoholic beverages as cultural properties, with 12 types selected as Important Intangible Cultural Properties, each hailing from its own locality (Cho, 2004; Park, 2005).

Refined Rice Wines

The Japanese sake is probably the best known refined rice wine, having undergone a recent impressive worldwide revival, although not in its homeland. It will be seen in later paragraphs, that there are several variants, differing mainly in the type and extent of filtration used. The Chinese and Korean equivalents are mijiu and yakju, respectively, the latter often being known as cheongju in Korea. One popular brand of cheongju is Chung Ha, which is widely available at Korean restaurants. There are various local variations, including beopju, which is brewed in the ancient city of Gyeongju in the southeast of the country.

Beopju is a traditional Korean rice liquor, of the cheongju family of liquors. It is made chiefly from glutinous rice, and has an alcohol content of about 15%. Beopju first appears in historical records in the Goryeo Dynasty (936–1392). The name literally means 'law liquor,' and refers to its being made in accordance with fixed procedures: an early example of production regulation. Today, it is associated with Gyodong in Gyeongju, where the Gyeongju Choe clan brew a particularly famous variety; this Gyeongju Gyodong Beopju is designated by the government of South Korea as Important Intangible Cultural Property No. 86-3.

Daepo, a branded yakju (literally 'medicinal alcohol') is a refined rice wine made from steamed rice that has gone through several fermentation stages. It is also called myeongyakju or beopju and is distinguished from takju by its relative clarity. Other varieties include baekhaju, which is made from glutinous rice and Korean nuruk and heukmeeju (literally 'black rice wine'), which is made from black rice.

The Traditional Korean Rice Wine Production Process

In Korea, the major crop has historically been rice, and thus most Korean traditional alcoholic beverages have been made from rice, of both the glutinous and nonglutinous variety, which are fermented with the aid of yeast and nuruk, a wheat-based source of amylolytic microorganisms (especially *Aspergillus* and *Rhizopus* spp.) and of a variety of fermentative microorganisms, including lactic acid bacteria (LAB) and *S. cerivisiae*. Additionally, Koreans often use fruits, flowers, herbs and other ingredients to flavor these beverages, to a greater extent than equivalent Chinese and Japanese wines (see later).

The Korean traditional cereal-based alcoholic beverages in general are divided into 'takju,' 'yakju' and 'soju'. Among these, yakju, which is made from takju by removing the residue ('gigemi') from it (by filtration), is the oldest one. Traditional soju can be obtained by distilling takju or yakju (Section 3.4.4). A generalized procedure for brewing traditional Korean rice wines is shown in Figure 2.7.2. It can be also regarded as being typical of Asian wine brewing processes, but with differences in various fine details for Chinese and Japanese equivalent beverages.

Normal brewing is conducted using nuruk, a mash of milled and cooked rice (grain) and water, and fermenting for a specific time at a regulated temperature. This fermentation process is repeated by addition of rice and water to give 1st brewed liquor, 2nd brewed liquor, 3rd brewed liquor even up to a 12th brewed liquor. The flavor of the rice wine changes with the number of brews performed: it gains in alcoholic strength, maturity and depth of flavor. The first three brewed liquors are regarded as the heart liquor; most of Korean traditional alcoholic beverages consist of 2nd brewed liquor (Park, 2005). Both the amylase enzymes for saccharification of cooked rice starches and the microorganisms (bacteria and fungi) for fermentation are supplied by nuruk, a cake made of malted and partially fermented wheat grains.

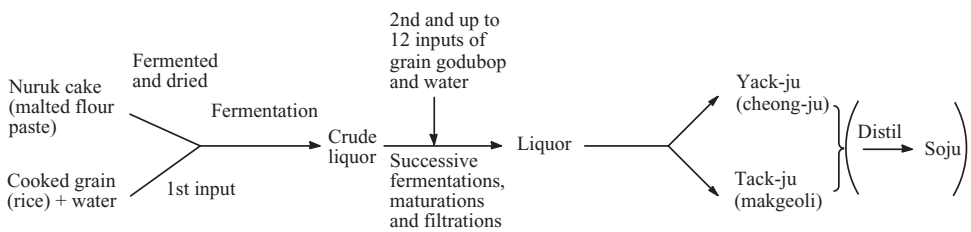

Figure 2.7.2 *Simplified scheme for the production of traditional Korean rice wine*

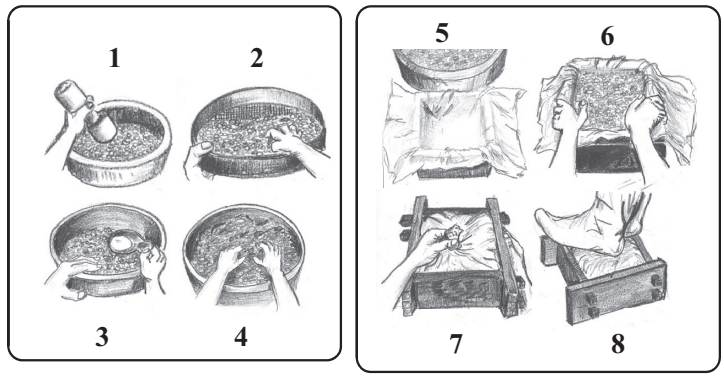
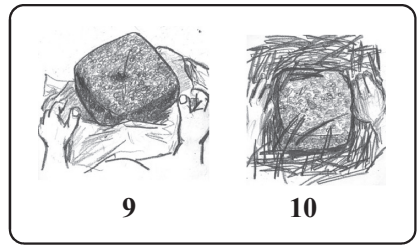


1. Preparation of rough whole wheat by grinding wheat grain with hand mill or pounding in a mortar.
2. Passing flour through a sieve to remove fine flour (about 30%).
3. Sprinkling water to whole wheat and mixing evenly.
4. Vigorous kneading of flour.
5. Putting wet hemp cloth-wrapper into the nu ruk mold.
6. Filling mold with dough.
7. Twisting the edges of hemp cloth wrapper to seal.
8. Forming the dough into flat cakes (sealed package upside down).



9 and 10. Unwrapping and placing on rice straw in warm, dry place to dry (later in sunny place with good air circulation).

Figure 2.7.3 *Preparation of nuruk*

Preparation of Nuruk

This can be regarded as the first step in brewing rice wine. The various steps in the preparation of nuruk are shown in Figure 2.7.3. Fermentations promoted by lactic acid bacteria (LAB) occur first, followed by alcoholic fermentations conducted by *Saccharomyces* and other species. This is soon superseded by the growth of other fungi, notably *Aspergillus* spp. and *Rhizopus* spp., so that after 30 days the nuruk appears to be covered in mold. After drying in the sun, excess fungal filaments can be shaken off, after which the cake is broken up with a hammer and the pieces are left in an airy and sunny place. The *Aspergillus and Rhizopus* species in nuruk provide glucoamylase (amyloglucosidase) and α-amylase (see Section 2.6.2) enzymes that convert rice starch to fermentable sugars, especially glucose and maltose. Some oligosaccharides (dextrins) are also formed, some of which are not readily fermentable, thus leaving some residual sweetness in the finished wine. Fermentative yeasts and bacteria are also supplied by nuruk, so that in the brewing of rice wines, amylolytic action and fermentation occur side by side. Yeast (*S. cerevisiae*) can also be added separately.

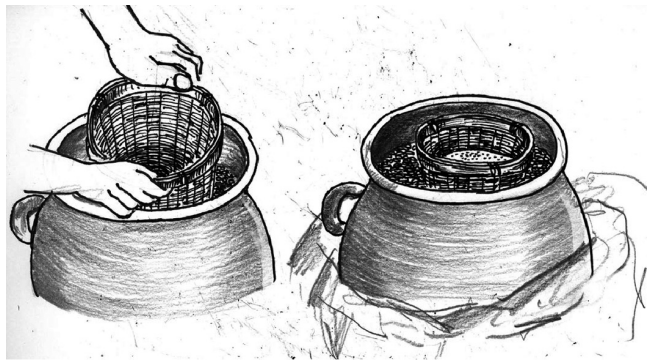


Figure 2.7.4 *Use of a traditional rice wine strainer to make chungju*

Brewing process

Freshly soaked and washed nonglutinous rice (some recipes use glutinous rice) is cooked in water for one hour to form a thin porridge. Small pieces of nuruk powder (∼15% w:w) are added to the cooled porridge in a small pot, which is then closed, wrapped in cloth and kept at 22–25 °C for 24–36 h. It is then unsealed and unwrapped, left in a cool, drafty place for a few hours, and then resealed, rewrapped and left in a cool place for 1–2 days. This first fermentation gives mitsul (밑술), which is essentially the starter; it will be used to ferment subsequent rice liquors, a process known as enrichment (teosul, 덧술 in Korean). Glutinous rice is steamed in an earthenware pot and when cooked, the rice is laid out on straw mats to cool. The cooled rice is mixed with cool water and the liquor from the first brew in a suitably sized pot and is put aside to ferment, as described above. This process can be carried out several times, as outlined in Figure 2.7.2.

Filtration

Chungju is obtained by placing a rice wine strainer in the fermented liquor and drawing out the relatively clear supernatant liquid. Takju, such as makkoli, is obtained by passing the thick porridge through a sieve. Figure 2.7.4 illustrates traditional filtering methods.

Traditional Rice Wine in Japan

Amazake is a traditional sweet, low alcoholic Japanese drink made from fermented rice. Amazake dates from the Kofun period and it is mentioned in the Nihon Shoki. It is part of the family of traditional Japanese foods (including miso, soy sauce and sake), made using inoculation with the fungus *Aspergillus oryzae*).

Sake is the major Japanese alcoholic beverage made from rice. This beverage is called ‘sake’ in English, but in Japanese, sake or o-sake refers to alcoholic drinks in general. The Japanese term for this specific beverage is nihonshu, meaning ‘Japanese sake.’ It is brewed using a similar process to that described for Korean takju and yakju, where the saccharification of rice starch and fermentation of the resulting sugars occur over the same period of time in the same vessel. The major difference is that fermented, malted wheat (nuruk) is not used as a source of saccharification/fermentation microorganisms. Instead cooked rice inoculated with the fungus *Aspergillus oryzae*, known as kōji, is used for this purpose. Like Chungju, most sake is filtered.

Moromi, the main mash sake is produced by the multiple parallel fermentation of rice, that is to say simultaneous saccharification, and alcoholic and other fermentations. The rice is polished to remove the

protein and oils from the exterior of the rice grains, leaving behind starch. A more thorough polishing leads to fewer native congeners and generally a more desirable product. Newly polished rice is allowed to 'rest' until it absorbs enough moisture from the air, so that it does not crack when immersed in water. After this resting period, the rice is washed clean of the rice powder produced during milling and is steeped in water. The length of the soak depends on the degree to which the rice was polished, from several hours or even overnight for an ordinary milling to just minutes for highly polished rice.

After soaking, the rice is either boiled in a large pot or steamed on a conveyor belt. The degree of cooking must be carefully controlled; overcooked rice will ferment too quickly for flavors to develop well and undercooked rice will only ferment on the outside. The steamed rice is then cooled and divided for different uses.

Some of the steamed rice is taken to a culture room and inoculated with kōji mold (麹, *Aspergillus oryzae*). The mold laden rice is itself known as kōji and is cultivated until the growth of the fungus reaches the desired level. This takes about two days.

When the kōji is ready, the next step is to create the starter mash, known as shubo (酒母), or colloquially, moto (酛). Kōji rice, water, and yeast are mixed together, and in the modern method, lactic acid is added to inhibit unwanted bacteria (in the slower traditional methods, formation of lactic acid occurs naturally). Next, freshly steamed rice is added and the yeast is cultivated over 10 to 15 days.

When the starter mash is ready, steamed rice, water, and more kōji are added once a day for three days, doubling the volume of the mash each time. Staggering the process in this manner allows the yeast to keep up with the increased volume. The mixture is now known as the main mash, or moromi (醪, also written 諸味).

The main mash then ferments. This takes two to six weeks. With high grade sake, fermentation is deliberately slowed by lowering the temperature to 10 °C (50 °F) or less.

After fermentation, sake is pressed to separate the liquid from the solids. With some sake, a small amount of distilled alcohol, called brewer's alcohol (醸造アルコール), is added before pressing in order to extract flavors and aromas that would otherwise stay in the solids. With ordinary sake, a large amount of brewer's alcohol might be added to increase the volume of sake produced. Next, the remaining lees (a fine sediment) is removed, and after that most sake is carbon filtered and pasteurized. The sake is allowed to rest and mature and then it is usually diluted with water to lower the alcohol content from around 20% to 15% or so, before being bottled.

Although there are many individual versions of sake (Figure 2.7.5), there are two basic types: futsū-shu (普通酒) and tokutei meishō-shu (特定名称酒). Futsū-shu, 'ordinary sake,' is the equivalent of table wine and accounts for the majority of sake produced. Tokutei meishō-shu, 'special designation sake,' refers to premium sake distinguished by the degree to which the rice is polished and the added percentage of brewer's alcohol or indeed the absence of such an additive. Teiseihaku-shu (低精白酒) is the general name for sake brewed with deliberately highly polished rice, whereas kuroshu (黒酒) is sake made from unpolished rice (i.e. brown rice), more like Chinese rice wine. Generally, more highly polished rice produces fruitier sake, whilst less polished or unpolished rice produces sake with more earthy, grainy flavors of the rice itself.

There are basic categories of special designation sake (Figure 2.7.5). Honjōzō-shu (本醸造酒), has a slight amount of brewer's alcohol added to the sake before pressing, in order to extract extra flavors and aromas from the mash – no more 116 l of pure alcohol for every 1000 kg of rice. Junmai-shu (純米酒), 'pure rice sake,' is brewed with only rice, water and kōji, with no brewer's alcohol or other additives. Ginjō-shu (吟醸酒), brewed with rice polished to 60% or less of its original weight. Sake made from rice polished to 50% or lower is called daiginjō-shu (大吟醸酒). The term junmai can be added to ginjō or daiginjō, resulting in junmai ginjō and junmai daiginjō.

Other types of sake are designated depending on clarity, lack of carbon filtration, lack of pasteurization and extent and type of maturation, as outlined in Figure 2.7.5. Thus, doburoku (濁酒) and nigorizake (濁り酒)

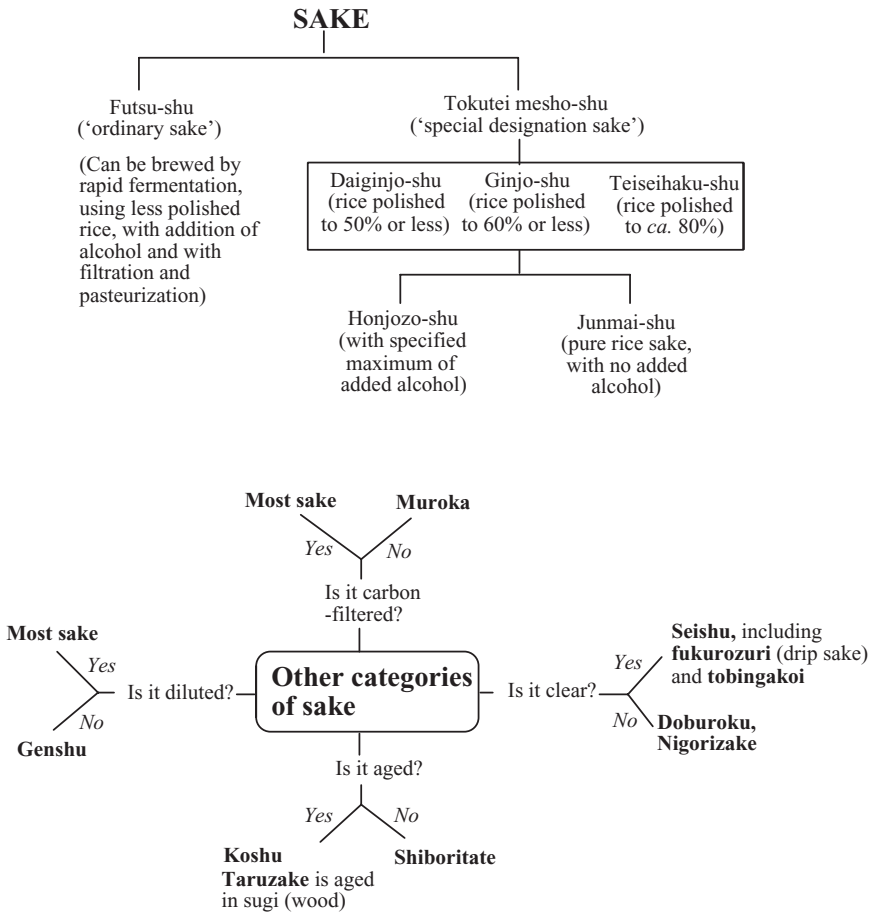

Figure 2.7.5 *Types of Japanese rice wine*

are cloudy versions, muroka (無濾過) is noncarbon filtered, namazake (生酒) is nonpasteurized, genshu (原酒) is undiluted sake (~20% ABV), koshu (古酒) is aged and shiboritate (搾立て) is unaged sake. Finally, taruzake (樽酒) is sake aged in wooden barrels (*Cryptomeria* (杉, sugi), fukurozuri (袋吊り) is made by hanging the mash in bags and allowing the liquid to drip out under its own weight and tobingakoi (斗瓶囲い) is matured in 18 l bottles ('tobin'). Additionally, sake can be distinguished by the way in which way the starter mash is made (Figure 2.7.6): kimoto (生酛) is the traditional method, yamahai (山廃) is a simplified version of the kimoto method, introduced in the early 1900s and sokujō (速醸), 'quick fermentation,' is the modern method of preparing the starter mash.

Sake varies in sweetness, which is indicated by the nihonshu-do (日本酒度) scale, also called the Sake Meter Value, or SMV, based on the specific gravity (Equation 2.7.1).

$$\text{SMV} = 1443\left(\frac{1}{\text{sp.gr.}} - 1\right) \tag{2.7.1}$$

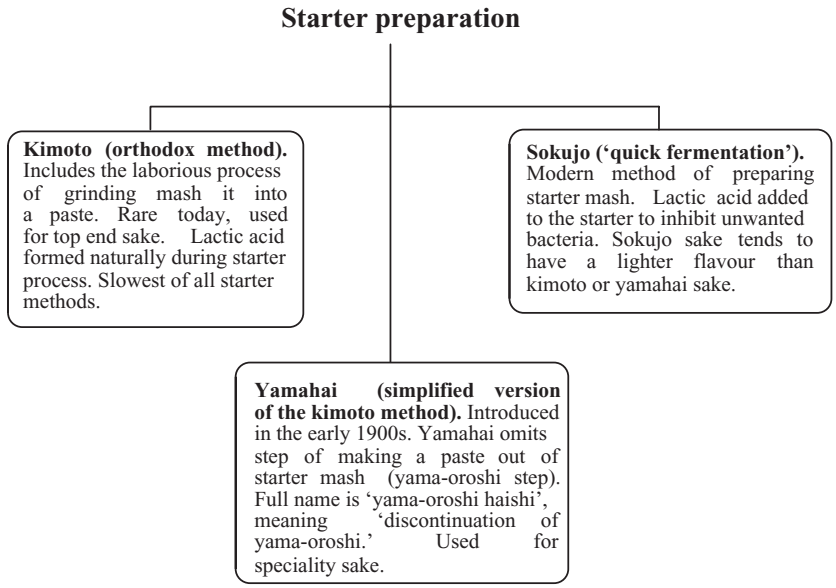

Figure 2.7.6 *Three methods of making a sake starter mash*

Specific gravity (sp. gr.) is measured on a scale weighing the same volume of water at 4 °C and sake at 15 °C. The sweeter the sake is, the lower the SMV. When the SMV was first introduced, 0 was designated the point between sweet sake and dry sake, but now this has been changed to +3.

As in all brewing and distilling processes, there is solid waste material. Kasu (粕) are pressed sake lees, the solids left after pressing and filtering. These are used for making tsukemono pickles, livestock feed and shochu, and as an ingredient in dishes like kasu soup. Rice wine cake is the Korean equivalent. A further product with a high concentration of ethanol (20.7% v:v) can be obtained from rice wine cake by adding crude glucoamylase from *Rhizopus* spp. grown on wheat bran (like nuruk), yeast and various nutrients (Kim and Van Hanh Vu, 2008). Such a wine could be distilled to produce a kind of soju, or grain neutral spirit.

Traditional Chinese Rice Wine

Rice wines are enjoyed all over China, where they are sometimes known as 'yellow wine' and they usually contain 16–20% ABV, having an annual consumption of more than 2 million kl (Luo *et al.*, 2008). Chinese rice wines are generally brewed using glutinous rice with wheat koji and/or red rice koji, which supplies the microorganisms, as with other Asian rice wines. Wheat koji (wheat 'qu') contains a wide range of microorganisms, including *Aspergillus* spp., *Rhizopus* spp., mucor, acetic acid bacteria, lactic acid bacteria and yeasts, while red rice koji contains mainly the purple fungus *Monascus purpureus*. The general brewing method involves cooking a rice–water mixture (1:1, w/w) in a large rice (pressure) cooker at 125 °C for about 1 h. After cooling to room temperature (25 °C), koji is then inoculated into the cooked rice mash in order to provide α-amylase, amyloglucosidase, glucoamylase and β-glucuronidase to break down the starch into oligisaccharides and monosaccharides, and also to liquefy the rice for more complete fermentation. More water is added and after thorough mixing, the liquor is transferred to fired clay containers, where fermentation takes place at 25–33 °C in the closed containers. The rice wine is usually collected after the alcohol content reaches 16–20%, which is after about 14–16 days of fermentation (Zhang and Wu, 1999). There are many

brands or types of Chinese rice wine, which differ mainly in the multiplicity of microbe group used in fermentation. Foshou, Nuomi and Guyuelongshan are fermented with wheat koji, Shousheng with wheat and red rice koji, while Hongqu is fermented with red rice koji. Also in Foshou, bergamot fruit (*Citrus medica* L. var. Sarcodactylis) is infused in the wine following fermentation (fruit:wine ratio ~ 1:10, w:v).

An alternative production method described by Luo *et al.* (2008) as being typical of the main rice wine regions of the south, Jiangsu province, Shanghai city and Shaoxing city (Zhejiang province), is described next. This method involves wheat qu, like the previous method, but also includes the use of a starter with added pure yeast culture and lactic acid. Wheat is milled, mixed with pure water, pressed into molds and then incubated at 28–30 °C for 48 h in a special room, before being dried at 45 °C until the moisture content is less than 12% (w:w). Preparation of the starter ('seed mash') involves mixing wheat qu with previously steamed glutinous rice (weight ratio 1:10) and spring water (weight ratio of steamed rice to water, 1:2). The pH of this mixture is adjusted to ~4 with lactic acid, pure yeast culture (3% w:w) is added and the starter is fermented at 25 °C for 48 h. After this time, the steamed glutinous rice, starter, wheat qu and spring water are mixed in the weight ratio 10:0.6:1:15. Fermentation is carried out over three weeks or so, after which the wine is filtered by pressing and is then transferred to tanks for clarification. The clear wine is colored with caramel, pasteurized at 88–90 °C for 3 min and then transferred to pottery jars, which are sealed and then left to mature for 1–5 or more years. Rice wines are generally blended to yield a consistent product of ethanol content 14–17% (v:v).

Chinese rice wine has many of the aroma/flavor characteristics of its Japanese and Korean counterparts, but with differences that most likely arise from the differences in materials and somewhat different production methods. Carbonyl compounds, carboxylic acids, esters and organosulfur compounds have all been reported to contribute to the aroma of sake, but the characteristic burnt caramel/nutty notes in the aroma of certain sake samples have been attributed to the presence of sotolon (3-hydroxy-4,5-dimethyl-2(5*H*)-furanone) (Isogai *et al.*, 2005). Sotolon is known to make important contributions to the aromas of many fortified wines, such as fino Sherry, tawny Port, vin doux naturel and others (see Chapter 2.10). Indeed, the aroma and flavor of some Asian rice wines, particularly well matured examples, have been compared with those of Sherry, and many western cook books on Chinese cuisine suggest Sherry as a substitute for rice wine in certain recipes.

Luo *et al.* (2008), using headspace SPME (HSPME) (Section 4.2.4) followed by GC-MS analysis were able to identify 97 volatile and semivolatile compounds in 10 typical Chinese rice wine samples, 39 of which were reported for the first time. Included in the headspace were 13 alcohols, 17 aromatic compounds, four carbonyl compounds, eight carboxylic acids, 28 esters, nine furans, three lactones, six nitrogen compounds, six phenols and three sulfur compounds. Of particularly high concentrations were 2- and 3-methylbutanol, benzaldehyde, diethyl butanedioate (succinate), 2-phenylethanol and di(*sec*-butyl) and 2-methylbutanedioate, but the contributions of the components are not known at the present date (2009), since GC-olfactometry and sensory analysis have not yet been carried out.

Traditional Rice Wine of Vietnam

The rice wine of Vietnam, like other Asian rice wines, has several categories and significant amounts of it are distilled. The distilled beverages are consumed per se, but are also used to fortify several of the undistilled rice wines. In the north and south of the country, there are ruou de or ruou nep; these are fermented from rice or glutinous rice, respectively, followed by distillation. In mountainous districts (e.g. Da Lat, Buon Me Thuot, and Dac Lac) Thuong people (an ethnic minority) produce ruou can that is fermented from rice, maize or cassava, with or without distillation. In the Mekong Delta to the south, ruou nep than (purple glutinous rice wine) is made from purple glutinous rice without distillation (Dung *et al.*, 2005).

Like other Asian rice wines, production of traditional Vietnamese rice wine involved the use of a starter to provide the required saccharification and fermentative microorganisms, but the production process favors

the former process first, followed by the latter, although both processes occur in the same vessel, unlike the brewing of European style beers. The traditional brewing method of ruou nep than (purple glutinous rice wine) involves soaking purple glutinous rice in water (mass:volume ratio approximately 5:6) for 4 h at room temperature, followed by steaming at 100 °C for 1 h. The gelatinized rice paste is cooled to about 35 °C and is then inoculated with powdered starter culture ('men') (rice:starter mass ratio ~100:4) and left at 30 °C for three or so days. During this period, most of saccharification processes occur, but a little alcoholic fermentation also occurs. Water (rice:water mass:volume ratio ~50:70) is added, whereupon alcoholic fermentation occurs for ~7 days at 30 °C. The natural ethanol content is about 7% (v:v) and so rice wine spirit is added to bring the content up to about 15% (v:v). The wine can be consumed cloudy or clear after filtration.

Nature of the Rice Wine Starter

The majority of Asian rice wines, including those destined for distillation, are brewed using a starter that contains microorganisms that perform both saccharification and fermentation processes side by side. In Korea, the starter consists of a rice porridge that has been activated by fermentation with nuruk, a dried malted wheat preparation in which *Aspergillus* spp., *Rhizopus* spp. (especially *R. oryzae*), lactic acid bacteria and yeasts (especially *S. cerevisiae*) have been cultivated over several days. In Japan, the starter is rice porridge that has been inoculated with *Aspergillus oryzae*, although pearled barley instead of rice is used for some wines that are to be distilled. Additionally, lactic acid is often added in modern fermentations of sake in order to supress the activities of unwanted microorganisms.

In Vietnam, starters ('men') are made by inoculation of rice and cassava flour dough by molds and yeasts, in which *Amylomyces rouxii* and *S. cerevisae*, respectively, are usually prevalent, although *Amylomyces* aff. *rouxii*, *Rhizopus oligosporus* and *R. oryzae*, and *Saccharomycopsis* (*Endomycopsis*) *fibuligera, Candida* spp. and *Pichia* spp. (respectively) also are normally present (Dung *et al.*, 2006; 2007). New 'men' is prepared by inoculation of the dough with previous (dried) 'men' samples, containing populations of the required microorganisms. The dough is divided into small flattened balls and incubated (e.g. for 1–4 days) on bamboo mats at ambient temperature (~30 °C) often after the addition of herbs or herbal extracts, such as those of 'tieu hoi' (fennel: *Foeniculum vulgare* Miller) and 'dinh huong' (clove: *Syzygium aromaticum* L.) (Dung *et al.*, 2005). The herbal extracts help subdue the activities of unwanted microorganisms and at the same time promote the growth of *Amylomyces* and *Rhizopus* species, as well as *S. cerevisiae* (Dung *et al.*, 2005). After this the dough is quite dry and can be used whole or broken up into granules; it has a 'shelf life' of a few months at ambient temperature.

One of the major problems faced by commercial brewers of rice wine in Vietnam, as with the brewers of other indigenous beverages, is the variable quality of the product. In Vietnam, variability in quality is strongly correlated with the microbiological character of the traditional starter tablets that are commonly used (Dung *et al.*, 2007). In recent years a stable, granulated starter has been developed, containing a defined mixture of mold and yeast cultures (*A. rouxii* and *S. cerevisae*) and defined herbal extracts (those of fennel and clove). This has proven to be shelf stable for more than three months, producing a purple glutinous rice wine of generally superior quality (Dung *et al.*, 2005).

Flavored Korean Rice Wines

Many plants used as herbal remedies are used to flavor Korean rice wines, especially yakju. Flavorings include acacia flowers, fruit of the Chinese matrimony vine, 산수유 (*Cornus officinalis*), ginseng (*Panax ginseng*), chamomile (*Matricaria chamomile*), the root of 'Korean Angelica' (*Ostericum grosseserratum*) (당귀), the root of kudzu (*Pueraria thunbergiana*) (갈근), dandelion (*Taraxacum platycarpum*) and the fruit of the 'Chinese date' *Zizyphus jujuba* var. inermis (대추) (Kim *et al.*, 2000; Lee *et al.*, 2002; Seo *et al.*, 2002). Mushrooms and

fungi, especially the fruiting body of *Ganoderma lucidum* and *Paecilomyces japonica* are also used to flavor yakju (Kim *et al.*, 2004). The triterpenoid ganodermic acid K, was found to be the major antihypertensive agent in *G. lucidum*-infused yakju; it was determined to be an angiotensin I converting enzyme (ACE) inhibitor. ACE regulates blood pressure by converting the inactive decapeptide angiotensin I to the vasoconstrictor octapeptide angiotensin II and at the same time inactivating the vasodilating nonapeptide bradykinin, thus causing high blood pressure. Although rice wines in general (with or without herbal infusions), such as sake, are known to have antihypertensive properties, due to the presence of a number of peptides (Saito *et al.*, 1994), the *G. lucidum* infused yakju exhibited a greater antihypertensive effect than either sake or yakju or a number of other flavored Korean rice wines. Furthermore its superoxide dismutase (SOD)-like activity (an antioxidant activity, see Section 5.8.4) was comparable with other flavored Korean rice wines (Kim *et al.*, 2004).

Geumsan Ginseng Wine is brewed in the Geumsan region of central South Korea from the roots of five year old ginseng shrubs and, rice, malt and clean mineral water by traditional cool fermentation since the fourteenth century. This is a true flavored rice wine and it has its own unique lingering aroma and flavor. It is very different from ordinary ginseng 'wines,' which are simply ginseng flavored soju or distilled liquor, more like liqueurs (Section 3.9.3) than wine. It was originally developed by a local noble family (Kim, Moon-Ki), in the fourteenth century, and has long been brewed in a traditional way, the recipe being handed down from generation to generation.

Ginseng is the most highly respected herb since ancient times by both Chinese and Native American herbalists and the red ginseng from the Geumsan valley is recognized as being one of the very best; it fetches high market prices. As has long been known by these ancient healers, this herb seems to help the mind and body to be in balance. Modern research has demonstrated that there are more than 28 therapeutic constituents in this vitamin rich plant. Regular use of Ginseng is helpful in the treatment of memory loss (Alzheimer's disease), in the balance of blood sugar levels (diabetes), in slowing down the aging process, in supporting the immune system, in regulating blood pressure, in drug abuse rehabilitation, in regulating the digestive system and in increasing stamina. [금산인삼주, http://www.ginsengm.com].

Beksaeju (백세주 or 百歲酒; literally, '100 years wine') is the most popular medicinal rice wine with the Korean younger generation, who sometimes drink it in place of soju (Section 3.4.4). It is a rice wine infused with ginseng and eleven other herbs, including astragalus, cinnamon, ginger, gugija (Chinese wolfberry), liquorice and omija (*Schisandra chinensis*). Sansachun (산사춘) is another commercial Korean rice wine (Bae Sang Myun Brewery), flavored with the red fruits of the sansa, or Chinese hawthorn (*Crataegus pinnatifida*).

2.7.2 Native Fermented Drinks of Africa and South America

In Africa, there are many traditional native beers based on sorghum or maize. They are named according to the language of the local tribes and so in the countries of modern Africa it is often possible to find more than one name for essentially the same beverage. In western states there is shakporo or tchapalo (Benin, Burkino Faso and Côte d'Ivoire), dolo (Burkino Faso and Mali), shukutu (Benin and Togo), pito (Ghana and Nigeria), bil bil (Cameroon) and buruktu (Nigeria). In central, eastern and southern states there is Bantu beer (South Africa), chibuku (South Africa), pombe (Kenya, Tanzania and Uganda) and umqombothi (South Africa). Northeastern Africa has bouza (Egypt and Ethiopia), and merisa (Sudan).

Sorghum provides the main crop for most of these indigenous beverages, although maize is often used, especially in southern Africa and plantains and palm sap are also used to make alcoholic beverages in several central states. The various varieties of sorghum are grown in many parts of the world, in a variety of soils and climatic conditions. The varieties grown in Europe and the USA are mostly of the *Sorghum vulgare* species, often known as broom corn, guinea corn or millet. In Africa, the varieties used for brewing are mostly of

Table 2.7.2 *Top ten producers of sorghum in Africa and Asia (2007)*

Country	Production/$\times 10^6$ tonnes	Country	Production/$\times 10^6$ tonnes
India	10.6	Mali	1.1
Nigeria	7.7	Sudan	0.79
Niger	2.8	Uganda	0.73
P.R. China	2.1	Chad	0.55
Burkina Faso	1.1	Ethiopia	0.50

S. bicolor (L.) Moench; they are well adapted to semiarid climates with less than 600 mm annual rainfall, although they have tolerance to both drought and water logging. Sorghum plants grow extensive root systems and their leaves have a waxy bloom that prevents excessive loss of water, making them suitable crops for dry climates.

The Ethiopians were probably the first people to cultivate sorghum, leading through the years to a gradual selection from wild sorghum between 5000 and 3000 BC. Its cultivation spread throughout Africa and into the Mediterranean countries and Asia, eventually reaching China via the Silk Route. In the seventeenth and eighteenth centuries, seeds were taken to the Americas as part of the slave trade. The USA is today's most important producer, whereas Nigeria and Sudan are the biggest African producers, and India and China are the most important Asian producers (Table 2.7.2). Most of the world crop is used to make flour; it is only in Africa that a substantial part of the crop is used to produce an alcoholic beverage, although sorghum 'wine' is made in China, mostly for distillation (Section 3.4.4).

Like other cereals, sorghum is a rich source of carbohydrate, initially as starch. It can be malted and used to brew Pilsner style beers (Section 2.6.2) or sorghum flour can be used as a beer adjunct (Section 2.6.2) or a substitute for maize or wheat in the production of grain whisky (Section 3.2.2). However, only its role in the brewing of indigenous beverages of Africa and Asia are discussed here.

Although there are many national and local variations in the production of sorghum-based alcoholic beverages throughout Africa, the process described next from western Africa for the brewing of tchapalo (shakporo) can be regarded as being typical. The production of tchapalo is rather complex, involving malting, mashing with cooked cereal and two fermentations, separated by a cooking step (Figure 2.7.7). Sorghum seeds are firstly malted (Section 2.6.2), sun dried and then milled to give malted sorghum flour.

Malting the sorghum is an important step in the process, since it enhances prolamin extractability and concentration, and results in the production of amylases, lipases and proteases, which act upon starch, fats and proteins in the sorghum flour part of the mash. This not only increases the fermentability of the wort, but also enhances the nutritional value of the resulting drink (Correia *et al.*, 2008).

The flour is mixed with water containing a sticky substance to form the mash, which is allowed to separate into a sediment and supernatant. The sediment is cooked for about 2 h at 100 °C, cooled and added back to the supernatant. The latter contains the amylases and limit dextrinase enzymes, as well as the yeasts and bacteria, whereas the cooked sediment contains gelatinized starch. This mixture, called wort, is left for about 12 h, whereupon enzymes hydrolyze some of the gelatinized starch to fermentable sugars (mainly maltose) and a variety of microorganisms perform fermentations ('acidification processes') that give the sour wort.

The major acids produced at this stage are lactic and acetic acids, derived from the fermentation of carbohydrates by species of *Enterococcus*, *Lactobacillus*, *Leuconostoc*, *Pediococcus* and *Streptococcus* and others (Vieira-Dalodé *et al.*, 2007), leading to a drop in pH from ~6 to ~4. In the production of dolo and pito in neighboring Burkina Faso and Ghana, *Lactobacillus fermentum* was found to be the dominant LAB

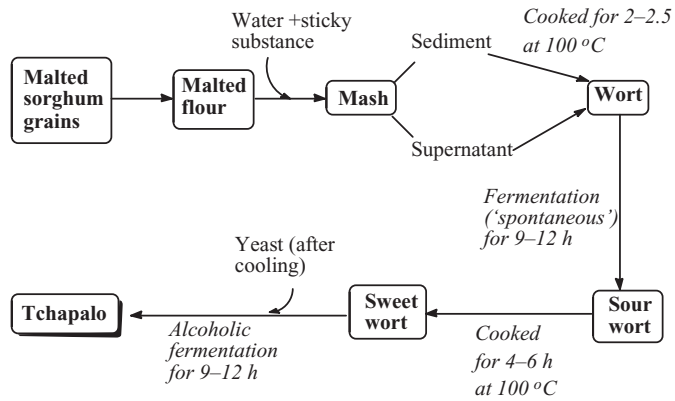

Figure 2.7.7 *Scheme illustrating the production of tchapalo and similar drinks in western Africa*

species (Sawadogo-Lingani *et al.*, 2007). *L. fermentum* was also observed to be a major LAB species for the fermentation of gowé, a sorghum-based drink in Bénin, whose production is like that of tchapa, except that there is no cooking stage (but a milder heating stage) in the process, and the fermented product is cooked before sale and consumption (Vieira-Dalodé *et al.*, 2007).

This first fermentation is 'spontaneous,' since acclimatized bacterial colonies are resident in the brewing equipment, as well as being present in the mash. The equipment is often left unwashed between brewing batches. After fermentation, the sour wort is cooked for 4–6 h at 100 °C to give sweet wort. The cooking procedure not only concentrates the sugars and acids in the wort (Aka *et al.*, 2008), but also kills most of the microorganisms responsible for the sour wort production, thus removing competition for the yeasts and bacteria of the starter used for the alcoholic fermentation (the next stage). After cooling, dried yeast from previous brews is added and alcoholic fermentation (the second fermentation) proceeds for about 12 h, after which time the tchapalo is ready for consumption and is usually drunk within two days from the start of the alcoholic fermentation.

Adding the dried yeast starter to the sweet wort ('back-sloping') helps the fermentation get off to a good start (in European breweries, the yeast slurry does the same job), so that after about 12 h the total soluble solids content has dropped from ∼13 °Brix to ∼ 7 °Brix and alcohol content has reached 3.5–4.5 % (w:v). The rate of inoculation (0.5–2% w:v) does not appear to have a big influence on the fermentation parameters (N'Guessan *et al.*, 2008). During alcoholic fermentation, the pH drops from ∼3.8 to ∼3.6 because the concentrations of citric, fumaric, malic and lactic acids increase somewhat, whereas the levels oxalic and propanoic acids are more or less unchanged (Aka *et al.*, 2008).

The dried yeast starter is prepared from the lees of a previous brew by drying it in the sun. This process may lead to some loss of viability due to UV irradiation or due to contamination resulting from slower drying during the rainy season (Holzapfel, 1997). Examination of yeasts in west African sorghum beers has revealed a varying composition of dominant species, although *S. cerevisiae*, *Candida* spp., *Kloeckera apiculata*, *Torulaspora delbruckii* and *Geotrichium candidum* are prevalent (van der Aa Kühle *et al.*, 2001). Examination of the *Saccharomyces* species found in dolo and pito (of Ghana and Burkina Faso) by chromosome length polymorphism (CLP), intergenic transcribed spacer (ITS), PCR and other techniques showed that alcoholic fermentation is dominated by previously unreported strains of *S. cerevisiae* (van der Aa Kühle *et al.*, 2001).

Several indigenous beers of South Africa and neighboring states are based more on maize than sorghum. Included in these is umqombothi, brewed by the Xhosa people of South Africa from crushed corn meal, crushed corn malt and crushed sorghum malt, and its method of production is similar to other indigenous

African brews. Firstly, the crushed grains are mixed with warm water and left overnight, whence a certain amount of saccharification of starches occurs and fermentation starts. Next, a small portion of the fermenting must is removed and placed on one side (it will be used as a 'starter,' later), while the remainder is boiled to form a thick porridge. The porridge is allowed to cool and poured into a vat, along with the 'starter,' and some additional crushed maize and sorghum malt are added, with vigorous stirring.

The vat is covered and the wort is allowed to ferment for about 24 h, after which it is strained through a large metal sieve, sediment is added to the strained liquor and the beer is served immediately from a communal vat, using cups. The ethanol content of umqombothi is around 3% (v:v) and it is a nutritious drink, with a high carbohydrate and vitamin B content. Like other indigenous beers, however, if maize contaminated with *Aspergillus* spp., *Penicillium* spp. or *Rhizopus* spp. is used, toxins such as ochratoxin A and zearalenone (Section 5.11.4) can get into the beer.

At the time of writing (2009) all the African sorghum- and maize-based drinks described above are produced by home brewers or small-scale industrial outfits, whose in house hygiene regimes differ markedly. The situation regarding the brewing of indigenous African beers is today similar to that of cachaça, pulque and Tequila a few years ago: there is growing interest by governments in regulated processing, to ensure standard and consistent quality, safety and product stability. Such regulated processing will require the use of yeast and LAB starters of typical indigenous microbial compositions in order to preserve the valuable integrity of the beers (van der Aa Kühle *et al.*, 2001; Sawadogo-Lingani *et al.*, 2007).

Chica is the name given to the numerous indigenous nondistilled alcoholic drinks of Central and South America. In many countries the name applies to fermented drinks based upon maize, but it can also refer to beverages brewed from cassava root, fruit or other sources of fermentable carbohydrate. It may even refer to certain nonalcoholic drinks.

Generally, chica de jova is a fermented drink prepared from yellow maize, whereas chica morada is an unfermented beverage made from purple maize and other ingredients. In Central America, the alcoholic beverage brewed from malted maize is known as chica fueste or simply chica, whilst chica batide or chica de maiz are unfermented beverages, often flavored with fruits or vanilla and served very cold. Alcoholic chica is most likely to be made from yellow maize grown at high altitude, but at lower altitudes and in river valleys it is often made form cassava (yucca or manioc) roots or plantains.

Traditionally, the starches in these sources were converted to fermentable sugars by chewing; the amylase enzymes in the saliva catalyzed the hydrolysis of starch to maltose and other sugars. Many of the indigenous fermented drinks of Afica and Asia, such as makkoli of Korea and sake of Japan, were originally prepared using this method (Section 2.7.1). Fermentation then occurred 'spontaneously' by the action of natural yeasts and bacteria in the source materials and in the brewing equipment. In the case of maize, the kernels were ground to flour, which was then moistened in the chica makers' mouths (several female family or community members would be involved with this). The moist flour was rolled into small balls, which were then flattened and left to dry in the sun. Water was added and, after stirring the mixture, fermentation soon commenced. The chica was consumed at celebrations, as a porridge, prickly with the carbon dioxide gas released by fermentation.

A similar process was used to make chica from boiled cassava roots, except after chewing a piece of root, the juicy fibrous pulp was spat into a bowl. When sufficient pulp was obtained, the bowl was placed on a fire and the pulp was cooked, and after cooling, fermentation commenced. Most chica is now made from malted maize, but the traditional methods are still used by some remote indigenous peoples.

A similar beverage named cauim is made from cassava root, or any suitable source of carbohydrate, by certain Amerindian tribes in Brazil. Here the substrate (such as sun dried, peeled cassava tubers and rice flour) is boiled in water to give a smooth paste. After cooling, the paste is inoculated with a mixture of masticated sweet potato and saliva. It is left to ferment for two days or so before being consumed as a porridge. During fermentation, both yeasts and bacteria act upon various constituents, especially carbohydrates, giving a variety

of products, including ethanol and acetate (both minor) and lactate (major). After two days, the pH of the mash has dropped from 5.5 to 3.4 (Almeida *et al.*, 2007). The major yeast at the start of fermentation is *Exophilia dermatidis*, but after two days of fermentation, when the yeast population reaches 6.9×10^7 cfu/ml, the major species were *Candida tropicalis*, *C. intermadia*, *C. parapsilosis*, *Pichia guilliermondii*, *S. cerevisiae* and *Trichosporon asahii* (Schwan *et al.*, 2007). However, bacteria are more abundant than yeasts at all stages of fermentation (by a factor of between 10 and 100). The dominant bacteria were found to be *Lactobacillus* spp. (e.g. *Lb. Pentosus* and *Lb. Plantarum*), *Corynebacerium* spp. and *Bacillus* spp. (Almeida *et al.*, 2007). Many of these microorganisms are able to hydrolyze starch to maltose, glucose and other sugars, which are then metabolized to give lactic acid as a major product.

Pulque is a popular alcoholic beverage of Mexico, but its origins are pre-Hispanic: it was for many centuries an important drink of Mesoamerican civilizations (Bruman, 2000). It is made by fermenting the sap (aguamiel) of various *Agave* species (maguey plants), which are also used to produce the distilled spirits mescal and tequila (Section 3.5.5). The name pulque is probably a Spanish corruption of the Aztec word poliuhquioctli, which means decomposed octli – octli being the Aztec name for this drink.

The maguey plants (wild or cultivated) used to brew pulque are of the species *Agave atrovirens*, *A. mapisaga* and *A. salmiana*, whereas *A. tequilana* var. azul ('blue maguey'), *A. angustifolia*, *A. inaequidans* and others are used to make the distilled beverages mescal and tequila (Section 3.5.5). Many millions of maguey plants are grown in Mexico for the production of these beverages, but only plants of 8–10 years old that are about to produce flowers are harvested for pulque. As a plant approaches flowering time, it makes a sugary sap to provide for the growth and development of the flower, which forms at the end of a tall stem (known as a quiote). This process occurs over 90–120 days, with the production of 200–1000 l per plant over this period.

The farmer first removes the large flower bud, leaving a cavity in the centre of the stem. After an aging period, during which time the cavity heals, the sap sugar content reaches 7–14% (w:v) (average values: 8–10% w:v). The cavity is then scraped, opening the sap vessels so that sap begins to accumulate in the cavity. This is sucked or siphoned out of the plant and the combined sap from many plants is fermented in 700 l open containers. Fermentation is either 'spontaneous' or is induced by adding a sap fermented starter or inoculum of yeasts and bacteria. Lappe-Oliveras *et al.* (2008) give a detailed, illustrated account of pulque production.

The making of traditional pulque is described in Figure 2.7.8. Fermentation starts with type I sap (the cleanest and sweetest) and hence the pulque made by the first fermentation is known as type I (pulque de pic de cuba). Commercial pulque is produced using a fermenting type I starter to ferment type II sap (cloudier and less sweet than type I sap) (Figure 2.7.8).

Agave sap of type I quality contains carbohydrates (fructans, fructose, glucose and sucrose mainly), proteins, amino acid, gums and mineral salts as the most important components (Ortiz-Basurto *et al.*, 2008), with its density being 5–7 °Baumé (∼36–51 °Oe, giving about 6.5 % ABV). Type II sap has a density of around 4.5 °Baumé (∼32 °Oe, giving about 4.5 % ABV). Both kinds of sap are rich in nutrients for the numerous species of yeasts and bacteria that are already present in the sap, but more importantly are present in the winery equipment and starter (pulque de semilla). Intitially (in the sap and during early fermentation), bacteria dominate over yeasts ($8–15 \times 10^8$ cfu/ml and $3–6 \times 10^6$ cfu/ml, respectively), reflecting the relatively high initial pH (7–7.4) of the early substrates. The bacterial population of pulque includes *Lactobacillus* and *Leuconostoc* spp. (LAB), *Acetobacter* spp., *Cellulomonas* spp., *Escherichia* spp., *Flavobacterium johnsoniae*, *Gluconobacter oxydans*, *Hafnia alvei*, *Kokuria* spp., *Macrococcus caseolyticus*, *Micrococcus luteus*, *Sarcina* spp. and *Zymomonas mobilis* (var. mobilis) (Lappe and Ulloa, 1993; Escalante *et al.*, 2004). Yeasts found in pulque include *Candida parapsilosis*, *Clavispora* spp., *Cryptococcus* spp., *Debaryomyces carsonii*, *Kluyveromyces* spp., *Geotrichium candidum*, *Pichia* spp., *Rhodotorula* spp., *Saccharomyces* spp. and *Torulaspora delbrueckii* (Lappe and Ulloa, 1993).

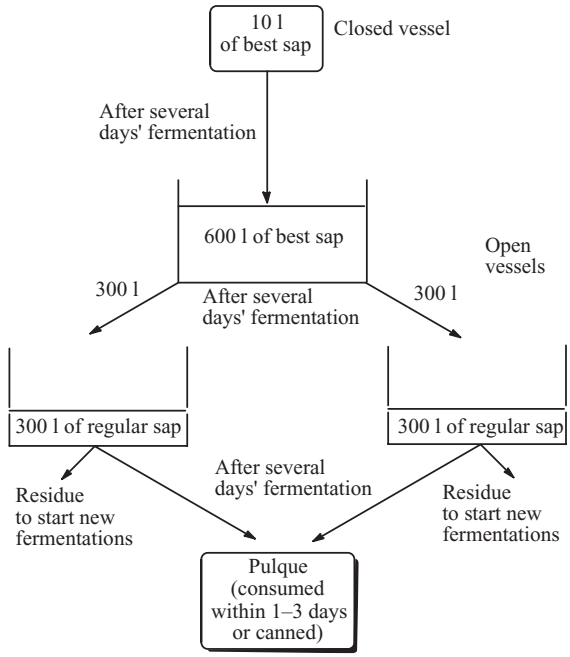

Figure 2.7.8 *Scheme showing traditional production of pulque using a natural (spontaneous) starter. Best sap contains ~10–14% sugar and is clear; regular sap contains ~7–10% sugar and is less clear*

Like other beverages fermented 'spontaneously' (see for example, lambic beer, Section 2.6.7), a succession of fermentations occurs with time, with different species predominating as the chemical and physical characteristics of the medium change. For pulque, the fermentative succession is outlined in Figure 2.7.9, although the beverage will either have been consumed or pasteurized and canned before the final three phases have occurred. *Leuconostoc* spp. are most active to begin with, producing lactic acid, ethanol, dextrans and numerous minor compounds, some of them flavor components. As the pH drops, *Lactobacillus* species become dominant, producing more lactic acid until yeast growth accelerates at pH ~4.5. In the second phase, non-*Saccharomyces* yeasts are most active early in the phase, producing a moderate amount of ethanol, whereupon *Saccharomyces* spp. generally dominate until the end of alcoholic fermentation. The most important *Saccharomyces* species appear to be *S. bayanus*, *S. cerevisiae* and *S. paradoxus* (Lappe-Oliveras *et al.*, 2008). *Zymomonas mobilis* (var. mobilis) also plays an important role in alcoholic fermentation, producing some lactic acid, acetic acid and other substances from fructose and glucose (Ramírez *et al.*, 2004). This species also produces gums and hence may be responsible, along with LAB (which produce dextrans) for increasing the viscosity of pulque.

Although there is very little information on the flavor components of pulque, there is good evidence to suggest that the beverage has significant nutritional value; it is a good supplement to the mainly corn diet of the Mexican low income population (Lappe-Oliveras *et al.*, 2008). It may also have some prebiotic value due to the presence of LAB and yeasts (Steinkraus, 1997) and fructans (fructose oligosaccharides) (Ortiz-Basurto *et al.*, 2008).

Industrialized production of pulque is not extensive at the time of writing (2009), but there are several companies producing a canned version, some of which is exported. Commercial versions are made by adding a starter of LAB, *S. cerevisiae* spp. and *Z. mobilis* spp. to pasteurized sap, the resulting pulque (sometimes

Phase	1 (Lactic) →	2 (Alcoholic) →		3 (Viscous)	4 (Acetic)	5 (Putrid)
Main organisms	*Leuconostroc* spp., then *Lactobacillus* spp.	*Kluyveromyces* spp., *Pichia* spp., then *Saccharomyces* spp.		Dextran producing bacteria	*Acetobacter* spp.	
Populations (cfu/ml)						
Total bacteria	~10^9	~10^8				
Total yeast	~ 3 x 10^6	~3 x 10^8				
pH #	7.5–6.5	~4.5	~3.8			
%ABV #	0	~1	~3–7			
Time*	0		20 h			

Figure 2.7.9 *Phases in the fermentation of pulque. *Time depends on temperature; the above time scale is typical of 12–13 °C and is quoted for a single fermentation. For double fermentation as outlined in Figure 2.7.8, the total time for pulque production is several days at 12–13 °C. #Depends on sap quality*

flavored) being pasteurized prior to canning. It has been suggested that new pulque industrialization processes should focus on hygiene, longer shelf life and nutritional value, thus providing low income consumers with a safe, nutritious drink of uniform quality (Ramírez *et al.*, 2004; Lappe-Oliveras *et al.*, 2008). However, pasteurization would remove some of the prebiotic value.

Palm wine, made from the sap of either the raffia palm (*Raphia raphia*) or oil palm (*Elaensis guineensis*) can be considered as the African equivalent of pulque. It is consumed by over 10 million Africans and is a very popular beverage in countries such as Nigeria (Nwachukwu *et al.*, 2006). Oil palm sap and raffia palm sap contain about 12.5% and 7.5% reducing sugars, respectively, thus giving drinks with potential alcohol content of about 7.5% and 6% (v:v), respectively.

After being tapped from the trees, palm sap undergoes a spontaneous fermentation for over three days, because of the presence of microorganisms in the sap itself and in the winery equipment. Alcoholic fermentation occurs first, when the level of ethanol rises sharply over the first 72 h (Nwachukwu *et al.*, 2006). As with other 'spontaneously' fermented alcoholic beverages, the non-*Saccharomyces* yeasts probably act first, followed by *Saccharomyces* spp. and similar yeasts, when the ethanol concentration rises above 2 or 3% (v:v). Yeasts that have been isolated from Nigerian palm wine include *Hanseniaspora uvarum*, *Hansenula anomola*, *Kluyveromyces marxianus*, *Pichia ohmeri*, *S. cerevisiae*, *S. globosus*, *Schizosaccharomyces pombe* and *Zygosaccharomyces fermentati*.

After 72 h of fermentation (at ~28 °C), the ethanol content drops, with concurrent drop in pH and rise in titratable acidity, suggesting that bacterial fermentations become dominant beyond this point. Bacteria that have been found in Nigerian palm wine include, *Acetobacter* spp., *Bacillus* spp., *Chromobacterium* spp., *Cornybacterium* spp., *Gluconobacterium* spp., *Lactobacillus* spp., *Micrococcus* spp., *Paediococcus* spp., *Peptostreptococcus* spp., *Pseudomonas* spp., *Streptococcus* spp. and *Zymomonas* spp. (Nwachukwu *et al.*, 2006). The drop in ethanol content (down to 2 or 3% v:v) between three and 20 days suggest bacteria that metabolize ethanol are active during this period. This, and the fact that pH drops to 1–2 during the same period, indicates the action of *Acetobacter* species (Chapter 2.4). Certainly, *Acetobacter* are present in the fresh sap and in the wine after 72 h of fermentation (Nwachukwu *et al.*, 2006).

It appears that the optimum time for consumption of palm wine is around three days after the start of fermentation, when the acidity is still reasonable (pH ~4), the ethanol content is at its maximum (5.5–8.3% v:v) and there is still some residual sweetness (~3 mg/ml reducing sugars). As with other indigenous alcoholic beverages (see shakporo, pulque (this section) and neera or toddy (Section 3.5.5)), interest is

growing in industrialized production of the beverage, but in the case of African palm wine, there has been interest expressed in the production of industrial ethanol (bioethanol) via the distillation of palm wine (Nwachukwu *et al.*, 2006). Bioethanol is an important and rapidly growing business on at least two continents, where its production competes with the production of certain alcoholic beverages (e.g. cachaça in Brazil). Bioethanol from palm wine could be realized using local palm sap fermented with a starter made of suitable microorganisms (those giving maximum ethanol production) and distilling the wine at three days into its fermentation. Measurement of palm wine viscosity may help decide optimum consumption or distillation time, since viscosity has been found to drop during active alcoholic fermantation, leveling off at its termination (Osuwa and Mbamara, 2008).

Cider and Perry

An apple-mill and press had been erected on the spot, to which some men were bringing fruit from divers points in mawn-baskets, while others were grinding them, and others wringing down the pomace, whose sweet juice gushed forth into tubs and pails.

—Thomas Hardy (The Woodlanders)

2.8.1 Introduction

It is likely that cider and perry have a similar antiquity to beer and wine. There is mention of apple orchards in *The Odyssey* (*ca.* 900 BC) and in other Greek and Roman literature there is ample reference to the production of alcoholic drinks from apples, pears and other fruits. Modern apple varieties are descended from two wild apple species, *Malus silvestris* and *Malus pumila*, which still grow in western Asia. Over the years, favorable varieties (those that give good yields of well flavored fruit, with a good balance of sweetness, sourness and bitterness) became preferentially cultivated and then propagated, mainly by grafting. Later, cross pollination produced newer varieties.

The development of cultivated pears probably followed a similar track; perhaps modern European varieties are descended from hybrids of *Pyrus communis*, *P. heterophylla*, *P. korschinskyi* and others. It is probable that alcoholic drinks made from apples and pears have been produced in almost every country of Europe and western Asia at some time or other.

The Hebrews drank 'Shekhar' and the Greeks drank 'Sikera,' but it is not until the fourth century that Palladius and Saint Gerome gave more detailed accounts of 'Sicera' and 'Piracium' (cider and perry). Nowadays, production of cider and perry is most important in countries that once formed the western boundaries of Celtic culture: Asturias (Spain), western British Isles, Brittany, Euskadi (the Basque country) and Normandy. Both cider and perry are made in other countries all over the world, particularly in those that have historical links with certain of the above-mentioned European countries, such as Canada and the USA (Section 2.8.8). Although at the time of writing (2009), the UK is the world's biggest producer of cider, the world's greatest apple producer is China (well over 2 billion tonnes per annum) (Xu *et al.*, 2007). Much of the apple juice concentrate that (mostly) large-scale cider manufacturers use for their base ciders (for blending) is from China (Section 2.8.6).

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

Traditional cider is the fermented juice of freshly crushed and pressed apples and perry is the fermented juice of freshly crushed and pressed pears. In the USA and some other countries, such as South Korea, the word cider refers to the unfermented juice of crushed apples or to some nonalcoholic drink based (at least in part) on apples. The term 'hard cider' is used in the United States for the alcoholic beverage described in this chapter. Almost any variety of apple or pear can be made into cider or perry, but naturally, some varieties give better results than others, as judged by balance of acidity, sweetness, bitterness, alcoholic strength and aroma/flavor characteristics.

It is generally accepted that the best varieties are those that are categorized as 'cider apples' or 'perry pears.' There are literally hundreds of these (although only a few dozen are used on a regular basis nowadays), many of which are of great antiquity and have survived into the present day simply because they have consistently produced good alcoholic beverages. Other newer varieties have been bred for the specific purpose of cider or perry making. Having stated this, some cider makers in the 'cider apple territory' of the west of England use culinary (e.g. Bramley Seedling) and dessert apples (e.g. Cox's Orange Pippin) for the production of both 'varietal' ciders and blends.

In Sections 2.8.4–2.8.6, it will be seen that blending is important in cider and perry manufacture. Moreover, good ciders can be made from culinary and/or dessert apples alone, as witnessed by the produce of southern and eastern England, the USA, Austria, Canada and Germany. These tend to be lighter and more akin to wine than cider or perry made from cider pears and perry pears, as in western England, northwestern France and northern Spain.

Apart from choice and blending of varieties, the variations in flavor and style arise mainly from the method of manufacture. The use of spontaneous (wild) fermentation, cultured yeasts, the speed of fermentation, use of additives and fruit juice concentrates, the mode and length of maturation, use of finings, filtration and pasteurization, and use of artificial carbonation all have influences on the nature of the finished product.

The distinctions between cider and apple wine, and between perry and pear wine are not clear. Traditional cider and perry tend to have more flavor (including 'bite'), body and color than products labeled as apple or pear wines, due to the greater use of fruit with high polyphenol content, the occurrence of spontaneous fermentation and a certain amount of oxidation. It is known that certain phenolic substances of apples undergo partial oxidation (catalyzed by polyphenoloxidase, PPO). The main reactant is chlorogenic acid (caffeoylquinic acid, see Figure 2.8.2): *o*-quinones are produced initially, which then undergo reaction with caffeoylquinic acid and flavan-3-ols, such as (+)-catechin, but dimeric flavan-3-ols are also produced (Bernillon *et al.*, 2004).

Mass produced cider and perry, as well as wines, tend to be made in a more tightly controlled, less oxidizing manner and are generally lighter in flavor, body and color. Diluted juice concentrate may have been used, along with glucose syrup and a lower proportion of high tannin fruit. Fermentation will have taken place using cultured yeasts and sulfur dioxide will have been used as a sterilant and antioxidant. It is also likely that the product has been filtered and/or pasteurized. Furthermore, apple and pear wines may be made from juice concentrates or from whole fruit by water infusion, along with addition of sugar syrup, acids and even concentrated grape juice.

Research into a range of aspects concerning cider apples, cider and related drinks is or has been conducted at numerous institutes and universities throughout the world. They include the following: Institut National de la Recherche Agronomique (INRA), Le Rheu, France; Université de Caen, France; Servicio Regional de Investigacíon y Desarrollo Agroalimentario (SERIDA), Villaviciosa, Spain; University of Oviedo, Spain; Euskal Herriko Unibertsitatea, Bilboa, Spain; Long Ashton Research Station, University of Bristol, UK; AFRC Institute of Food Research (Norwich and Reading, UK); East Malling Research Station, UK; Cornell University, Ithaca, NY, USA; University of Bath, UK; University of Glasgow, UK; University of Ontario, Canada. Some of the above (e.g. INRA, SERIDA) have departments or sections dedicated to cider, others have research groups whose interests include some aspect of cider.

2.8.2 The Basic Ingredients

Cider apples are classified according to their acidity (which gives sharpness of flavor), phenolic compound ('tannin') content (which gives bitter taste and astringent mouthfeel) and sugar content. The four basic categories are sharp, bittersharp, bittersweet and sweet. EU classification is according to titratable acidity, as malic acid, and phenolic ('tannin') content; it is summarized with examples for each category in Table 2.8.1. Ciders are usually made from a blend of apples from the different categories, the composition of the blend depending on the wish of the producer, the prevailing traditions or commercial demands on the particular area of production (see Section 2.8.8). Despite this, there are examples of single and double variety ciders, especially from smaller, traditional producers. Perry pears are classified in a similar manner to cider apples, but with rather more ambiguity, owing to greater variation in acidity and phenolic compound content (i.e. there is more overlap between categories). Nonetheless, a classification devised originally by Pollard and Beech is widely used in the UK. This is summarized, with examples and typical sugar contents in Table 2.8.2.

Unlike apples, several pear varieties possess appreciable citric acid content. English varieties of this kind include Brown Bess, Gin, Oldfield, Taynton Squash and Yellow Huffcap (all with >0.3% w:v citric acid) and

Barland, Holmer, Parsonage, Pine and Rumbles (all with <0.3%). The major acid of apples and most pears is (*S*)-(–)-malic acid, but minor quantities of shikimic acid, pyruvic acid and others are present in the fruit, along with sugar acids (e.g. gluconic acid), especially in riper fruit. It can be seen from Tables 2.8.1 and 2.8.2 that the total acid content for both cider apples and perry pears is from 0.2 to over 0.6% (w:v).

Almost all the sugars of cider apples are either monosaccharides or disaccharides, nearly all of which are fermentable by yeast, so there is normally very little residual specific gravity left in fully fermented ciders. The major sugars are fructose, sucrose and glucose (*ca.* 74%, 15% and 11% w:v, respectively, on average). The original gravities of most cider apple musts are in the region of 1050–1060, giving about 6–7.5% alcohol by volume when fully fermented.

Perry pears tend to possess rather more sugar than cider apples; many perry musts have original gravities over 1060 (Table 2.8.2). However, pear juice, unlike the juice of most apples, contains significant quantities of nonfermentable sugar alcohols, the most abundant of which is sorbitol. Thus, final gravities of perry may well be over 1005, giving a little residual sweetness, but with alcoholic strengths comparable with those typical of cider. Both apple and pear musts contain starch and soluble pectin (polygalactouronate). The former diminishes significantly upon full ripening, which is the main reason for the traditional process of sweating: storing harvested fruit in a dry place for several days to two weeks before crushing and pressing. Amylases convert the starch to monosaccharides during this period.

The phenolic components (especially the polyphenols) of both apples and pears are important; it is these that give cider and perry their characteristic bitter (even astringent) tastes. The major classes of phenolic

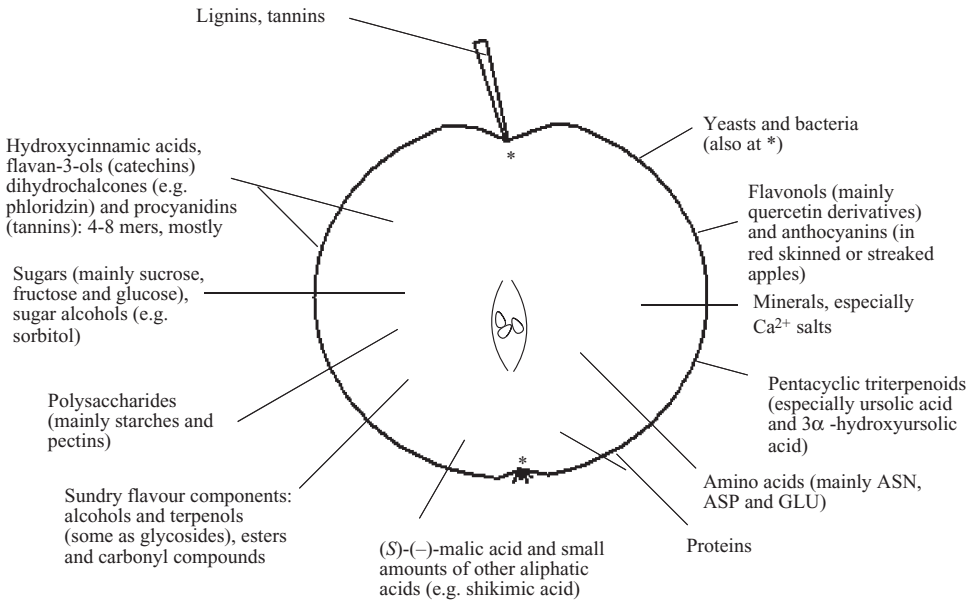

Figure 2.8.1 *Major components of cider apples and their approximate locations*

compounds in cider apples are hydroxycinnamic acids, dihydrochalcones, flavan-3-ols and procyanidins (oligomers and polymers of flavan-3-ols), found in both the skins and flesh (see for example Sanoner *et al.*, 1999; Guyot *et al.*, 2003). To these can be added flavonols and anthocyanins, found mostly in the skins. Figure 2.8.1 illustrates the distribution of important chemical components of apples, including the phenolic substances. Note that, except for anthocyanins and flavonols, phenolic substances are found in both the flesh and skins; they are also found in pips and stalks, but normal crushing and pressing methods should release very little of these.

Typical culinary and dessert apples tend to have lower (sometimes much lower) total phenolic contents (TPC) than typical cider apples. For example, juices made from German cider apples possessed from *ca*. 800–1000 mg/l TPC (Boskoop and Brettacher) to *ca*. 300 mg/l TPC (Kaiser Alexander and Kaiser Wilmhelm) (Kahle *et al.*, 2005). Compare these figures with those in Tables 2.8.3 and 2.8.4.

*Other procyanidins not included
nd = not determined
†Of these varieties, also contains high levels of phloretin-2′-xyloglucoside
‡Of these varieties, also contains high levels of *p*-coumaroylquinic acid

The most important hydroxycinnamic acids are caffeoylquinic (chlorogenic acid) and *p*-coumaroylquinic acids (Figure 2.8.2). The major dihydrochalcones are phloridzin (phloretin-2-glucoside) (Figure 2.8.2) and phloretin-β-xyloglucoside. Although the most abundant flavan-3-ol is (–)-epicatechin (Figure 2.8.2), (+)-catechin is present in fair amounts in some cider apples. Table 2.8.3 displays some individual polyphenol contents of some French cider apples (Sanoner *et al.*, 1999) and Table 2.8.4 lists similar data for selected English cider apples (Marks *et al.*, 2007). The proanthocyanidins are essentially polymers of flavan-3-ols, mostly (–)-epicatechin, and range from dimers, trimers and tetramers through to polymers with seven or more units, up to 60 or so. An especially common proanthocyanidin is procyanidin B2 (Figure 2.8.2; Table 2.8.4).

The phenolic components of pears are quite different; flavan-3,4-diols (leucoanthocyanins) and their colloidal polymers predominate in the cortex (up to 1% w:v) These polymers may be responsible for the hazes and sediments that are characteristic of perry, rather than of cider.

Both apples and pears contain flavonols in their skins, the most abundant of which are quercetin glycosides (Figure 2.8.2; Table 2.8.4) (Marks *et al.*, 2007). Isorhamnetin-3-glucoside, other glycosides (including acylated ones) and diglycosides of isorhamnetin are present in pear skins, but in apple skins only isorhaminetin-3-glucoside and 3-galactoside have been found, in the German cider variety Brettacher (Schieber *et al.*, 2002). Again, flavonol contents of peel and flesh of cider apples tend to be greater than those of culinary or dessert apples, but some of the latter (e.g. Cox's Orange Pippin and Jonagored) have comparable flavanol contents (Price *et al.*, 1999).

Anthocyanins are present in red or dark skinned fruit and in the cortex of the small minority of red fleshed fruit. However, total anthocyanin content of apple must is rather low, usually less than 50 mg/l, and not much of this survives fermentation through to maturation because of the formation of oligomers with other polyphenols, notably (–)-epicatechin. The major anthocyanins of apple and pear skins are based on cyanidin and are illustrated in Figure 2.8.3. The anthocyanin content of apple and pear skins varies widely (witness the range of skin colors) and although the cortex of most fruit is essentially colorless, there are some varieties with red flesh, either just under the skin or more rarely, throughout (e.g. apple variety Red Field) (Espley *et al.*, 2007). Anthocyanin synthesis in apples, like other fruits, is controlled by an MYB transcription factor, MdMYB10, along with two bHLH proteins (MdbHLH3 and MdbHLH33) that are expressed along with MdMYB10 (Espley *et al.*, 2007).

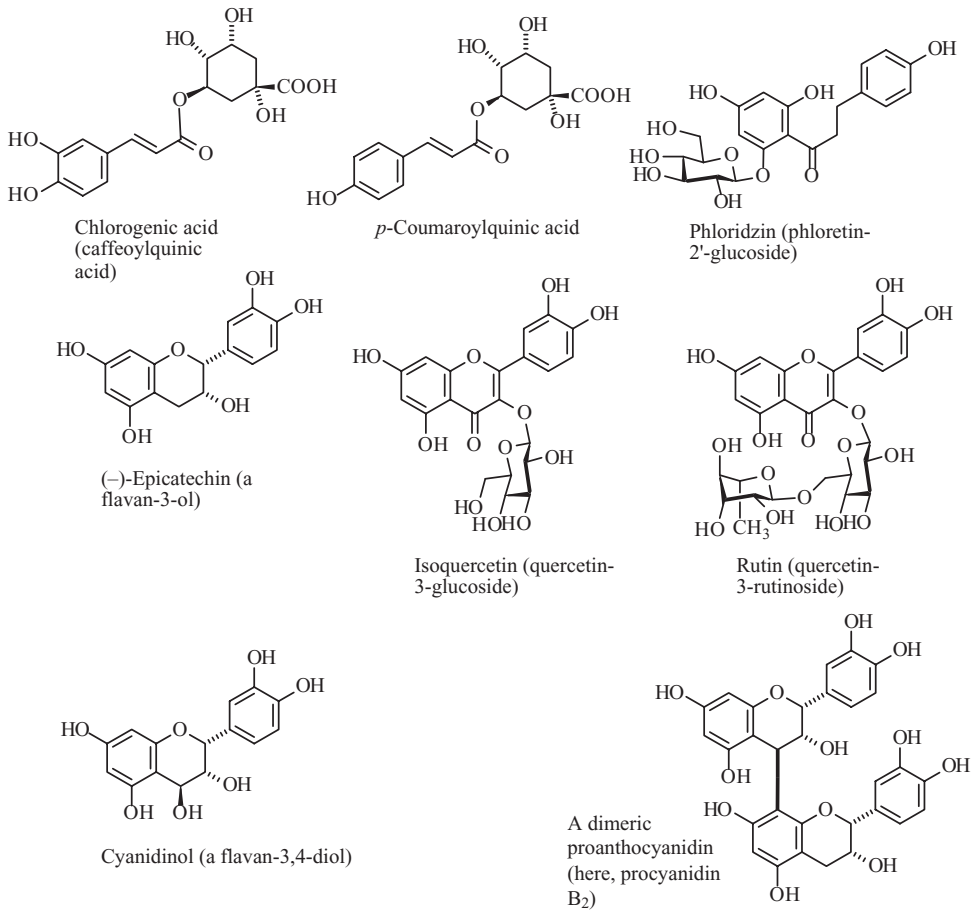

Figure 2.8.2 *Typical phenolic compounds in apples and pears*

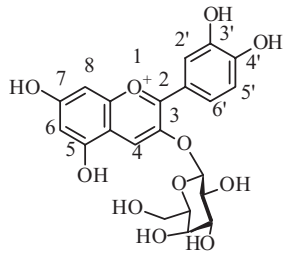
Both apple and pear juices contain rather low levels of amino acids (mainly asparagine, aspartic acid and glutamic acid) and proteins, with pear juice generally being the poorer of the two. Thus, compared with beer wort (Sections 2.6.3 and 2.6.4), apple and pear must is rather poor in yeast nutrients. Proteins are also present in apple must; five major proteins have been found in Asturian apple must, with molecular weights between 16 000 and 110 000 Da, with one of molecular weight 36 400 Da being the most abundant (Blanco-Gomis *et al.*, 2003a). As with beer, some of these proteins contribute to the formation of foam (Section 2.6.9), whilst others are involved in the formation of hazes in media that are generally rich in phenolic substances (Section 2.6.9).

Similarly, apple and pear juices are rather low in mineral content, the most abundant species being Ca^{2+}, K^+, NH_4^+, Cl^-, SO_4^{2-} and phosphates. Calcium ions play an important role in the traditional process of défécation or keeving (Section 2.8.3), in which they form a gel with pectins.

Various pentacyclic triterpenoids, such as ursolic acid and 2α-hydroxyursolic acid, are found in apple skins. These may contribute to the proposed anticancer activity of apples; certainly many have potent antiproliferative activity against cancer cells *in vitro* (He and Lui, 2007) (Section 5.11.2). However, it is unclear how much of these substances are extracted from the skins and survive into the mature cider.



Cyanidin-3-galactoside (most abundant apple anthocyanin

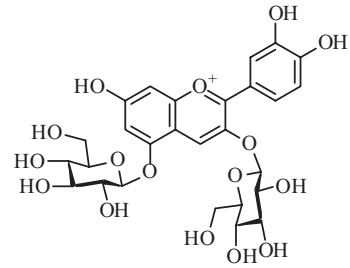
Cyanidin-7-arabinoside



Cyanidin-3,5-diglucoside

Figure 2.8.3 *Anthocyanins in dark apple skins. Gómez-Cordovés* et al. *(1996).*

The major fungal microorganisms present on the skins of ripe, undamaged apples and pears are *Aureobasidium pullulans*, *Candida* spp., *Hanseniaspora valbyensis*, *Kloeckera apiculata*, *Metschnikowia* spp., *Saccharomyces* spp. (especially var. *cerevisiae* and *uvarum*), *Saccharomycodes ludwigii* and *Torulopsis* spp. In the spontaneous fermentations used to make traditional cider and perry, *S. uvarum* or *cerevisiae* eventually dominates because of its greater ability to live in a sweet alcoholic medium (Section 2.8.5). Bacteria are generally present on the fruit skins in lower numbers than fungal species. These include *Acetomonas* spp. and a variety of malolactic bacteria, such as *Leuconostoc mesenteroides*, *Lactobacillus collinoides*, *Lb. hilgardii*, *Lb. plantarum*, *Oenococcus oeni* and *Pediococcus cerevisiae*.

Various pathogenic bacteria can also be found on the skins and outer flesh of apples and pears, especially on stored fruits that have been bruised or damaged (Basaran *et al.*, 2004). These include *E. coli* O157:H7, *Salmonella* and *Listeria monocytogenes* (Chen *et al.*, 2004). Although the presence of these organisms may have been responsible for outbreaks of disease caused by drinking unfermented juice (called cider in North America) (Basaran *et al.*, 2004), there is no evidence whatever that they survive in the alcoholic medium of the fermented juices. Indeed, in earlier centuries, cider, perry and alcoholic beverages in general were drunk in preference to water because of much greater possibility of contamination by pathogenic bacteria of the latter.

2.8.3 Harvesting, Crushing and Pressing

Different varieties of apples and pears ripen at different times and hence are sometimes harvested separately, made into cider or perry and then mostly blended, although a certain amount may be sold as varietal

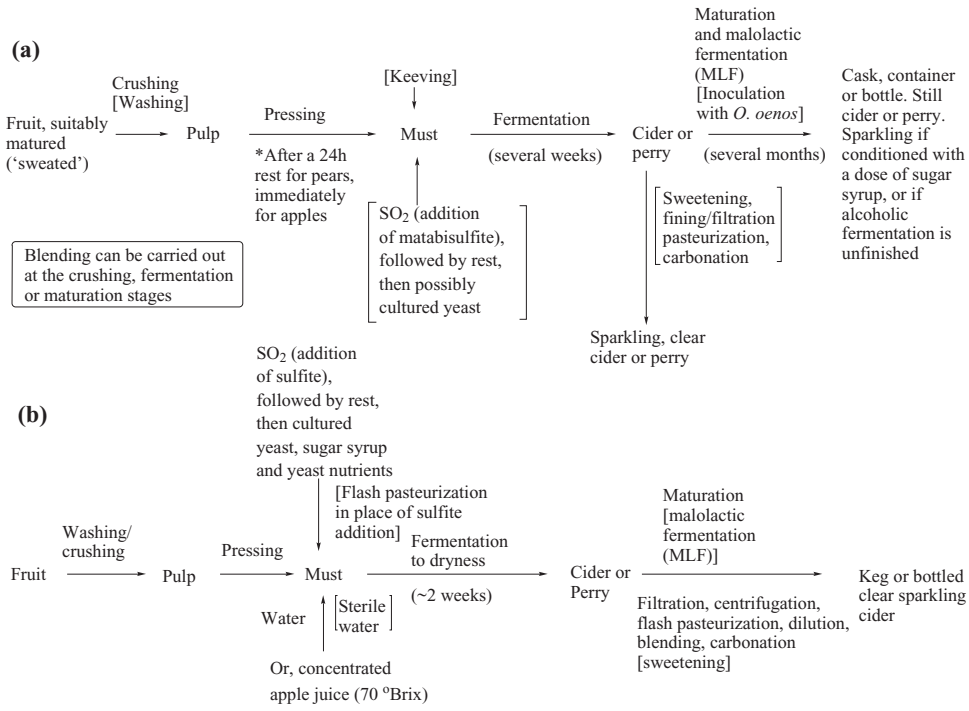


Figure 2.8.4 *Flow diagrams illustrating the production of typical (a) traditional/small-scale and (b) mass produced cider and perry. Optional modifications of the most basic traditional process are shown in square brackets. In practice, combinations of (a) and (b) may be used*

drinks. Traditional, small-scale and mass production methods of cider and perry production are outlined in Figure 2.8.4.

Cider apples are often harvested by shaking the trees, where the 'ripe' apples fall into a plastic sheet or net. Sometimes they are left for a week or so spread out on shelves in a dark room before crushing, in order to gain a bit more maturity. This is sometimes called sweating. Pears have more of a tendency to rot from the core, so are sometimes given a shorter maturation rest, if it all, depending on the ripeness and softness of the fruit. The maturing time for apples allows extra sugar and flavor components to form, and at the same time softens the fruits, making them easier to crush.

Crushing (grinding or milling) is traditionally carried out in a 'scratcher,' a mill consisting of two studded rollers that turn in opposite directions. These mills are rather like grape crushers and can be hand operated or electrically driven. They tend to give rather coarsely crushed fruit, in contrast to the fine pulp produced by more modern centrifugal mills (Figure 2.8.5). Fruit, introduced via the hopper is pulverized by a rotor blade system in the milling chamber, whence the pulp is discharged (sometimes through a perforated mesh screen) into a pomace trough, where it can be conveyed or pumped to the press for the next stage.

Modern cider producers often use a combined washer/crusher/press system (Figure 2.8.5), where the washed fruit is continuously elevated into the mill system, and the resulting pulp pressed by a continuous belt press (see next paragraph). Machines like the ones described above can work at a rate of *ca.* 300–6000 kg of fruit per hour. The combined system has the advantage of minimum exposure to air, as the pulp is pressed immediately. However, this system may not be advantageous in the production of perry, where a 24 h time

lapse is desirable between crushing and pressing, in order to reduce the quantity of precipitated polymeric phenols.

The traditional cider press, which can also be used for perry, is the rack and cloth press (Figure 2.8.5), where the apple pulp is wrapped completely in strong, open weave cloths which are then placed between two slatted wooden boards (stacks), the whole being known as a 'cheese.' Several cheeses of pulp can be pressed at the same time, depending on the pressure capability and design of the press, and the throughput of fruit pulp to juice depends on the cloth and rack sizes. Pressure is applied gradually, either by a manually operated rack and pinion system or, more likely nowadays, by an electrically operated hydraulic system. In this way, pressures of up to *ca.* 30 tonnes/m^2 may be applied and throughput can be anywhere between 0.5 and 6 tonnes per day.

Belt presses have a much higher turnover than rack and cloth presses. Here, fruit pulp is fed continuously onto a rotating porous belt, where it is pressed against a series of stainless steel rollers (see Figure 2.8.5). Throughput from this type of press can be up to 6 tonnes per hour and pressing efficiency (production of juice from pulp) is comparable to a typical rack and cloth press. Pomace conveyors can be used to move the dry spent pomace from the discharge side of belt presses, thus completing the automation and removing the labor

that is involved with shoveling and shifting spent pomace. When using rack and cloth presses, the pomace is pressed until it is solid and no more juice is produced. The press is then racked up, the cheeses are opened and the pomace mass broken up by hand to be reracked and repressed. Spent pomace can be used as cattle feed, orchard fertilizer, or when dried, it can be used for the manufacture of pectin.

Despite the several outlets mentioned above, spent pomace remains something of an environmental problem, especially in areas such as Asturias, where in excess of 20 000 tons are produced annually. The pomace is high in dietary fiber and polyphenols and is known to have considerable *in vitro* antioxidant activity; the Folin index of pomace from a large number of Asturian cider makers was 2.3–15.1 g gallic acid/kg of dry matter (Diñeiro-García *et al.*, 2009). Hence, there is considerable interest in the use of pomace for human nutritional, pharmaceutical and cosmetic purposes. Diñeiro-García *et al.* (2009) showed that apple pomace had antioxidant capacities, according to the DPPH and FRAP methods (Section 4.4.3), of 4.4–16.0 g ascorbic acid/kg of dry matter. Partial least squares regression analysis gave reliable statistical models, allowing prediction of antioxidant activity (by DPPH, FRAP) as a function of phenolic profile (by HPLC), with phloridzin, procyanidin B2, rutin, isoquercetin, protocatechuic acid and hyperin having the higher modeling power (in that order).

Several treatments to the apple or pear juice can be applied before fermentation begins. The first of these is called 'keeving,' used on apple juice by cider manufacturers in Brittany and Normandy. Keeving (from the French cuvee) or défécation often involves the addition of calcium chloride and pectin methylesterase (PME) to the juice (see Section 2.8.6 for variants of this process and more detail). This causes denaturation and precipitation of proteins, with some hydrolysis of pectins. The proteins are precipitated as a skin on the surface of the must and are subsequently skimmed off. Keeving thus aids the clearing process, but at the same time reduces the nitrogen nutrient content of the juice. This leads to a slow fermentation of the must (typically over several weeks), which is often incomplete, leaving a relatively low alcohol cider (~5% ABV) with residual sugars. This is an important process for French cider manufacturers (although it was developed from smaller-scale producers) because the relatively low alcohol, semi-dry or semi-sweet ciders with complexity of flavor are seen by many as the goal for high quality (see Section 2.8.6).

Other treatments include the addition of sodium or potassium metabisulfite (Chapter 2.5, Section 2.8.4) or application of flash pasteurization, adjustment of acid content, addition of sugar syrup, addition of yeast nutrients and blending of other freshly pressed juices or diluted apple juice concentrate, depending on the style of the producer.

2.8.4 Fermentation and Maturation

This section is closely linked with the following two sections, where specific technical aspects of alcoholic, malolactic fermentation and a number of process aspects (fining, filtration, sulfiting, carbonation and others) can be compared for traditional and small-scale production (Section 2.8.5) and large-scale (factory) production (Section 2.8.6). In the present section, a description is given of alcoholic, malolactic and other fermentations as they relate to cider and perry. A more complete general account of these fermentations (particularly of the organisms, the metabolic pathways and the biochemical end products) can be found in Chapters 2.1–2.4.

The most important microbial agents of alcoholic fermentation in the production of cider and perry are strains of *Saccharomyces cerevisiae*, as in the making of most other alcoholic beverages. However, in the spontaneous fermentations used for traditional cider in northern Spain, northwest France and western England, important contributions may be made from *Kleockera apiculata*, *Hanseniaspora valbyensis* and *Saccharomycodes ludwigii,* as well as other species of the genera *Saccharomyces* and *Kloeckera*. Nevertheless, *S. cerevisiae* dominates and the metabolic pathways associated with this species give rise to similar end products as found in wine (Section 2.2.11) and fruit wine (Section 2.11.3).

Table 2.8.5 *Most aroma active compounds of North American and Chinese cider*[‡]*)*

Aroma compound	Flavour descriptor	Aroma compound	Flavour descriptor
Butanoic acid	Cheesy	4-Vinylphenol[§]	Smoky
2-Methylbutanoic acid	Cheesy	Ethyl butanoate	Pineapple
Octanoic acid	Sweaty	Ethyl 2-methylbutanoate	fruity
2-Phenylethanol	Rose	Ethyl hexanoate	Floral
Eugenol[§]	Clove	Ethyl decanoate[§]	Grape
4-Ethylguaiacol[§]	Clove	2-Phenylethyl acetate[*]	Rose

[‡]Chinese cider made from Fuji, Gala, Ralls and Starking apples.
[§]Much more pronounced in N. American cider.
[*]Much more pronounced in Chinese cider.

A brief list of the more flavor active compounds in cider is given in Table 2.8.5, most of which are metabolic end products of alcoholic or malolactic fermentation (Xu *et al.*, 2007). The main alcohols (apart from ethanol) produced during alcoholic fermentation of apple must are isoamyl alcohol, 1-butanol, isobutanol, methanol, 2-phenylethanol and 1-propanol (Vidrih and Hribar, 1999). The process of maceration (allowing a period of time – usually 24 h – between crushing and pressing) (Section 2.8.3) results in somewhat increased production of these alcohols during fermentation (Vidrih and Hribar, 1999), presumably because of increased absorption of oxygen. Maceration is carried out by traditional Spanish cider makers (and by some English traditional producers), whereas the related process of défécation (keeving) (Sections 2.8.5 and 2.8.6) is performed by cider manufacturers in Brittany and Normandy. The total quantity of fusel alcohols in cider was found to be inversely related to the nitrogen content of the apple must (Vidrih and Hribar, 1999) and also inversely related to the extent of sulfiting. Thus, traditional ciders tend be rather higher in these alcohols than ciders made from sulfited apple must that has been enriched with yeast nutrients (ammonium salts).

The standard yeast alcoholic fermentation metabolic pathways (Section 2.2.9) are not the only source of alcohols in cider; certain alcohols are also present in apple juice as nonvolatile glycosides. During fermentation, some of these glycosides are hydrolyzed to give free alcohols, which may be flavor active in their own right, or may react with other compounds during fermentation or maturation to produce flavor compounds (Lea, 2004; Lea and Drilleau, 2003). Included here are 2-phenylethanol and octane-1,3-diol. The former is a well known flavor compound (rose, honey notes) found in many fruit juices and wines, whereas the latter may be unique to apples. During fermentation and maturation, octane-1,3-diol and the related (5*Z*)-octene-1,3-diol form cyclic acetals (1,3-dioxolane rings) by reaction with acetaldehyde, a major fermentation metabolite (Figure 2.8.6). The dioxolanes are reckoned to be important contributors to cider flavor (cidery, green notes) (Lea, 2004).

Other aroma and flavor active compounds in cider are esters, principally ethyl butanoate, ethyl hexanoate, ethyl 2-methylbutanoate and 2-phenylethyl acetate (Xu *et al.*, 2007). Mostly the end products of yeast metabolism during alcoholic fermentation, these contribute significant fruity and floral notes, as in other alcoholic beverages (Sections 2.2.11 and 2.6.4). A number of carboxylic acids are produced during alcoholic fermentation, although many at levels that (by themselves) contribute little to aroma and flavor (volatile acids) or taste (nonvolatile acids). The nonvolatile acids produced include fumaric acid, lactic acid (mostly the (*R*)-isomer), malic acid, shikimic acid and succinic acid. Some volatile carboxylic acids contribute cheesy notes, the two most abundant of which being butanoic and octanoic acids, although a number of others are also present (Xu *et al.*, 2007). Amongst the hundreds of other substances present in cider

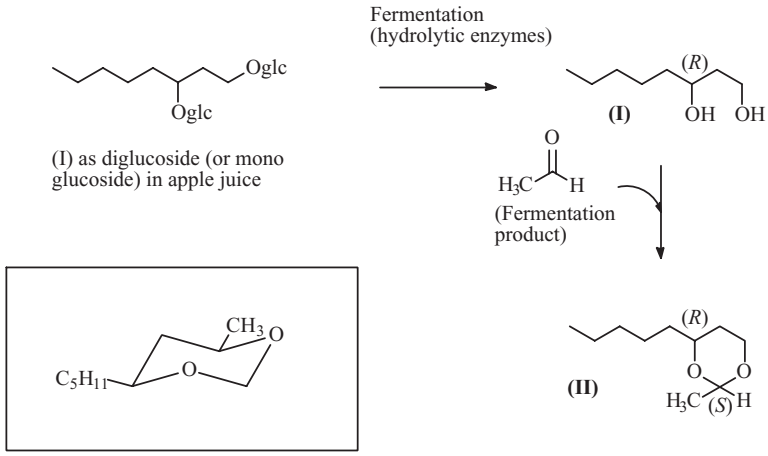

Figure 2.8.6 *Formation of (2S,4R)-4-pentyl-2-methylcyclohexa-1,3-dioxolane (II) from (3R)-octane-1,3-diol (I) and acetaldehyde during cider production. (Lea, 2004), various volatile phenolic compounds contribute spicy, clove-like or smoky notes to the overall aroma and flavor of cider. This is especially noticeable in traditional or small-scale produce from cider apples in the UK, France and Spain, but some Canadian and American ciders also possess these flavor characteristics.

Ciders made from culinary or dessert apples, as in China and many other parts of the world, have fewer of these aromas and flavors in their profiles. The phenols contributing most to aroma and flavor include catechol, 4-ethylguiacol, 4-ethylphenol, isoeugenol, eugenol and 4-vinylphenol. These are produced in part by the shikimic acid pathway (via phenylalanine, cinnamic acid and others), during the ripening of fruit or during alcoholic fermentation and in part during the malolactic fermentation, by the decarboxylation, hydrolysis and reduction of various more complex natural phenolic substances in the must (Lea, 2004). Figure 2.8.7 illustrates routes to some of these phenols; thus 4-vinylphenol may be produced by the decarboxylation of *p*-coumaric acid, itself formed from the hydrolysis of *p*-coumaroylquinic acid, a natural phenol of apples. Some of these phenols and others, such as vanillin, may be derived from containment of the cider in wooden fermentation or maturation vessels, or from the effect of added oak chips. However, as with wine, leaching of phenolic (and other) substances from the pores of wooden vessels tends to fall off significantly with continued use of the vessels.

During malolactic fermentation (MLF), the major process is the conversion of (*S*)-(+)-malic acid to (*S*)-(–)-lactic acid and carbon dioxide (Chapter 2.3), leading to a softening of acidic character, as in wine. In traditional English and French cider production, alcoholic fermentation and MLF tend to be sequential, with MLF occurring any time after the finish of the former, or even during its final stages, depending on (amongst other factors) the temperature, acidity and quantity of nutrients present. For traditional British and French cider, the malolactic fermentation can be considered a part of the maturation process, since it frequently starts in the spring following the harvest.

On the other hand, there is good evidence to show that alcoholic and malolactic fermentation occur more or less simultaneously in the production of traditional Spanish cider (Lea and Drilleau, 2003). This may be because of the richer bloom (with higher populations of malolactic bacteria) on apples grown so much further south than those of northern France or western England, but is more probably because of the high

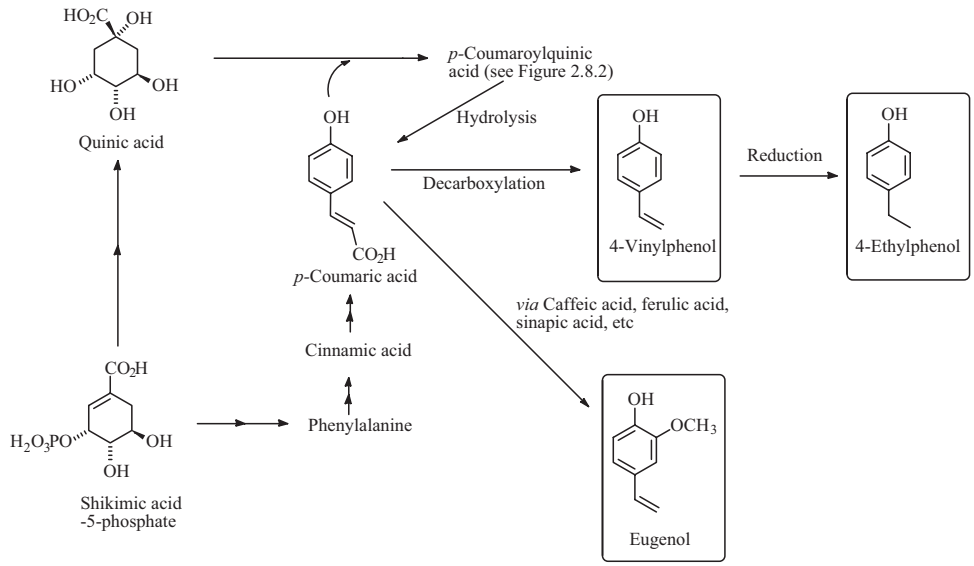

Figure 2.8.7 *Formation of some volatile phenols during alcoholic and malolactic fermentation of apple must. The nonvolatile phenolic precursors may be apple must constituents or fermentation products*

fermentation temperatures (~22 °C) often utilized by Spanish cider makers, and the high populations of malolactic bacteria that exist in the fermentation vats and other equipment.

The simultaneous fermentation by particular bacteria (largely *Oenococcus oeni*, *Leuconostoc* and *Lactobacillus* spp.) under Spanish conditions may explain the somewhat elevated levels of acetic acid in Spanish cider, compared with its English and French counterparts. Far from being a fault, this is much prized by Spanish manufacturers and drinkers alike (Section 2.8.8). However, research on Chardonnay must involving a comparison of sequential and simultaneous alcoholic fermentation/MLF (by inoculation at 19–20 °C) suggests that there is very little difference between the two, and acetic acid levels are only slightly elevated by the simultaneous fermentation procedure at this temperature (Jussier *at al.*, 2006).

As with wine, MLF leads to a large number of bacterial metabolic end products that are considered to give additional complexity of aroma and flavor. Probably the most important of these end products is diacetyl (2,3-butanedione), giving buttery or butterscotch notes below concentrations of *ca.* 5 mg/l. Much above this concentration, diacetyl spoils alcoholic beverages with a powerful rancid butter flavor. Diacetyl is produced in cider and perry by bacterial metabolism of citric acid, as in wine. *Lactobacillus* species produce α-acetolactate as an intermediate (compare with Figure 2.6.15, Section 2.6.4), whereas *Oenococcus oeni* and *Leuconostoc* spp. apparently do not. Otherwise, their metabolic pathways from citrate and pyruvate to diacetyl are similar (Figure 2.8.8).

O. oeni uses a route that involves direct coupling of the thiamine pyrophosphate (TPP) adduct (the 'active acetaldehyde') and acetyl coenzyme A (Figure 2.8.8). Besides diacetyl, acetoin (3-hydroxybutan-2-one) and butylene glycol (butane-2,3-diol) are also produced, but these are flavor inactive. The latter compound, however, when included with glycerol (produced during both alcoholic fermentation and MLF) may contribute to a smoother mouthfeel. Like many yeasts, *O. oeni* exhibits β-glucosidase activity and so nonvolatile glycosides of terpene alcohols and C_{13} norisoprenoids are hydrolyzed during MLF, thus releasing the aglycones to give spicy, floral and honey notes. In red wines, these aglycones include linalool, farnesol and

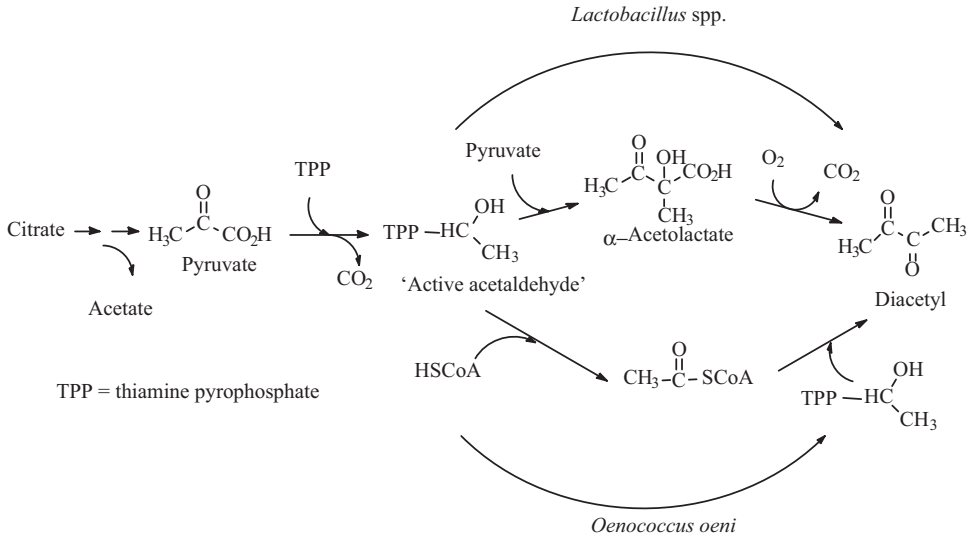

Figure 2.8.8 *Comparison of* Lactobacillus *spp. and* Oenococcus oeni *pathways to diacetyl*

β-damascenone (Ugliano and Moio, 2006). It is probable that such reactions occur in cider that is undergoing MLF, although the levels of terpene alcohols and norisoprenoids are in general considerably lower in cider than in red wine (Xu *et al.*, 2007; Ugliano and Moio, 2006).

Biogenic amines (Section 5.11.3) have been found in cider, as well as in many other alcoholic beverages, particularly wine. Because of the early participation of lactic acid bacteria in the production of traditional Spanish cider, some of the many LAB species were suspected as producers of biogenic amines. Garai *et al.* (2007) were able to isolate 54 LAB strains from Basque country cider. It was demonstrated that six of them (five lactobacilli and *Oenococcus oeni*) were able to produce biogenic amines in culture media. *Lactobacillus diolivorans* was the most intensive histamine producer, whereas this species, as well as *Lb. collinoides* and *O. oeni* produced tyramine. Interestingly, *Pediococcus parvulus* displayed no ability to produce histamine, putrescine or tyramine, even though it is a known biogenic amine producer in beer and wine.

In Europe (but not in Britain), much cider is destined for the pot still or column still to be turned into apple spirit, such as Calvados (Section 3.8.2). In the production of whiskies and rum, distillation is carried out soon after a rapid fermentation, when the maximum ethanol content of the beer has been achieved. Apple spirit could be produced in a similar way, but it has been found that a few months maturation time improves the organoleptic character (particularly the aroma) of the new make spirit (Rodríguez Madrera *et al.*, 2010). The continued action of malolactic bacteria over a longer maturation period gives higher levels of acetic acid, certain alcohols, certain esters and some phenols, which have a notable influence of the aroma of fresh spirit, giving it greater fruity, spicy character.

2.8.5 Traditional and Small-Scale Cider and Perry Production: Fermentation and Beyond

Traditional cider and perry are made only from the juice of freshly crushed and pressed fruit. With the general exception of anthocyanins, the juices contain the range of components described for the fruit in Section 2.8.2 and they contain a wide variety of microorganisms (also described in Section 2.8.2). Alcoholic

fermentation starts almost immediately, initiated by *Kloeckera apiculata* and others until the alcohol content rises above about 2% by volume. At this stage, most of these pioneering microorganisms cease to function and fermentation is taken over by *Saccharomyces* species (especially *cerevisiae* var. *ellipsoides*) that originate from both fruit skins and the winery equipment with which the juice has made contact. Alcoholic fermentations of this kind are often called 'spontaneous'; they can be slow to become established when using new equipment for the first time, due to lack of sufficient contamination by *Saccharomyces* species. Once established, alcoholic (primary) fermentation can take weeks or even months to complete, depending mainly on the ambient temperature and original gravity of the juice. Primary fermentation of traditional cider is relatively rapid

in northern Spain, presumably because of relatively high ambient autumn daytime temperatures (~20 °C), whereas in England and northwestern France slower fermentations occur at 10–15 °C.

The final gravity of traditionally fermented cider is often around 1000 in the UK, but about 1010 in France, where it is desirable to bottle cider with a certain amount of residual sweetness (Section 2.8.8). English sweet or semi-sweet traditional ciders can be made by racking the liquid off the yeast deposit and debris when the gravity reaches 1015 or 1010. A slow fermentation may well continue after racking, but if the cider is destined for cask (which is most likely), it may be yet consumed while there is a sufficient degree of sweetness. In the UK, the majority of traditional ciders are dry, whether served from cask or bottle (still or naturally sparkling – that is, bottle conditioned).

Traditional cider is often known as scrumpy in the west of England. The name comes from scrump, which means a small apple (in essence a cider apple), but nowadays the term scrumpy is used to describe any hazy cider, whether or not it has been pasteurized (Section 2.8.8). In France, when the cider reaches the above gravities, it is often filtered through kieselguhr into bottles where further alcoholic fermentation and maybe malolactic fermentation take place at *ca.* 10 °C. Traditional French cider is usually bottle conditioned (sparkling or 'bouché') in the style of Champagne, although still ciders also exist (Section 2.8.8). The final gravity of perry is often about 1010 because of the existence of higher concentrations of nonfermentable sugars and sugar alcohols (especially sorbitol) in pear juice (Section 2.8.2).

Cask-conditioned traditional cider and perry (a specialism of the UK) are either flat or lightly carbonated and will probably be hazy, although often only very slightly so. The ciders will be mostly dry, although there are some semi-sweet and sweet cask-conditioned ciders (Section 2.8.8), whereas cask-conditioned perry is most likely to be semi-sweet or semi-dry. Bottle-conditioned cider is made by either bottling whilst primary fermentation is terminating, as in Brittany and Normandy, or by dosing a fully fermented cider or perry with sugar syrup just before bottling, as in much of the UK. Traditional English perry is nearly always served still, from cask or bottle; bottle-conditioned traditional perry is rare (but see Section 2.8.6 for large-scale sparkling perry production). In Asturias, the Basque country, Germany, Luxemburg and some other countries, traditional cider is mostly bottled, either still or semi-sparkling (Section 2.8.8) and is mostly dry.

Malolactic fermentation (MLF) is important in the making of traditional cider and perry, especially when sharp and bittersharp fruit constitute a considerable proportion of the blend, as in northern Spain, particularly. Apart from the overall reduction in acidity (Section 2.8.4; Chapter 2.3), there are subtle beneficial biochemical changes (discussed in Section 2.8.4) that occur during MLF. The general opinion is that MLF makes an important contribution to the perceived extra complexity of flavor of MLF ciders, as opposed to non-MLF ciders. The predominant malolactic microorganism found in English traditional cider vats is *Lactobacillus plantarum* (Swaffield *et al.*, 1997), whereas *Oenococcus oeni* appears to the major organism found in traditional French cider making equipment. In northern Spain, two major species have been isolated from cider or equipment: *Lactobacillus hilgardii* and *Oenococcus oeni* (Herrero *et al.*, 2006).

In England and northwestern France, MLF normally occurs in the spring of the year following primary fermentation, when the ambient temperature is around 15 °C. Under these conditions, MLF may be sluggish and can take several weeks to complete. On the other hand, in Asturias and the Basque country primary fermentation and MLF are reckoned to take place simultaneously at temperatures (~20 °C or higher), which encourage a more rapid biological action. The malolactic conversion, given favorable conditions, is reported to take place when bacteria populations have surpassed 10^6 cells/ml, nutrients for initial growth being provided by both the medium and various yeast metabolites and autolysis products. Populations of lactic acid bacteria in the bloom on apple and pear skins in England and northwestern France are rather low, but it has been shown that bacteria originating from oak vats or casks give rise to MLF in traditional English cider (Swaffield *et al.*, 1997). Large populations of these bacteria (and yeasts) live in the pores of the wood, despite hot wash cleaning between successive cider fermentations.

Traditional wooden cider casks are often bigger than their equivalents in the wine industry (typically 546 l, as opposed to 228 l capacity) and are often several decades old, as opposed to 5–6 years old. It has been shown that in as little as 10 weeks contact between vat or cask wood and cider containing MLF bacteria resulted in penetration of the bacteria into the pores by more than 1 cm (Swaffield *et al.*, 1997).

Nowadays, much traditional cider and perry is fermented and matured in stainless steel, fiber glass or concrete vats, rather than in wooden vats or casks. These smoother surfaces are also colonized by lactic acid bacteria (and other microorganisms), but not to the same extent as wooden vessels. In England, there are still some small-scale and medium-scale cider and perry producers who use oak vats for fermentation and/or maturation. Vat capacities range from 5000 l to 200 000 l, with those of 22 700 l and 45 500 l (5000 and 10 000 gallons, respectively) perhaps being most typical. Cask sizes on the other hand vary from under 200 l to over 600 l; the traditional cider cask size is the 'butt,' of 546 l (120 gallons). Unless the vats or casks are new, they will make little (if any) contribution to the aroma and flavor of the finished product through leeching of oak substances into the beverage. Unlike in some areas of the wine industry, there appears to be no concerted movement in the cider/perry industry for fermentation or maturation in new oak. This may be partly because the prohibitive costs, partly because of the differences in expectations and attitudes between wine drinkers and cider or perry drinkers and partly because of the differences in social function between the beverages. It is possible that this situation will change somewhat (see Section 2.8.7).

In England and Wales, smaller-scale producers often use modified forms of the traditional process described above, for some or all of their products. The major modifications are listed below, but the majority of small-scale cider makers use only a selection of these:

- Purification of must by added sodium metabisulfite
- Fermentation using cultured yeast
- Addition of glucose syrup or invert sugar to must prior to fermentation
- Use of other additives or apple juice concentrate
- Use of fining agents
- Application of filtration and/or pasteurization
- Use of artificial carbonation.

Most small-scale cider makers ('farm cider') employ spontaneous fermentation of the must, with no added metabisulfite, but those that do purify the must normally add enough metabisulfite to give no more than about 60 ppm of SO_2, the active agent (Chapter 2.5). After a 24 h standing period (which also allows a certain amount of clarification), spontaneous fermentation proceeds or an activated yeast culture is added. In this way the most troublesome yeasts and bacteria are eliminated, but sufficient populations of desired yeasts and bacteria survive giving a mixed microflora fermentation, which is thought to produce a greater complexity of flavor. For more discussion on the good and bad points of using metabisulfite and cultured yeasts in cider and perry making, see Section 2.8.6.

It is mostly the larger UK cider and perry producers who use apple or pear juice concentrate, sugar syrups and other additives (Section 2.8.6), although a few medium-sized cider makers use some of their own must for conversion to apple juice concentrate in times of plenty, or buy in concentrate in times of shortage.

It is in the postfermentation treatments that many small-scale producers deviate most from a purely traditional process. Finings are quite widely used, with bentonite being the most popular agent, as it selectively adsorbs proteins, the major cause of haze in cider and perry. It can be added to the must at the same time as pitching the activated yeast culture. Indeed it is possible to purchase mixtures of granulated wine yeast, bentonite and diammonium phosphate (yeast nutrient); suitably activated, an inexpensive 60 g drum of this

mixture will ferment and clarify 200 l of must. However, in the majority of cases, finings are added after fermentation, prior to blending, filtration and bottling. In place of bentonite, isinglass (as for beer – see Section 2.6.9) or albumin (or egg whites, as for wine – see Section 2.9.4) may be used. Other fining agents include gelatin, chitin and kieselguhr.

Filtration in the UK is often carried out by plate and frame or sheet filter systems (Section 2.6.9), although some medium-sized cider makers also use cross flow membrane filtration. Pasteurization normally follows filtration; it can be carried out in bulk before cooling (e.g. by use of a flash pasteurizer – see Figure 2.8.9), carbonation and bottling, or in bottle, after carbonation. Smaller producers tend to use carbonation/bottling machines to bottle the cider or perry under CO_2 pressure at low temperature (Figure 2.8.9). The bottles are then pasteurized by immersing in a hot water bath (e.g. 60 °C for 15 min) (Figure 2.8.9).

Blending can be performed at many points in the cider or perry making process. Some smaller producers who make only blends tend to crush, press and ferment the whole mixture of apple or pear varieties from their orchards. Many others, particularly cider makers who produce single variety ciders as well as blends, prefer to process the varieties separately and formulate the blends at a later stage in the production. Typically, blending is carried out after the maturation period, but before filtration and packaging. Any other adjustments (e.g. acidity, sweetness or color) can also be made at this stage.

In Brittany and Normandy, the ciders produced by small-scale farmers using apples from their own orchards ('vergers') are known as 'cidres fermiers.' The methods of production differ from those used by smaller-scale UK concerns in a number of ways: spontaneous fermentation is almost always utilized, with minimum use of additives. Also, the process of défécation (keeving) (Section 2.8.3) is more or less universal, and filtration tends to be carried out using kieselguhr plate and frame filter systems. Much cidre fermier is bottled, after filtration, in the spring following the harvest, whence further fermentation (by surviving yeast cells) and possibly malolactic fermentation occur, thus producing CO_2 in the bottle. This is known as cidre bouché and is the French equivalent of the English bottle-conditioned cider. In order to promote this bottle fermentation, metabisulfite is never added at the bottling stage. The process of défécation prior to fermentation depletes the apple must of some yeast nutrients, especially nitrogenous compounds, and is reckoned to result in a slow fermentation that is incomplete at the time of bottling. Thus, there may be 30 g/l of unfermented sugars in the newly bottled cider upon which the yeast may feast. If MLF has not already occurred in the bulk cider before filtration and bottling, it may occur in the bottles, which are often stored for several months before sale.

Slow fermentation is of considerable importance to Norman or Breton cider makers. It can be achieved both by juice clarification (keeving) before fermentation, as described above, but also by reducing the biomass at some point during the fermentation via a racking, filtration or centrifugation process. Yeast populations are kept at low levels ($\sim 10^7$ cfu/ml, as opposed to $\sim 10^8$ cfu/ml used for beer or wine production) by application of one or other of these techniques. Obviously, these methods must be applied with care, so that the yeast population does not fall to such a low level that fermentative activity is too low to prevent spoilage, by the action of *Acetobacter*, for example.

Recently, it has been found that a single decimal reduction of biomass (e.g. by filtration) is best carried out when the density of the juice has dropped by 5–10 kg/m^3 (e.g. from an initial gravity of 1055 to 1050 or 1045), corresponding to consumption of 12–24 g/l of sugar (Nogueira *et al.*, 2008). This relates to the growth phase of the yeast. If this biomass reduction is performed at a later stage, the fermentation velocity became too low to reach the desired density.

In northern Spain, small-scale cider makers still use a largely traditional process that involves spontaneous fermentation (with no additives, including metabisulfite) of the naturally clarified must in chestnut casks. As in England, these casks are rarely renewed, and so over the years have acquired large populations of microorganisms. It has been demonstrated that both the alcoholic fermentation and MLF occur more easily

when the crushed apples are pressed in a traditional wooden press and fermented in chestnut casks compared with the use of a modern pneumatic press and fermentation in stainless steel tanks (Blanco Gomis *et al.*, 2003b). This was once again considered to be because of the larger populations of fermentative microbes residing in wooden equipment. Higher levels of fusel alcohols and esters were also apparent in the cider produced by the all wood traditional method, compared with that made by the modern equipment or any combination of wooden and modern equipment (Blanco Gomis *et al.*, 2003b). The all wood process gave cider with low methanol and high 1-propanol contents, which have been shown (along with low levels of acidic polysaccharides) to produce foam with the best sensory characteristics when served in the traditional Spanish way (Section 2.8.8) (Mangas *et al.*, 1999; Lobo *et al.*, 2005).

A molecular genetic study, using mtDNA restriction analysis, of *Saccharomyces* species isolated from Asturian cider fermentations has shown that there was a succession of genetically different strains of *Saccharomyces* during cider production (Suárez Valles *et al.*, 2007). *S. bayanus* dominated the early stages of fermentation, giving way to *S. cerevisiae* in the later stages. Five strains of *S. bayanus* (III, VII, VIII, XV and XVII) were present in significant frequencies in all the fermentation tanks (for two consecutive harvests), while cluster analysis showed higher similarities for patterns in all but the last above-mentioned strains, indicating that these were important microflora of this particular cider plant.

The foaming characteristics of cider are considered very important by the cider makers and drinkers of northern Spain. Good foaming behavior includes good initial foam production, when the cider is poured from a height (the traditional way of serving Spanish cider), rapid collapse of the main body of foam, but leaving of a thin residual layer of foam and tiny bubbles of CO_2 in the cider. Foam quality of a large number of cider samples has been correlated with the presence (or absence) of a number of components, as mentioned above. Additionally, as with beer (Section 2.6.2), high quality of foam has been correlated with the presence of proteins, especially high molecular weight proteins (Blanco Gomis *et al.*, 2007) and fatty acids, especially caprylic acid with regard to foam stability and linolenic acid with respect to foam height (see also Section 4.6.3) (Magolles Cabrales *et al.*, 2003).

It is believed that the most effective proteins regarding foam formation and stabilization are those with relatively little disulfide bridge cross linking and a high proportion of hydrophobic amino acid residues. Both these factors facilitate molecular flexibility, allowing the proteins to unfold and, by interacting with each other (via hydrogen bonding, hydrophobic and ionic attractions), to create a stabilized film around the bubbles. The protein film increases the elasticity and viscosity of the medium at the liquid–gas interface and at the same time decreases interfacial tension.

Good foaming properties of still or 'natural' Asturias cider has been shown to be associated with the presence of low to medium molecular weight proteins from traditional manufacture (Blanco Gomis *et al.*, 2007), whereas the presence of higher molecular weight proteins, more typical of fast press production, was not so good for foam production. For sparkling ciders, foam quality has been found to be more closely related to the yeast species used in the foam production step (Blanco Gomis *et al.*, 2009). More recently, the same group have shown that both still and sparkling cider can be characterized on the basis their HPLC derived hydrophobic protein profile and foam characteristics, using multivariate analysis chemometric methods to process the large amount of data (Blanco Gomis *et al.*, 2010). The computed multivariate regression allowed the prediction of foam parameters: foam height, foam stability height and foam stability time.

Traditionally, Spanish cider is fermented at rather higher temperatures than its traditional English and French cousins: 22 °C is not uncommon. At such temperatures, alcoholic and malolactic fermentation usually occur simultaneously, or at least in overlapping succession. Laboratory-scale cider making using inoculation of must with *S. bayanus* and *Lactbacillus hilgardii* has suggested that simultaneous fermentations at 22 °C led to cider with increased levels some aroma compounds in the resulting cider. Alcoholic fermentation at 15 °C, followed by MLF at 22 °C resulted in a cider with normal levels of aroma constituents, suggesting that

this may be a way to a more delicate product rather in the French style, but which has had full MLF (Herrero *et al.*, 2006).

2.8.6 Large-Scale (Factory) Production of Cider and Perry: Fermentation and Beyond

Large-scale cider production is very different in England and France, so separate accounts are given in the following paragraphs, followed by discussion of factory made perry. UK and other northern European factory-scale cider making is not generally closely allied to the traditional method, as discussed in Section 2.8.5. Apple juice concentrate (AJC) is the common basis of most of these ciders and bulk AJC, purchased on the world market, is used for making the base ciders. Much of this is of Chinese origin (China is the world's largest apple producer) and is made from apple varieties such as Fuji, Gala, Ralls and Starking. Besides the bulk concentrate, the largest cider producers convert all their native apple juice to concentrates in the factory at the time of the harvest. In this way, juices of bittersharp apples, such as Bulmers Norman or Kingston Black, and bittersweet varieties, such as Dabinett and Tremlett's Bitter, with gravities of about 14 °Brix (∼1060) are (after sulfiting) converted to concentrates with gravities of around 70 °Brix or higher. The concentrates are kept in stainless steel or epoxy resin lined mild steel tanks of 2 500 000 l (or greater) capacity. The big advantage of using concentrates is that cider can be made the whole year round, like the brewing of beer, instead of being confined to the few weeks following the harvest. The two largest UK cider manufacturers (see Section 2.8.8) use in excess of 60 000 tons of (mostly local) apples per year, thus generating large amounts of dry pomace from the pressings. This is sold to companies for the extraction of pectin for use in jam making. Prior to fermentation, apple juice concentrate is diluted with filtered water, and glucose syrup or invert sugar is added to bring the gravity up to 1090–1100 (∼23 °Brix); this gives a cider of 12–13% ABV when fermented to dryness. If any natural apple juice is used, it is flash pasteurized first. Acidity is adjusted with malic or citric acid and yeast nutrients (diammonium phosphate and thiamine) are added. Pectinases are sometimes added at this stage to prevent haze formation at later stages. Before addition of yeast, the must is aerated with compressed air to provide oxygen for the rapid growth of the yeast population in the early stages of fermentation.

For fermentation, various strains of cultured cider and wine yeasts are used, the former imparting cider aromas and flavors and the latter promoting rapid, efficient fermentation. Strains of *Saccharomyces bayanus* (a Champagne yeast) are popular (Johansen, 2000). Although the larger manufacturers have their own strains of cider yeast, the tendency (unlike brewing) is to use a newly cultured yeast starter for each batch, rather than use the collected lees of one batch to start the fermentation of the next batch.

Yeast strain is important in cider production, as for other alcoholic beverages; the wrong choice can give less than optimum quality cider. In general, strains of *S. cerevisiae* used for brewing beer do not give the best cider, wine yeasts being more suitable. Even so, careful choice should be made, based upon correlation of chemical analysis (e.g. of aroma components by gas chromatography) and sensory analysis of the finished cider with yeast strain. Recently, the results of a combination of these two methods were analyzed by fuzzy comprehensive evaluation (FCE) (Peng *et al.*, 2008) in order to rank the cider making qualities of eight *S. cerevisiae* strains commonly used in Chinese cider production. The FCE technique overcomes the problems of imprecise subjective judgments from sensory analysis and incomplete objective data (from chemical analysis).

Fermentation occurs at ∼22 °C in thermostatted tanks (often of the cylindroconical type – see Section 2.6.5), fitted with agitators. These vessels are typically of from 100 000 l to over 600 000 l capacities, and are usually made of stainless steel. At 22 °C, fermentation is rapid, taking only 7–14 days, after which time the new cider is cooled to around 10 °C. After pumping the new cider off the yeast deposit (lees) into fresh tanks, metabisulfite and finings are added and the cider is allowed to stand for two days while clarification takes

place. The cider is then pumped into buffer tanks for a few weeks' maturation period. Some of these tanks, all of stainless steel or epoxy resin lined mild steel, are of 2 500 000 l capacities and higher (see Section 2.8.8) and are situated outdoors, like the largest fermentation/maturation tanks of the really big breweries (Section 2.6.6). These tanks are well insulated and thermostatted. The larger cider companies in the UK make six or so basic ciders in this way; eventually these will be blended in proportions that are decided by the blenders for each brand. High gravity ciders (12–13% ABV) will need dilution with pure water to the desired alcoholic strength (usually 5–8% by volume) before blending. Adjustment of acidity, sweetness or color may also be necessary. Blending can either precede or follow filtration, but adjustments are made at the same time as blending. Acidity is adjusted with either pasteurized sharp apple juice, citric acid or malic acid; sweetness is adjusted with sugar syrup or artificial sweeteners (Lea, 2004) and color is usually adjusted with caramel. Cross flow filter systems (using filters down to 0.2 μm pore size) or continuous membrane microfiltration systems are used for the final filtration and flash pasteurization may be applied before the cider is cooled to about –2 °C and carbonated in bright cider tanks, often of around 1 800 000 l capacity. It is from these tanks that the cider is packaged into bottles (glass and PET), cans and kegs. Some cider may be pumped into tankers and then taken off site to be packaged. Big companies that produce scrumpy cider brands (naturally hazy – see Section 2.8.8) apply only pasteurization to the ciders that are destined for these brands. The two largest producers of cider in the UK are H.P. Bulmer (Hereford) and the Matthew Clark group (Shepton Mallet, Somerset) (Section 2.8.8).

The rigorous sulfiting (addition of metabisulfite), filtration and pasteurization regimes of the UK large-scale cider producers ensure that the malolactic fermentation does not occur. This is in sharp contrast to the methods of many small-scale UK cider makers, as well as to those of some large-scale manufacturers in France. The roles of metabisulfite are to reduce the risk of infection by harmful microorganisms and to prevent extraneous oxidation. At the same time, of course, malolactic bacteria are inhibited. The active agent of metabisulfite is sulfur dioxide, SO_2 (Section 2.5.2). As in winemaking, SO_2 reacts with many components of must and cider or perry, both reversibly and irreversibly (Section 2.5.3). Bisulfites are formed with carbonyl compounds (acetaldehyde, α-ketoglutaric acid, pyruvic acid and others) or potential carbonyl compounds (sugars and their derivatives). Additionally, sulfonic acids are formed by reaction with polyphenols. In order to allow for this binding and to ensure that enough SO_2 remains in solution ('free SO_2') for optimum antimicrobial activity, metabisulfite is frequently added to apple juice (prior to fermentation) to give total SO_2 levels of ~100 ppm (Herrero *et al.*, 2003). The legally permitted limit in many countries (e.g. those of the European Union and the USA) is 200 ppm. Excessive binding of SO_2 is evident when apple juice concentrate is used or when significant amounts of damaged fruit are used to prepare the must. In the former case, this is probably because the heat treatment used to produce the concentrate results in higher levels of carbonyl compounds and other oxidation products (Jarvis and Lea, 2000). In the latter case, the action of acetic acid bacteria on the damaged fruit produces sulfur dioxide binding substances, notably oxo acids, such as 2-ketogluconic acid and 2,5-diketogluconic acid, as well as oxidized sugars, like 5-ketofructose.

Apple and pear juice concentrates are produced in many countries, including Argentina, China, Italy, New Zealand, the UK and the USA. Clean, sound fruit are crushed and pressed, and the resulting juice is depectinized and microfiltered before undergoing ramped low temperature vacuum concentration. Concentrates are usually of 70 °Brix gravity: *ca.* 1.35 kg/l density, with about 950 g/l sugar content. They are usually bright with turbidity ratios of less than 2 nephelometric turbidity units (NTU) (Section 4.6.3), although cloudy concentrates are also available. They can be purchased by the tanker load or in 200 l metal or plastic drums. Their lifetime is about six months if stored at temperatures below 7 °C. Beyond this storage time, the suppliers cannot guarantee insignificant deepening of color. Many juice concentrate firms also produce essence and flaked or powdered products. The larger UK cider manufacturers make their own apple juice concentrates from local apple varieties, such as Bulmers Norman, Dabinett, Tremlett's Bitter and others; they often add metabisulfite prior to subjecting the juice to the concentration process.

Factory production of cider in Brittany and Normandy is generally much more allied to traditional and small-scale practices than in most other countries. Under EU specific food law for France, only 10% of the must may be made from apple juice concentrate and additions of sugar (or sweeteners) and coloring agents are not allowed in the production of cidre. Interestingly, these additions are allowed if the product is given the English name 'cider.' In one particular kind of prefermentation treatment, some factory procedures differ considerably from the traditional method. This is the use of a counterflow diffuser. After securing the juice from the first pressing of the crushed apples, the pomace is conveyed along a long tube where apple juice is pumped in counterflow to extract extra sugars from the pomace. The pomace is then dried and sold to companies for pectin extraction, as in UK factory cider production.

The process of défécation or keeving is practiced by large and small French cider makers alike. Keeving occurs naturally in fresh apple must, as hydrolytic enzymes in the juice (principally pectin methylesterase) act upon pectins by hydrolyzing their side chain methyl ester groups to carboxylic acid groups. The demethylated pectins (essentially polygalacturonic acids) form gel-like salts with juice cations (mainly Ca^{2+}) and the gel rises to the surface to form a brown frothy crust (the 'chapeau brun'). Haze particles are trapped in the gel, so that when the crust is skimmed off, a partially clarified must is left behind. Weak interactions (probably dominated by hydrogen bonding) with pectin and cell wall debris also traps substantial amounts of proteins and higher polymers of flavan-3-ols, themselves potential haze producers (Hubert *et al.*, 2007). Thus, although keeving is a clarification process, it also leads to a less nutritious medium for yeasts, and additionally there is loss of bitterness and astringency caused by removal of some polymeric phenols.

Natural keeving can be a rather a slow process, often needing several days, so manufacturers often use pectin methylesterase (PME) from *Aspergillus niger*, along with calcium chloride as a supply of Ca^{2+}. The must is then often pressurized with nitrogen gas, so the gel of calcium pectinate rises quickly to the surface. This method, known as flotation, causes more rapid formation of chapeau brun. Although haze particles are still trapped in the gel, there is no time for effective interaction with polymeric phenols, which remain in the juice. Hence the flotation method gives a lower depletion of the higher polymers of flavan-3-ols, leading to more bitter juice (Hubert *et al.*, 2007).

After removal of the chapeau brun, the must is often further clarified by centrifugation or filtration before undergoing a long, slow spontaneous fermentation, sometimes at temperatures below 10 °C for several months. Malolactic fermentation may or may not occur, depending on the style of the manufacturer. After fermentation, clarification is effected with albumin, gelatin or bentonite, followed by either centrifugation and/or filtration, using a kieselguhr drum filter system. Some brands that are called 'cidre fermier' (farm cider) are not filtered at this stage.

The ciders are then blended and are stored in stainless steel or painted mild steel tanks at low temperatures (*ca.* 7 °C) before packaging. The largest producers (see Section 2.8.8) make both still ('table') and sparkling ('bouché') cider of varying degrees of sweetness and alcoholic strength (2–6% ABV). The sparkling cider is artificially carbonated before packaging. French cider is mainly packaged in bottles (glass and PET) of sizes up to 1.5 l. The wine bottle size (750 ml) is popular. The largest cider producers in France are Volcler and Loïc Raison (Section 2.8.8)

In Ireland, the method of production of factory made cider resembles those of some medium sized companies in the west of England. Rack and cloth presses are used, and the must undergoes spontaneous fermentation in oak or stainless steel vats at ∼20 °C for up to eight weeks. This is followed by several months maturation (some in oak vats) before filtration, blending, chilling, further filtration, carbonation and packaging. The main bulk cider producer in Ireland is Bulmer of Clonmel (not related to the Hereford Bulmer), known as Magners outside Ireland (Section 2.8.8).

There are fewer factory-scale perry producers and many of these actually manufacture both perry and cider (see Section 2.8.8). As in the case of cider, the must can be made of freshly crushed and pressed fruit or by

dilution of fruit concentrate. The must is often sterilized by addition of metabisulfite, but up to 150 ppm of total SO_2 may be required (compared with 50–100 ppm in apple juice) because of higher concentrations of SO_2 binding components in typical pear juice. These include acetaldehyde, a number of ketones, sugars and phenolic compounds. Although the legal limit for total sulfur dioxide in alcoholic beverages is 200 ppm in many countries, legislation may well reduce this limit in the near future, in response to constant lobbying by health organizations and consumer groups (Section 5.9.2). An alternative way to sterilize the must is to give it flash pasteurization treatment (Section 2.6.9). This kills both wild yeasts and lactic acid bacteria (as well as spoilage and pathogenic organisms), but it is certain to alter the flavor of the finished perry, compared with an unpastuerized product. The sterilized must is then fermented by addition of activated cultured yeast, often a champagne yeast, such as *Saccharomyces bayanus*. Sugar, acid and yeast nutrients may also be added at this stage. As with factory made cider, fining, centrifugation and filtration of perry can be performed at a number of stages in the manufacturing process. Blending of perry is as important as cider and tasting the blends may result in the decision to adjust sweetness by addition of sugar syrup or sweeteners. Centrifugation or filtration is always carried out after maturation and blending, but before committing the perry to bulk storage tanks at low temperatures for assessment of haze stability. The perry is next sulfited or flash pasteurized before packaging. It may well be given a final membrane filtration at this stage. The cooled perry is finally given an artificial carbonation in the bottle by use of counter pressure bottle filling machines. The best known brands of factory made perry are probably Babycham, Brothers, Kopparbergs and Pomagne (see Section 2.8.8).

2.8.7 Newer Techniques, Recent Developments and Innovations

Apple and pear harvests usually occur over a limited number of weeks in the autumn, the exact spread of harvest depending mainly on the varieties grown and the seasonal weather. The cider or perry maker is thus often presented with a large mass of fruit within the space of a few weeks at most, which (after appropriate sweating or storage) has to be converted into cider or perry. The net result is that the fermention and storage equipment is all used together until the spring or early summer of the following year; there are 4 or 5 months at least where the equipment is not in use, except in cases where maturation is extended over several months. This situation is particularly acute for large-scale producers during a protracted harvest; small-scale manufacturers can at least make separate vats of varietal ciders or perrys and blend them later, as required. For most large-scale and some medium-sized operations, the main answer to this situation is fruit (apple or pear) concentrates (Section 2.8.6), purchased and/or produced from their own fruit. These concentrates have useful lifetimes of around six months if stored at low temperatures (Section 2.8.6) and hence their use can extend cider and perry making activities over virtually the whole year, thus maximizing use of equipment, but without overloading at any one time. Careful blending can ensure consistency of flavor for particular brands. Thus, factory cider or perry manufacturers who use concentrates are in a similar situation to brewers: their basic ingredients can be stored for long periods and are used as demand dictates. In contrast, small-scale producers are in a situation similar to winemakers. Fruit juice concentrates have been used for many years, but it is only during the last decade or so that they have actually become the focus of factory made cider and perry.

Cider apples and perry pears, on the other hand, generally cannot be stored for much more than two weeks or so before being processed. Traditionally, the fruits are stored just long enough for them to ripen, but they are checked regularly for softness and processed immediately they are judged to be ready. Many pears and some apples do not store well (e.g. Jonathan, used for cider in North America); they are either processed immediately or are given just a day or two of storage time. Overextended storage of any fruit leads to age related deterioration (senescence) and other faults, even in sound (undamaged) fruit. It has been shown that

spraying fruit on the tree with ethephon – (2-chloroethyl)phosphonic acid – accelerates the ripening process, so that harvest can begin a full two weeks before the traditional harvest (Gómez-Cordovés *et al.*, 1996). This compound works by releasing ethylene, a fruit ripening hormone, as a result of hydrolysis inside the fruit. It also minimizes premature fruit drop in certain varieties of apples. On the other hand, application of seniphos delays ripening and extends the storage lifetime (without senescence) of the harvested fruit. In this way, use of these two agents may extend the harvest and storage time over several more weeks, thereby relieving pressure on equipment and other facilities.

Flavored ciders, mostly from the larger companies, have been available for the past few years (Section 2.8.8). The range of flavors in present use, however, is much narrower than with beer (Section 2.6.13), and at the time of writing (2008) is more or less limited to fruit flavors, such as bilberry, pear and raspberry. Cider flavored with lemongrass and ginger is made by Westons (Hereford, UK) (Section 2.8.8). Except when traditional cider or perry is fermented and/or aged in new oak vats or casks, oak aromas and flavors are not prevalent in these fermented beverages. Oak vessels are expensive and are not often renewed by cider and perry makers. Traditional producers use oak vats or casks largely for the accelerated aging that occurs via the gradual ingress of oxygen through the pores of the wood into the beverage, eventually resulting in a smoother, more mature product. Also important are the colonies of microorganisms that inhabit the pores of used vats and casks (Section 2.8.5); these organisms are responsible for both alcoholic and malolactic fermentation in traditional cider and perry. The oak aroma compounds (Section 2.9.5) are largely leached from the wood after a few seasons of cider or perry fermentation or maturation. So, all in all, oak aroma and flavor are not commonly associated with cider and perry. In any case, chestnut casks, with less intense flavoring capabilities, are used in place of oak casks by some producers, particularly in northern Spain. Socially, cider and perry are closer to beer than to wine, but in flavor and in most of the production methods they are closer to wine. Distinct oak aromas and flavors are common (and popular) in some wines (e.g. red Bordeaux and red Rioja, to name just two), but only very rarely in beer, cider or perry (see Section 2.6.13 for an oak flavored beer).

Oak chips have long been used by some wineries as an inexpensive means of producing red and white wines with oak character. So far, this has not been applied to the large-scale manufacture of cider or perry, or to the production of a speciality oaked cider or perry by a large company. It has been demonstated that the aroma profile of cider matured with added oak chips is attractively modified (Fan *et al.*, 2006). Moreover, as with wine, oak aroma can be fine tuned according to whether American, French or Chinese oak is used, and according to the level of toasting. Also, the modest oak chip maceration times gave typical oak aroma profiles without significant increase in tannic mouthfeel. This is noteworthy because both cider and perry (especially the traditional types) are already rich in polyphenols, including tannins. There is no doubt that the finest cider and perry rival many white wines in overall quality, so it would be interesting to witness an increase in the production of oaked cider and perry.

As with wine, the malolactic fermentation in cider and perry production presents something of a controversy. Traditional and small-scale cider and perry makers in England and France tend to encourage its occurrence, by the use of wooden vats or casks, long maturation times and minimal or zero levels of sulfur dioxide. Even here, however, occurrence of MLF is by no means universal (Johansen, 2000). In northern Spain, the general process and conditions favor MLF, which tends to occur simultaneously with alcoholic fermentation (Section 2.8.5). The situation with the largest cider manufacturers in Brittany and Normandy (including Loïc Raison and Volcler) is mixed: some encourage MLF, some do not, although whilst not taking steps to actively discourage it. On the other hand, factory-scale producers in England and northern Europe operate processes that actively discourage MLF (Section 2.8.6), the philosophy being to keep everything under tight control, largely for the sake of consistent product quality. The control option chosen is prevention of MLF, rather than the opposite option of adding activated lactic acid bacterial (LAB) starter cultures to ensure the occurrence of MLF. Indeed, it appears that the use of LAB cultures such as *Oenococcus oeni* or *Lactobacillus brevis* is

rare in commercial cider and perry production, with only a few smaller companies in the USA and Canada practicing this regime.

Recently, it has been found in the USA that a cider substrate (produced from noncider Braeburn, Fuji, Golden Delicious and Red Delicious apples) of between 6 and 11% ABV can be induced to undergo rapid MLF at 20 °C, by inoculation with *Oenococcus oeni*, provided the total SO_2 level is lower than 80 ppm (Reuss *et al.*, 2010). This resulted in a considerable drop in titratable acidity and suggested that the inoculation technique could be used by winemakers to produce high quality cider outside the winemaking season, thus providing a useful extra income and allowing more efficient use of winery equipment. Consumption of (hard) cider in the USA is in a definite upward trend.

The English and northern European factory cider manufacturers take the preventative option probably because, at the time of writing (2009), it is both easier and more reliable to prevent MLF than to promote it with certainty on an industrial scale. Nevertheless, there has been considerable interest and activity amongst research workers in the formulation of processes that both accelerate and maximize MLF in the production of wine, and to a lesser extent, cider.

Apart from spontaneous MLF and MLF brought about by addition of starter cultures, processes involving high cell concentration techniques have been described in the literature (Zhang and Lovitt, 2006). The latter techniques, which unlike the older former two methods, do not require the actual growth of the LAB in the medium during the malolactic process, include both batch and continuous versions. The latter can be subdivided into immobilized cell and membrane bioreactor (MBR) methods. Immobilized cell methods involve passing the juice or cider through packed bed bioreactors containing entrapped cells in matrices such as oak chips, poly(vinyl alcohol) hydrogel and calcium alginate. Malolactic fermentation of apple juice and cider has been described using hydrogel (Durieux *et al.*, 2000) and alginate (Herrero *et al.*, 2001) matrices, and simultaneous alcoholic fermentation and MLF of apple juice using entrapped *Saccharomyces bayanus* and *Oenococcus oeni* has been described using an alginate matrix (Nedovic *et al.*, 2000).

These processes are all described for small-scale (laboratory or pilot plant) conversions. They may suffer from the mass transfer and scaling up problems that have been encountered in the continuous production of beer by immobilized yeast cells (Section 2.6.8). Use of membrane bioreactors (MBRs) could improve large-scale continuous fermentation methods, since they perform both the fermentation and filtration (biomass medium separation) stages during a continuous process and furthermore, they do not have the mass transfer problems associated with matrix entrapped systems. At present, there is relatively little literature in the MBR field applied to cider manufacture (Zhang and Lovitt, 2006) and it remains to be seen whether the process will be adopted in large-scale cider or perry manufacture.

Some research in the present decade has focused on the effect of prefermentation fruit or juice treatments on both the juice and the resulting alcoholic beverage. Aiming at an assessment of different laboratory-scale prefermentation processes for possible use by a fledgling Ontario commercial cider business, Wilson *et al.* (2003) studied the effects of storage time, (Sections 2.8.5 and 2.8.6) (with and without addition of metabisulfite) and freezing/thawing on the chemical and organoleptic character of cider. Of particular interest was the possibility of extension of apple storage time by freezing whole apples sealed in ziPLOC® bags at –27 °C for 2–4 months. After thawing at 5 °C and then at ambient temperature, the juices extracted from these apples showed increased amounts of suspended matter and did not undergo keeving on standing. Moreover, this juice contained greater yeast and other fungal populations than juice from nonfrozen apples and the resulting cider had higher methanol levels.

Prefermentation clarification of beer wort and its influence on the character of the finished beer have been well studied (Section 2.6.2), but there are relatively few reports on the effects of analogous processes in cider and perry making. In a recent study (Hubert *et al.*, 2007), at both laboratory and commercial scale, the polyphenol contents and colors of cider apple juices were compared after five different treatments of the juice. The traditional method of keeving (défécation) had the highest impact on the reduction of both flavan-3-ol

content (Section 2.8.1) and the number average degree of polymerization. This corresponds to juices with relatively low bitterness and astringency. Fining with gelatin gave a lesser depletion of juice polyphenol content, but much more so than a depectinization method using a mixture of pectolytic enzymes. Flotation and gel fitration had little effect on polyphenol content, although the latter process led to a greater depletion of protein (as measured by nitrogen quantification).

2.8.8 Cider and Perry from Around the World

Cider and perry were staple beverages of northern Europe (along with beer), southern Europe (along with wine) and certain countries that were colonized by certain of these peoples, such as America and Canada. In many of these countries, the fortunes of both cider and perry waned in favor of either beer or wine (or other beverages) during the nineteenth century. Since the 1950s, cider and perry have had revived fortunes, firstly in their native heartlands of northern Spain, Brittany, Normandy and western England, eventually resulting in their almost global availability. Large companies grew up, especially in the UK, increased their output using modern equipment and methods, streamlined their products, implemented promotion schemes (marketing and advertising) and distributed their products widely. They bought cider orchards or commissioned farmers to produce cider apples, providing them with inexpensive saplings to enlarge their orchards or plant new ones, thus consolidating the supply of cider apples.

Nowadays (2009), there is the greatest area of apple orchards in northwestern Europe since the nineteenth century and cider apples are a more profitable crop than culinary or dessert apples. These companies pioneered the use of apple juice concentrate (AJC), so that cider could be made the whole year round, not just at harvest time. In the UK, drinks such as Babycham and Pomagne (sparkling perry) became popular in the 1950s and 1960s and this period saw the establishment of national brands, such as Bulmer's Strongbow, Taunton Blackthorn and Merrydown Vintage Apple Wine, which are now known internationally.

Western and northern Europe are the principal sources of cider and perry, but substantial quantities (especially of cider) are produced in Australia, Canada, New Zealand, some South and Central American countries and the USA. These beverages range from hazy, still drinks served from casks, flagons or bottles, to bright, sparkling drinks in sophisticated bottles, and alcohol contents vary from ~2% to over 12% (by volume), the norm being 5–6% ABV. This account emphasizes beverages made by indigenous companies from local produce; imported beverages or famous foreign brands made under license are mentioned here only in passing.

British Isles

Most cider and perry is produced in the western regions, notably Gloucestershire, Hereford and Worcester, Somerset, Devon, Cornwall, Wales and Ireland, for cider, and Gloucestershire, Hereford and Worcester for perry. The emphasis here is generally on traditional tannic cider apples (Brown's Apple, Bulmer's Norman, Dabinett, Foxwhelp, Kingston Black, Michelin, Somerset Redstreak, Tremlett's Bitter, Yarlington Mill and others) and perry pears (Barnet, Brandy, Gin, Moorcroft and others). However many cider makers in these regions also use a certain proportion of culinary apples (e.g. Bramley's Seedling and Grenadier) and dessert apples (e.g. Cox's Orange Pippin and Katy) in their blended ciders and even in a few single variety ciders.

The two biggest companies are H.P. Bulmer (Hereford), owned by Scottish and Newcastle Breweries (bought jointly by Carlsberg and Heineken) and Matthew Clark (Shepton Mallet, Somerset), part of the Constellation Group. They both concentrate their production on cider and use apple juice concentrate, but a large fraction of this is normally made on the premises from local apples of the varieties mentioned above. Producing nearly 300 million liters annually, gives Bulmer world top position, but Matthew Clark is not far behind,

with a yearly production of over 200 million liters. At both company sites, fermentation, maturation and all processing operations (as outlined in Section 2.8.6) are carried out using modern, highly automated equipment.

The Bulmer site possesses the biggest beverage container in the world (Guinness Book of Records) – a maturation tank of 7.3 million liters capacity. Blending is of prime importance in maintaining consistency of quality in the seven or eight brands produced by each company. The major brands of Bulmer are Strongbow, Woodpecker and Scumpy Jack, the last named being an unfiltered (but pasteurized) hazy cider that is marketed under the Symonds name. Matthew Clark's main brands are Olde English and Blackthorn. Bulmer also produces Pomagne, a sparkling perry and Matthew Clark make a similar product known as Babycham. Both these companies export their products to many countries and they both have stakes in or own foreign companies (e.g. H.P. Bulmer and Woodchuck Cider in USA).

In Ireland, the biggest cider manufacturer is C&C of Clonmel, County Tipperary, whose market name is Bulmers (not related to H.P. Bulmer) – known as Magners outside Ireland. The company maintains that this cider is made from Irish grown traditional cider apples, using oak vats for fermentation and storage for some of beverage. The production methods are rather more traditionally oriented than those of the big UK producers, resembling more the methods of some of the medium-sized English West Country producers. Like most of its English counterparts, Bulmers is chill filtered and carbonated prior to bottling. Clever advertizing has ensured a growing market for this cider in both Ireland and the UK, where it is supped from glasses that are half filled with ice (Section 1.3.8).

After H.P. Bulmer and Matthew Clark, Brothers (Somerset), Knight's (Malvern, Worcesterhire), Sheppy's (Taunton, Somerset), Thatchers (Sandford, Somerset) and Westons (Much Marcle, Herefordshire) represent the medium-sized cider and perry makers of the west of England, some of them making up to around 10 million liters annually. These companies use a mixture of traditional and modern methods, as described in Section 2.8.5. However, most of their products are pasteurized and/or filtered – only Knight's, Sheppy's and Thatchers produce traditional cask-conditioned ciders, but Westons make (pasteurized) bottled scrumpy.

Some of these companies make cider or perry for other companies as 'own' or 'special' label brands, a prime example being Duchy Original cider produced by Knight's. Brothers is a mainly perry producing concern that is run by four brothers who are descendants of Francis Showering, the originator of Babycham. Their major product is called 'pear cider,' an American term also used for perry produced by various Scandinavian breweries, although (apple) cider is also made.

Apart from the above-mentioned companies, there are numerous smaller producers (particularly of ciders) in the western British Isles, the majority of them being located in Devon, Gloucestershire, Somerset, Hereford and Worcester. In many ways, they maintain the tradition of farm cider or perry and many of their products are the equivalent of cidre fermier of northwestern France. Most of them concentrate on traditional beverages, although many of them use filtration, pasteurization and carbonation for some of their products. It is not possible to list them all here, as many are small businesses with only a local distribution area, but the reader is referred to www.ciderandperry.co.uk for an inventory of UK cider and perry firms and for general information.

Some of the better known west of England small producers are Bollhayes (Cullompton, Devon), Burrow Hill (Kingsbury Episcopi Martock, Somerset), Cornish Orchards (Liskeard), Countryman (Tavistock, Devon), Dunkerton's (Pembury, Hereford), Hayle's (Cheltenham, Gloucestershire), Orchard's (Gloucestershire), Perry's (Ilminster, Somerset), Minchew (Tewkesbury, Gloucestershire) and Westlake (Chilla, Devon). The Ross on Wye Cider and Perry Company produces both beverages matured in whisky or rum casks, as well as a standard range of traditional ciders and perrys. Burrow Hill is famous for the production of Royal Somerset Cider Brandy (Section 3.8.2) and various other beverages based on this, such as Pomona, a blend of apples and cider brandy, matured in oak casks for two years. Along with the Hereford Cider Museum's product, Royal Somerset is the only cider brandy produced in the UK at the time of writing (2009).

In Wales, there has been a recent revival of farm cider making, with present emphasis being on traditional methods (see www.welshcider.co.uk). Producers of Welsh cider (seidr) and perry (paeri) include Blaengawney Farm (Newport, Gwent), Ralph's (Radnor, Powys) and Tojola Orchards (Lampeter, Dyfed). Although cider and perry are made throughout Wales, there are concentrations of producers in Gwent and Powys, which are adjacent to Gloucestershire, and Hereford and Worcester, respectively. There is a lively interest in seeking out and maintaining local varieties of apples and pears and it is probable that some of these are unique to Welsh cider and perry. Apple varieties include Breakwell's Seedling, Broom Apple and Pen Caled; pears varieties include Gwenelog, Little Cross Huffcap and Welsh Gin.

There are two factory-scale manufacturers of cider and perry outside the western parts of the British Isles. These are Aston Manor Brewery (Birmingham) and Merrydown (Sussex). The former has a number of cider and perry brands on the market and sells much to supermarkets for selling as 'own' brands. This is one of just three breweries in the UK that brew cider and perry alongside beer on the same site (the others are Pitfield Brewery of Great Horkesley, Essex and Samuel Smith of Tadcaster), like some Scandinavian breweries. Merrydown, well known for its vintage cider (ex-vintage apple wine), is owned by the SHS group, and has recently switched its production site to Belgium.

Cider is made on the small and medium scale in most counties of England. Traditionally, the cider of East Anglia (mainly Essex, Norfolk and Suffolk) and those of the southeastern counties (especially Kent, East Sussex and West Sussex) were made from a blend of culinary and dessert apples and as such was lighter and more vinous than traditional West Country ciders. This is still much the case, but there are some companies using traditional cider apples and perry pears. Many of the ciders of the light, vinous type are produced by English vineyards, or by companies having an interest in English wine production. These include Biddenden (Kent), La Mare (Jersey), Rosemary (Ryde, Isle of Wight), Sedlescombe (Robertsbridge, East Sussex) and Shawsgate (Framlingham, Suffolk). In additional to these, Avalon Vineyard (Somerset) and Porthallow Vineyard (Cornwall) in the west of England also make cider using traditional cider apples; the former also produces apple wine from dessert apples.

East Anglia, like the Channel Islands, once had a strong cider tradition that waned considerably in the nineteenth and twentieth centuries to be revived toward the end of the latter century. In East Anglia, perhaps the best known cider makers are Aspall (Suffolk), Crone (Norfolk) and Whin Hill (Norfolk). The last named uses traditional cider apples and perry pears to produce a bottle-conditioned cider, as well as pasteurized, carbonated ciders (including single variety types) and a superlative perry.

Brittany and Normandy

Here too, the cider industry is undergoing a revival after an extended period of depression. Even so, the entire annual cider output of northwestern France is less than that of H.P. Bulmer alone. The largest companies are Loïc Raison (Brittany) and Volcler (Normandy), the former being part of the Pernod Ricard group. Annual production is around 30 million and 10 million liters, respectively. As in the western British Isles, these larger companies generally obtain their apples from both their own orchards and from local farmers, usually under contract. Only traditional cider apples are used, of which there are many ancient varieties, including Avrolles (sharp), Bedan (sweet), Binet Rouge (bittersweet), Douce Coetligne (sweet), Fréquin Rouge (bitter) and Kermerrien (bitter). To these can be added newer varieties that have been bred with in built disease resistance: Judeline, Judor, Juliane and others. There are around 800 cider apple varieties in the germplasm collection at INRA, Angers.

In France, unlike the UK, large and small cider makers generally use traditional methods in which the process of défécation (Sections 2.8.6 and 2.8.7) is important, although some companies, such as Volcler, use the flotation variant of this process (Section 2.8.7). The only additives allowed are sodium metabisulfite (with total SO_2 $<$200 ppm) and apple juice concentrate ($<$10%). Ciders from the larger (and many of the

smaller) companies are available in various bottled forms: cidre table (still), cidre bouché (bottle-conditioned or carbonated) and cidre fermier (unfiltered). With regard to sweetness, these can be brut (extra dry), sec (dry), demi-sec (semi-dry) and doux (sweet), residual sugar being (in % w/v) approximately 0.5 for brut, 1.5 for sec, 3.0 for demi-sec and 5–8 for doux.

Cidre fermier is made by numerous smaller producers, who use traditional methods with only relatively coarse filtration (or none at all), so that enough yeast is present for bottle fermentation; the favorite style of cidre fermier is bouché. Examples of cidre fermier producers include Bordelet (Charchigné, Normandy), Drouin (Pays d'Auge, Normandy), Dupont (Pays d'Auge, Normandy), Guillevic (Morbihan, Brittany), Kerisac (Guenruet, Brittany), Verger de Giverny (Giverny, Normandy) and Vergers du Val de Sée (Brécey, Normandy).

Unlike the British Isles, a considerable quantity of cider, especially in Normandy, is converted to apple brandy (Calvados) and pommeau, a drink made from apple juice and Calvados (Section 3.8.2). Calvados is matured in wooden casks for three, five and 10 years and pommeau for up to two years. Brittany has its own version of kir ('kir Breton'), made with cider (in place of white wine) and blackcurrant liqueur.

Perry is produced by a number of cider makers in Brittany and Normandy (although usually as a minor product) from the fruit of such varieties as Autricotin, Champagne, De Cloche, Plant du Blanc and others. Produced in a similar way to cidre fermier, French perry often has around 8% (w:v) of residual sugar, so falls into the doux category, even though the acid and tannins largely mask the sweetness. Elsewhere in France (e.g. Alsace), much perry or pear wine is converted to Poiré by distillation (Section 3.8.2).

Asturias and the Basque Provinces (Euzkadi)

Cider is the traditional drink of the provinces of northern Spain that border the Atlantic Ocean, principally Asturias and the Basque provinces of Vizcaya (Bizkaia) and Guipuzcoa (Gipuzkoa), but some cider is also made in Galicia, Cantabria and Navarre. Known as sidra in Asturias and sagardoa in the Basque country, it is made from the fruit of traditional cider apple varieties, nearly all of which are unique to northern Spain and many of which can be traced back through many centuries. The Centro de Experimentación Agraria at Villaviciosa (Asturias) houses a germoplasm collection of over 500 cider apple varieties. It is also a focus of research on all things relating to cider, although research of this type is also carried out at many of the local universities (e.g. Oviedo and Gijón).

The smaller producers of Asturias concentrate their efforts on making bottled cider in a traditional manner, often using chestnut vats or casks and always involving malolactic fermentation. Larger companies also make this type of cider, though not necessarily in a wholly traditional way, and some make Champagne style ciders in the French fashion, for export. In the Basque country, some cider is enjoyed on draught – it is served from jugs straight from the wooden maturation cask in the spring following the harvest.

Spanish cider is intermediate in style between the full bodied craft ciders of western England and the cidre de table of northwestern France; it is usually fruity, with a definite tang of acidity. It is very much an everyday social drink; most is consumed from unlabeled bottles (but with branded corks) by family and friends in local sidreries (Asturias) or sagardoategiak (Basque provinces), with an evening meal. Most of the cider makers use a high proportion (up to 40%) of sharp apples (Section 2.8.2) in their blends and single variety ciders are not generally known (compare with the UK and North America). English and French ciders generally possess greater proportions of bittersharp and bittersweet apples in their blends and sweet apples often form the greater part of North American ciders. Spanish cider apple varieties include Blanquina, Collaos, Coloradona, Durón Arroes, Limon Montes, Meana, Picona Rayada, Raxao and Xuarina.

In Asturias especially the traditional way of serving cider in a sidreries is the method of 'echar un culín.' The bar tender pours a small quantity (50–100 ml) into a wide glass by holding the bottle high with one hand

and the glass low with the other hand. The mechanical agitation not only puts air into the cider but also releases residual CO_2, thus giving the cider a short lived lightly sparkling head (mousse). It is then drunk immediately – before the head subsides. The textural characteristics of this mousse are important and traditional Spanish cider making practices produce cider with the balance of components that give the desired texture (Section 2.8.5). Notable producers of Asturian cider include Asturiana de Vinos (Xixón), Industrial Zarracina (Xixón), Llagar Castoñón (Villaviciosa), Llagar Herminio (Oviedo) and Sidra Acebal (Gijón). Basque cider producers include Petritegi, Sidreria Barkaiztegi, Zapiain (all Guipuzcoa) and Sidra Axpa, Sidra Edikoetxe (Vizcaya).

Europe

Some cider (and a little perry) is made in almost every country in Europe. In Germany and Luxemburg, cider is generally known as Apfelwein, Apfelmost or Viez (from the Latin vice, meaning second or substitute wine). German cider production is centered on Frankfurt (Hesse), Merzig (Saarland), Trier (Mosel) and Saarburg, near the Luxemburg border. German apple varieties are generally low to medium tannin, high acid (sharp) types and include Boskoop, Brettacher, Kaiser Friederich, Kaiser Wilmhelm and Winterambur. Consequently, most German ciders are very dry and racy, with 5–7% ABV. They are usually served still, from bottles. Some Luxemburg ciders, on the other hand, have rather more body and are reminiscent of English West Country scrumpy. Prominent German cider makers include Boller Fruchsäfte Stolz AG, Kelterei Hoppe GmbH, Kelterei Jörg Stier, Obsthof am Steinberg and Treuschs-Schwanen.

In Sweden and Finland, factory produced cider and perry have been popular since the late 1990s and some brands are exported to the UK and North America. Like Magners, they are seen as chic drinks for young people. The best known are probably Kopparberg, Herrljunga (both Sweden) and Upcider (Finland); they are produced by breweries and usually have 4.5–5.0% ABV. Some of these companies make cider flavored with fruit syrup or essence; cranberry, blueberry, and raspberry seem to be the most common. Elderflower is another flavor and both Kopparberg and Herrljunga make perry (called pear cider or pear flavor).

Unlike Finland and Sweden, Denmark makes only a little cider at the present time (2008), but production is growing, as is the import of cider. Fejø, Ørback Bryggeri and Pomona are the main producers. Scandinavian people like to make alcoholic beverages at home, including beer, cider, liqueurs, perry, sahti (Section 2.6.13) and schnapps (Section 3.4.3). Home brewed cider is made in southern Norway; there is an annual cider festival at Øystese in the Hardanger area, the country's main fruit growing region.

Central and South America

In most European countries, cider and perry are everyday social drinks, along with beer in the north and wine in the south. The two beverages hold a similar status in North America. In Central and South American countries, such as Mexico, Argentina and Chile, cider is usually of the filtered and carbonated type, often packaged in Champagne style bottles. It is often served on special occasions, taking the place of (more expensive) Champagne and other sparkling wines, rather like Babycham (a sparkling perry) did in the UK in the 1950s and 1960s.

Canada and USA

There are four main cider production areas of Canada: British Columbia, New Brunswick, Ontario and Québec. The ciders are mostly made from local indigenous apples, such as Delicious, MacIntosh, Northern Spy (sweet), Cortland, Golden Russet, Ida Red (bittersweet), and Paula Red and Sir Prize (sharp). Sometimes crab apples (e.g. Virginia Crab) are added to the blend for greater astringency, since none of the aforementioned apple varieties are really rich in polyphenols.

Until the last two decades, the cider industry in Canada was minor, although home brewed cider has been made and consumed in Ontario homes for many years. Furthermore, cider manufacture in Québec was suppressed in the early days of British rule in favor of beer production. Nowadays in Ontario, New Brunswick and British Columbia there are several companies making various styles of cider: still, carbonated and Champagne style bottle fermented. These include Applewood (Ontario), County Cider (Ontario), Gagetown (New Brunswick), Merridale (Ontario), Waupoos (Ontario) and Wyder's (British Columbia). Some perry (pear cider), fruit wines and pommeau (apple and apple brandy) are also made by some of these companies.

In Québec, cidre de table (still cider), cidre bouché (Champagne style bottle-fermented cider) and ice cider (pomme glace or cidre de glace du Québec) are made from indigenous apples by companies such as Domaine Pinnacle and Le Minot. The latter also makes a rosé sparkling cider from a red fleshed apple called Geneva.

Cider and beer were the most important alcoholic beverages of the early colonials of the USA, almost all farms making their own brews, including those of George Washington at Mount Vernon. As in many other countries, changing tastes and economic circumstances, coupled with two world wars, conspired against cider and perry production. Also, in the USA's case we can add the influence of temperance movements and the prohibition period of the 1920s. However, also like many other countries, there has been a revival in making and consumption of commercial cider and perry over the last two decades, although not on quite the same scale as the microbrewery revolution.

The main modern centers of cider and perry production are in the New England states of Massachusetts, New Hampshire and Vermont, but cider and perry are made in many states west of these, from New York to the Pacific states. The emphasis is on cider made from local apple varieties similar to those of Canada, with the addition of some others, such as Baldwin, Roxbury Russet and Red Field. The factory ciders are made from apple juice concentrate and sugar; other additives, such as apple essence or apple flavors may also be present. The best known brands are probably Cider Jack, Martinelli and Woodchuck, the latter coming from Vermont.

A considerable number of craft cider makers has come into being during the last two decades, some of them using classic European cider apple varieties, mostly from west of England, Norman or Breton stock that are becoming increasingly available at plant nurseries. Craft producers include Aeppel Treow (Wisconsin), Doc's (New York), Farnum Hill (New Hampshire), Oliver (Indiana), Original Sin (Vermont), Sow's Ear (Maine), West County (Massachusetts), Westcott Bay (Washington) and White Oak (Oregon). West County makes single varietal ciders from Baldwin and Red Field, a red fleshed variety, and many of these small companies make perry and flavored ciders. Although good ciders are already being made from local varieties, there are trials well underway to evaluate the potential of classic European cider apple varieties. Much of this work is centered on Cornell University and the USDA-ARS Plant Germoplasm Repository Unit at Geneva, New York state.

Asia, Australia and New Zealand

China grows more apples than any other country, though the emphasis is on a few varieties of dessert apples (e.g. Fuji, Delicious, Gala, Ralls, Red Star and Starking) and much of the produce, mostly from Shandong province, is converted to concentrate for export to many countries, including the UK and USA. Very little cider is actually made in China (e.g. Gansu Zhenghangde in Gansu province), although there have been some experiments and various foreign companies export cider or perry. Korea and Japan are also big apple producers, but cider in these two countries means a sparkling nonalcoholic drink, which may or may not be based upon apples. Some of the indigenous fruit liqueurs (called wines) (Section 3.9.2), as well as nonalcoholic juices, have apple juice as part of their constitution.

Much of the rest of southern Asia and much of Australia have unsuitable climates for the successful growing of apples, although cider is made from the apples of high altitude orchards in the northern Indian states of Himachal and Uttaranchal Pradesh. Probably the best known brand is Tempest, produced by Green Valley Cider of Himachal Pradesh. In Australia, cider making is limited to the cooler (or high altitude) regions of South Australia, Tasmania and Victoria. Probably the best known cider is the Mercury brand of the Cascade Brewery in Hobart, Tasmania, but Thorogoods and Henry make traditional ciders at Burra, South Australia and Harcourt, Victoria, respectively. The climate of New Zealand, especially the South Island, is more suitable for apple growing, although most effort goes into producing dessert apples such as Braeburn and Granny Smith. Nevertheless, scrumpy style (hazy, still) cider is popular (e.g. Ballydooly Cider, Hawkes Bay) and a number of wineries and country winemakers produce some cider, examples being Alpine Gold (Central Otago), Celtic Winery (Taranaki) and Cottage Wines (New Plymouth).

2.9

Wine

My glass of wine, dear Valentine,
With what can it compare?
When ruby, with your lovely lips,
When golden, with your hair,
The rosé with your damask cheek
On which long lashes lie,
And in my glass of fizz I see
The sparkle of your eye. . .
—Cyril Ray

Wine is one of the world's oldest and most popular beverages. Wine (according to one definition in the Oxford English Dictionary, 1995) is: '. . . fermented grape juice as an alcoholic drink.' Hence, by definition, the grape (*Vitis vinifera* in Europe, and including other *Vitis* species such as *V. labrusca* in North America, etc.) constitutes the raw material for producing wines. This definition does not, of course, include any reference to the quality of wine made from the grapes, as quality is dependent on a wide range of factors other than the grape species. However, the potential quality of the wine lies (for the most part) in the grape, so it is important that components within the grape chemistry that determine the quality of the wine are preserved during the winemaking process. The winemaker should have good knowledge of these components and the factors that enhance or detract from them.

This chapter begins by considering important factors in the production of white wines (Section 2.9.1), red and rosé wines (Section 2.9.2), and sparkling wines (Section 2.9.3). Next, winemaking aids, such as fining and filtration are discussed (Section 2.9.4), followed by an account of the important factors involved in and major consequences of maturation and ageing (Section 2.9.5). The chapter is concluded by a discussion of some modern techniques and recent innovations (Section 2.9.6).

Recent technical books on wine or that include chapters on wine, include Margalit (2004), Zoecklein *et al.* (1995), Boulton *et al.* (1996), Jackson (2000), Lea and Piggott (2003), Goode (2005) and Ribéreau-Gayon *et al.* (2000; 2006). A useful general book is that of Robinson (2006). Books with much information on grapevine varieties include Galet (1958; 1962), Jackson and Schuster (1981) and Robinson (1986). There are also many informative websites, including those of wineries (e.g. Dunkery Vineyard, UK; http://www.winegrowers.info/) and those of groups, societies and research institutions, such as Australian and New Zealand Winemakers,

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

Australian Wine research Institute (AWRI), California Wine Institute, English Wine Producers, Office Internationale de la Vigne et du Vin (OIV), Geisenheim Institute and The Wine Institute and Wines of South Africa (WOSA). Additionally, there are websites of the many universities that possess departments or institutes of enology, wine or related subjects, including (this list is not by any means exhaustive) Adelaide, Deakin, La Trobe (Australia), Brock, Niagara (Canada), Victor Segalen (Bordeaux), Dijon, Montpelier, Strasbourg (France), Auckland, Lincoln (New Zealand), Stellenbosch (South Africa), California (Davis), Cornell, California State (Fresno) (USA) and Plumpton College (UK).

2.9.1 White Winemaking

Ribereau-Gayon *et al*. (2006a) state that grape maturity level is the first factor, and certainly one of the most decisive ones, in determining wine quality. Grape maturity is intricately related to vine variety, growing conditions or *terroir* (which includes soils, aspect of vineyard and climate) and vintage. One vintage (year of production) will differ in subtle and sometimes significant ways from another due to variations in the principal factors affecting grape development that year: light, heat and water availability. The variation of these conditions during the grape ripening period greatly influences a given grape composition and quality at maturity, but viticultural practices such as trellising, leaf stripping and bunch thinning also have a profound effect. It is therefore perfectly acceptable to state that a ripe grape is the result of a great number of complex physiological and biochemical phenomena, and that perfect ripeness in any vineyard is neither an easy thing to predict nor to achieve.

It is certainly possible to turn good quality grapes into poor quality wine through bad winemaking practices. If a winemaker is lucky enough to have access to good fruit, the task is relatively easy: to prevent quality deterioration and enhance the quality potential of the fruit.

Jackson (2000a) states that the division of still table wines (the most common category) into red, white and rosé, is the oldest wine classification system and takes into account distinct differences in flavor, use and production methods. The style of wine is determined by the grape variety or cultivar, the growth conditions of the grapes and the winemaking techniques used. White wines were originally intended for consumption with meals and are therefore still produced with an acidic character to accentuate and harmonize with food proteins and flavors.

Grape Varieties for White Wine Production

The following are brief descriptions of some of the better known and more widely grown white *V. vinifera* varieties of the hundreds known, which includes non-*vinifera* varieties and hybrids (interspecific crosses). It should be noted that many cultivars have local pseudonyms, so there may be many names for essentially the same variety (see Robinson, 1986).

Chardonnay

This is a highly popular green grape variety used to make white wine. It was originally from Burgundy, but is now grown wherever wine is produced. Because it gained so much popularity in the 1980s (the 'Bridget Jones' phenomenon), a glut of the wine on the market in the 1990s led a number of wine drinkers see the cultivar in a negative light. Despite this, it is planted in more wine regions than any other variety – including Cabernet Sauvignon. One of the reasons Chardonnay remains so popular is because it is so versatile. It is relatively easy to grow, and can adapt to different conditions of soil type and climate. It is a highly vigorous vine, and vineyard managers counteract this with careful pruning and canopy management so that the fruit

is not adversely affected. The grape itself is thin skinned and 'neutral,' with many of the flavors commonly associated with the wine coming from the effects of *terroir*, vintage and winemaking practices. It is made in many different ways, from the elegant, dry wines of Chablis to full, rich Meursault wines and more modern New World styles that emphasize the tropical fruit aromas. The neutral character of chardonnay and its ability to age make it an important component of many sparkling wines around the world, including Champagne. The 'green-apple' acidity (a trademark of Chablis wines) helps make some of the best ageing examples of dry white wines in the world. French oak tends to be favored over American for Chardonnay fermentation and maturation, as American oak may impart a sweet vanilla aroma that can overpower the white wine bouquet. Barrels are usually of the 'lightly toasted' variety rather than heavily charred for the same reason. The wines also are able to undergo malolactic fermentation without detrimental effect to the style, and in fact the buttery, fatty flavor of the diacetyl produced during the process will enhance the fuller Chardonnay styles.

Sauvignon Blanc

Sauvignon Blanc is a green skinned grape variety from the Bordeaux region of France and is also used to make the famous sweet dessert wines from Sauternes and Barsac. The vine ripens early, which allows it to perform well in warmer climates if harvested at the right time, and the cultivar flourishes in cooler climate areas such as New Zealand, and the south and west coast of South Africa, where it gets cool onshore sea breezes (Figure 2.9.1). If subjected to high temperatures, the grapes over-ripen and produce wines with cooked vegetable aromas and little acidity. The variety is now planted all over the world, and is usually made as a crisp, dry, white wine that shows very distinctive cultivar characteristics due to the aroma compounds present in the grape, which include some of the mercaptans, as well as a number of methoxypyrazines. Depending on the climate or conditions under which it is grown, Sauvignon Blanc is recognized as having two 'styles': austere, grassy green from cooler areas (very easy to identify) and softer and more tropical from warmer areas. Fine examples of these wines in the 'cooler' style come from New Zealand's Marlborough region where sandy soils with good drainage and poor fertility lead to low yields, and concentrated flavor. A producer can tailor his style through changing vine canopy management, harvesting at different times, varying yeast strain

Figure 2.9.1 *Healthy Sauvignon Blanc grapes at KWV in Paarl, South Africa. Note ripeness, lack of damage, lack of mould and healthy bloom.* Photo courtesy of Paul Gerber

and manipulating oxygen levels and fermentation temperatures. Sauvignon Blanc was one of the first fine wines to be bottled with a screw cap in commercial quantities, especially by New Zealand producers, some of whom declare their wineries 'cork-free zones.' The green style of the wine is usually consumed young, as it does not particularly benefit from ageing. The more tropical wines can be fermented or matured in wood to produce the Pouilly (or *Blanc) fumé* style.

Chenin Blanc

This is a white wine grape from the Loire valley in France. It has a high natural acidity and is a neutral cultivar, so it is used to make everything from sparkling to dessert wines. It is the most widely planted variety in South Africa, where it is called 'Steen,' but a lot of the grape is being grubbed up to make way for other cultivars, as fashions in wine drinking swing away from the semi-sweet style that was popular there in the 1960s. Chenin Blanc is not fussy about soil type, and is fairly resistant to vine diseases, but the tight clusters are prone to rot in damp conditions, and the grapes are thin skinned and prone to sunburn. In cool wine growing regions, the juice is sweet, but high in acid with a full bodied palate. In warm climates, the main problem is controlling the natural vigor of the vine. If this is not carefully managed, the grapes produce bland wines of mediocre quality that are really only suitable for blending. Chenin, as a dry wine (Anjou style), has flavors of quince and apples. An off dry ('demi-sec') style (like some Anjou and Touraine wines) will emphasize honey and floral characteristics. If the conditions are right (cool, damp conditions followed by warm dry spells), the grapes will be left on the vines so that they become infected with *Botrytis cinerea*, which concentrates the juice and produces rich dessert (noble rot) wine, which can be aged for years.

Colombard

Colombard is an early ripening white variety traditionally grown for distilling into Cognac and Armagnac brandies. It has a neutral character, and is grown in Bordeaux to make fruity white wines (both dry and sweet). This grape has good natural acid and is used to provide 'backbone' and 'structure' for white blends. In South Africa, it is known as Colombar, is the most widely planted variety after Chenin Blanc, and is used in blends, to make varietal wine, and brandy base.

Gewürztraminer

Sometimes known simply as Traminer, this is an aromatic wine grape with a strongly terpenic aroma profile and pink or red skin. Gewürztraminer has particular requirements for soil and climate – it performs best in cooler climates, does not do well on chalky soils and is very susceptible to disease. The vine is vigorous when grown in the right conditions, so needs careful vineyard management. It buds early, and ripens erratically. In hot climates it produces large amounts of sugar and loses acidity, which means it can make an unbalanced wine if the winemaker is not attentive to his grape composition. If it is picked too early, varietal aromas, which are very important in the aromatic cultivars like this one, fail to develop. The variety is usually used to produce wines that are off dry, with a bouquet of lychees, roses, passion fruit and flowers. Its aromatic flavors and richness make Gewürztraminer one of the few white wines that are suitable for drinking with strongly flavored food like curries, game and smoked salmon. In South Africa, the Neethlingshof Estate makes a well known example.

Muscat

Strictly this name refers to a big and ancient family of white grape cultivars, with four principle (and many minor) varieties, which reputedly originated in North Africa, and have been grown for millennia around the Mediterranean. Muscat d'Hamburg and Muscat d'Alexandrie have been cultivated as table or raisin grapes as

well as for wine production, particularly in Australia and South Africa. In South Africa, Muscat d'Alexandrie is known as Hanepoot, and used for making sweet fortified wines of the same name. The vines thrive in a hot climate and are sensitive to cold during the flowering season. Like Gewürztraminer, Muscat wines have high concentrations of terpenes and are therefore floral in aroma, which tends to favor a sweet or semi-sweet style. In South Africa, Muscat Blanc à Petit Grains or Muskadel is the variety frequently used to make late harvest style wines and Jerepiko (fortified grape juice). In Italy it is used to make the famous Asti Spumante, a sweet, semi-sparkling wine, whereas in France, Muscat d'Alsace is dry (although nowadays Muscat Ottonel tends to be predominant).

Riesling

The true Riesling (Weisser, White or Rhine) originated in Germany, where it is a very important cultivar and generally produces the best wine; some of the best in the world. It is an aromatic grape variety, which can display flowery, perfumed aromas as well as high acidity. It is used to make a range of styles of wine from very dry, right through to very sweet, and even sparkling white wines. Riesling wines are usually made without blending with other varieties and are seldom wooded. It is considered to be one of the best white wine varieties for producing top quality wine, as it has great character, good acidity and is expressive of its *terroir*, (i.e. the character of wine as influenced by its origin). Other than Germany, Riesling is grown in the French region of Alsace, as well as in most wine producing regions. In warm climates, Riesling does best in cooler locations, and prefers a long, slow ripening and proper pruning to keep the yield low and the flavor concentrated. Riesling wines are crisp, fruity and aromatic, have relatively low alcohol concentrations and are often consumed when young. They may develop complex aromas of green apples, grapefruit, peach, honey, roses or cut grass, and can undergo extended ageing. The cultivar does not, however, lend itself to barrel treatments, as the typical floral, fruity aromas of Riesling are not complemented by wood. The famous German sweet wines like *Beerenauslese* and *Trockenbeerenauslese* are especially suited for long maturation since the very high sugar content helps to preserve them. However, sometimes Riesling wines tend to acquire a rubber or kerosene aroma with age ('*goût petrol*') as a result of the development of trimethyl dihydronaphthalene (TDN) and vitispirane. Experienced wine drinkers accept the rubberiness that comes with age as part of Riesling's character, but is off putting to most consumers. Most of the best ageing white wines in Germany including dessert wines, noble rot wines and Eiswein are made with Riesling. In South Africa and Australia, the French cultivar Crouchen Blanc (now almost extinct in France) is known as Cape (or Paarl) and Clare Riesling respectively. There are many other (lesser) cultivars that have acquired the prestigious Riesling tag on their names; Goldriesling, Welsch Riesling and others (see Robinson, 1986).

Viognier

This variety was once fairly common, but by 1965 the grape was almost extinct and there were only eight acres remaining in Northern Rhône. Recently, popularity and price of the wine have risen and thus the number of plantings has increased dramatically. Viognier is difficult grape to grow because it has low and unpredictable yields and is prone to powdery mildew. Vines produce better wines when they are older (15–20 years), and prefer warmer slopes and a long growing season. Grapes need to be picked when fully ripe, or they fail to develop aroma and taste. When picked too late, (and some Californian and South African Viognier can be) the wine is flat, alcoholic and unbalanced. Winemakers may choose to carry out skin contact to enhance color and perfume, but this has to be managed carefully due to the high pectin and phenol content of the grapes. When optimally ripe the grapes have a deep yellow color and produce wine with a strong aroma (apricots, orange blossom, honey) and good levels of sugar. The color and floral aromas of the wine suggest that they should contain sugar, but most Viognier is dry. Although it is suitable for ageing if the acidity and alcohol

is appropriate, the wine is usually consumed young. It is sometimes blended with Shiraz in cofermentations to soften the tannins, stabilise the color and enhance the nose of the red wine. Surprisingly, for a floral, fruity variety, Viognier often benefits from malolactic fermentation, wood ageing (in oak and acacia) and *batonnage*.

For an account of many other widely grown white wine vine varieties, as well as many others that are rather obscure or their cultivation is perhaps limited to one or two small regions, the reader is directed to Robinson (1986) and Galet (1956; 1962).

Physical Composition of Wine Grapes

Wine grapes are smaller in size, have thicker skins and a more intense flavor than table grapes. Wine grapes are not particularly pleasant to eat as they have far higher acidity as well as a high concentration of tannins if they are red/black, but these physical and flavor differences determine the characteristics of the wine.

For winemaking purposes, the grapes are divided into stems, skins, pulp ('juice cells') and seeds. The juice, which contains most of the sugar and acid from the grape, is mainly contained in the flesh (pulp) in large, fragile cells within the grape interior. The major volume of a pulp cell is taken up by an oversized vacuole in which juice is stored, surrounded by a membrane, which is easily broken by pressure.

The main function of crushing the grapes is to break the berry so that the juice can drain from the pulp cells. Grape juice in most cases is pale in color (except in Tenturier varieties) and is extracted from the berries before fermentation in white wine production. In red wine production the skins, pulp and juice are fermented together. The size of the berry has an influence on the percentage of juice, e.g. Palomino has large berries with a relatively large amount of juice in comparison with a small berry such as Chenin Blanc. During fermentation on the skins in red winemaking, the cell walls become more porous and release juice more easily, so skin fermentation produces a higher yield of wine once the skins, or *marc* (fermentation cap), is pressed. If grapes are over-ripe or botrytized, grapes become very hard to press due to raisining and dehydration effects, and juice yield will be far lower.

The stems or stalks make up between 3 and 7% of the bunch depending on the variety and fruit set, with some cultivars, (e.g. Cinsaut) having a low percentage of stems, while others (like Cabernet Sauvignon and Muscat d'Alexandrie) have a high percentage. In the preparation of red and white wines in New World winegrowing areas, destemming is frequently carried out at the same time as crushing. In the case of mechanically harvested grapes the stems are not brought to the cellar, but left behind on the vine, and this leads to a difference in the tonnage delivered. The equipment used to crush the grapes should not damage the stems as this can release unpleasant, astringent substances into the juice, as the stems are rich in tannins and other phenolic compounds – around 20% of the phenolic composition of the grapes, according to Ribereau-Gayon *et al.* (2006a). The inclusion of stems in a red wine fermentation can lead to higher levels of tannin and potassium, and the winemaker will need to adjust the style of wine to take the higher concentration of phenolics into account.

The grape skin consists of the cuticle, epidermis and hypodermis, and is around 1.5 to 4 microns thick, depending on cultivar. It is covered by a layer of interlocking waxy plates called the 'bloom' which provides a waterproof coating and protection against injury, and contains fatty acids and sterols which stimulate yeast growth. Most winemaking varieties have small berries, which give a high skin to pulp ratio (for example, Cabernet Sauvignon). The thickness of the skin influences the resistance to diseases and damage, and consequently the health of the grape. The skin contains most of the polyphenols found in grapes, including the anthocyanins and tannins, so fermentation must take place on the skins in the preparation of red wines in order to extract these substances. However, as the tannins are astringent, a long fermentation on the skin can make the wine very harsh, and it will need a long maturation period before it will be pleasant to drink. The aromatic substances are also found in the skin, so white wines (particularly those that are dependent on varietal aroma for typicity like Sauvignon Blanc and Riesling) can benefit from cold skin contact prior to

fermentation. Winemakers may choose to ferment white wines on the skins to maximize aroma extraction, but as other substances can also be extracted which may be detrimental to wine quality, this process has to be carried out with care.

Seeds (pips) are rich in tannins, phenolic compounds and oils (mainly oleic and linoleic acid). If the seeds are damaged by the presses or the crusher rollers, tannins will be released, which will make the wine more astringent. Apparatus is usually adapted so that it does not have detrimental effects, and these days a lot of crusher rollers are inert rubber or pliable plastic and therefore less likely to cause damage to the seeds. Seeds contain between 20 and 55% of the polyphenols in the berry, depending on cultivar. During the fermentation of red wine the seeds are usually present, and these polyphenols are extracted by the increasing concentrations of alcohol, but seeds and skins are generally removed prior to fermentation in white winemaking so will make less of a contribution. Seed tannins can bind with anthocyanins after extraction, and help to stabilize color. As the wine matures, the seed tannins will also polymerize with other compounds and become less astringent.

Sugars

The sugars are important because they are fermented and converted to alcohol and carbon dioxide by yeast cells. Sugars also give the sweet taste to wines that contain residual or added sugar. The sugar level of the grapes determines the amount of alcohol present in the wine after fermentation, and therefore affects the style to be made. The most important two sugars are glucose and fructose, which occur in approximately equal quantities in ripe grapes. Fructose is twice as sweet as glucose. Sugar concentrations are measured as must density, and expressed as different units in different wine producing regions. In Europe, sugar concentrations are often measured in °Oeschle (related to the specific gravity of must; actually °Oe = [specific gravity – 1.00] × 1000), and in the New World, in °Brix or °Balling (both a measure of % w:v sugar). In physiologically ripe grapes, sugar content can vary from 18 to 26 °B (g/100 g), but in over-ripe and botrytized grapes the sugar quality may be well over 30 °B. See Table 2.9.1 for typical sugar content of ripe grapes, according to desired wine type.

Table 2.9.1 *Approximate grape ripeness criteria for different wine types. Given for major categories only. Typical values fall within regulation requirements, which can differ not only from between countries, but between regions within a country*

Wine Type	Criterion	Unit	Typical values
White wine	Sugar	°Brix	19–22
	Titratable acidity*	g/l	7.5–9.0
	pH	–	3.0–3.3
Red wine	Sugar	°Brix	22–24
	Titratable acidity	g/l	7.5–9.0
	pH	–	3.3–3.6
Fortified wine	Sugar	°Brix	24
	Titratable acidity	g/l	6.0
	pH	pH	< 3.8
Special late harvest	Sugar	°Brix	22 and higher
Noble late harvest	Sugar	°Brix	28 and higher

*Expressed as tartaric acid

Winemakers can use a rough conversion factor of 0.55 times the °Brix or °Balling measurement to predict the alcohol yield from fermentation, but this will depend on factors like yeast strain and fermentation temperature.

In most grape producing regions with warm climates, the juice for wines may not be sweetened (chaptalized) and sweetening wine for stylistic purposes may only be done with grape sugar or concentrated grape must. In cooler climates, where chaptalization is allowed, sucrose may be added before fermentation, but may not be used for sweetening. In grapes, some hexose and pentose sugars cannot be fermented by yeast, and may remain in the wine as residual sugar, which should be taken into consideration if wines are sweetened, in order to comply with legislation for the style. Usually a dry wine will contain less than 5 g/l of sugar. However, a wine containing less than 10 g/l of sugar (glucose + fructose) may be classed as dry, as long as the acidity is high enough. Legislation regarding sugar levels differs considerably between winemaking regions.

Other carbohydrates

Pectin is made up of polygalactoronic acid molecules, which are responsible for the 'sliminess' of the skins and the opacity of the must. Pectins are present in grapes in small quantities, especially around the vascular bundles and the seeds. High concentrations of pectins make it difficult to extract and/or clarify grape juice and filter wine. These substances are modified by heat and alcohol, so that during a red fermentation the skins become less gelatinous and easier to press, and the must becomes clearer. Pectins can be broken down by pectolytic enzymes, added during processing (see below).

Acids

The most important acids in grapes are (+)-tartaric acid and (–)-malic acid, which constitute more than 90% of the total acids present at harvest, and at maturity they are usually in a 1:1 ratio. These acids are responsible for the relatively high acidity and low pH of grapes compared to other fruit, and the crisp taste of wine. The increase in sugar concentration which occurs during maturation of the grape is accompanied by a decline in acidity. The total amount of titratable acidity (TA) in the juice of grapes varies between 3.0 and 12 g/l calculated as tartaric acid (in the New World), depending on ripeness level and cultivar, with the pH of the must usually between 2.8 and 4.3. In France, TA is calculated as sulfuric acid, which can be obtained from total acidity expressed as tartaric acid by use of a conversion factor of 0.6535. In other words, 5.0 g of TA expressed as tartaric acid is the equivalent of 3.3 g expressed as sulfuric acid. When Australian or South African winemakers discuss acidity with French winemakers, they may be surprized at the seemingly low levels of TA in the French wines, not realizing they need to multiply the French TAs by a factor of 1.530 to achieve equivalence. See Table 2.9.1 for typical total acidities of ripe grapes.

The sugar:acid ratio is used as an important measure of the maturity of grapes, with values from 2.5–3.0 regarded as desirable, but this differs from region to region, from cultivar to cultivar and even within vineyard blocks in a region. The buffer capacity of must is high due to the presence of large quantities of tartrate, malate, potassium and other ions, which has implications for sulfur dioxide use and even oxidation potential. Lactic, succinic and acetic acids may be present in very low quantities, but are usually an indication of microbial spoilage. The tartaric acid concentration decreases during fermentation due to the precipitation of potassium bitartrate which is less soluble in alcohol than in water. Malic acid can be reduced by some strains of yeast or malolactic fermentation.

Phenolics

Phenolics are a group of chemical compounds that affect the wine color, texture, astringency and bitterness. They are important in the style and quality of wine, even though they are present in relatively small quantities.

Anthocyanins and colored tannins are responsible for red wine color and are found in the skins of red grapes (Section 2.9.2). Tannins in the skins, stalks and seeds can all contribute positively to the structure of wine, if not present at excessive levels. Phenolic extraction is very important in red winemaking and will be discussed in detail in Section 2.9.2. Phenols that are present in the skins of white grapes are colorless, but may have implications for the oxidation potential (redox status) of the wine. These are usually nonflavonoids and include benzoic and cinnamic acids, but flavonols and smaller tannins may also be present. At high enough concentrations the latter compounds can be astringent and bitter, and lead to browning during maturation. See Section 5.4.3 for nutritional aspects of the phenolic content of grape juice and wine. Also, see Chapter 5.8 for a discussion of phenolic substances with regard to their general chemical characteristics, including their *in vitro* antioxidant properties, and possible health benefits.

Inorganic ions

These are not important in juice and wine, unless they are present in relatively high concentrations. If grapes are incinerated, the ash quality is from 0.2 to 0.6% of the fresh weight. The most important components in the ash are K^+, Mg^{2+}, Ca^{2+} and Fe^{3+}cations, as well as certain carbonates, oxides, phosphates and sulfates. Copper and iron are important oxidation catalysts (Danilewicz, 2003). At certain levels, metal cations give rise to complex hazes in the wine called iron, copper or aluminium 'casse.' Haze formation may occur with only a few mg/l of dissolved metals in total, but is far less common than it was previously when metal levels were not as carefully controlled. Iron, copper and aluminium may be leached into juice and wine from brass, copper and steel surfaces containing these metals, which is one of the reasons why stainless steel has become ubiquitous in wineries. Even stainless steel can contain welding sites that leach metal ions into solution, or act as 'electron guns' and promote oxidation reactions. Copper has also been implicated in the formation of protein hazes. The potassium content is important as the potassium salts of the organic acids may precipitate as potassium bitartrate, potassium tartrate or potassium tartromalate in the bottle if the wine is not properly stabilized. See Sections 4.3.3, 4.4.3 and 4.4.4 and Chapter 4.5 for chromatographic, colorimetric, atomic spectroscopic and electrochemical methods (respectively) for the determination of inorganic ions in beverages, including wine. Also, see Section 5.4.2 for nutritional aspects of minerals in wine and Section 5.10.3 for health aspects regarding inorganic residues, including pollutants.

Nitrogen containing compounds

Proteins, amino acids and ammonium salts all contain nitrogen. Yeast and bacteria need nitrogen sources to build the polypeptides and proteins in cell structures. The total organic nitrogen quality of must varies from as low as 60 mg/l to around 2400 mg/l, depending on cultivar, ripeness level and climatic conditions during growth (Ribéreau-Gayon *et al.*, 2006a). In cooler regions and vintages, concentrations of amino acids within the berry will be higher due to limited synthesis of proteins. The nitrogen compounds are present mainly as amino acid and proteins as well as ammonium compounds, which are the most easily assimilable by yeast. It is generally recognized that yeast prefer free amino nitrogen (FAN) concentrations of between 200 and 350 mg/l, but this will depend on the sugar concentration of the must. A higher sugar concentration will require larger concentrations of FAN (as high as 900 mg/l in the case of very sweet musts) in order that the yeast may complete fermentation. Nitrogen is also involved in the formation of higher alcohols during the synthesis of amino acids by the yeast cell, and it is recognized that nitrogenous compounds will affect the development of aroma, bouquet and foaming characteristics in sparkling wines (Section 2.9.3).

Proteins (which contain a significant proportion of nitrogen) denature and flocculate, and may give rise to hazes if they are present in wine at high concentrations (Section 2.9.4). These proteins can be removed by addition of bentonite or other fining agents before, during or after fermentation (Section 2.9.4). The

assimilable nitrogen concentration of the juice is often supplemented (not always necessarily) using diammonium phosphate (DAP) before fermentation by the winemaker in order to ensure a complete fermentation. See Sections 4.6.3 and 4.4.2 for digestion (or combustion) and infrared spectroscopic methods of assessing total nitrogen or total protein content (respectively) of raw materials and drinks. See also Sections 4.3.3, 4.4.5 and 4.6.1 for chromatographic, mass spectrometric and electrophoretic methods (respectively) of characterizing proteins, including their molecular weights.

A large variety of enzymes, extracted from the grape skins during pressing, occur in the juice or must. The concentrations of oxidative enzymes, including the polyphenoloxidases that cause browning of white must, vary between grape varieties. For example, the polyphenoloxidase content of the Cape Riesling (actually Cruchen Blanc) is relatively high, so its juice oxidizes very easily. Also, *Botrytis* contaminated grapes contain high concentrations of the fungal polyphenoloxidases laccase and tyrosinase, so botrytized juice tends to brown (oxidation) easily as a result. Although most enzymes will be inactivated by alcohol, some of the enzyme can remain in young wine and catalyze the more detrimental wine oxidation.

The most general method of deactivating undesirable oxidative enzymes is by moderate applications of SO_2, or through bentonite additions, which entrain and help precipitate proteins (and therefore enzymes) from juice or wine. Pasteurization by heating the crushed grapes for three minutes at 70 °C is also effective as it denatures the proteins within the enzymes and renders them inactive, but may have consequences for wine flavor. The use of winemaking enzymes is discussed in more detail later this section.

Pectic (or pectolytic) enzymes hydrolyze the pectins (water soluble colloidal carbohydrates) by breaking up the chains of polygalactoronic acid molecules, producing clearer juice and aiding filtration. The enzymes also help to effect an increase in free run juice (and therefore yield) from crushed grapes, especially the fleshier varieties. Commercial preparations of pectic enzymes are available to boost natural levels.

Aroma compounds

There are many aromatic compounds and precursors to wine aroma present in grape juice in trace amounts. The situation in wine is very complex, with synergy between groups of compounds as important as, if not more than, the individual compounds present. A distinction is made in wines between primary grape flavors, (e.g. terpenes in the aroma of Muscats), secondary fermentation flavors, (e.g. higher alcohols and esters) and tertiary flavors, (e.g. wood aroma compounds, bottle bouquet).

Ferreira *et al.* (2008) identified three 'odor patterns' in wine. Firstly, wines with a large quantity of distinct volatiles, deriving from grape types, which may be classified as 'aroma rich' – cultivars with clearly recognizable aromas in the grape that pass unchanged to the wine. Examples include Muscat varieties (various terpenoid components) and *Vitis labrusca* (methyl anthranilate). The author's second grouping are wines derived from grapes containing a large number of nonodorous precursors (glycoside or cysteine conjugates) specific to varietal flavor and released by microorganisms during winemaking. Cultivars with plenty of flavor in the grape, which produce characterful wines are 'aromatic' and include Sauvignon Blanc (grassy/tropical), Weisser Riesling and Gewürztraminer (floral and spicy), Cabernet Sauvignon (grassy and/or berry-like), Merlot and Shiraz (berry-like). 'Neutral' cultivars do not contain a specifically recognizable flavor and the fermentation bouquet and the flavors due to ageing and other processes are of more importance. These include Chardonnay, Chenin Blanc and Colombard. Chardonnay often produces a wine that has a fuller character. Ferreira's third aromatic division of wines rely on acid catalyzed hydrolysis and rearrangements during maturation and ageing, which yield highly odor active compounds eg: *cis*- and *trans*-rose oxide in Gewürztraminer or trimethyl dihydronaphthalene (TDN) in Riesling.

Despite the number and complexity of volatile compounds and their low concentrations, winemakers consider these components as crucial to wine quality, and try to optimize their extraction, and conservation during processing. The aroma and flavor characteristics of the grapes (the primary aroma compounds) are

paramount for a fruit driven wine style, but other contributors like esters from fermentation or certain volatile phenols from oak are very important in styles that are less dependent on primary aroma.

Alcohols

Alcohols should not be present in grapes unless there is rot, or wild yeast has fermented a small portion of the juice from broken grapes in holding tanks. The ethanol (a two carbon alcohol) that is present in wine is produced during fermentation by yeast from grape sugar. Trace amounts of other alcohols with three or more carbons (higher alcohols, fuselols or fusel oils) are also produced by rot, and during fermentation, and these contribute to the flavor of the wine and the complexity of the aroma. At higher concentrations, fuselols have unpleasant cloying aromas, and give a burning sensation on the palate. Glycerol, which can be produced in significant amounts when grapes are over-ripe or infected with *Botrytis cinerea* (noble rot), has a beneficial effect on the viscosity and sweetness of wine.

Berry Ripening

There are four stages in the development of grape berries. The first is the vegetative period (Figure 2.9.2), which extends from the formation of the berry (after fertilization of the vine flowers) until ripening starts. The berries are small, hard and green, and photosynthesize like the other green parts of the plant. Acid levels are high, and berries are bitter and unpleasant to eat due to the presence of tannins and stilbene phytoalexins, which help in the defence of the immature seeds. The second stage is veraison, which marks the beginning of the ripening period (see Figure 2.9.3). The berries change color from green to yellow (for white varieties) and to light then dark red (for red varieties). The color change is abrupt, and is accompanied by the grape becoming more translucent and less opaque. The sugar content of the berry increases. The berry ceases to photosynthesize, and becomes a storage organ. The third stage of development is the maturation of the berry, or accumulation stage. This stage lasts for 40–60 days. The grapes swell, the concentration of sugar increases and the acid concentration decreases. At physiological maturity the berries have attained their maximum diameter and sugar concentration. The accumulation stage is characterized by a steady increase in glucose and fructose. The vacuoles in the pulp cells become filled with water (juice), and this uptake is reflected in

Figure 2.9.2 *Early vegetative stage in Chardonnay berry development showing young inflorescence and growth points.* Photograph courtesy of Professor Piet Goussard

increases in berry weight, volume and diameter. During this stage the concentration of acids decreases. Malic acid is respired, as is tartaric acid if ambient temperatures are high during the ripening period. Anthocyanins and tannins accumulate in the skins of red grapes giving them their characteristic color, and this accumulation is influenced by the grapes exposure to light. The proportion of soluble polyphenols rises during ripening to a maximum then decreases. The flavor of the grapes increases with ripening, with the majority of the flavor volatiles accumulating later when the sugar increase slows down. For any one vineyard there is a general association between the progression of aroma and flavor development in the berry and sugar accumulation. Descriptive characters at the early ripening stage are usually associated with lower sugar levels (for example, acidic, tart, green, citrus). At maturity, descriptors for the fruit will usually be associated with the typical characters present in the wine (for example, peach-like, tropical, full, floral).

The last stage is when the berries are left on the vine and they become overripe (Figure 2.9.4). The fruit becomes shrivelled as it dehydrates and the sugar and acid in the juice becomes more concentrated. Flavor changes also take place, and the juice will take on raisin or madeirized characters.

Figure 2.9.4 *Over-ripe white Muscadel grapes, shrivelled, but with no 'noble rot.'* Photo courtesy of Professor Piet Goussard

In winemaking the ripeness criteria are different for different wine styles, and the decision to pick the grapes will be based on the sugar, flavor and acid levels required, and the personal experience of the winemaker. In some cases, grapes are picked a long time after physiological maturity has been reached, for example, red grapes are frequently picked over-ripe in order to achieve maximum color and tannins, when the stems are shrivelled and woody, and the skins are puckered. Chardonnay grapes destined for sparkling wine base, on the other hand, are picked before physiological ripeness when sugar is lower and acid higher than for a full bodied white wine. For aromatic and terpene rich wines the main criteria are the flavor and aroma of the grapes.

It is especially important to follow the flavor development of grapes for fruit driven white wine styles. Flavors are monitored by tasting the grapes as samples are taken for ripeness assays.

Berry Sampling During Harvest

Berry monitoring is a crucial part of the process of winemaking, and samples are usually taken from soon after veraison, throughout the maturation period. Taking a representative sample of berries from the vineyard is essential if the real state of maturity of the vintage is to be assessed. It is generally recognized that a minimum sample size of 200 berries per hectare of vines, taken randomly from vines, and ensuring that not only ripe bunches are sampled. Back at the laboratory, the berries are crushed, the juice strained, and the must is then tested for indicators of ripeness, such as total soluble solids, titratable acidity and pH. Lastly there is one ripeness indicator that is too often overlooked: the taste of the berry. Other sensory assessments of the berry might include firmness, elasticity, appearance of the seeds and greenness or woodiness of the stems. The juice should always be assessed for sweetness, acidity, fruit flavor and aroma.

Winemaking Principles

Winemaking is the process of turning grapes into wine, and it starts as soon as the grapes are picked. At a very minimum, winemaking techniques should include procedures to prevent or minimize three problems:

- microbiological spoilage
- problems related to too much or too little oxygen during winemaking and after bottling
- formation of other off odors and taints.

At the 2006 International Wine Challenge in London, where approximately 13 000 wines from all over the world were assessed, it was found that around 7% of wines were faulty, and of these wines, around 2% were found to have oxidative or reductive issues that were bad enough to disqualify them from competition (Thomson, 2007). Other problems included volatile phenols (usually associated with *Brettanomyces* infection), and cork taint. Although the author acknowledges that around half the problems are due to closures, it was also stated that winemakers needed to be aware of problems so as to deliver quality and consistency in their products.

The most important characteristics of fruit destined for the production of premium quality table wines are lack of rot or premature fermentation, and the correct degree of ripeness for optimum fruit aroma and flavor. Intact grape skins act as a barrier, which protects juice from the effects of oxygen, microbial spoilage and metal contamination, therefore it is beneficial to minimize damage to berries during picking and transport to the winery. Once the skin is broken the juice requires protection, and the extent of the use of antioxidants such as SO_2 and ascorbic acid should be proportional to the risk of spoilage. Good quality (rot free, ripe) fruit makes the task of the winemaker less arduous, but it is certainly possible to turn good quality fruit into poor quality wine through negligence. With good winemaking it is possible to make sound, ordinary wines

from mediocre fruit, and large volumes of such wines are made and sold at the entry level of the market. A winemaker will try to incorporate the following winemaking objectives into the production of quality white wines during the various stages of the process:

During harvesting of grapes, there will be selection of juice or wine fractions with best possible composition most appropriate to the style required and preservation of flavor.

During crushing and destemming, there will be avoidance of unnecessary damage to berries, seeds and stems, use of additional techniques such as skin contact and enzymes to increase fruit flavor extraction.

During juice collection, the winemaker will undertake correction of composition if necessary, e.g. by acidification or chaptalization. There will also be additions made to prevent major microbiological spoilage and oxidation.

During alcoholic fermentation (and malolactic fermentation, if appropriate), the most appropriate yeast (and bacterial strain) will be used and optimum fermentation conditions employed. The winemaker will also try to prevent or remove off flavors (e.g. undesirable fermentation characters).

The winemaker will employ appropriate clarification techniques for the style and correct potential instabilities which may reduce market acceptability (e.g. protein and bitartrate instabilities).

The winemaker will 'fine tune' the wine during stabilization and ageing to add complexity/balance/finesse (e.g. wood maturation, specific fermentation characteristics, blending).

Bottling the wine should be of sufficient quality to ensure protection from oxidative and microbial spoilage – so as not to undo all the good work carried out during the previous operations.

Naturally each wine style will have a slightly different phases and treatments. *Blanc de noir* and rosé table wines from red grapes are made in a similiar way to white table wines and may be prepared as dry, sweet, still or perlé wines. Red wines are fermented on the skins, and pressed after different periods of skin maceration, depending on the style. Considerations for red winemaking will be addressed in Section 2.9.2.

Wine Analysis and Monitoring the Ripening Process

Wine analyses provide the winemaker with essential facts concerning the quality and composition of the juice. This information may be used to modify the natural winemaking process, if necessary. Essential information is usually obtained by conducting the necessary analyses and includes the microbiological status, the chemical composition of grapes and wine, and the sensorial quality of the wine.

Sugar

The sugar content of grapes is one of the most important ripeness indicators, and is determined approximately by measuring the density of solution (total soluble solids) using calibrated hydrometers (in °Balling, °Brix or °Oeschle, depending on the country where the wine is being made). At 20 °C, pure water will have a Brix reading of 0 °B, 18% sucrose will read 18 °B, and 95% alcohol will read –7 °B (Morgan *et al.,* 2006).

Other than determining how ripe the grapes are, sugar concentration is also used for remuneration of growers, certification and monitoring of fermentation. The sugar concentration can also be used to determine the potential volume percentage alcohol (as previously described, °Balling × 0.55), but this is an approximation as the efficiency of conversion into alcohol is difficult to predict.

Refractometry (Section 4.6.3) also measures the density of juice, but through the refractive index of the liquid. Hand held refractometers are used in the vineyard to give a rapid indication of berry ripeness but as the °Brix level varies within the bunch and from vine to vine, it is not an accurate assessment of the ripeness of the whole vineyard. Laboratory refractometers are used for a more accurate assessment of sugar in juice expressed from larger, more representative sample of grapes. The measurement is very temperature dependant, the temperature of the refractometer being more important than the temperature of the sample.

Titratable acidity

Determining titratable acidity by titrating (Section 4.6.3) with an alkali such as NaOH, provides information on the ripeness of the grapes, the 'sourness' of the wine and also of wine stability. Generally speaking, riper grapes have lower acidity and unripe grapes are very acidic, with high levels of malic acid. This acid can be determined by enzymatic/colorimetric methods (Section 4.4.3), chromatography (see Chapter 4.3; especially Section 4.3.3), or (if the vineyard has access to technology) through the use of an infrared spectrometer (Section 4.4.2) like a Foss scanner. Malic acid levels will give an indication of whether malolactic fermentation needs to occur, and if decreases in this acid are accompanied by increases in lactic acid, the fermentation will be underway or may have completed.

pH

Measurement of pH (defined as $-\log [H^+]$) is determined by means of a pH meter (Section 4.5.1), and is important for microbiological and oxidative stability. Sulfur dioxide is far more effective at lower pH levels and oxidation reputedly happens faster at higher pH.

Volatile acidity

Volatile acidity (mainly acetic acid and ethyl acetate) can be determined by distillation (Section 4.6.3) or by titration and gives some indication of the microbiological health of the wine. If the technology or means of analysis are available, it is useful to determine tannin and color levels, esters and aldehydes, and to know whether metals (particularly Cu and Fe) fall within an acceptable range. Sensory evaluation of the grapes and juice are also essential, and inspection of the grapes should be carried out visually to determine the health of the harvest and seed and stem ripeness.

Sulfur dioxide

Knowing concentrations of sulfur dioxide throughout the winemaking process is important for the health and longevity of the wine, as it is crucial to microbiological stability and reducing capacity (oxidation condition) of the wine. As a generalization, half the added SO_2 will be bound to other components in solution (such as acetaldehyde) almost immediately on addition, and half will be available as free bisulfite to carry out the antioxidasic and antiseptic functions. The addition should be checked after a few hours when the equilibrium between free and bound will be reached. The ratio of free to bound SO_2 is affected by the amount of the addition (lower with smaller additions) and the temperature (lower with lower temperature). More detail on the activity of sulfur dioxide can be found in Sections 2.5.2 and 2.5.3, and health aspects relating to SO_2 content of wine and other drinks are discussed in Section 5.9.2.

SO_2 is determined by titration with iodine (the so called Ripper method; see Section 4.6.3), or by aspiration (Section 4.6.3) and titration with sodium hydroxide.

Alcohol

Alcohol, or more strictly ethanol, is determined most accurately by distillation, measuring the density of the distillate with a calibrated hydrometer, and then reading off the actual alcohol value corresponding to the density from a set of tables (Section 4.6.3). It is also possible to use an ebulliometer which operates on the difference between the boiling temperature of pure water and the boiling temperature of the alcohol mixture (wine) (Section 4.6.3). As the boiling temperature of water differs according to the barometric

pressure of the atmosphere, both boiling temperatures must be read each time the alcohol concentration is needed, and a boiling point of 100 °C cannot be assumed for water.

The alcohol level provides more information on the microbiological condition of the wine, but it is also very important in determining remuneration and the amount of excise duty to be paid.

Harvesting Procedures

During harvesting the grapes are physically removed from the vines and transported to the winery. The aim of this operation is to pick the grapes and transport them to the winery in the best possible condition, with the minimum delay. In so far as possible, the grape crop should also be harvested under favorable climatic conditions as rain dew, fog and mist may dilute must. Ideally, harvest should begin once the sun has dried the vines, but not so late in the day that the grapes are warm. There are two main options available for the actual picking operation: hand or machine harvesting. Hand harvesting is used when the grape quality is of prime importance, in small vineyards that cannot justify the cost of a harvester and in older vineyards, which were not been set up for a harvesting machine. Hand harvested grapes arrive at the winery in whole bunches. Whole bunch pressing is often used in premium sparkling wine production and always when grapes are to be used for carbonic maceration. Hand picking is also used when it is necessary to select bunches or parts of the bunch, as in the preparation of noble late harvest wines. Pickers can also be instructed to avoid unripe second crop bunches, or grey rot, and to avoid including leaves in the harvest. Machine harvesting has become very widely used since its introduction in the early 1970s (see Figure 2.9.5). It is fast, efficient and much cheaper than hand picking, particularly in areas where there is a lack of local labor. Large quantities of grapes can be picked quickly at the optimum ripeness, and it is possible to harvest at night when the temperature is lower. The drawbacks of machine harvesting include the high capital cost of harvesters, damage to sensitive fruit, and the requirement for suitable vineyard layout and vine trellising to accommodate the harvesting machines.

Figure 2.9.5 *Machine harvesting, Paarl, South Africa.* Photograph courtesy of Paul Gerber

Figure 2.9.6 *Spraying dry ice on grapes awaiting processing at KWV, Paarl, South Africa.* Photograph courtesy of Paul Gerber

Prolonged maceration of warm, harvested grapes in their juice should be avoided, as microbial spoilage and oxidation will result. Enzymes come into direct contact with substrates resulting in what Ribereau-Gayon *et al.* (2006a) describe as 'explosive' enzymatic reactions. For example, the laccase secreted by *Botrytis cinerea* will, in the presence of air (oxygen) cause oxidation of phenols, turning juice brown. Certain grape varieties (for example, Semillon) are more prone to damage than others and machine harvesting is a less desirable option then hand picking for these varieties. Low fruit temperatures can help reduce oxidation reactions and wild yeast growth. In warmer climates, picking is avoided during the hottest part of the day, and often carried out at night or in the early morning. Ideally grapes should be transported as quickly as possible to the winery, and in instances where grapes are transported long distances, provision should be made to keep them cool. Once the grapes have arrived at the winery it is easier to control the conditions they are kept under, but it is still important that processing is carried out promptly. In particular, care must be taken to protect the juice from oxidation and excess phenolic extraction. This can be done by sprinkling sodium or potassium metabisulfite over the grapes or preferably covering the grapes with an inert gas (N_2 or CO_2) or spraying them with 'dry ice,' as shown in Figure 2.9.6.

The treatment of the grapes at the winery depends upon the wine being made. In white winemaking the juice is separated from the grapes, then fermented, whereas red grapes are crushed and fermented with the juice

Destemming and crushing

Most grapes are crushed and destemmed during a white winemaking process. Crushing breaks the berries and allows the juice to escape, and the mixture of skins, pulp, juice and seeds produced is called must. The

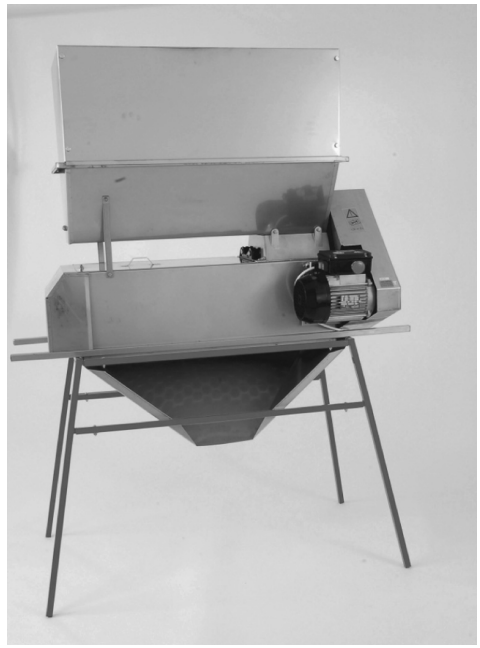

Figure 2.9.7 *Motorised crusher with stand.* Photograph Courtesy of Vigo Ltd., Dunkeswell, UK

winemaker can choose to leave in the stems or take them out, depending on the condition of the stems and the style of wine being made.

The grapes are normally destemmed either before or after crushing in the same machine (*egrappeoir*). The most common type of crusher is a roller crusher with fluted rubber or metal rollers to crush the grapes by a wringer action. This is normally coupled with spirally arranged, radial fingers which rotate over a perforated cylinder. The berries are knocked off the stalks and drop through the holes in the cylinder to be fed out through the crusher sump. The stalks are moved through the cylinder by the spiral fingers and thrown out of the end to be collected and removed. Additions made at the crusher may include sulfur dioxide as a preservative, and pectolytic enzymes to improve yield of juice from the grapes and juice clarification. From the crusher the must is pumped to a drainer or a press. Many crusher sumps are fitted with failsafe mechanisms, which ensure that the pump only operates when there is must to pump. The crushed pulp may be cooled by passing it through a cooling unit, if the grapes are warm.

During the crushing and destemming operation (see Figure 2.9.7), juice is aerated, and although a certain degree of aeration is essential for a healthy fermentation, too much oxygen can cause oxidation of the juice, especially if rotten grapes are crushed, due to the action of oxidizing enzymes from fungus and bacteria present on the rotten grapes. Herbaceous and astringent flavors may be increased if crushing is too harsh, breaks seeds and tears stems. If stems are left in the press (as when whole bunches are pressed), they can help to facilitate juice extraction by forming 'flow channels,' and preventing the press cake from becoming too compact. If a difficult pressing is suspected (as in the case of dehydrated berries, or difficult cultivars like Viognier), packing the press with alternate layers of grapes and stalks may facilitate release of juice. Fermentation in the presence of stems during white winemaking is rare.

If whole bunches are required (for example, in the preparation of sparkling wine base), then these must be handled and tipped manually direct from harvest trays or bins into the press.

Protection of the must and juice

Nowadays white must is usually protected against oxidation in order to avoid browning and loss of primary aroma. The most abundant phenolic compounds in white grapes are hydroxycinnamic acids, and when white grape juice is processed without sulfur dioxide, enzymatically induced oxidation occurs, leading to a precipitation of these phenolic compounds as insoluble brown pigments. Must resulting from extended skin contact will be high in flavones and endogenic enzymes, and therefore particularly susceptible to oxidation. The other changes caused by oxidation of the juice include color changes, and increases in bitterness and volatile acidity, with associated decreases in quality, particularly in the case of delicate, aromatic white wines where the wine depends on fruit aroma and flavor. The spoilage occurring as a result of contamination of grapes and juice by wild yeast and bacteria can also be slowed down considerably by the effective addition of sulfur dioxide, which is usually added as potassium metabisulfite powder or solution. Sulfur dioxide at levels around 50 mg/l will inhibit the action of oxidizing enzymes, and will also react with oxidation products like hydrogen peroxide and acetaldehyde to prevent further damage to the composition of the must and wine.

The extent of the use of antioxidants such as SO_2 and ascorbic acid is usually proportional to the risk of oxidation, which depends on the quality of the juice and processing conditions. Oxygen consumption is higher if the temperature of the juice is high and the grapes are moldy, as enzymes are more active. Two main oxidases exist (tyrosinase in healthy grapes and laccase in botrytized fruit). These transform the principal white grape phenolic compounds into quinones, which tend to polymerize, forming brown compounds.

The methods used for limiting oxidation, other than adding antioxidants, include using inert gas to cover juice and fill vessels, processing the juice as quickly as possible and cooling the juice to slow the rate of reactions, particularly those initiated by polyphenoloxidase. Ascorbic acid, also at around 50 mg/l, may be added at this stage as an antioxidant, but sulfur dioxide should be present if it is to be used, as it has been found to have pro-oxidant capabilities in the presence of phenols (Bradshaw *et al.,* 2003).

In some cases juices are treated oxidatively, as the resulting wine is less susceptible to faults associated with reducing conditions in the bottle (off aromas from sulfides and mercaptans). Working more oxidatively usually leads to a different style of wine which has less obvious fruit aroma and flavor, and which seem to display more resistance to oxidative quality degradation during ageing. Adding pure oxygen in limited quantities to unprotected juice before clarification can also improve the stability of white wine color without producing oxidation type flaws. This process is called hyperoxygenation (sometimes, and less correctly, hyperoxidation), and consists of oxidizing and polymerizing sensitive juice polyphenols to precipitate them so that they be easily removed during the normal racking process. When phenols are eliminated from must by enzymatic oxidation, they do not affect wine quality by undergoing chemical oxidation in the bottle later.

Thus, although oxidized musts are very dark, the resulting wines are lighter and more stable in sensory qualities than those produced by conventional reductive methods (Schneider, 1998). In order to precipitate must flavonoid contents lower than 100 mg/l (as catechin), one saturation concentration (9 mg/l) of oxygen may be sufficient. Higher contents of phenolics obtained by skin contact would require an oxygen concentration of about 30 mg/l, corresponding to approximately three saturations (Schneider, 1998). Excessive oxygen supply is usually highly detrimental to white wine quality, and this should be avoided. Hyperoxygenation is very cultivar dependent, and is more likely to be used for a neutral, full bodied style of wine (for example, Chardonnay) that may be given oak treatment. It can also used to remove color from musts from red grapes destined for white wines (Morgan *et al.,* 2006).

Microoxygenation is another process involving deliberate oxidation of wine, using a bubbler to deliver very small quantities of oxygen (about 3 ml/l month) to imitate the effect achieved during barrel ageing. This is reputed to 'open' wines up that would otherwise be 'tight' or 'closed,' remove reductive smells or problems developing on the lees, and smooth and soften red wines for earlier drinking.

As well as being more sensitive to oxidation than red juice, white must is also more susceptible to microbial attack because of the lack of polyphenols, which help to control sensitive organisms. If the conditions are suitable, microorganisms present on the grapes or in the winery will multiply rapidly and may spoil the juice. Other than the use of SO_2, good hygiene, low temperatures and rapid processing will also help to retard growth. Wine yeasts are adapted to low temperatures and sulfur dioxide and are therefore less affected than wild yeast and bacteria.

Skin contact and enzymes

If the grapes are healthy, destemmed and optimally ripe, it is often the case that the must is left in contact with the skins before pressing, in order to extract more flavor and aroma. This process can produce wines that often age better, with more varietal character, more body and a deeper, more attractive color. It is not usually used for light, delicate styles of wine, as the process also extracts phenols and tannins from the skins. Skin contact is used frequently when wine is made from certain varieties, notably Sauvignon Blanc, where volatile aromatic characters are crucial to wine typicity and quality. It can also be used in the case of red varieties like Pinot Noir and Merlot where some prefermentation skin contact at low temperatures allows color extraction without tannins, with a softer wine resulting. The temperature of skin contact is a key control feature and should be around 10 °C. Often the crush will be protected from excess oxidation by neutral gas (nitrogen) blanketing and around 50 mg/l sulfur dioxide, which also helps to weaken membranes and make cells more permeable. Maintaining the vintage at low temperatures is essential as high temperatures favor the extraction of harsh tasting phenolics, and the activities of microorganisms and enzymes. The time of contact is dependant on the level of extraction required, usually only 2–8 h for white crushes, but sometimes as much as 24 h if the grapes are in very good condition (Morgan *et al.,* 2006).

Use of enzymes

A variety of enzyme preparations exist for different winemaking purposes. Depending on the reason for use, they may be added at this stage, or later in the winemaking process. Commercial enzyme preparations are added to must at rates which vary from 20–100 g per ton, depending on the advice of the manufacturer. Enzymes are proteinaceous in nature, and are therefore inhibited by the factors that will denature proteins, i.e. low or high pH, low or high temperatures, high sulfur dioxide content and high alcohol concentration.

Commercial pectolytic enzymes are a mixture of enzymes, which catalyze the hydrolysis of methylated polygalacturonic acid (pectin) breaking down the colloidal polymers into lower molecular weight polymers or soluble galacturonic acid. The enzymes present include pectin methylesterase (PME), polymethylgalacturonate lyase (PMGL), polymethylgalacturonase (PMG), polygalacturonate lyase (PGL) and polygalacturonase (PG). PME hydrolyzes the methyl esters of galacturonic acid sequentially within the pectin macromolecule, liberating the acid functions and releasing methanol into the juice (Ribereau-Gayon *et al*., 2006c). PGL and PG sever the 1,4-glycosidic linkages between galacturonic acid molecules only when the carboxylic acid functions are free of their methyl groups. PMGL and PMG are able to act on 1,4-glycosidic linkages when adjacent galacturonic acid groups are methylated. The effect of breaking down the pectin is that the juice is easier to extract, draining is facilitated and the treatment enhances the yield of free run juice. Pectolytic enzymes can also be added after pressing at between 5 and 50 ppm to assist in juice clarification. The length of time that the enzyme takes to act depends on the strength of the enzyme solution, factors like pH and temperature, and the amount of pectin present, which varies with variety and season. Effectiveness of the treatment depends on temperature, holding time prior to pressing and the presence of natural proteases in must. Generally speaking, pectolytic enzymes are not inhibited by SO_2 unless the concentration is very high (around 400 mg/l), but are inhibited below 15 °C and above 60 °C.

Terpenes, essential components of varietal aroma in Muscat cultivars, Riesling, Gewürztraminer and others, exist in solution mainly as the glycoside form. When bound to glucose, terpenes are not aromatic (Ribereau-Gayon *et al*., 2006c). Normally the glycosides are separated from the terpenes through acid hydrolysis during ageing, helping to enhance varietal character later in the life of the wine. Glucosidase enzymes will hydrolyze the monoterpene from the glucose during skin contact, and thus release it as its aromatic form immediately, so improving the aromatic quality of early release wines. Malolactic bacteria have also been shown to exhibit limited glycosidasic activity (Liu, 2002).

Grapes that have some degree of rot (specifically an infection of *Botrytis cinerea*) will contain glucans (high molecular weight glucose polymers), which lead to clarification and filtration problems. Commercial preparations of the antifungal enzyme are produced by extraction from *Trichoderma* spp. Glucanase will hydrolyze the bonds and break the molecules up, thus aiding filtration and clarification. The enzymes are sensitive to temperature and ethanol (activity is halved at 10% v:v), so they should preferentially be used before or early on in fermentation. Like pectolytic enzymes, glucanases are also fairly insensitive to SO_2 (Ribereau-Gayon *et al.*, 2006c).

Pressing

The draining and pressing operations happen before fermentation in white winemaking (Figure 2.9.8), and after fermentation when making red wines. Once the grapes have been crushed and destemmed, in larger concerns, the crushed grape mass (or *marc*) may then be transferred (using a specialized crush pump) to static batch drainers. These act in principle like large sieves, which can be operated with a slight pressure of carbon dioxide or nitrogen to hasten juice removal. Drainers are generally completely enclosed to prevent juice oxidation (Figure 2.9.9). Continuous drainers or dejuicers have an inclined Archimedean screw inside a cylindrical screen, and the crush is carried up the drainer and continuously agitated so that juice runs through the screen, promoting high yields of free run. Inclined dejuicers are generally coupled with continuous presses and used in large wineries for bulk wine production. The juice quality from these drainers is generally good, as the bed of skins acts as a filter and retains a lot of finely divided solids. Draining may be speeded up by the addition of pectolytic enzymes. The disadvantage of drainers, and the associated movement of the marc,

Figure 2.9.8 *Loading the press.* Photograph courtesy of Paul Gerber

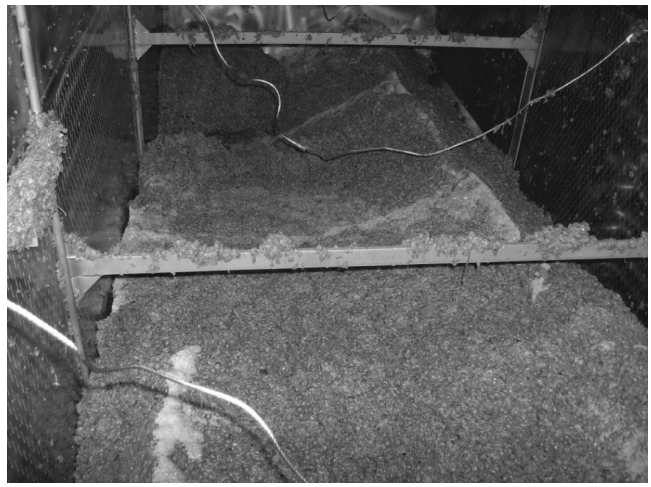

Figure 2.9.9 *A draining tank (Sauvignon Blanc) at KWV, Paarl, South Africa*. Photograph courtesy of Paul Gerber

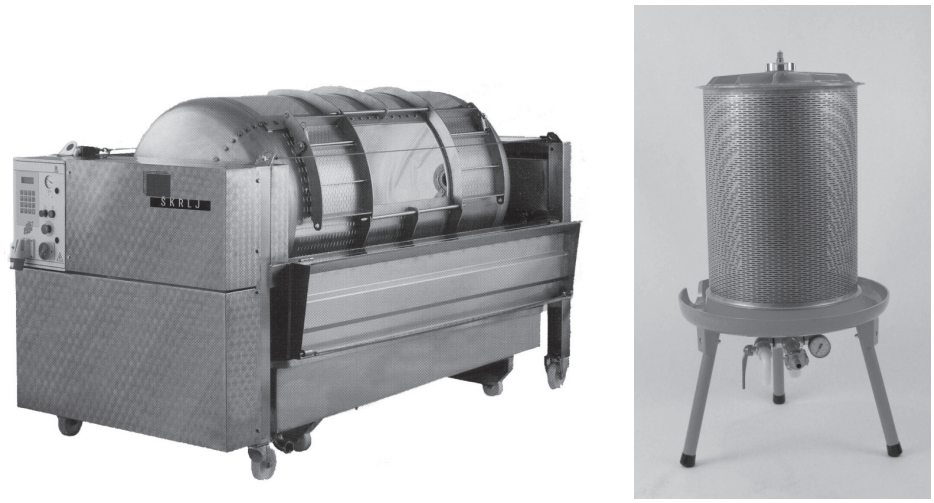
is that damage to skins can occur, which results in lower quality pressings. The actual yield from the drainer and quality of the juice vary depending on the type of equipment used, the fruit variety, ripeness and quality, and any previous treatments that may have been made to the must (skin contact or partial fermentation on skins, pectolytic enzyme treatment and retention of stalks in white must all improve the yield, separation speed and quality of free run and light press fractions). When the free run (about 60–80% of the yield of juice, depending on cultivar and condition) has drained off, the remaining solids are pressed to extract more juice.

The simplest method of getting the juice from the grapes is by whole bunch pressing. This method is obviously only suitable for hand harvested grapes, as machine harvested grapes have been torn or shaken from their stems and are no longer in bunches. The pressing breaks the skins of the grapes and the quality of the juice released is good, but the yield is lower than for other methods of juice extraction. The first juice released (the free run) is low in phenolics and has the highest sugar, acid and flavor, and is frequently used for high quality wine production, like the *vin de cuvee* (Section 2.9.3). As the grapes are pressed, the juice composition changes. Sugar and acid decrease, and phenolics increase as the pressure increases.

In smaller concerns, unnecessary capital outlay on expensive equipment is avoided through presses such as membrane (bladder) presses being used for combined draining and pressing. This also avoids transfer between a separate drainer and the press and any associated damage to the skins. Depending on the winemaking goal, press program will have been set up to achieve the desired levels of extraction. The first of the pressings (approximately 10–20% of the yield) may be added back to the free run juice, but generally the subsequent, high pressure pressings are kept separate as they contain increased concentrations of phenols (including tannins), which may lead to astringency and bitterness. These pressings may be used for fortified wines or distillation, if local legislation allows.

The oldest and simplest form of press still used is the basket press. It consists of a basket of wooden slats seated in a steel juice collecting tray. The *marc* (crushed grape mass) is loaded into the basket and then compressed by a large plate which is forced hydraulically into the basket, and the juice is expressed through the gaps between the slats making up the sides of the basket. These presses are used mainly in small, traditional cellars and larger versions are used in Champagne making. Disadvantages of basket presses include the slow and inefficient nature of the batch process, the gap between the slats (which allows grape solids



(a) (b)

Figure 2.9.10 *A horizontal pneumatic press (a) and a hydropress (b).* Photographs by courtesy of Vigo Ltd, Dunkeswell, UK

to extrude), and the restricted ability to loosen the cake between pressure applications. Fairly high pressures are required, and juice may also be subject to oxidation as it runs out between the slats. Horizontal screw presses work on the same principle as the screw operated basket press, but the basket is horizontally mounted and revolves to loosen the cake between pressure applications. The pressed marc is emptied through doors in the basket.

Bladder (or pneumatic) presses initially consisted of a horizontal, rotating slotted stainless steel basket with an inflatable rubber air bag in the center. The marc was loaded through doors in the side of the basket, distributed evenly by rotating the basket and then pressed by inflating the bag. Because of the relatively short distance the juice had to travel to the basket only low pressures were required and the pressing action was gentler. More modern versions of bladder presses include tank presses, which consist of a fully enclosed vessel which contains a membrane and juice collection channels. These are gentle in action, and are used in applications such as sparkling wine production where recovery of phenolics is necessarily very low. Pressing occurs at relatively low pressures with minimal damage to the skins and seeds giving good quality juice. The horizontal pneumatic press (Willmes) is an inflatable cylindrical bladder or diaphragm with compressed air or cold water (Figure 2.9.10). Pressures are easily controllable, and very gentle, and yield juice of high quality. The 'tank' press (Bücher) is a totally enclosed variant of the pneumatic press, which has the advantage that it can be prefilled with nitrogen to minimize oxidation.

The continuous screw press gives the greatest yield of juice, is very quick and efficient, but does not yield the best quality juice. Grapes are moved through a perforated steel tube by an archimedean screw, pressure is easily adjustable, but pressures can get extremely high, and the quality of the juice expressed can be poor and fit only for distillation.

Prefermentation treatments and additions

According to Ribereau-Gayon *et al.*, (2006c) the total nitrogen contents of musts range between 0.1 g and 1 g of soluble nitrogen per liter with free amino nitrogen (FAN) or 'easily assimilable' nitrogen is usually

less than 100 mg/l, but can be as high as 400 mg/l. Slow or incomplete fermentations are often linked to a lack of FAN, as multiplying yeast is dependent on must nitrogen for the growth of their cell constituents. A satisfactory fermentation of 160–250 g/l of sugar requires between 70 and 140 mg/l of assimilable nitrogen. In marginal and cooler climates, a lack of nitrogen is generally not a common problem, however warmer conditions, later harvesting and a significant proportion of rot in the vintage will mean that natural grape FAN will be lower. There is also a winemaking requirement for higher FAN levels when yeast is likely to be stressed i.e. in cool, hot or very high sugar fermentations. Under these circumstances, yeast is likely to produce higher levels of hydrogen sulfide in the absence of FAN. It is therefore advisable to add diammonium phosphate (DAP). A 200 mg/l addition is usual if DAP is required.

Higher protein levels can cause filtering problems and can coagulate in the wine causing cloudiness (protein haze). Bentonite treatments have also been recommended in the past, to eliminate proteins in the juice which may be responsible for instability of juice clarity. Bentonite is a montmorillonite clay which in water swells to adsorb charged protein elements. Its use before (or during) fermentation removes heat unstable proteins and also solids that may darken and coarsen wine. Treating juice in this way is recommended mainly for wines which are to be further clarified (e.g. by filtering) and bottled soon after fermentation. However, despite this treatment, white wines may be unstable at bottling and require additional bentonite treatment. Also, if white wines undergo barrel or tank 'on lees' ageing, bentonite treatments are not necessarily recommended. The bentonite may damage the organoleptic quality of lees stirred wines and also even be redundant due to the protein stabilizing effect of yeast autolysis.

The usual dose employed is 0.5–1 g/l, but higher doses can be used for wines from vigorous vines as they have a high protein content. Some bentonite preparations can be used by just sprinkling on the surface of the wine (with mixing), but usually it must be mixed with 10 times its weight of water and allowed to swell for 24 h. Some fining may be done prefermentation, but most fining is carried out on wine. PVPP (polyvinylpolypyrolidone) is used to remove low molecular weight phenolics which may cause problems during ageing, and activated carbon may be used with caution to modify color if it is too deep. Further information on fining and clarification treatments can be found in Section 2.9.4.

Juice clarification

The removal of grape solids from juice is a physical problem so various physical methods are used. Juice clarification is widely practiced to reduce the risk of oxidation by removing the grape derived oxidase enzymes which tend to remain in the solid fraction. It also reduces the risk of wild fermentation as the wild yeasts are removed with the solids. Clarification produces cleaner fruitier wines, and is said to assist in removing herbaceous aromas. Although fermentation on solids, particularly when large amounts are present, may produce unclean wines with unpleasant cardboard and lees flavors, a number of winemakers are moving away from 'water clear' juice, and carrying out what is perceived to be a more natural 'high solids ferment.' With care, this can give a wine of interesting complexity and uniqueness, such as found in some white Burgundies. High solid ferments are not recommended for lighter fruit driven styles, but can also prevent problems which can occur with sluggish or incomplete fermentations.

When juices are highly clarified prior to fermentation, yeast may struggle due to the removal of nutrients, importantly long chain fatty acids and sterols, which are required by yeast growing in anaerobic conditions for cell wall production. A common approach is therefore to remove most of the solids, but to leave some fine material, giving an 'opalescent' rather than perfectly clear juice. The physical methods used for clarification are cold settling, centrifugation, filtration and flotation. These methods are discussed in detail in Section 2.9.4.

Following the clarification stage, the juice is theoretically ready for yeast inoculation and the start of fermentation, but there may be several steps a winemaker may wish to include before then, for example, sugar and acidity adjustments should be carried out after clarification.

Chaptalization

In cool climate vineyards, with reduced photosynthesis, continued vegetative growth and excessive crop yields, grape sugar accumulation is limited. Enrichment of must with sugar (chaptalization) in order to achieve 'normal' alcohol levels in wine is therefore usually permitted by local legislation. Although the given wisdom is that wine should be purely the product of the grape, and that the addition of sucrose from a sugar beet or cane is undesirable, it is generally recognized that wine made in cooler climates is greatly improved by the addition of sugar before fermentation. If the addition is carried out within the recommended guidelines, the extra alcohol improves the balance and body of the wine and helps in wine preservation. If the addition of sugar is too great, the flavor components will be diluted by the extra alcohol, and the wine may well be undrinkable. Therefore, the amount of sugar (potential alcohol) added is strictly controlled and permission from the relevant authority is normally required. In the EU, enrichment must not exceed 3.5% v**:**v in total (in a 'good' year) or 4.5% v**:**v in a 'poor 'year (Morgan *et al.,* 2006). Whether the vintage is a poor or good one is decided at an appropriate point by the local authority. The enrichment methods that are allowed include the addition of dry sucrose, concentrated grape must (CGM) or rectified concentrated grape must (RCGM).

Sucrose is converted to glucose and fructose by exocellular enzymic hydrolysis, and the monosaccharides are then imported and metabolized by the yeast. If sucrose is used, 17 g sugar/l of juice is required (white) and 19 g/l (red) would need to be added in order to raise levels of alcohol by 1% v:v, i.e. 180 g sugar becomes 92 g ethanol and 88 g carbon dioxide (Jackson, 2000b). RCGM (rectified concentrated grape must) is a purified form of grape juice, which, by law has a pH less than or equal to 5, and a refractive index of 61.7%. The nonpurified form is CGM, which is obtained by heating and can be dark in color. As it still contains acids, it can also have a very low pH. It is also rich in iron, which has implications for haze formation and oxidative stability in wine in which it is used (Morgan *et al.,* 2006).

The other implications of chaptalization are mostly associated with dilution. As stated, the natural grape contribution in terms of flavor and aroma is weaker. As potassium bitartrate, the most common salt of tartaric acid, decreases in solubility as ethanol increases in concentration, bitartate precipitation increases, and the total acidity decreases by 0.1–0.2 g/l for every percent volume alcohol added. In red winemaking, phenolic extraction increases by 5% for every 1% alcohol added.

Subtractive techniques can also be used in order to concentrate sugar in solution before alcoholic fermentation, but most of the methods are quite difficult to control in terms of how much the must is concentrated. An associated issue that other components are concentrated at the same time as the sugar: for example, iron and malic acid. Partial must concentration can be carried out by gently heating the juice (25–30 °C) and evaporating off water under vacuum. A thermocompressor can extract part of the must vapor and between 10 and 80 hl of must per hour can be treated, evaporation capacity: 150–1200 l/h (Morgan *et al.*, 2006).

Over-ripening of the grapes on the vine or in prepared areas is one way of concentrating the sugar in the grapes, but it will also lead to a completely different wine with possible madeirized or raisiny characters. This obviously has risks associated, such as loss of aromas and caramelization (browning) if the temperature is too high. A very nonquantitative method is to use cryoextraction, which involves the freezing of the juice and removal of the layer of ice from the surface. Reverse osmosis and ultrafiltration (see Section 2.9.4 for more detail on these methods) can also be used, with more controllable results. The maximum permitted volume reduction using subtractive techniques is 20% or an increase in potential alcohol of 2%.

Acidity adjustments

The sugar–acid balance of a wine is one of its most essential features. High levels of acidity, which are not accompanied by appropriate sugar levels will lead to wines that are tart and unpleasant, and acid levels that

are too low may mean the wine is bland and uninteresting. Good levels of acidity are necessary in white table wines for a number of reasons other than taste. A low pH favors the antioxidant and antimicrobial properties of sulfur dioxide, and microbial spoilage therefore happens less readily in a more acidic environment. A low pH also enhances freshness and fruitiness, and discourages oxidation.

Legislation concerning acidity adjustments differs according to climatic region, and usually tries to compensate for any deficits in the grape chemistry. Climatic regions that are cool will more than likely produce wines with high acidity and low sugar levels, so adding acid in these regions is prohibited, but chaptalization is allowed. There are few restrictions on must and deacidification in England and Wales, for example, but tartaric and malic acidification is prohibited in all circumstances – only citric acid may be added, and this is usually only used for ferric stabilization. In warm climates (e.g. Mediterranean winemaking regions like Spain, Portugal and South Africa), juice often has high pH and low acidity, and the wine runs the risk of being bland and easily spoiled, so the legislation in these regions will allow for additions of acid, but forbids sugar additions.

If must needs acidification, it is usually tartaric (preferred), malic or citric acids that are added. Acids that are not present in grape juice (for example, hydrochloric, sulfuric or nitric acids) are forbidden. Ideally, chemical addition would be avoided, and the winemaker would have had the foresight to harvest some of the grapes 'green' and freeze the juice in order to blend this acidic juice to that of grapes harvested later. In cases where tartaric acid is added, Ribereau-Gayon *et al.* (2006c) recommend addition before or during the fermentation, mainly to optimize volatile flavor compound production and also to ensure a balanced end product (addition after fermentation may make the wine coarser). Early addition of acid also confers the benefits of low pH during processing and allows the maximum time for integration of the acid. Must or juice with pH greater than 3.5/3.6 require acidity adjustment, ideally for white wines to 3.1–3.3 and for red to 3.2–3.4. Legal limits in Europe are for addition of 150 g/hl in musts and 250 g/hl in wine. The tartaric acid addition is best made at the crusher where the acid is weighed and dissolved in the minimum quantity of cold water or juice and added to the grapes before crushing or to the must immediately afterwards.

Deacidification (increasing the pH of the wine) happens naturally in wine during processing as most wines lose around 1 g/l of acidity by tartrate precipitation after the alcoholic fermentation. Under favorable conditions, lactic acid bacteria will transform malic acid into lactic acid during the process of malolactic fermentation, and this will increase the pH by around 0.2 units as well as 'rounding off' of the taste and aroma (discussed in more detail in Chapter 2.3). The malolactic fermentation is fairly normal in the elaboration of red wines, and is also used in dry white wine production when acidity levels warrant it. Certain yeasts belonging to the genus *Schizosaccharomyces* break down malic acid completely to carbon dioxide and ethanol (Swiegers *et al.*, 2005). Certain strains of *Saccharomyces* will degrade malic acid by up to 45%, and research is ongoing to try and increase this.

If deacidification is to be carried out 'artificially,' only three additives are authorized for the process: potassium tartrate, calcium carbonate and potassium bicarbonate. These are available in different combinations in commercial products specifically for acidity reduction in wine and beer. In principle, the tartaric acid will react first with the bases to form insoluble tartrate salts, which can be racked or filtered off. If calcium carbonate is used alone, it is accepted that 100 g of tartaric acid will consume 67 g of calcium carbonate in 100 l of must to form calcium tartrate, which will precipitate at wine pH.

Once the tartaric acid has been neutralized, malic acid then reacts to form malate salts with the excess base. These do not precipitate at wine pH and can have a bitter taste. If the deacidification is carried out in a large quantity of must, the deacidification agent will be 'used up' by tartaric acid, and malic acid will be left in solution, which will change the tartaric to malic ratio and has implications for the chemical and microbial stability of the must and wine. Therefore, if large acidity reductions are needed (above 2 g/l), it is recommended that they are carried out initially on a smaller quantity of the must. This is known as the

'double salt deacidification' method, which neutralizes a portion (around 10% of the volume of the must) to around pH levels of around 5–6, at which pH the malate salts also precipitate, and this portion is then added back after the precipitates have been removed.

The method reduces malic and tartaric acids simultaneously, and ensures that the remaining acid in solution will be a representation of the original acid structure, and not artificially high in malic and other acids. It should be stressed that the success of the double salt deacidification does depend on the initial tartaric:malic ratio, which needs to be as close to 1:1 as possible, and the procedure should only be carried out if musts require large deacidifications. It is prudent to quantify the acids before carrying out this procedure, but in must from unripe grapes it can be assumed that malic acid will be present at significant levels.

Again, legislation exists for this operation in the EU, which must be sanctioned by the control agency in Europe. Also, for example, table wines must have a minimum final acidity of 4.5 g/l as tartaric acid. This treatment must be declared and cannot be combined with an acidification.

White Wine Fermentation

The biochemistry of fermentation is discussed in general detail in Section 2.2.9, so a more technical, but less biochemical account is given here.

All winery surfaces normally support a residential or winery yeast flora. The viability of this flora will depend on a number of factors, including the type of surface; for example, wooden surfaces are almost impossible to sterilize, whereas stainless steel is relatively easy to clean, as well as the cleaning and sanitizing program within the winery. Equipment, particularly if it has areas that are difficult to reach and clean, forms the major reservoir for spores and live yeast, especially in older wineries. Mechanical harvesters, delivery containers, crushers and pumps can all act as a source of yeast and bacteria if they are not kept dry and clean (preferably sterilized).

Although a natural fermentation can give a complex, interesting product that might be viewed as more 'organic' and expressive of the *terroir*, it should also be noted that wild yeasts are known to be unpredictable in their efficiency to convert sugars to alcohol, can produce off tastes, including hydrogen sulfide, and may not finish the fermentation to dryness. The natural microflora may be of high quality and produce an excellent result, but there is no guarantee of this for the producer. As white wine is more sensitive to off flavors and usually dependent on expression of some delicate fruit character, wild fermentations are not as common. White wine is seldom fermented on the skins, and the natural yeast population in the juice may not be sufficient to kick off a healthy, active fermentation.

Aeration of must is beneficial for the growth stage of the yeast colony as it ensures the presence of sterols in the yeast cell wall, which later assist in the transfer of components, and resistance to the toxic effects of alcohol. Most yeast strains produced commercially are able to grow very well in totally anaerobic conditions for up to three generations before their viability will be affected by anaerobiosis. Insufficient oxygen during the initial growth phase of the population may result in a lack of 'survival factors' in the yeast population. These survival factors include sterols (particularly ergosterol) and certain long chain fatty acids, and if oxygen is lacking, they do not develop in the membranes sufficiently to ensure resistance to accumulated toxins such as ethanol and acetic acid later in the fermentation, which may result in an incomplete metabolism of the sugar in solution. Another disadvantage of working anaerobically has become obvious as greater quantities of wine (white and red) are bottled with screw caps rather than corks. While corks have contributed their fair share of problems to wine (including sporadic oxidation, and 'cork taint'), they are not generally accused of causing reductive problems. Although the extent of reductive problems is at times overstated, it is generally accepted that wine that is destined to be bottled under screw cap needs to be made under more oxidative conditions in order to prevent the development of off odors associated with reductive conditions in the bottle later.

The yeast population, for example, should be given sufficient oxygen and assimilable nitrogen so as to prevent the development of hydrogen sulfide. Even at levels that are undetectable at bottling, sulfides can undergo reactions in the bottle to form disulfides and mercaptans with much lower detection thresholds, and associated 'eggy,' vegetal and sulfurous smells. Many winemakers will carry out an automatic copper fining (copper sulfate at a few mg/l) in order to strip out any sulfides that may have developed during fermentation.

The wine should not go into the bottle in an oxidized state, but equally, should not contain compounds that can be converted under reductive conditions. Wine that is destined for cork may certainly be treated differently. Cork, arguably, allows the very slow permeation of oxygen into the bottle, thereby avoiding reductive conditions. Cork itself contains oxygen in small cells and pockets, which may also be exchanged at the wine surface.

Another cause of incomplete fermentations is a lack of available nitrogen, sometimes due to overclarification of the must before fermentation. It is common practice in modern wineries to add diammonium phosphate (DAP) to the juice in order to ensure adequate nutrition for the growing yeast population in the form of the ammonium ion, which is easily assimilable by the organisms. In the event that the temperature is too cold in white must, fermentation slows down or becomes stuck, risking the production of off flavors. If this happens, it is usual to raise the temperature of the fermentation to around 18 °C, and to pump the wine over to oxygenate it. Between 10 and 15 mg/l DAP may be added, as may amino acids L-phenylalanine at 2 mg/l and thiamine at 50 mg/l. If fermentation does not restart after these measures, a new yeast starter culture will be introduced, as the old population may have become unviable.

Ideally, a yeast strain for white wine production has the following characteristics: it will be resistant to high alcohol levels, and tolerant of high initial sugar levels and normal doses of sulfur dioxide. It will enhance the quality of the wine by adding fresh, fruity aromas, glycerol and esters, and it will not contribute negative characteristics like mercaptans, sulfides, acetic acid or ethyl acetate. It will be able to convert sugar to alcohol efficiently and completely, at a specified (and sometimes very low) temperature, using low levels of vitamins and oxygen.

The onset of fermentation will be rapid, even in highly clarified juice, and the fermentation will proceed predictably and will be controllable through temperature manipulation. Minimal amounts of foam will be produced during fermentation, and the yeast will flocculate rapidly once the wine is dry, and contribute pleasant autolysis character if required. This is a lot to ask of a simple eukaryote, but centuries of selective breeding by vintners have ensured that almost every wine yeast used these days fulfils most of the criteria listed.

The ADWY (commercial active dry wine yeast) strain selected has a significant effect on the progress of the fermentation (fermentation kinetics) and the development of aromas. Some yeasts produce high ester concentrations such as QA 23 and these are used for neutral grapes as the yeast characters can add to the wine. Other yeasts such as VL3 are used with Sauvignon Blanc as they intensify the varietal aroma. In some cases yeasts such as CY 3079 are chosen for their influence on the body of the wine. In red winemaking, yeasts such as F10 are chosen for color and flavor extraction for early drinking reds. If fermentation difficulties are encountered then EC1118 is a good yeast strain to use for restarting stuck ferments, but this strain is known to produce a 'medicinal' aroma profile associated with elevated levels of vinyl guaiacol, as is Vin7, a popular yeast strain for Sauvignon Blanc fermentations in South Africa.

Yeast lees (also called yeast ghosts or hulls) are sometimes added to musts to provide nutrients for the yeasts and absorb chemical spray residues and long chain fatty acids, as well as other substances that may retard the progress of fermentation. The only yeast nutrients permitted by legislation in most wine producing areas are diammonium phosphate (up to a limit of 0.96 g/l in the EU) and thiamine (1 mg/l). Ammonium sulfate may be used instead of DAP at similar levels (Morgan *et al.,* 2006).

If these nutrients are lacking in the must because the grapes are rotten or juice is very highly clarified, their addition will produce a more efficient, purer and more complete fermentation, so a number of yeast

manufacturers now sell products which contain these compounds in combination with yeast lees as a fermentation supplement. If yeast is producing detectable levels of H_2S, it is a sign of yeast stress and may be caused by a nutrient deficiency, so adding DAP is usually one of the first actions taken on detection of the gas.

Preparation/inoculation of yeast starter culture

Once white juice has been clarified, it is transferred to the fermentation vessel. Approximately 10% of the vessel volume should be left empty to avoid the overflowing of foam produced during the tumultuous phase of alcoholic fermentation.

The freeze dried wine yeast will be activated following the manufacturer's directions for the specific yeast, on a tank by -tank basis (in buckets, drums or small tanks), or through large propagation tanks of yeast starter maintained with the addition of sugar or grape juice. White grape juice should be inoculated with yeast at a concentration of 10–15 g/hl (or $5–10 \times 10^6$ cells/ml of juice) (Ribereau-Gayon *et al*., 2006c). The culture is normally pumped over from the lowest valve in the tank, via an open bin, to the top of tank. Fermentation usually begins within 24 h, is vigorous after four or five days (Figure 2.9.11) and typically lasts two or three weeks, depending on conditions.

Similarly, for crushed red grapes, these should only be filled to 80% of the tank capacity to allow for the large volume increase in the pomace cap during fermentation. Enzymes can be added at this point to improve the aroma, and other attributes of the wine. The vessels used for fermentation nowadays are mainly stainless steel tanks (Figure 2.9.11), but glass fiber and epoxy-lined concrete are in common use. Barrel fermentation is also used for white juices, and to finish off fermentation in drained/pressed red wines.

Additional information on red winemaking can be found in Section 2.9.2. The fermentation should be started up as soon as possible, in order to limit the amount of time in which the must is liable to oxidation and to microbial spoilage. If the fermentation is too slow, yeasts and bacteria can produce volatile acidity and by-products, which are coarse or even foul tasting. If the fermentation is too fast, there is a great loss of volatile aromas and those formed are coarse, leading to a considerable loss in finesse. For these reasons, it is very important to monitor the alcoholic fermentation and to control its development.

Figure 2.9.11 *An active fermentation of white grape juice.* Photograph by courtesy of Derek Pritchard

To monitor the fermentation, it is essential to measure the temperature and density of the must in each vat at least once a day. This monitoring will enable the producer to follow the development of the fermentation, and anticipate possible problems, such as overheating and stuck fermentations.

If the fermentation rate is high, the temperature will increase, carbon dioxide will be generated more quickly, and there will be a concomitant loss of volatile components. If a fast fermentation is allowed to continue, the heat produced may be sufficient to kill the yeast, and the fermentation will not complete before all the sugar is consumed. This type of problem is more likely to occur in production facilities with large tank volumes at high ambient temperatures. It is generally recognized that the control of temperature is vital in the production of fine white wines as high temperatures encourage oxidation, microbiological spoilage and instability. Desirable aroma and flavor compounds and alcohol are depleted by volatilization, and above 35–38 °C, yeast will be compromised. Different beverages will have different requirements in terms of ideal fermentation temperature, but for white wines, the temperature is adjusted to obtain a uniform sugar reduction of approximately 1.5 °Brix per day, which corresponds to a fermentation temperature of 12–16 °C. For red wines a reduction of around 3 °Brix per day is achieved at temperatures between 18 and 24 °C.

Cooling systems range from low temperature water in an insulated vessel to direct glycol cooling through heat exchangers. The entire facility may also be subject to temperature control through air conditioning, and this will probably be sufficient to keep smaller fermentations at lower temperatures, but high volume fermentations need to be conducted in jacketed tanks so that temperatures can be controlled in individual tanks. A sudden fall in temperature can also adversely effect the fermentation, and in the final stages a significant temperature drop can drastically slow or stop it completely.

It is important to act quickly if off odors are seen in fermentations, as they are usually warnings of yeast stress. As stated previously, if H_2S is detected, DAP should be added. If the rate of fermentation has slowed significantly, the must may be aerated, or the temperature increased to boost metabolism. If the acetic acid concentration rises, the fermentation rate and temperature should be checked and if a wild ferment is being conducted, reinoculating with a known culture may help to alleviate the situation. When altering the fermentation temperature it is important to do so incrementally, as sudden changes can affect the yeast adversely. The aroma compounds produced during fermentation and the factors affecting them are discussed more fully in Section 2.2.9. Even without the means to control (reduce or increase) tank temperature, following the course of the fermentation temperature and density will give a good indication of the progress and health of the process. A further check is to measure yeast colonies/ml of solution.

It needs to be noted at this point that the carbon dioxide generated by fermentation poses a hazard to workers as it has a higher density than air and collects in the production area, in tanks, and in low cellars. It is potentially lethal, and good ventilation is essential where fermentations are carried out, as are precautions such as never entering a closed fermenter (or empty tank) without measuring for adequate oxygen levels. Large concerns should be equipped with alarms for low oxygen levels.

The alcoholic fermentation of a white wine seldom exceeds 12 days, except in the case of exceptionally high sugar concentrations. Most red wines and dry white wines are fermented to dryness (contain less than 2 g/l sugar), which should be confirmed by chemical analysis. A complete fermentation should not leave residual sugar in which further growth of bacteria or yeast could occur. The density of the fermenting solution is measured daily to monitor alcoholic ferment kinetics, and when it drops to *ca*. 0.993–0.994, sugar concentrations are then quantified to verify completion. In red wines (because of solids extraction) the finished density is higher, usually *ca*. 0.996–0.998. It must be noted that hydrometers are calibrated for dissolved solids in water solution. When alcohol (less dense than water by a factor of 0.7893) is present the hydrometer no longer gives a true reading and therefore sugar concentrations should be checked chemically using a full reducing sugar test. In a winemaking context, a stuck fermentation is when more than 2 g/l of sugar are left at the end of fermentation. This can be very risky if not spotted straight away, as lactic or acetic spoilage can result, with the production of off odors and flavors. An incomplete fermentation implies a higher

residual sugar (usually fructose which tastes significantly sweeter than glucose) than originally planned for by the producer, leading to an unbalanced wine.

Towards the end of fermentation residual reducing sugar levels are measured. A number of producers use Clinitest® (tablets formulated for monitoring low levels of reducing sugars in urine by Bayer Healthcare) for an initial screening test and later they use a more accurate method such as the Lane and Eynon method (Section 4.6.3) or the Rebelein method for quantifying residual sugar (Iland *et al*., 2004). If a residual sweetness is desired in the end product, the fermentation may be stopped by racking, cooling, filtering or centrifugation and by the addition of large doses of sulfur dioxide (200–250 mg/l), or alcohol, in the case of fortified wines, by alcohol addition.

If the must does not contain sufficient sugar to generate the required alcohol level before the fermentation is stopped, rectified concentrated grape must or 'sweet' reserve may be added to boost sugar levels. This needs to be in compliance of local legislation for sugar levels for the style of wine. Any beverage containing natural sugars needs especially clean and careful handling, close monitoring and maintenance of free sulfur dioxide levels and a sterile filtration (preferably through a 0.45 μm membrane filter) before bottling. At this point, unless malolactic fermentation or a long lees contact is desired, wines are racked and the sulfur levels checked. In the event that previous additions of sulfur dioxide have been moderate, 60–100 mg/l of sulfur dioxide may be added to bring the free sulfur dioxide level up to 30–40 mg/l. It is important to add SO_2 as soon as the wine has cleared and is racked off lees. If a residual sweetness is desired in the wine, the fermentation can be stopped by racking, cooling, filtering or centrifugation and by the addition of large doses of sulfur dioxide (200–250 mg/l), or alcohol, in the case of fortified wines.

Any wine containing natural sugars needs close monitoring of free sulfur dioxide levels, which should be maintained at around the 50 mg/l level before bottling. The additions need to be in compliance with local regulations for sulfur dioxide maxima. In South Africa, for example, the legal limit on sulfur in a dry white wine is 210 ppm or mg/l over the entire winemaking process. Even in the event that total sulfur measure only 150 ppm before bottling in the wine, if 210 mg/l have been added, the wine is not permitted any more sulfur.

Once the wine has fermented to dryness, the yeast will settle out naturally if the wine is left in a cold place, and the clear wine can be racked off and filtered. It is important to monitor wines regularly after fermentation has finished. Attention should be paid to the level of wine in the tank (ullage), the surface of the wine, the level of SO_2 and the temperature. The greater the ullage, and the higher the temperature, the more chance there will be oxidative or microbial spoilage. The wine is no longer protected by actively fermenting yeast and the generation of carbon dioxide and poor storage conditions will quickly lead to spoilt wine.

White wines may be run into barrels for ageing after fermentation, or the whole fermentation may take place in the barrel in the first place. Although the modern tendency is to make fruit driven styles of white wine in stainless steel, fermentation in oak is still used for some styles.

If lees contact (or *sur lie*) is required, but malolactic fermentation is not desired, the wine may be cooled to around 10 °C and the lees stirred by pumping over, avoiding oxygen dissolution. Wines are given time on lees to improve the mouthfeel and structure, and they should be stirred or pumped over every 2–3 days to keep the lees in suspension and maximize contact with the wine. Pumping over or stirring lees through the wine prevents the formation of reduction odors (H_2S) in the lees, and helps with the breaking up or autolysis of the cells. The release of the cell contents, including mannoproteins from cell membranes, has been found to assist in the protein stabilization process. After one to two weeks the wine is sulfured at to the appropriate level and racked off the yeast lees.

Wines which have been barrel fermented are often left on lees for extended periods to improve the body and mouthfeel of the wine. They acquire flavors and aromas which can be described as creamy, yeasty, bread-like or toasty, which certainly suits more neutral cultivars like Chardonnay and Chenin Blanc. This property is used to improve the flavor of 'Muscadet sur lie,' which can even be bottled unfiltered. The flavor and creamy

texture of Champagnes, especially Bollinger (up to 10 years on its lees) is reputedly due to the time left on lees.

The aim of the producer is a smooth, reliable and controlled fermentation giving the results desired for the style of beverage being made. The fermentation should be carried out with no off flavors and where possible a positive contribution to the flavor and aroma. These can be influenced by the choice of yeast, the nutritional factors and the environmental conditions of the fermentation.

Postfermentation Operations

If wine is saturated with air the oxygen is consumed slowly in chemical reactions with wine components and is usually undetectable after a week. The oxidation reactions are chemical in nature and the exact reactions depend on the composition of the wine. Some of the more readily oxidizable substrates in wine are phenols, sulfite and ascorbic acid. The capacity of wine to consume oxygen is roughly proportional to its total phenol content, which in the case of most white wines is low. Any oxygen not taken up by phenols, sulfur dioxide or ascorbate will be free to cause oxidation reactions which may damage the wine's color and flavor profile. The slow insidious progress of oxidation can go unnoticed until irreversible damage has occurred, the wine contains detectable levels of acetaldehyde and ethyl acetate, and the color has taken a brown tint. It is judicious, therefore, to limit contact with oxygen in the latter stages of a white wine's processing, and atmospheric oxygen contact can be substantially reduced by displacing air above the wine with inert gas, either CO_2 or N_2, or a mixture of the two. This is a basic level of protection and prevents the initial dissolving of oxygen in the wine. The displacement of air from the headspace of storage tanks helps prevent the growth of film forming microorganisms, but complete control requires additional treatment such as SO_2 addition. It is now general practice in some wineries to flush all hoses and equipment with inert gas before any transfer or operation and to fill receiving vessels with inert gas before wine is pumped in. Low temperatures reduce the risk and rate of both oxidative and microbial spoilage. It is desirable to have low temperatures at virtually all stages of winemaking. When temperatures are high the winemaker must pay extra attention to inert gas use and SO_2 usage.

Malolactic fermentation

If MLF is to occur successfully SO_2 levels must be very low (none should be added after primary fermentation) and the temperatures should be 20 °C or above. This means the only protection available against oxidation and film yeast growth is air exclusion. This is achieved by either inert gas usage or ensuring all vessels are completely filled and air tight. While MLF is being encouraged extra care must be taken to ensure effective air exclusion and to detect the early stages of spoilage. This is especially important in white winemaking as the effects of spoilage would far outweigh the gains hoped for by having an MLF. MLF should be achieved in as short a time as possible, and the course of MLF should be followed so that action can be taken. If MLF is slow or incomplete the conditions should be checked. The wine can be reinoculated and nutrients added or MLF may be terminated. As soon as MLF is completed the wine should be checked and pH, SO_2 and/or temperature correction be carried out.

More on malolactic fermentation and its effect on the wine can be found in Chapter 2.3.

Fining and Filtration

Most white wines, particularly those that contain sugar, will undergo some form of filtration before bottling, although recently winemakers have moved away from excessive filtrations and overprocessing of wine towards gentler alternatives. A number of white wines are now marketed as 'unfiltered.' If fining is carried out for any

reason, (for example, a bentonite addition for protein stability), the wine will need to be filtered to remove fining residues. The wine should also be cold stabilized to precipitate any excess potassium bitartrate, and the winemaker may want to filter out any microscopic crystals that have not settled out during the process. It could be argued, however, that a well made dry white wine that has been in contact with clean, inert surfaces and is protected with appropriate levels of sulfur dioxide should not need any filtration. See Sectoins 2.9.4, 2.6.9 and 2.8.6 for more detail on fining and filtration of wine, beer and cider, respectively.

Removal of reductive odors

Despite the use of low sulfide producing yeast strains and the addition of yeast nutrients new wines still often have sulfide off colors at low levels. At low levels, these mask desirable fruit flavors while at higher levels they may be responsible for a range of off odors from 'struck flint' to 'canned vegetable' and even 'garlic.' It is preferable to remove any sulfide off characters as soon as possible after fermentation before they develop into more complex problems in the bottle. A simple addition treatment for removing and/or preventing sulfide is copper sulfate, at levels of up to about 1.5 mg/l of copper (6 mg/l copper sulfate). This treatment is generally effective against hydrogen sulfide odors, and has been shown to be relatively effective in the prevention of formation of mercaptans and disulfides later in the wine's life. The wine should be clarified, and small-scale trials conducted to determine the most appropriate treatment and addition rate of the copper sulfate.

Blending

There are several reasons for blending wines. These include: producing the best wines possible using some or all of the wines available, producing a consistent product, year after year, 'stretching' good quality wine by blending it with wine of average quality, correcting problems such as excess acidity or sweetness and blending away bad or faulty wines. Producing a consistent product is especially important with branded wines, in order to satisfy the consumers' expectations, and it is essential that the blender has appropriate experience of the product. Skilful blending can add to the value of the wine and maximize the contributions of different cultivars or wines to the whole. A great number of the world's best wines are blends.

There are many considerations to be taken into account when blending wines. Blending can be undertaken at any point during the winemaking process (from grape batches to finished wines), although it is most often carried out after individual batches have been taken to completion and, therefore, just prior to bottling. It could be said that in some cases (Portugal, for example) blending actually starts as far back as the vineyard, where different varietals are planted in the same vineyard and no efforts are made to keep them separate at harvest. If blending is carried out after the wines have been stabilized it is essential that the stability of the blend is checked as the new composition of the wine may have adversely affected some of the components. If the pH changes, for example, the sulfur level may need to be adjusted, or if the alcohol level changes, the blend may no longer be tartrate stable. Newly blended wines are generally allowed time to 'marry' before final stability testing and (potentially) final filtering prebottling.

Blends may include different cultivars, different vintages, different fermentation lots or even wine from different countries. The legal situation varies, but usually there are limits which must be kept to in order to label wines in certain ways, for example in South Africa, in order for a wine to be considered a 'cultivar wine,' 85% of the grapes in the blend must be of one particular varietal.

Bottling

Bottling lines are capital intensive pieces of equipment, often used only once per year and for many small wineries, third party (i.e. 'contract') bottling is the most prudent and economical choice. In turn, this

consideration has prompted many wineries with bottling lines to offer the service themselves. If the winemaking has been careful, a brilliantly clear, stable wine should be presented for bottling. The bottling process cannot correct any faults that are inherent in the wine, and can certainly add faults that were not there previously, if all is not in order. A poor bottling, in other words, can undo months (even years) of hard work and care on the part of the viticulturalist and winemaker, and therefore it is crucial that problems are foreseen and prevented. The common problems associated with bottling include faulty filtration, faulty pumps and nonsterile lines; excess dissolved CO_2 in the wine, exposure to oxygen; faulty corks, screwcaps and closure, nonsterile bottles and capsuling problems.

Prebottling checks are absolutely essential if the product is to have the best possible chance. The final filtration should not perform a 'dirt removing' task, but should be a sterile operation at below 45 microns. Bottles must be washed and sterilized with SO_2 solution and/or hot water or steam. If the manufacturer has guaranteed bottle cleanliness, and the bottles arrive in sealed packs, it is still worth checking random samples before the bottling starts. The filling operation itself requires slow opening inlet and nonreturn valves to help protect the wine feed, and preferably the bottles should be prefilled with nitrogen gas to avoid oxidation. The filling operation may also include vacuum corking and/or use of CO_2 in the bottle's neck to reduce oxygen pick up. The bottling operation itself, whether carried out 'in house' or by third party should be under conditions of scrupulous hygiene. This chiefly concerns sterilization of the bottling line equipment and all wine contact surfaces (e.g. pumps and pipes) with a caustic solution (e.g. 1% NaOH) followed by water rinsing, acid dilution (e.g. 1% citric acid) and final rinsing with sterile water. The most effective systems also incorporate pressurized steam cleaning of the lines. Cleaning must also include the corking equipment, and, especially, the filter system and wine filler heads. A typical six head filler in an English winery is shown in Figure 2.9.12.

The bottle closure, traditionally cork, is another key feature that may cause loss of wine quality. In a fault monitoring exercise that was carried out at the 2006 International Wine Challenge, around 'fifty percent of the faults detected were related to the type of closure' (Thomson, 2007). Bird (2001) notes that natural cork has the benefit of being a good oxygen barrier, by virtue of its composition and the way its elasticity compresses

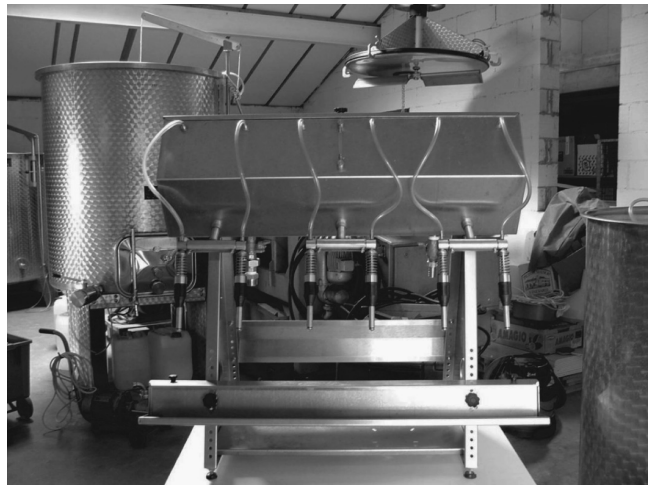


Figure 2.9.12 *A six head wine bottle filler, typical of those used in small wineries.* Photograph used by courtesy of Derek Pritchard, Dunkery Vineyard, UK

it tightly in the bottle's neck, but the problem of cork 'taint' has resulted in a significant decrease in the popularity of natural cork. One of the prime causes of taint is a mold in the cork's crevices, which releases 2,4,6-trichloroanisole (TCA) (amongst other compounds) as a metabolite. TCA has a powerful moldy aroma, which, at the very least, deadens the fruit character of the wine. Most cork producers avoid any kind of chlorine based sterilants now and use peroxide based products instead, but the problem of natural cork 'taints' is not yet resolved. Wines under cork are still showing around 2% taint, which equates to a large volume of wine annually.

Alternatives to natural cork have already made great headway. Initially plastic 'replica' corks were the leader, but the recent rise of the metal screw cap (ROTE, or 'roll-on-tamper-evident'), mainly for white wines, has taken off in recent years, particularly in New World winemaking areas. By 2009, screw caps accounted for 65% of South Africa's bottled wine production, for example. More and more red wines are being put under screw cap as consumers become more accepting and winemakers become adapted to new bottling requirements.

The choice of bottle (or other container) is important, based on (legal) sizes and protective and robustness functions. If glass is chosen, it is usual for red wine to be in a 'green' bottle, which will help avoid light causing oxidative bleaching of the wine color. Glass is by its nature heavy, and producers are looking to lighter options; in 2010, 750 ml wine bottles closed with screw caps and weighing only 350g will be available to wine producers. These compare with an average bottle weight of over 500 gs just four years ago. Lighter bottles are essential in reducing transporting costs and associated greenhouse emissions and are excellent in providing visible evidence of a producer trying for a smaller carbon footprint.

In addition to glass, plastic bottles, aluminium cans, bag in box and cardboard brick packs are now in common usage.

Final Wine Analysis and Records

For most quality wine schemes all over the world, a final analysis is required to be carried out. This can be by self-certification, or by an accredited laboratory. In addition to such final wine analysis, the legislating authority usually requires the keeping of records in such a format as meets their needs for the information shown on their preferred record format.

2.9.2 Red Wine Production

Although red and white wine have major similarities in their making, unlike white wine, red wine fermentation takes place in the presence of grape skins, seeds and sometimes stalks. During fermentation, color, tannins, fruit flavor and other chemical components are extracted from the skins and to a lesser extent from the seeds, giving the wine its color and character, which may be further modified by malolactic fermentation (if carried out) and the ageing process. The main consideration in red winemaking is the management of the extraction of phenolics, which takes place during fermentation.

Grapes for Red Winemaking

Cabernet Sauvignon

This variety is believed to have Cabernet Franc and Sauvignon Blanc as parents, and is probably the best known red (or black) wine grape in the world. Cabernet Sauvignon is easy to cultivate – the vines are hardy and resistant to rot and frost, and the grapes have thick skins, which resist disease and express the

typical character (typicity) of the variety to produce some of the world's finest wines. The vines are planted just about anywhere wines are made, but the grape is only successful in regions that are warm enough to encourage phenolic ripeness. If grown in cool areas, or if the grapes are picked too early, the wines may show herbaceousness (leafiness or green peppers). As the grapes are small, with thick skins, there is a high ratio of skin to juice, and seed to pulp, which means that there will be a large extraction of phenols and tannins during periods of maceration (skin contact before, during or after fermentation). In Bordeaux, Cabernet Sauvignon is an important species, and the maceration period was traditionally around six weeks, giving extremely harsh, rich wines, which needed to mellow or mature in barrel or bottle for about 10 years before drinking. Nowadays, winemakers try to make wines that may be consumed far earlier, so maceration times are reduced to as a little as a few days. In Bordeaux, the wines of Pauillac are dominated by Cabernet Sauvignon, but in many others, Cabernet Franc (as in the wines of Château Cheval Blanc, St. Émilion) or Merlot (as in the wines of Château Palmer, Margaux and in Pomerol wines in general) may be more in evidence. As a pure varietal, Cabernet may lack 'middle palate' and for this reason, in the New World it is often blended with Shiraz or Merlot, both of which help to give add more fullness and complexity. The 'Bordeaux Blend' of Cabernet Sauvignon, Merlot and Cabernet Franc is copied all over the world. Cabernet Sauvignon may also be blended with Tempranillo and Sangiovese before, during or after fermentation, to give full bodied red wines that last well in the bottle. Good Cabernet Sauvignon may also be found in Spain (Navarra), Bulgaria (Suhindol), California, South Africa and Australia. The wine suits the use of oak during production, which brings out the fruit and spice nuances of the grapes, and helps to boost the middle palate. Maturing the wine in small oak barrels before bottling Cabernet is common in order to achieve the best quality wine. Cabernet Sauvignon aroma and flavor characteristics include deep color, good tannin structure (astringency), blackcurrant and red berry flavors, also cherry, cedar wood and tobacco, with some 'green' characteristics like green pepper or olive.

Shiraz/Syrah

This grape is known as Syrah in France and Shiraz in the New World winemaking areas. The vines grow very vigorously, but when planted on the right vineyard site may produce grapes that give wines of intense color and flavor, well suited to wood maturation. In warmer climates like Australia, the grape produces wines that are sweeter and riper tasting. In cooler climates like the Rhone valley of France, the grapes often give a wine that has more pepper and spice aroma. Shiraz may be consumed while it is still fairly 'young' (i.e. within two years of harvest), or it may be aged for a long time before release (e.g. Hermitage in France and Penfold's Grange in Australia).

In France, Syrah is often blended with Grenache (a more neutral red grape) and is an essential grape in the production of the famous and very expensive wines of Chateauneuf du Pape. The grape is the most widely planted red grape variety in Australia where it is sometimes blended with Cabernet or occasionally with Mourvèdre (a strong, tannic cultivar).

Wines made from this cultivar are often quite powerfully flavored and full bodied, with a wide range of flavors, depending on the climate and soils where it is grown, and vineyard management. Normally, aromas range from violets to dark berries (as opposed to strawberry and raspberry), as well as chocolate and coffee, with black pepper, and blackberry and pepper in young wines. After time in the bottle, leather, smoke and truffle aromas may emerge in the bouquet. In the Rhône, as well as in most other areas, Syrah is famous for producing big spicy wines, with intense color, capable of considerable ageing. Hermitage and Côte Rôtie produce well known examples. The latter may be blended with up to 20% Viognier (a white variety) to give aromas of orange peel, cinnamon and plums. Amongst the New World winemaking countries, Australia has put its stamp of ownership on the Shiraz cultivar, with very good examples made in the Barossa, Eden and Clare Valleys, and McLaren Vale.

Merlot

This variety is a close relative of Cabernet Sauvignon, but ripens earlier and hence is able to mature its grapes more readily in cooler seasons or in cooler climate regions. However, it is very sensitive to growing conditions (particularly at flowering time), the vines are susceptible to fungus and mold, and therefore quality of the wine depends on location and vineyard practices. In hotter growing conditions, the grapes may tend to produce flabby wines. This variety was first successful in Bordeaux, in France, and dominates certain blends there, particularly in the wines of Pomerol and St-Émilion. A famous example of Bordeaux Merlot, Chateau Petrus, is one of the most expensive wines in the world. Generally Merlot is lower in tannins than Cabernet, and therefore makes wines that are soft, fruity and smooth, with ripe berry components in the bouquet. It can make good varietal wine on its own, or be blended with Cabernet to produce wines that are more approachable and less aggressively tannic when young. Merlot can have long ageing potential, but most are ready to consume within five years. The wine can be served at slightly lower temperatures than the normal 20–25 °C serving temperature of red wine.

Tempranillo

This is a thick skinned Spanish varietal, which is also known as Cencibel and Tinta de Toro (and Tinta Roriz in Portugal), the ability of this cultivar to thrive in the most unfavorable climates has led to it being grown in most red wine producing regions. It blends well with fruitier varieties and suits oak treatments, which give it the smooth vanilla notes commonly found in the wines of Rioja. It can produce light, early drinking wines right through to deep colored, tannic wines with spice, tobacco and strawberry flavors.

Pinot Noir

This variety is one of the most difficult grapes to grow and work with, particularly in warm climates, but if made well can produce very fine wines. Pinot produces a small crop of grapes with low tannin and color levels, and fairly high acidity, with strong cherry and strawberry aromas (Graves, 1990). The grapes need warm days and cool nights to mature optimally, and are fussy about ripening conditions. In Burgundy, if days are too cool, the cultivar gives thin wines with little tannin and color. Excessive heat during the ripening season can, however, lead to jammy, characterless wines which do not age well. It is the most abundant red grape in the Burgundy (Bourgogne) region of France, and has also become important in Oregon in the United States, as well as in New Zealand. It is known as Spatburgunder in Germany. The ageing potential can range from three to 12 years depending on the quality and style of the wine, and unusually for a red wine, is a good match for grilled seafood. Pinot Noir is also used in Champagne production, where it adds length and body to the blend of Chardonnay and Pinot Meunier (Section 2.9.3).

Pinotage

This cultivar can be considered *the* South African red wine variety; it was created in South Africa (in 1925) by Professor Perold, the first Professor of Viticulture at Stellenbosch University. Perold attempted to combine the best qualities of the robust Cinsault (known as Hermitage in South Africa) with Pinot Noir, a grape that can be difficult to grow. Pinotage is fairly easy to cultivate, and is a good cropper, producing high sugar levels (and therefore higher alcohol concentrations in the wine), but has had a few criticisms. The production of isoamyl acetate during fermentation can lead to the aroma of banana, and varnish (duco). Since its first appearance, the grape has been a victim of fashions within the South African wine industry, sometime experiencing a resurgance in popularity, but more often being maligned. Pinotage, if made well, makes smooth textured wines with lots of fruit flavors which can be drunk early. It stands up to wood ageing very well, and produces coffee and chocolate characteristics when matured in oak barrels of particular sources.

Tinta Barocca

Tinta Barocca is a fast growing, early maturing cultivar, frequently used in the production of port. It is grown primarily in the Duoro region in Portugal, but is also planted in South Africa. The vine produces large, thin skinned berries, and wines with delicate and subtle flavors. It grows best in cooler situations and can be blended with other varieties in order to soften the blend, add perfume to the aroma and lengthen the finish (aftertaste). In South Africa, a few producers make it as a varietal (containing 85% of the named cultivar) wine, but it is often used in blends.

Cabernet Franc

This is one of the major red grape varieties worldwide. It is usually blended with Cabernet Sauvignon and Merlot, but can also be made into a varietal wine. It is one of the five varieties legally allowed in Bordeaux blends (the others being Cabernet Sauvignon, Malbec, Merlot and Petit Verdot). Typically having lighter color and less tannin than Cabernet Sauvignon, Cabernet Franc produces fragrant, slightly green wines with blackcurrant leaf aromas. In Canada, it can be made into ice wine (wine made from the juice of frozen grapes). It shares many of the same phenolic and aroma compounds as Cabernet Sauvignon, but with some noticeable differences. Cabernet Franc may be served slightly chilled, and has pronounced aromas of raspberries, blackcurrants, violets and graphite. It has slightly less pronounced tannic structure than Cabernet Sauvignon and tends to produce a wine with a smoother mouthfeel. The grape is less common in New World regions, but in South Africa, acreage of Cabernet Franc has slowly been increasing, and producers often delay harvesting the grapes to try and minimize the green leafy notes. The grape contributes finesse and a peppery perfume to blends with more robust grapes.

Barbera

This Italian variety produces wine of good fruit flavor, with a high level of natural acidity that has no doubt helped its popularity in warmer climates. Great examples of Barbera are to be found in South America and Australia, and the grape is increasingly being planted in other warm regions like South Africa. Barbera blends well with Cabernet Sauvignon and Sangiovese. Overproduction on the vine encourages acidity, but low yields give beautiful, balanced wines.

Gamay

Gamay Noir à Jus Blanc is the dominant red grape of Beaujolais in South Burgundy. Whole bunches are placed in a tank pressurized with a carbon dioxide seal and the grapes undergo ‘carbonic maceration’ to produce wines with low tannin levels and fruit flavors of berries, ‘tutti-frutti’ and banana. The wines are traditionally drunk young. Although Gamay will never make a big, full bodied wine, California, South Africa and Australia are producing some excellent examples of the light, scented red style of the grape.

Grenache

Grenache grows across huge regions of southern France and Spain, and is also grown in the New World (notably Australia). It is high yielding variety, and is typically overcropped and under-rated, producing thin wines with little character. Due to its affinity for warm climates, if subjected to proper management, the vines produce fruit that makes dense, peppery wines with high alcohol content. In Rioja, Garnacha is blended with Tempranillo, and in France, it is either made as a varietal or blended to produce reds such as Châteauneuf du Pape.

Figure 2.9.13 *Pea sized berries in the early stages of Pinotage fruit development*

For an account of many other red wine vine varieties, some of which, such as Nebbiolo and Tannat are as important for quality (but are perhaps less widely cultivated) as the above varieties, the reader is directed to Robinson (1986) and Galet (1956, 1962). The reader will also find here information on 'workhorse' red wine varieties, such as Aramon, Alicante Bouschet, Carignan, and others – big yielders of basic, everyday wine.

Fruit Maturity and Phenolic Content

The main difference between white and red wines is the phenolic content from grape seeds and skins of the latter, which gives red wine its color, structure and longevity. Up to the point of veraison (see Figures 2.9.13 and 2.9.14, below), red and white grapes look very similar. During veraison, the red grapes will start to

Figure 2.9.14 *Veraison stage for Pinotage. Black, red and green grapes are present in the same bunch.* Photograph by Prof. P. Goussard, used with kind permission of Wineland, South Africa

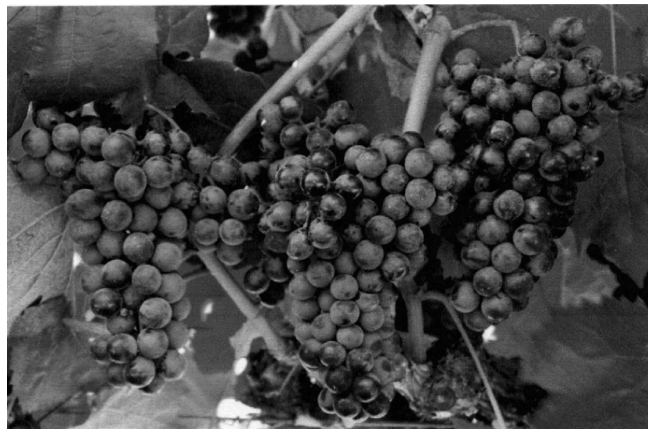

Figure 2.9.15 *Black grapes ready for harvest. To the eye, the berry skin color is quite uniform.* Photograph by courtesy of Prof. P. Goussard

gain pigment, and gradually become darker and darker in color until they attain full maturity (Figure 2.9.15). White grapes will become more translucent, and gradually may become more gold or for some varieties (e.g. Gewürztraminer, Pinot Gris) pinkish in color, but will never attain the same concentration of phenols as red grapes, even in advanced stages of ripeness. White wine is also made from juice that is separated from the skins before fermentation, and is therefore low in polyphenols.

Red grapes are frequently harvested after physiological maturity (maximum sugar accumulation and berry size) as winemakers seek intense color and flavor in their wines. It is not unusual for red grapes to be picked when they are starting to pucker and dehydrate (though it is unlikely that the grapes will be as over-ripe as those shown in Figure 2.9.16). The making of red wines involves extraction and management of high concentrations of polyphenols from skins and seeds during fermentation, with the extraction rate increasing

Figure 2.9.16 *Over-ripe black grapes. Some of the berries have shriveled and may have less skin pigmentation.* Photograph by courtesy of Prof. P. Goussard

with time of contact (maceration), higher temperature and higher alcohol content. The other sources of phenolics in wine are oak treatments and additives such as commercial tannins.

Research into the types of associations and interactions between polyphenols in wine has produced reams of information, some of which are relevant and interesting to winemakers (see Waterhouse and Laurie, 2006; Fulcrand and Cheynier, 2006 for two recent papers, and Chapter 5.8 and Sections 2.6.9, 2.8.2, 2.10.7 and 2.11.2 for examples and citations; see also Part 4 for methods of separation and analysis of phenolic substances).

In short, a phenolic compound has phenol as its basic structural unit – a six membered carbon (C_6) aromatic benzene ring backbone with at least one hydroxyl functional group attached. This structure gives compounds in which it occurs great stability due to the delocalization of electrons around the ring. Here is presented a brief, general account of phenolic substances in black grapes and red wine – for details of the major families (including structures) of phenolic compounds found in wine and other drinks, see Figures 5.8.6 and 5.8.7 in Section 5.8.6. For information on individual phenols (and their reactions) in other beverages or their raw materials, see Sections 2.8.2, 2.10.7 and 2.11.2, and Chapter 3.2.

There are two main groups into which phenolics are usually divided. The *nonflavonoids* are all based on either the hydroxybenzoic acid (C_6-C_1) backbone, or the hydroxycinnamic acid (C_6-C_3) backbone. With the addition of extra functional groups on the basic structure, C_6-C_1 compounds include gallic, vanillic, salicylic acids. The C_6-C_3 compounds in wine include coumaric and caffeic acids. These nonflavonoid acids are usually present as esters – combined with sugars or alcohols and form polymers called 'hydrolyzable' tannins. Grape derived nonflavonoids are not possessed of strong aromas or tastes, but may act synergistically to enhance the mouthfeel and aroma of the wine. When they polymerize, they form relatively weak bonds, which can break and reform under the acidic conditions in wine. Yeast metabolism may provide other nonflavonoids that include tyrosol and tryptophol.

Few volatile phenols or phenolics derivatives appear to come from grapes, but those that do fall into the nonflavonoid group. Methyl anthranilate is a phenol derived ester which is an important component of the characteristic foxy aroma (loved by some; hated by others) of some *Vitis labrusca* varieties. The rose-like fragrance of 2-phenylethanol often distinguishes varieties of *V. rotundifolia*. In addition, several volatile phenol derivatives, such as 2-phenylethanol, vanillin and zingerone, occur in nonvolatile conjugated forms in several *V. vinifera* cultivars. Release by enzymatic or acid hydrolysis could significantly influence the sensory impact of the compounds. Wines matured in oak will contain high levels of hydroxybenzoic acid type phenols (such as gallic acid) by hydrolysis of ellagic acid, pentagalloylglucose and similar hydrolyzable tannins, which themselves arise from the breakdown of phenol–sugar polymers within the wood. Breakdown of lignin will also provide cinnamaldehyde (cinnamon aroma), benzaldehyde (almond/maraschino cherry odor) and the important aroma contributors, eugenol (clove-like notes) and vanillin (vanilla or caramel-like notes).

Another source of volatile phenolic aldehydes involves the heating of must or wine. Fructose, for example is rapidly converted to 5-(hydroxymethyl)-2-furaldehyde during baking or very slowly during ageing. Furfural is commonly produced during distillation and the 'toasting' of oak staves during barrel construction.

The transformation of hydroxycinnamates into volatile phenols occurs under the action of enzymes derived from either *Brettanomyces* spp. or lactic acid bacteria. The derivatives, 4-ethyl guaiacol and 4-vinyl guaiacol, could add smoky, vanilla and clove-like notes to wine. Eugenol, a volatile phenol that smells strongly of cloves, may also occur. Guaiacol which has a sweet, smoky odor may be generated by *Brettanomyces* and by the barrel toasting process, but the concentration is usually insufficient to influence the bouquet directly. Guaiacol and 4-methyl guaiacol may be involved in an off odor derived from contaminated stoppers, and have definitely been implicated in the smoky smell associated with vines and grapes that have been exposed to bushfires, as has happened recently in Australia and South Africa.

The other main group of phenols in wine, the *flavonoids* have a name that is derived from the Latin word for yellow ('flavus'), and have a C_6-C_3-C_6 structure, i.e. two C_6 aromatic rings separated by a chain of three

carbon atoms. The C_3 chain usually, but not always, forms a six membered heterocycle, using an oxygen atom to complete the ring (along with two carbon atoms of the benzene ring). The flavonoid group can be further subdivided into subgroups such as flavones, flavanones, isoflavones, flavonols (yellow pigments), chalcones (yellow-brown) and anthocyanidins (other colors). These subgroups each have a distinctive structure, depending upon what other functional groups are attached to the basic C_6-C_3-C_6 backbone. Classification of flavonoids is based on the ease of hydrolyzing tannins, and tends to be more of historical interest than practical use. Copolymers can be formed from flavonoids and nonflavonoids, making this classification system somewhat complicated, as previously noted. Some examples of specific flavonoids are quercetin, malvidin, catechin (also called flavan-3-ols), and leucoanthocyanidins (also called flavan-3,4-diols), but see Figures 5.8.6 and 5.8.7 in Section 5.8.6 for further details.

Procyanidins (polymers of catechins and cyanidins) condense in turn to form tannins, each containing between two and five procyanidin units with molecular masses of between 500 and 3000 amu. They are very stable and have a high protein binding property. Sugars bond to flavonoids and give rise to molecules such as malvidin-3,5-diglucoside, which is used as a marker for testing juice from *Vitis labrusca* species, where it is present. Diglycosides are found only in trace quantities in *Vitis vinifera* grapes.

Polymerization continues as the wine ages, so the concentration of larger molecules containing flavonoids and nonflavonoids gradually increases in wine, and the concentration of monomers and smaller polyphenols decreases. Polymerized flavonoids are known as condensed tannins, and as these are held by strong covalent bonds, they are relatively stable and will not easily be hydrolyzed in the conditions found in wine.

Pigment molecules such as *anthocyanins* can also be bonded to tannins to form colored copolymers. Anthocyanins are glycosides of anthocyanidins, that is, the free anthocyanidin (or aglycone) is bonded to glucose which increases the chemical stability and water solubility of the free form. Examples of anthocyanidins (with their main color in parentheses) include malvidin (purple), cyanidin (magenta), delphinidin (blue), petunidin (purple) and peonidin (magenta). Although abundant in young red wines, anthocyanins contribute little to the taste of wine. The most common anthocyanin in *Vitis vinifera* species is malvidin-3-glucoside.

The concentration and form of anthocyanins markedly influences the hue and color stability of the wine, both properties of which are directly affected by the hydroxylation pattern of the anthocyanidin B ring, and the charge on the central heterocycle, which in turn is influenced by pH. Blueness increases with the number of free hydroxyl groups, while redness increases with the degree of methylation.

Color in red wine comes primarily from the small proportion of anthocyanins that exists in the red colored flavylium (positively charged) state, which is favored by low pH. At pH above 4, anthocyanins will lend blue and purple hues to the wine, while at lower pH (3.5 and below), the red form predominates. Sulfur dioxide bleaches free anthocyanidins, and renders them colorless, but reaction is reversible, so if the sulfur dioxide concentration decreases, the equilibrium will shift, and sulfur dioxide will be released from the bound form, restoring the color. The sensitivity of anthocyanins to oxidation is influenced by the presence of vicinal *o*-diphenols (adjacent hydroxyl groups) on the B ring, which are particularly reactive to both enzymatic and nonenzymatic oxidation. Except for laccase, most polyphenoloxidases oxidize only *o*-diphenol sites. Because of the sensitivity of free anthocyanins to oxidative degradation, it is preferable that polymerization occur early during wine maturation.

In the fruit of red grape varieties, anthocyanins tend to exist in loose complexes held together by hydrophobic interactions between the anthocyanin moieties and hydrophilic attractions of the glucose components. Other flavonoid phenols, hydroxycinnamoyl esters and polyphenols are often involved in these complexes. Heating grapes or must (thermovinification) initially helps to release anthocyanins into solution, but can lead to a serious loss by precipitation of these compounds during wine maturation if insufficient tannins are extracted from the grapes to help stabilise the color in other pigment complexes.

Alcohol also destabilizes the hydrogen bonding between anthocyanin aggregates, so must fermented in contact with skins for only a few days may show a loss in color as fermentation continues. In addition to

anthocyanins, flavonoid tannins are extracted from the grape skins, stems and seeds (pomace or cap) later on in the fermentation. Grape stems are known to contain significant amounts of polyphenolic compounds, especially phenolic acids, flavonols and flavanonols. Tannins in the stems mainly consisted of (–)-epicatechin units along with smaller amounts of (+)-catechin, (–)- epicatechin gallate and (–)-epigallocatechin (Souquet *et al.,* 2000). These compounds begin to polymerize with free anthocyanins and anthocyanidins. Polymerization is an important factor in stabilizing wine color by protecting the anthocyanidin molecule from oxidation or other chemical modifications. When they are attached to one or more other phenolics, anthocyanidins are more resistant to decolorization by sulfur dioxide or high pH.

As tannins are released during fermentation, more stable pigment complexes are formed. Initially, the procyanidin molecules found in wine are small and highly soluble, and form complexes with anthocyanins. By the end of a normal red wine fermentation, around a quarter of the anthocyanins have polymerized with tannins, and this level may rise to nearly 50% within a year, depending on storage conditions. Polymerization, especially when associated with oxidation, increases the proportion of both the flavylium and quinoidal states, but will change the color of the molecules to yellow-brown. In combination with red color loss, the yellow-brown of the anthocyanin/tannin polymers results in the wine progressively taking on a brick red shade. After this, polymerization continues at a slower pace until all the phenols in the wine will be in polymeric form after several years. Higher degrees of polymerization will cause the wine to darken (which is not the same as intensifying) and eventually to go brown. Even very stable pigment complexes will become colloidal and form hazes and deposits, given enough time and the presence of oxygen.

Reduction and oxidation affect the degree of polymerization of the pigment molecules, as do temperature, pH and light (Section 2.9.5). Procyanidin/anthocyanin polymerization does occur in the absence of oxygen, but it is a relatively slow process, and it is generally accepted that most polymerization in wine is due to acetaldehyde induced copigmentation after oxidation. Acetaldehyde is produced from ethanol through the action of hydrogen peroxide released during the oxidation of phenols and, by reacting with anthocyanins, acetaldehyde forms a complex that facilitates bonding with catechin and procyanidins. This helps stabilize the color in red wine by limiting anthocyanin oxidation and decolorization by sulfur dioxide. In addition, it consumes acetaldehyde and restricts the development of a stale, oxidized odor. This type of polymerization helps to explain the color enhancing and stabilizing effect of exposing young red wines to small amounts of oxygen (about 40 mg O_2 per year) before bottling.

It is now accepted that phenols are involved in both the progression and limitation of oxidation through their own oxidation and reduction. This apparent anomaly results from the involvement of various phenols in the generation of peroxide and/or the reduction of oxygen to water. As a consequence, oxygen is consumed by phenols, and is therefore unavailable to oxidize other wine constituents. One of the initial reactions in must appears to involve the enzymatic oxidation of phenols, such as caftaric acid, to quinones. The latter may be reduced back to phenols through the coupled oxidation of procyanidins or ascorbic acid, which has the advantage of inducing the polymerization and early precipitation of readily oxidizable phenols before or during fermentation. In the presence of oxygen, *o*-diphenols are oxidized to *o*-quinones, and the oxygen reduced to hydrogen peroxide. Subsequently, the hydrogen peroxide oxidizes the predominant substrate in wine, ethanol, to acetaldehyde. Because quinones react with other phenols, they enhance phenol polymerization. By slow structural rearrangement, quinone/phenol dimers can generate new *o*-diphenol dimers, which may subsequently react with additional oxygen molecules, producing more peroxide, and ultimately even more complex polyphenols.

The antioxidant (oxygen assimilating) action of phenols is improved if oxygen penetration is slow or infrequent. Because of the efficient removal of oxygen, phenols can help maintain the low redox potential of a wine. This is considered beneficial in the development of an aged bouquet during long in bottle maturation. The low phenolic content of white wines makes them particularly susceptible to oxidative browning.

The two main effects of phenols, other than contributing color and contributing to the redox balance of the wine, are astringency and bitterness. Astringency (Section 4.7.2) is due mainly to tannins, and is caused by the hydroxyl (–OH) groups in tannins binding with the protein molecules in the saliva, causing them to lose the ability to lubricate the surfaces of the mouth. Bitterness is a taste (see Section 4.7.2) and is caused by the lower molecular weight phenolics, particularly from seeds. Most phenolics acids, such as caftaric acid, are slightly bitter, but occur at concentrations well below the detection thresholds in wine. Combinations of phenolic acids have lower thresholds than the individual components, and may contribute jointly to the bitterness and flavor of the wine phenolics, especially at higher alcohol concentrations. Higher sugar content tends to mask bitterness, but higher alcohol levels will enhance it. Bitterness is masked by astringency, so when tannins are removed bitterness may become more obvious. Hydrolyzable tannins, such as those extracted from wood cooperage, tend to be more astringent than condensed tannins.

Phenols are also known to exert antimicrobial action, which may be due to the binding of tannins with proteins, which limits enzyme activity by modifying enzyme solubility and structure. The antimicrobial activity of phenolics could also be the result of tannins binding membrane phospholipids and proteins, disrupting membrane function. Phenols also have strong chelating properties that may restrict access of sensitive microorganisms to essential minerals.

Under normal fermentation conditions, phenols do not inhibit the growth or metabolism of yeasts, but high levels may complicate the initiation of the second fermentation of sparkling wine. For this reason, red wines are seldom used in the production of sparkling wine, and the recent trends to make rosé and red sparkling wines are restricted to light styles.

The interaction between tannin and proteins, which leads to flocculation and precipitation, is often used in wine fining to remove excesses of either compound. Red wines are usually protein stable due to their tannin content, and if they contain excessive amounts of tannin (making them overly astringent), they can be treated with protein fining agents like gelatine or isinglass to strip out some of the tannin and make them more palatable. Unlike red wines, white wines (particularly certain cultivars like Sauvignon Blanc and Schönberger) may contain high levels of colloidal proteins, and enological tannins can be added to white wine to precipitate colloidal proteins and prevent haziness. Fining can also, to some degree, selectively remove phenolics by molecular weight and therefore reduce bitterness or astringency separately. Gelatine is commonly used to remove tannins and so reduce astringency in wine. Casein and polyvinylpolypyrrolidone (PVPP) react with the lower molecular phenolics and so may be used to reduce bitterness in wine. These principles are discussed in more detail in Section 2.9.4.

Harvest

The criteria for ripeness and harvest date will be determined by the style of wine which is being made. For a light red wine designed for early drinking, the sugar concentration in the berries will not need to be as high (19–21 °Brix or °Balling) as for a full bodied red designed to withstand ageing (23–26 °Brix or °Balling). Acidity for red grapes is generally lower than that of white grapes, as acidity enhances astringency, and is not as necessary for microbial stability in red wines due to the presence of phenols. For full bodied red wines, the winemaker may wait until the grapes are over-ripe and puckering in order to achieve the phenolic (color and tannin) levels required in the finished wine. Other factors that are taken into account when deciding on the time of picking would be the fruit condition, weather and the logistics of picking and processing the grapes.

Harvesting equipment and transport of grapes to the winery for red winemaking have the same issues as white wine (see Section 2.9.1). As there is no draining and pressing, and as red wine is 'protected' (to a degree) by its phenolic composition, there is less opportunity for oxidation or the growth of unwanted wild yeast and bacteria during the early stages of red winemaking. The grapes may be transferred straight after crushing to a

tank and the addition of an actively fermenting selected yeast culture added to scavenge any oxygen present and prevent growth of unwanted wild yeast and bacteria. Before fermentation, the effective incorporation of additives into the must is challenging, as the grape mass is not homogenous. Materials such as pectolytic enzymes and sulfur dioxide can be added to the receival bin so mixing takes place as the grapes are processed or liquid additions can be metered in to the crushed grape mass after destemming and crushing using an automated in line metering or dosing pump. If additions are made into the fermentation tank it is necessary to pump over the must to ensure adequate mixing.

Crushing and Destemming

Most red grapes, except those destined for carbonic maceration, are crushed to release juice before fermentation or pressing. The best crushers (usually those with rubber rollers) will break, but not excessively damage the skin, leaving the stems and seeds intact.

In most modern wineries, crushing and destemming are carried out in the same machine. Destemmers will usually incorporate crushing rollers, which ensure that the berries are broken, liberating the juice, before the crushed grape mass is transported (manually or with a crusher pump) to the fermentation tank. There are systems that rely solely on the pump from destemmer to tank to do the crushing. Modern destemmer/crushers remove stems before crushing, and thus the extraction of sap from stems, which may contribute colorless, bitter and astringent phenolic compounds to the wine, is avoided. If the stalks are green the extracted character may also be herbaceous and unpleasant. Despite all their negative characteristics, stem phenols are known to improve color stability, so a proportion of ripe stems is sometimes added back to the fermentation. It is also well recognized that stems contribute potassium ions to the maceration. The benefits of destemming also include increased tank capacity (around 30% better usage), removal of source of color and alcohol sapping (absorbing) stems and minimizing losses of acidity through precipitation as potassium bitartrate.

If bunches are crushed but not destemmed, or stems are added back to the crush, there will be better initial aeration within the must so that lag phase of fermentation is shortened and the fermentation will proceed more quickly. With stems present, heat is dissipated more evenly through the cap of skins and there is better juice extraction during pressing, although larger press capacity is needed. Stems can help protect wine color from oxidasic casse (because laccase is inhibited by stem phenols), and sometimes stems will be deliberately included in the fermentation in order to increase tannins. Despite overall increase in phenolics with stems present in a red wine fermentation, color diminishes as the stems absorb a certain amount from the fermenting juice. However, as less stable color compounds within the juice react to form more stable polymers with the stem tannins, color in these wines will decrease less on ageing. Up to a quarter of the tannin in a red wine fermentation may come from stems if they are present, and these tannins tend to be harsher and more astringent than skin tannins.

Aliphatic carbonyl compounds (like hexenals), identified as ‘green’ odorants in macerated stems, are higher in leaves and berries, but the methoxypyrazine (also herbaceous and vegetal) content of stems is generally higher than those of the berry or leaf samples (Hashizume and Samuta, 1997), so if they are included in the fermentation, these compounds may extract and contribute to the wine odor. This issue is gaining relevance, particularly in South Africa, where herbaceousness is seen as a problem in Merlot and Cabernet Sauvignon wines, is the presence of insects in the macerating grape mass. Harlequin ladybirds (*Harmonia axyridis*) are known to release a potent mixture of pyrazines as a defence mechanism during stress. Locusts (*Locustana pardalina*), common in vineyards in the Western Cape, may also release compounds that can detract from the quality of the wine if they are included accidentally in the harvest, but there has been little research conducted (probably unsurprisingly) to quantify the effects. Even the presence of ‘jacks’ (the broken off remains of the pedicel in the berry) can increase herbaceousness in the wine, which does not usually fit in with the red

berry/'warm' aromatic profile of a red wine. Ribereau-Gayon *et al*. (2006c) noted that, in general, when a fine quality wine is desired, destemming is indispensable.

As stated, the presence of air in the stems acts as a growth factor for yeast, and the fact that the stems do not ferment brings down the overall temperature of fermentation, which also helps in yeast survival. Stems modify wine composition as a result of their low sugar content, and additionally, they have the effect of lowering alcohol concentration by up to 0.5% due to absorption of alcohol from the fermented mass. Stems are rich in K^+, which may contribute to the precipitation of tartaric acid as less soluble potassium bitartrate as alcohol levels increase.

After crushing and destemming, in areas with warm temperatures during the harvesting season, the crushed grape mass is usually chilled from ambient to between 5 and 10 °C, especially if there is a waiting period before processing, or prefermentation cold maceration is to take place in order to extract color. Cooling helps to limit fermentation by wild yeast, and oxidation reactions.

Sulfur Dioxide Additions

Sulfur dioxide behaves differently in red juice and wine to how it behaves in white juice. In red juice, it becomes lightly bound to the anthocyanins causing them to lose color. When the wine is analyzed for free sulfur dioxide by the aspiration method, these weak bonds are usually broken by the addition of acid to the wine.

Sulfur dioxide is frequently added just after crushing and destemming at levels between 50 and 100 mg/l, depending on the state of the grapes. The main reason for using it is to counteract the increased oxidation associated with damaged fruit, which is also likely to have an increased population of wild yeast, mold and bacteria. For fruit in sound condition little sulfur dioxide is required, but many winemakers add a nominal amount, often 50 mg/l. It is known to inhibit wild yeast growth and favors dominance by the added yeast culture, which is usually more resistant to the effects of the compound. The amount used is kept to a minimum as it has an effect on color, and residual SO_2 after fermentation, although bound to other compounds, does inhibit malolactic fermentation. Normal residual levels of total sulfur dioxide are between 20 and 80 mg/l, depending on the initial level and the yeast strain used. The current trend for decreasing the use of sulfur dioxide may account for the increase in the amount of wines infected with *Brettanomyces* seen in various wine competitions, and the decreasing ability for wines, particularly white wines, to undergo ageing successfully.

The practice of cold maceration or cold soaking of the skins in the juice has been shown to give extraction of different color and flavor components. Sulfur dioxide will usually be added at levels up to 150 mg/l (depending on local legislative restrictions) to a prefermentation maceration. The grapes may be allowed to soak for up to four days either at ambient temperature or cooled (often through the addition of dry ice). There is no cap as there is no fermentation and the skins remain distributed throughout the juice. The high levels of SO_2 increase the permeability of the grape skins and allow the diffusion of the pigment and flavor into the liquid. The juice (which should be red from extracted pigment) becomes pink in color due to the bleaching effect of the sulfur dioxide. After maceration the juice may be separated and the skins pressed, and then the juice fermented to completion without the skins to give a light fruity red wine. The juice may also be fermented on the skins for a time to increase the color and flavor extraction. Sometimes desulfuring of the juice is carried out using hydrogen peroxide, but this is not legal in all winemaking areas (Morgan *et al*., 2006). If this is carried out, the color of the juice increases dramatically as the sulfur dioxide is removed and the bound pigments are released. Alternatively, prefermentation maceration may be carried out at less than 10 °C with a lower level of SO_2, such as 50 mg/l. In this case, less color will be extracted and fermentation will be carried out with the skins for a few days. During prefermentation maceration the extraction of phenolics with the juice gives a different result than when the phenolics are extracted with alcohol, as during fermentation. The color and

fruit flavors increase, but bitter or astringent tannins are extracted to a lesser degree and there is usually a marked increase in color in the juice within a day or two.

Acidity Adjustments

The pH in red wines varies considerably, but is usually between 3.3 and 3.8. Higher values are more common in hot climates, but winemakers recognise that useful advantages of lower pH include reduction of the incidence and effects of undesirable bacteria, and slower rates of oxidation. Improvement of the intensity, hue and stability of color are also benefits of lower pH, as well as improved flavor balance as high pH wines sometimes suffer from bitterness, possibly as a result of oxidation of certain polyphenols. During malolactic fermentation, pH is also an issue, as *Lactobacillus* or *Pediococcus* species will dominate at a higher pH, rather than the more beneficial *Oenococcus oeni*. The pH may rise by 0.2 units during alcoholic fermentation due to the extraction of cations, especially potassium, from the skins, and subsequent precipitation of the acid as potassium bitartrate, which is less soluble in the alcoholic solution. It will increase by an additional 0.2 units if malolactic fermentation takes place because of the metabolism of malic acid.

The acid addition rate to reduce the pH of the juice to the desired level should be determined by small-scale trials, but it is generally accepted that 1 g of tartaric acid per liter of must reduces the pH by 0.1 units (Morgan *et al*., 2006). If pH adjustment is required it should be done as soon as possible in order to gain the full benefit, and reduce risks associated with high pH. Additional discussion on must adjustments can be found in Section 2.9.1.

Carbonic Maceration

This is a process for making early drinking red table wines by preliminary storage of whole uncrushed grape bunches in an inert (oxygen free, anaerobic) atmosphere, usually in a tank pressurized with carbon dioxide gas (hence 'carbonic' maceration). The grape berry usually has an aerobic metabolism (sugar and oxygen metabolized to water and carbon dioxide), using respiration to produce its energy needs. Whole, uncrushed berries may develop anaerobic metabolism (fermentation) if deprived of oxygen, in order to meet their cellular energy needs. During this anaerobic metabolism, ethanol is produced as a by-product in the berry, along with volatile flavor compounds. As grape berry cells are not tolerant of alcohol, the level of production is only 1.5 to 2% (v:v) before cells being to atrophy and die. The internal cell structure of the berries becomes compromized, and alcohol, flavor compounds and anthocyanins ar able to diffuse through the berries. The weight of the berry mass in the tank will eventually crush the weakened grapes below them, and they will release their juice. A limited fermentation by wild yeasts may start in the juice at the bottom of the tank, generating more carbon dioxide. Carbonic maceration fermentation is allowed to continue for an extended period (usually between 7 and 12 days) after which the fermentor is emptied and the pomace pressed. Free run and press wine are blended together, and the wine finishes alcoholic fermentation without the skins present.

The main difference between wines made this way and those made through a 'normal' fermentation are that a much lighter style of wine is produced with lower levels of phenolic compounds, particularly tannins. The wines are therefore softer, and the intracellular fermentation also gives a unique 'carbonic maceration' aroma that has been described as 'tutti frutti,' with strong strawberry, maraschino cherry and plum notes. The technique is ideal for making early drinking 'primeur' wines, such as the Beaujolais Nouveau wines of the Gamay cultivar. Carbonic maceration is carried out on a large scale in the south of France, and these wines are amongst the first released each year in that country (usually November), with associated festivals and celebrations to mark the event.

The fermentation is then continued in a normal fashion. This method is also used as a way of increasing the complexity on Pinot Noir wines, sometimes by leaving a relatively high proportion of uncrushed grapes

in the ferment, which then undergo carbonic maceration, and release the juice when they are pressed, adding small amounts of sugar, and interesting fruit flavors to the wine.

Yeast Selection and Inoculation

The yeast used for fermentation has an influence on the resulting wine, as discussed in Section 2.9.1. Yeasts are selected based on similar criteria for those used in white wine (they must carry out the fermentation to completion and with a positive contribution to the flavor), but with the obvious proviso that the red wine strains are resistant to higher alcohol levels and concentrated phenols. Producers of dehydrated yeast will have recommendations for strains for different cultivars and red winemaking applications. As more research is being carried out on the specific attributes of wine yeast strains, interesting properties are emerging which go some way to explaining the products that are formed. Anchor yeast, for example recommends WE372 for most red wine fermentations, as it enhances the red berry characteristics of the grapes. It has also been recently implicated in forming fairly high levels of succinic acid during fermentation, so for low acid/ high pH musts, this yeast could be advantageous. Other Anchor yeasts include the 'NT' range (NT116, NT202 and NT 50), as well as Fermicru XL (for 'New World style Merlot') and Collection Cepage Cabernet, which is said to enhance blackcurrant, chocolate and tobacco in the aroma of this cultivar.

Lallemand also have a range of different strains for different red winemaking purposes, with yeast listed in the annual catalog under aroma attributes. BM4×4 and BM45 for example, are listed as 'plum' aroma producers, and are recommended for fermentation of Grenache, Shiraz and Cabernet Sauvignon. Product catalogs also contain a wealth of information on rehydration and nutrition of yeast and, usually, lactic acid bacteria and their requirements and characteristics. For commercial yeast strains used to make red fruit and country wines, see Table 2.11.4 in Section 2.11.3.

Red grape juice is a good growth medium for wild yeast. Unlike white must, red must is rarely cooled, has a relatively low SO_2, is partially aerated, rich in nutrients and has abundant solids which provide a physical substrate for yeast growth (Morgan *et al.*, 2006). Skins are present and wild yeast cells cannot be effectively reduced by clarification, so rates of inoculation are usually higher than those used in white winemaking even though it has not been proven that the resident population of ambient yeasts are dominated, or killed off, by an early inoculation of selected culture. The lyophilized cultured yeast is usually rehydrated and added to the filled tank according to the manufacturer's recommendations, and an appropriate dose containing 250×10^6 cell/ml ensures rapid onset of fermentation with the desired yeast strain.

In more traditional institutions (and more adventurous modern concerns), winemakers will conduct natural fermentations, using the population of yeast present on the skins, and from spores in the air and tanks in the winery. Investigations have shown that these spontaneous fermentations do contain some interesting variants like *Kloeckera, Candida, Metschnikowia* and *Pichia* in the early stages, but that these genera are usually killed off as the alcohol level approaches 5% v:v after which *Saccharomyces cerevisiae* will dominate. To conduct a wild fermentation, a winemaker will prepare a '*pied-de-cuve*' or starter yeast preparation (Morgan *et al.*, 2006). The method is as follows: A small proportion of healthy, ripe grapes (up to 5% of total vintage volume) is picked a few days early. They are then crushed and destemmed, and the crush is divided into two lots: A (around 10% by volume) and B (the other 90%). A is heated to around 30 °C to encourage fermentation, and the equivalent of about 30 mg/l sulfur dioxide is added to B in order to acclimatize the yeast to sulfur dioxide. When A is fermenting strongly B is added to A very slowly. The culture is then ready for use, and is placed at the bottom of the first few tanks to be filled (the 'pied' of the tank). Additional tanks are inoculated with fermenting musts from the first tank. Sometimes a proportion of juice is separated from the must immediately after crushing. This may be done to increase the skin:juice ratio for better color, or for the production of rosé or white wine from red grapes.

Nutrients are not usually added, as the inclusion of the skins and grape solids provides adequate nutrients to ensure complete fermentation. Diammonium phosphate (DAP) may be added to prevent or cure the production of H_2S during fermentation. This is more of a problem if wild yeasts are used for fermentation. In studies conducted with Shiraz must by Ugliano *et al.* (2009), it was found that addition of DAP to a final yeast assimilable nitrogen (YAN) level of 250 or 400 mg/l resulted in an increased formation of hydrogen sulfide by *S. cerevisiae* compared to nonsupplemented fermentations (100 mg/l YAN). Supplemented fermentations also showed prolonged formation of hydrogen sulfide into the later stage of fermentation, which increased this compound in the final wines. *S. bayanus* showed a different H_2S production profile, in which production was inversely correlated to initial YAN. For both yeasts, DAP supplementation yielded higher concentrations of organic volatile sulfur compounds in the finished wines, including sulfides, disulfides, mercaptans and mercaptoesters. The authors commented that these results raise questions concerning the widespread use of DAP in the management of low YAN fermentations with respect to the formation of reductive characters in wine.

Fermentation Conditions

During red winemaking, the aim is to extract the phenolic compounds (color and tannins), through maceration (mixing juice and skins) during and after the fermentation.

The conventional fermentation on skins is the most common method of red winemaking used in most premium wine producing countries of the world. It relies on the increasing concentration of alcohol making the skin cell membranes permeable to allow extraction. In order for the extraction of color and phenols to occur there must be intimate contact between the skins and the liquid.

During fermentation with skins, carbon dioxide production and the buoyancy of the skins combine to cause the skins to rise to the surface and form a 'cap' (sometimes called the *marc*). The cap may rise above the surface of the liquid and become dry if the skins are periodically immersed in the wine. If the skins are not in sufficient contact with the liquid, diffusion of the pigments cannot occur, and the wine will lack color and structure. 'Cap management' is therefore a crucial aspect of red winemaking, and a great deal of time and energy is devoted to its practice. Methods of cap management will be discussed in detail a little later in this chapter.

Open fermentors obviously expose the fermenting juice to the air, which stimulates yeast growth and provides a faster onset and higher rate of fermentation, leading to lower alcohol yields and more biomass. Extraction of anthocyanins and tannins is enhanced at higher temperatures, and it is not normally usual to cool red mash, unless a cold prefermentation maceration is required. Aeration can also be achieved in the must by pumping over (extraction of must from the lower racking valve and pumping it back over the floating cap of skins), or punching the cap down into the wine on a regular basis. These actions also help to extract color, which will be discussed in detail later in this section.

The availability of oxygen increases the possibility of bacteria spoilage in the cap, especially towards the end of fermentation when the generation of carbon dioxide by the yeast slows down. Pumping over and punching down will help to discourage bacterial spoilage due the presence of alcohol and anaerobic conditions in the juice.

A limited exposure to oxygen is important for promoting the condensation of tannins and anthocyanins to enhance stability of color in the final wine. The phenolic compounds and color intensity usually increase rapidly for the first five or six days, with maximum color being attained a little before the end of fermentation, when around three quarters of the sugar is utilized. After this, total phenolics continue to rise mainly due to tannins being extracted from the skins, but the color intensity decreases slowly due to polymerization, adsorption on solid particles and decolorization by alcohol. It is generally recognized that wines that retain the most color later in the bottle are fermented dry, or even left on the skins for up to 40 days, as in the case

of some of the great French examples. Wines pressed at the peak of color density during fermentation may precipitate color during the early months in the bottle, as the stability of color compounds is dependant on sufficient tannin being present to stabilize the anthocyanins by complexing with them. Addition of tannin, as enological tannin powder, or by stalk addition, to early pressed wines may also help to stabilize the extracted color, and the use of tannins is far more common than most winemakers will admit.

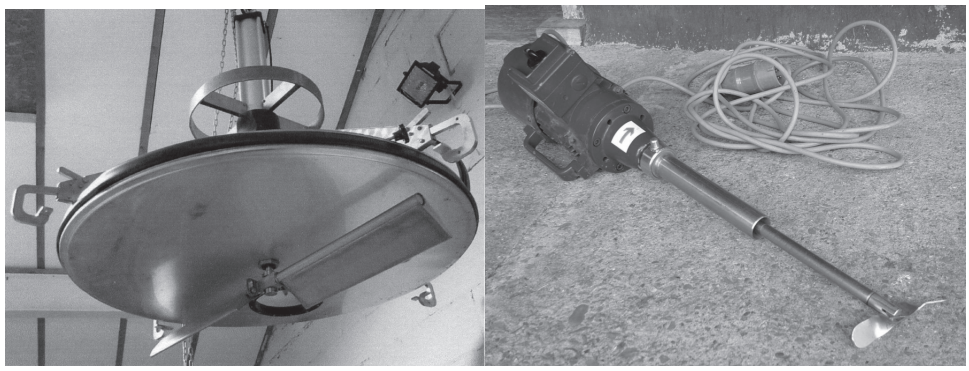
Temperature has a strong influence on the success of color extraction, and the start of fermentation (and its ultimate progress) depends to a large degree on initial temperature. Red ferments are carried out at significantly higher temperatures than for white, where the objective is to extract and preserve aromas and flavors. The dissolution of compounds occurs more quickly and completely at higher temperatures as heat degrades grape tissues, increases dissolution and accelerates maceration. However, at the temperatures necessitated by color and tannin extraction, the yeast may be less efficient at metabolizing, and a stuck fermentation may result. Even for the red fermentations a measure of temperature control is therefore desirable, if not essential. Tank temperature controls may thus be most useful in attaining the desired wine style, and jacketed tanks that can circulate water through their outer skins are popular. These tanks may also help if the grape crop is too cold for normal ferments to start, e.g. fermentation initiation needs to be at 20 °C to assist yeast in its growth phase, and the must can be warmed.

Early aerations at the beginning of fermentation will help to prevent stuck ferments. At this time, the yeasts are in their growth phase and oxygen is used to improve their growth and produce survival factors. The temperature chosen by the winemaker for a red wine fermentation will reflect the desired wine style. A lower temperature of fermentation (e.g. around 18–20 °C) usually leads to a wine in which the fruit aroma derived from the grapes is retained along with the estery fermentation bouquet. The wine may lack complexity and body, as lower levels of color and tannin are extracted at these temperatures, and wines will be suitable for early drinking. Wines that are fermented at more moderate temperatures, i.e. between 20 and 27 °C (the traditional fermentation temperature for red wines), will lose a proportion of the fruit aroma by volatilization, but yeast metabolism at these temperatures gives characteristic metabolic by-products, which contribute to traditional red wine bouquet. The wine may be complex, full bodied and able to age fairly well, but may lack fruit character when compared to a wine fermented at a low temperature. In standard winemaking, moderate temperatures favor primeur style wines; good color extraction is allied to fruity aromas and minimal tannin.

Higher temperatures (30 °C) extract the tannins required for premium wines capable of long ageing, but wines fermented at above 27 °C may also run the risk of having a cooked, caramel bouquet. They lack fruit aroma and are therefore not as complex as wines fermented at a lower temperature. More color and phenols are extracted at higher temperatures, but the amount of extra color is not significant and under normal conditions the detrimental effect of added astringency and/or bitterness may negate any benefits. High temperature fermentation may result in stuck ferments and a high volatile acidity and higher alcohol concentrations, as the yeast becomes stressed and produces by-products that are unpleasant. In lighter colored varieties, such as Pinot Noir grown in cool conditions, the argument for higher fermentation temperatures may have merit. It may be advantageous to let the temperature of the fermentation rise (to 28 °C, for example) for a short time before lowering it to 20–25 °C, in order to give some wine complexity, but at the same time allowing the retention of some fruit character.

Phenolic Extraction During Red Winemaking

As previously mentioned, the essential feature of red winemaking is the extraction of colored anthocyanin pigments and phenolics. The extraction of color, tannin and aroma from the grapes is a complex issue, and the decisions taken during fermentation of red wines affect the style and quality of the final wine. Other than the temperature of the fermentation, the degree of extraction of phenolics is dependent on many factors, including the cultivar, the ripeness of the berries (which in turn depends on canopy management in the vineyard and the



(a) (b)

climatic conditions of the vintage), the duration and type of maceration, the pH, sulfur dioxide concentrations and the alcohol content of the must. Other factors affecting extraction are the mechanical damage to the cell structure which occurs during crushing, the length of time the skins are in contact with the liquid, and, significantly, the treatment of the cap.

The skin cells are the only cells containing pigment in the big majority *Vitis vinifera* red varieties. There are certain *Vitis vinifera* species, the 'Teinturier' varieties, such as Alicante Bouschet, Grand Noir, Dunkelfelder and Roobernet (in South Africa), which have colored flesh as well as skins. These are often used to boost the color of juice from paler red varieties. Here, we are concerned with the problems of extraction of pigment from grape skins. The permeability of the cell membrane is bought about by the killing of the grape skin cells. The methods of bringing about the cell death include exposure to alcohol, heat, SO_2 or asphyxiation with carbon dioxide. The diffusion of the anthocyanins requires contact between the dead cells and the juice/wine. This is achieved in various ways, such as immersion of the skins in the liquid, by use of adjustable rotating blades attached to the lid of the vat (Figure 2.9.17), by 'pumping over' (Figure 2.9.18) or fermentation in a rotary fermenter. The proportion of the phenols extracted and the relative composition of the wine are very much affected by the processing techniques and equipment used. The conditions that encourage extraction of anthocyanins also encourage the extraction of other phenolics, but it is fairly well known that anthocyanins extract early on in the fermentation, and tannins later, being more alcohol soluble. The latter compounds may contribute high levels of astringency and/or bitterness to the wine. Extraction and diffusion are increased by the mechanical breakdown of cells during crushing, but excessive pulverizing of the berries may have a detrimental effect as the bitter and astringent tannins in the stalks and seeds may also be extracted. The presence of sulfur dioxide, as mentioned previously, assists in making cells more permeable, but bleaches color temporarily. Bisulfite also increases color extraction in wines made from partially rotten grapes due to the inactivation of oxidasic enzymes like laccase, which are then not able to cause browning of color compounds.

Phenolics extracted from red grape skins during primary fermentation may be extracted into fermenting must and stay there, but they may also be adsorbed on to yeast cell walls, precipitate with grape proteins or react with acetaldehyde produced during fermentation to give colorless or insoluble polyphenols. Colorless phenolics found in grape skins are mainly monomeric or dimeric flavonoids and these are released along with the anthocyanins. Grape seed polyphenols, mainly small to medium sized tannins, are not released until

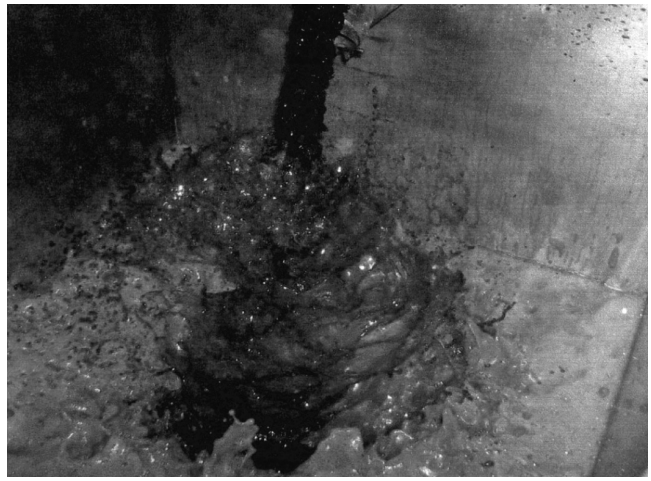

Figure 2.9.18 *'Pumping over' an active red wine fermentation.* Photograph by courtesy of P. Gerber

fermentation is well advanced and alcohol has had time to dissolve the protective layer of oils and pectic substances around the seeds. Seed tannins are more easily extracted if the seeds are damaged, and contribute to the total phenol of the wine. The ratio of nonpigment phenol to pigment is increased by fermenting on skins for a long period and allowing extended maceration after fermentation. The tannin astringency is softened during extended skin contact after fermentation due to polymerization of the phenolics.

Heat treatment (sometimes called thermovinification) of crushed red grapes, generally in the range 45–80 °C, damages cell membranes and thereby assists in extracting color from the skins without fermentation. The juice produced is densely colored, has low tannin and produces a soft early drinking wine. It is not generally practiced outside Europe where it is used to produce large amounts of beverage quality of wine. The crushed grapes are heated to a specific temperature in a variety of ways, for example by using a double mantle tank provided with stirrers, or through the use of a canal heat exchange apparatus. Depending on the winemaking objective, a number of treatments may be used. These include heating of must and skins to 45–65 °C for a few hours, heating of must and skins to 60–78 °C for an hour or so or heating of a portion of the must and skins to higher temperatures for a short time (flash heating methods). During the latter option, whole grapes may be heated in a pressure chamber for a very short time (10–20 s) with the aid of superheated steam, or crushed grapes are heated by means of a heat exchange unit to between 70 and 85 °C and then cooled. The effect of heat includes the denaturing of proteins and pectins, which makes the cell walls more permeable so that the juice and coloring matter can be released more easily. Heat treatment of grapes, which are infected with mold is effective in destroying the fungal oxidase enzymes which may otherwise cause problems later in winemaking.

The problems related to heat treatment of grapes are mainly connected to color losses as a result of oxidation of phenolics by enzymes and/or precipitation of oxidized pigment, difficulties experienced with clarification, high cation extraction giving high pH, undesirable changes in color and a loss of bouquet due to protracted exposure to heat. Energy/electricity expenditure obviously increases with the application of heat to large volumes of grapes, but appropriate heat recovery equipment may assist in keeping the cost of the energy required within reasonable limits. Thermovinification for a longer period to a more moderate temperature (e.g. to 45 °C) was developed as part of automated or large-scale winemaking and is used during continuous production to speed color extraction and enhance the efficiency of the winemaking process.

Phenolic Extraction During Fermentation

Red wines were traditionally fermented in open vats, and a great deal of red wines are still produced this way, with regular punching down or pumping over of the cap of grape skins. Nowadays, red wines are fermented in a wide variety of different tanks and vats, with varying degrees of oxygen exposure and automation in their making.

The manner in which the cap is managed will influence color extraction, the degree of maceration of skins, ease of temperature control, draining efficiency, marc disposal, duration of maceration and nett cost, and control of oxidation and spoilage. The physical separation of the skins from the juice and tendency for cap to become hot leads to stratification of temperature in the tank, and therefore temperature may be monitored at several points in the tank, particularly in closed systems. An important facet of conventional red wine fermentation is the surface area and depth of skins in the buoyant cap, which can influence the degree of juice/skin contact and the heat exchange properties of the cap. Shallow, wide tanks with a large surface area have a large area of contact between the juice and the cap, which encourages extraction and heat transfer, but also have a large surface exposed to oxidation. These tanks are costly and inefficient in their use of space. Tall, narrow tanks, which give rise to a much thicker/deeper cap of skins, are also able to dissipate heat more easily from the cap due to the relatively large tank wall surface area in contact with the skins.

Methods Used to Enhance and Control Phenolic Extraction During Red Winemaking

In order for most of the color and moderate quantities of tannin to be extracted efficiently from the cap of floating skins, it needs to be submerged and mixed effectively with the fermenting wine, which will leach the phenolics out of the skin cells. Other than extraction of phenols, keeping the skins wet with alcoholic solution also prevents overheating in the cap, the development of aerobic/acetic bacteria and oxidation of components by prolonged exposure to the air. The pressed juice from the cap will also have higher levels of color and phenolics, and higher level of cations, particularly potassium, which leads to lower acidity and higher pH. If contact is reduced, insufficient color and tannin will result, and the wine may be thin and lacking in flavor. The appearance of aerobic bacterial spoilage and high VA production in a neglected cap is common, especially at the end of fermentation.

The efficacy of cap management treatments in extracting phenolics and enhancing the color of the wine will depend on the way in which they are carried out. The best method of mixing cap and wine is to irrigate the cap evenly and gently until it is submerged, as physical damage to the skins leading to harsh flavors within the wine. If wine is fermented in open tanks, the most common methods of cap management for color extraction, prevention of oxidation and microbial control are pumping over and plunging (or punching down).

Plunging or punching down

This involves pushing the cap under the surface of the juice using a wooden (often handmade!) or stainless steel plunger to break the mass of skins up and mix it with the liquid. It is an effective method of achieving juice/skin contact, and can be carried out in a number of different ways depending on the size of the operation. Treading by foot is the traditional method used in shallow open tanks, during which the grapes are crushed as well as being submerged (see Section 2.10.7). Manual plunging is often used in smaller volume open fermentations, but is not practical for larger volumes. In small, open fermentations, punching down is carried out fairly frequently to ensure the cap does not dry out and become liable to oxidation and microbial spoilage. It is hard work, and in larger tanks, can even be dangerous due to the generation of carbon dioxide through the cap, which may be inhaled and cause dizziness.

Additionally, handheld electric rousers (Figure 2.9.17) or rotating tank lid blades, like those of the KTM red wine fermenting tank systems (Figure 2.9.17), can be used to break up the cap in a gentle manner. The former is particularly useful for small pilot or specialist red wine fermentations and can be used on nongrape wine pulp fermentations too (Section 2.11.3).

In larger fermentations, mixing is usually achieved using a variety of mechanical or semi-mechanical fermenters (see later in this section) which are able to handle much larger volumes and operate either automatically or as programed by the winemaker. Punching down may be combined with pumping over (see below) to may be carried out on its own.

Pumping over

Pumping over (see Figure 2.9.18) involves circulating the must from within the tank over the cap of skins by means of a pump, which provides a percolation effect where the juice passes through the skin bed. The weight of the must on top of the skins, and the physical action of the pressured liquid hitting the skins acts to break up the cake and wet it. Pumping over may be ineffective if the juice travels through fissures in the cap leaving much of the cap untouched, but if done well, it provides effective mixing and temperature equilibration between the cap and juice and increases the extraction of anthocyanins and other phenolics. It is common to add deflector plates or sprinklers to deflect the juice over a wider area so that channels do not develop. In smaller wineries a racking plate is sometimes added to the delivery tube to sprinkle juice back over the cap, while in large operations special rotating irrigators are used. Pumpover frequencies vary according to wine style, but satisfactory results may usually be obtained by pumping over twice a day for an hour each time. After pumping over the cap temperature rises quite rapidly. Pumping over is a popular method of color extraction in larger concerns as it can be carried out on large volume fermentations, and uses equipment that is already present in the winery, so no additional capital expenditure is required. It is also physically a lot easier to carry out than punching down. As the juice is aerated at the same time the tannins partially polymerize and become softer, making the wine less tannic and astringent. In France, in certain wineries, the aeration during pumping over is even greater as wine is run along open channels between tanks before being returned to the cap.

Heading down boards

As exposure of the cap to air increases the risks of oxidation, growth of acetic acid bacteria, and inefficient extraction of color, some producers choose the option of keeping their caps permanently submerged during fermentation. In order to keep the cap positioned below the surface of the liquid, ‘heading down boards’ will be fitted into the fermentation tank to hold the skins in place. Heading down boards may be employed in open or closed tanks, but their use is usually limited to smaller fermentation tanks which must be designed or adapted to cope with the large forces involved in static headed down ferments. As a result of the compression of the skins by the pressure from below, ‘hotspots’ or areas of increased temperature (differences of over 20 °C) may develop due to the heat produced by fermentation, lack of liquid flow and insulation. The juice inside the cap (also called the pomace) will ferment faster as a result of higher temperatures, and the possible presence of air trapped in the skins. At pressing, the free run juice may still contain significant amounts of sugar, while the pressed juice from the cap is dry. If there is sufficient circulation of juice through the submerged cap, color extraction is good, because of the constant contact between the juice and the skins. The juice in the tank may also be fermented cool so that the temperatures in the cap are controlled to a degree, and some tanks will be fitted with temperature monitors so that temperature can be checked regularly. Aerobic spoilage is minimized as the cap is kept below the fermenting liquid surface in an oxygen free environment. The cap is not continually punched and

disturbed as it is during punching down or automated mixing, and so extraction of harsh phenolics from pulverized skins will be decreased. Pumping over is mainly used for large volume fermentations without heading down boards, but it may also be used with heading down boards to provide circulation through the cap.

Rotary tanks are horizontal, cylindrical, closed fermentation tanks, which revolve around a central axis. They usually have a fixed device inside, which helps break up the cap and assists in emptying the fermentor after use.

Closed tanks have the same problems of color extraction and temperature control as open tanks, but are more versatile, and can be programed. With an enclosed top the wine is less susceptible to oxidation and bacterial spoilage as there is less exposure to air, but throughput is relatively slow and ease of operation depends on the design of the tank. The color extraction is moderate to good depending on the rotation regime used, but as oxygen is excluded, color stability may not be as good. Some enclosed tanks have good draining efficiency with a screen to separate the skins, excellent marc disposal with a sloping bottom, well placed opening and door, which makes them able to double as drainers (also for white winemaking), as well as storage tanks. Some rotary tanks are very easy to operate, the rotation may be programed and emptying is very simple. Although these tanks are expensive, they allow rapid fermentation and are versatile in their applications. As the cost and the availability of manual labor becoming more of an issue, this type of tank is becoming more common in larger operations.

Pressing the Fermenting Pulp

After fermentation, depending on the style of red wine being made, there may be a period of extended maceration on the skins. This will lead to a very robust style of wine, rich in phenolics and tannins, which lends itself to a long maturation period. In past times, maceration periods of up to 40 days were the norm in France, but nowadays, it is more usual to separate the skins and wine directly after fermentation is complete (i.e. as soon as the sugar has fermented out and the wine is dry). The fermented skins are prone to shredding and release of suspended solids, giving turbid, astringent and sometimes bitter wines. Marc (fermented skin) disposal is labor intensive, slow and messy, especially if it has to be heaved up over the wall of a concrete tank using spades. Sometimes the skins will be drained of free run wine, which will be kept separate, but more usually financial constraints will mean that free run and press fractions are added and matured together. The decision to blend press with free run wines is crucial and relates to wine style desired, as press fractions are often drier than the free run due to the increased fermentation rate within the cap, and the sweeter free run is perceived as fruitier, softer and more pleasant. For premium wines some press wine is usually desirable for body, and herbaceous notes can decrease over time, or get masked by other characters as the wine matures.

The main press types are as those for white wine grape juice extraction, namely vertical and horizontal hydraulic presses, pneumatic presses and continuous presses. Dependent on press type and levels of pressure, the resultant press wine may constitute up to 15% of the total finished wine made, as the chosen method of pressing will affect the composition of the 'press' fraction, with quality being enhanced if pressing is carried out in slow and regular pressure increments. Usually the first portion of the press wine ('first press') is more easily obtained and is better quality, and later press fractions ('second' and subsequent) are only obtained after breaking up the press cake one or more times, and reapplying pressure. Later press fractions are likely to be herbaceous and astringent, adding to the already higher tannins in the first press, and the overall make up of press wine is 'concentrated,' i.e. higher in phenolics, residual sugars and cations. However, press wine may also contribute fruit flavor and complexity, as the volumes involved are usually small in relation to the free run. Delaying the blending of free run and press fractions until after natural or fining induced clarification may improve wine quality overall.

Malolactic Fermentation

Malolactic fermentation (MLF) has been discussed in more detail in Chapter 2.3. During red wine production, MLF is often spontaneous and difficult to stop due to the presence of naturally occurring bacteria on the skins, warmer fermentation temperatures and lower sulfur levels used, which encourage the growth of indigenous lactic bacteria. Winemakers allow it to proceed or actively encourage it early in the life of a wine, rather than have it happen in an uncontrolled fashion in the bottle. After undergoing MLF, the wine is considered to have greater microbiological stability due to the loss of malic acid as a substrate for growth. The effect of the process on the wine varies, but it has a reputation as a destroyer of fruit character, red wine color and acid balance in low acid wines from warm areas. On the other hand, in high acid wines of colder regions, it may help to lower high acidity, make the wine more balanced and produce complexity of bouquet (see Section 2.3.16). Malolactic fermentation contributes to the character of traditional red wines (full bodied styles from cool areas), but it may not be appropriate in New World styles of fruity red wine. Conditions that encourage MLF include pH 3.3–3.5, low levels of sulfur dioxide and a temperature of 18 to 25 °C. The fermentation may start with difficulty below 15 °C. The fermentation will often occur spontaneously in wine left on lees for an extended period, but wine can also be inoculated with a commercial starter culture (usually *Oenococcus oeni*) at the same time as the yeast is added (coinoculation) or after fermentation. Lactic acid is not as intense in taste as malic acid, so the wine loses its hard, acidic character and becomes more supple, mellow and full bodied, and softer and rounder. The aroma becomes richer due to the contribution of malolactic fermentation by-products like diacetyl, glycerol, ethanol, succinic acid and mannitol. Color may decrease due to the effect of the increased pH on anthocyanins and other pigment compounds in solution. The malolactic fermentation may take from a few days to several weeks, or even months if the conditions are cold. Temperature is the most easily monitored and controlled of the factors influencing the fermentation, and winemakers are starting to realize the benefits of coinoculation, or adding bacteria during alcoholic fermentation, which takes advantage of the higher temperatures and good nutritional state of the must/wine. If the wine is run off to barrel (sometimes to finish fermenting), the malolactic fermentation will often happen spontaneously if it has not already occurred, encouraged by yeast autolysis products. In the event that malolactic fermentation is to be prevented (for example when making lighter fruity red styles for early drinking), the immediate addition of relatively high levels of sulfur dioxide at completion of the alcoholic fermentation is required. Early filtration of the wine and early bottling with sterile filtration are also good preventative measures.

Postfermentation operations like filtration and fining are less crucial during the making of red wine when compared with white wine due to the presence of phenols in red wines, which makes them naturally more stable and less prone to oxidative or microbial spoilage. Some winemakers will do an egg white (albumin) fining either in the tank, postfermentation or in the barrel, in order to remove unstable tannins and soften the wine, and gelatine can be used for the same purpose. Filtration will usually only be carried out on less robust styles, or styles that contain some residual sugar. Most well made red wine is perfectly capable of withstanding bottle ageing without being filtered, and some winemakers even claim that filtration damages the phenolic structure of the wine and removes color and flavor. Fining and filtration of wines are discussed in more detail in Section 2.9.4.

Barrel Maturation of Red Wines

Red wines are oak aged after fermentation (after skin separation), as opposed to white wines, which will be barrel fermented and then aged in the same oak, if this is the style that is required. Red wines may be aged for several years in barrels, but it is a time consuming, labor intensive and expensive process, which will increase the final price of the product significantly. The effects of barrel maturation on red wine should include a slow change in color progressing from cherry red to a deeper red to brick red, with an associated

softening of the grape (and oak) tannins as they polymerize and eventually precipitate as sediment. It is generally accepted that tannins become less aggressive and the color more stable as a result of a slow ingress of oxygen into the wine, but there is very little scientific evidence to demonstrate that atmospheric oxygen actually permeates through oakwood. The slow oxygen supplementation (around a few milliliters a month) is more likely to happen during topping up and through absorption from the porous cavities and cells of the wood itself. Certainly wine that has been stored in new barrels shows as much color density as wines that have had microoxygenation treatments. Wines in second and third fill barrels (i.e. older barrels in their second and third year of use), where the internal surfaces have been covered in a fine layer of tartrate and phenolic deposits, show reduced oxidative effects and impart less flavor than new barrels. Wines kept in small barrels have been shown to mature (soften and stabilise) more quickly than those kept in tanks or larger barrels due to the larger surface to volume ratio, and therefore a relatively higher exposure to oxygen. Even in wines that are high in alcohol, full bodied and tannic, with great ageing potential, it is prudent to avoid too much oxygen contact as the wine may become oxidized, prematurely aged and be susceptible to oxidative bacterial spoilage.

The stabilizing effects of barrel ageing also relate to the process of natural clarification (sedimentation) at cool cellar temperatures and the reactions of wine and oak tannins with colloidal proteins. The composition and balance of the wine are important determining factors for the time of oak maturation. A period of two years in a second or third fill barrel is quite normal for a full bodied style, with a lesser period of time for lighter bodied wines or wines in new barrels.

Maturing wine in oak barrels also imparts oak flavor, which adds to the complexity and quality of the product. In order to bestow the benefits of oak flavor on early release wines, producers may add products to the wine ranging from oak powder to full staves, for a prescribed period. However, many winemakers are not concerned with flavor extraction into the wine from the oak; indeed heavily oaked wines are no longer as popular as they used to be and overoaking is seen as a fault by many consumers.

The effects of oak treatment relate to the soluble flavor components inherent in the various types of oak. Geographical origin and species have a considerable influence on the aromatic and polyphenol content in oak. *Quercus robur* (French pedunculate oak) has a low odoriferous content, but a fairly high concentration of extractable ellagitannins. *Quercus sessilis* (French sessile oak) has a tighter grain and less extractable ellagitannins, but relatively high concentrations of lactones, volatile phenols, and phenolic aldehydes. *Quercus alba* (American white oak) has low concentrations of phenols, but is known to be highly aromatic, particularly in methyloctalactones (coconut aroma) and vanillin.

A discussion of the effects of oxygen, temperature, pH and time on anthocyanins and other wine components during wine ageing can be found in Section 2.9.5.

The implications of reactions during maturing of red wine for the winemaker are that the wine must be held under conditions appropriate for the structure and pH of the style of wine being made, i.e. wine that is released soon after harvest will undergo different winemaking procedures to one that is to be matured for years before drinking. If maturation reactions are unwanted, as during the production of a light or medium bodied fruity red style, the wine will not undergo barrel ageing, will be protected from oxygen andwill be held at low temperatures.

Bottle Ageing

A detailed discussion of the effects of bottle ageing on wine components can be found in Section 2.9.5. During bottle ageing the wine has virtually no exposure to air, and a measurement of redox potential in the bottle will usually show that it is at a minimum some months after bottling, particularly under screw cap. The length of time a wine will benefit from bottle ageing is dependant on the structure and flavor of the wine, as stated, and wines which were made to drink early do not benefit from bottle ageing. Because of their

ability to act as 'electron sinks' in wine, phenols help maintain the low redox potential in the bottle, and any residual oxygen in solution after bottling will be absorbed in reactions involving phenols rather than other wine components. This is considered beneficial in the development of an aged bouquet during long in bottle maturation, as the development of acetaldehyde and acetic acid will be limited. Many of the great French wines, due to their excellent phenolic concentrations, do not display their full potential until they have spent a decade or more in the bottle. The low phenolic content of white wines makes them particularly susceptible to oxidative browning, and less suitable for extended ageing.

Rosé Wine

Rosé wines are those of a color somewhere between red and white wines, and are usually chosen by consumers on the basis of their color and sugar content. There is no strict legal definition of a rosé wine, but they are usually made from red grapes with colorless juice by a process involving limited skin contact and phenolic extraction. It is illegal to make rosé wines by blending red and white wines (except for pink Champagnes), but blending red and white grapes or musts is permitted.

The qualities usually sought in a good quality rosé wine are an attractive appearance, freshness and crisp acidity, good fruit flavors and fresh, fruity or floral aromas. Although some rosé wines may have a higher alcoholic content than red wines from the same vintage, as less alcohol is absorbed by the marc, the trend nowadays is to make lighter styles in line with healthier lifestyle choices by consumers. A high alcohol concentration does not always suit the fresh, fruit driven style that winemakers aim for in a good rosé, and the wines are usually drunk within 24 h of purchase, so they are not made for prolonged ageing. In the past, rosé wines were not always produced with as much care as whites or reds and sometimes unripe or rotten grapes from mediocre varietals were used. This led to the perception that rosé wines were an inferior style, but this is changing with the emergence of examples of excellent quality, varietal rosés and a wide range of red and pink sparkling wines.

The color of rosé wines is a key quality indicator for the style and has a range of descriptions which are not legally defined, such as blush, '*pelure d'oignon'* (onion skin) or 'clairet.' Most consumers dislike orange tints, and see the wine as faulty, even if it tastes and smells excellent. The level of extraction of anthocyanins (red color) depends on the cultivar, the ripeness level of the grapes, the skin contact time and temperature, and the dose of sulfur dioxide used. As sulfur tends to bleach the anthocyanins, winemakers may try to avoid its use during the initial skin contact phase so as not to overextract and end up with too dark a color later on.

The two main methods of making rosés are direct pressing, and prefermentation skin contact. When direct pressing is used the vintage is crushed, often drained, then pressed immediately. Color is extracted with the first pressings, and later pressings are more yellow and higher in tannins and so are not usually blended into high quality rosés. The juice is then treated as a white juice, with SO_2 addition and prefermentation settling. As it is a fruit driven style, appropriate steps will be taken to avoid oxidation. Malolactic fermentation may or may not be carried out, depending on the type of wine desired and the acid level of the juice. The fermentation is carried out as for a fruity aromatic white style wine, using an aroma enhancing yeast and low temperatures.

After fermentation, a moderate dose of sulfur dioxide is added to preserve fruit aroma and flavor. Clarification and stabilization is as for white wines, but it is more easily carried out due to the tannin content. Sweet rosés are produced by ending the fermentation prematurely by racking, cooling, filtering and adding sulfur dioxide. The wine may also be fermented dry then sweet reserve, or rectified concentrated grape must added to the desired sugar level.

For short skin contact rosés, the berries are destemmed, crushed, sulfured and left to steep in their own must for up to 24 h, depending on the state of ripeness and health of the vintage. The level of color extraction must be monitored frequently, taking into account that there will be some color loss later. This is an aqueous maceration rather than an alcoholic one, so that color and fruit flavor are extracted rather than tannins. A

small dose of sulfur dioxide and low temperatures help protect against oxidation and the onset of a wild fermentation.

After skin contact the must is drained and the marc pressed. Often only the free run juice is used for rosé. Blending white and red grapes was the traditional way of producing Bordeaux claret, and although it is no longer carried out for this purpose, it is a permitted method of rosé production under the EU regulations. A proportion of the vintage is direct pressed (usually half), and the rest is crushed. The two portions are then mixed, and the vinification is carried out as in red wine production. Successful rosés have also been produced by short carbonic macerations. Wine may also be bled off a red wine ferment early in the fermentation to produce a robust rosé (the *Saignée* method), which increases the skin to juice ratio of the remaining red fermentation, resulting in a better color and higher tannin level in the red wine. It is important to do this early in the fermentation before too much tannin is extracted.

2.9.3 Sparkling Wines

A sparkling wine is one that contains a significant concentration of dissolved carbon dioxide, which is, of course, released when the bottle is opened. There is a wide range of such wines, which vary according to the grape varieties used, the method of production and the extent of carbonation. The latter can vary from very light ('pétillant') through medium ('crémant') to heavy. The emphasis here is on Champagne and its method of production ('Methode traditionelle'), but methods of producing other sparkling wines are discussed in the later paragraphs.

Champagne and Traditional Method Sparkling Wines

Champagne, arguably the most famous style of wine in the world, is named for the 35 000 ha region under vine in northern France from which the style originates. The region is one of the most northerly wine production areas in the world, with yearly heat summation for the growing season (total degree days) averaging only 75% of that for the Napa Valley in the United States (Zoecklein, 2002). Heat summation is defined here as (mean daily temp in °C – 10 °C) × number of days.

The conditions in Champagne and the methods of production have combined to produce a range of wines that are associated with luxury and celebrations, and which have been copied in many other wine regions with varying degrees of success. Over time, the name 'champagne,' to the chagrin of the c*hampenois*, became synonymous with any effervescent wine in which a second alcoholic fermentation was carried out in a bottle, no matter what sort of quality it showed. In order to protect the reputation of the true product and region, since 1994, it has no longer been possible to use the term 'champagne' unless it is the 'real thing.' Robinson (2006a) noted that at the time of publication of her *Oxford Companion to Wine*, champagne accounted for less than one bottle in 12 of total production of sparkling wine. The production of champagne is controlled by the CICV (Comité Interprofessional du Vin de Champagne) and wines which are produced in the approved way to required standards are awarded the AOC (Appellation d'Origine Controlée) (Ribereau-Gayon *et al.*, 2000). The term allowed to describe other sparkling wines in which the second fermentation has happened in the bottle is 'Méthode traditionelle' or the 'Traditional Method,' also known as 'Méthode champenoise' in the Champagne region. Each production region makes use of its own adaption of the term, for example, in South Africa, the traditional method is known as 'Méthode Cap Classique.'

Sparkling wines are those containing a significant level of carbon dioxide and are classified on the basis of production or the source of this CO_2. The excess CO_2 can be formed by the fermentation of the residual sugar from the primary fermentation (e.g. Asti Spumante). It may be formed during malolactic fermentation

e.g. Vinho Verde from northern Portugal and Frizzante from northern Italy, or by the fermentation of sugar added in the bottle after the primary fermentation, as in Champagne.

Carbon dioxide can also be added through carbonation in a large tank designed to withstand the pressures involved (as in the Charmat process – see Other Methods of Sparkling Wine Production) or as a result of carbon dioxide injection. By definition, sparkling wines are those that contain a visible excess of CO_2, with a minimum pressure of around 1 bar (0.392 g/100 ml) in bottle at 20 °C from the first or second fermentation (Amerine and Singleton, 1977). The carbon dioxide pressure in champagne and similar style sparkling wines is frequently far higher than this, about 4 atm ('mousseaux'), and wines with less than 2 atm are usually marketed as 'perlé' or semi-sparkling, under various names including 'crémant.' In addition to their major house wine, many producers in Champagne will make single vintage champagnes, typically around three or four a decade (Robinson, 2006a).

There are numerous rules attached to the production of Champagne, some of which have interesting relevance for other sparkling wine producers. For example, only three cultivars: Chardonnay, Pinot Noir and Pinot Meunier are permitted in the blend, and grapes should be hand harvested. Since 1992, the maximum permitted yield in Champagne is 65 hl/ha, with high vine densities and dates for picking fixed village by village (Robinson, 2006a).

Due to overproduction, and steady reduction in sales during the two preceding years, some champagne houses were calling for this to be reduced by half during the 2009 vintage (Fallowfield, 2009). However, balancing reductions in sales in Europe with increasing demands from emerging economies such as China, India and Russia is a challenge for the *champenois*. Expanding the volume produced by increasing the amount of land registered for production in the Champagne AOC would lower property values of vineyards throughout the region. The legal wranglings associated with attempts to change classifications in Bordeaux in recent years prove what an unpopular move this might be with present landowners and producers. Another possible solution might be to increase the output of existing vineyards. At higher crop loads, (for example 80 hl/ha), the grapes take far longer to achieve physiological maturity and are perfect for the neutral, slightly acidic style needed for a base wine, whereas at 50 hl/ha, the ripe fruit flavors become too concentrated to make good champagne (Fallowfield, 2009).

Alcohol concentrations in sparkling base wine are usually lower than in table wine, but in quality sparkling wine (EU legislation) 10% v:v is a minimum (Morgan *et al.,* 2006). Information on the label must include the vintage year, cultivar, reference to geographical area of production and whether the product was fermented in the bottle in which it is being sold. Preparation of base wine must be in accordance with local regulations for still wine. In Europe, the *cuvée* (particular blend to be used for sparkling wine) can be acidified by up to 1.5 g/l tartaric, and there is no limit on deacidification. Alcohol level in the base wine should be a minimum 8.5% v:v (Morgan *et al.,* 2006). Second fermentation can take place only in the bottle or in a closed (pressurized) tank. The wines must be aged in the producing winery for a certain minimum period starting from the onset of secondary fermentation ('prise de mousse') before release: 15 months for nonvintage, three years for vintage champagne. Liger-Belair (2004) noted that the best and most expensive champagnes will be aged for five years or more before being released.

Terms like 'crémant' and 'petillant' have been developed to describe the various sensations of the mousse (froth, foam or sparkle) in the mouth. Crémants have a slightly greater effervescence than petillants, but less than mousseaux, which should have an excess carbon dioxide pressure of around 3 atm at 20 °C. The term crémant was originally used in France to define those wines with a carbon dioxide pressure lower than 2.5 bar, but since 1992, has become the generic term for any sparkling wine made in France in an AOC outside Champagne, for example: crémant d'Alsace, crémant de Bourgogne, etc. The word is also associated with the sensation produced by lower carbon dioxide pressure on the palate. Petillants are generally made in two regions (the Loire valley and Bugey-Cerdon) and have a lower alcohol concentration than other sparkling wines in France, as well as carbon dioxide pressures that are lower (between 1.5 and 2 atm).

The size and duration of bubbles in a sparkling wine can also suggest which process was used in its production. The quality (persistence and fullness) of the mousse is tied to conditions during the second fermentation, concentration of nitrogenous compounds in the cuvee, and yeast autolysis products, such as proteins and high weight polysaccharides in solution. Champagne and sparkling wine made according the *Méthode Traditionelle* process has a small 'bead' (bubble size), which rises vertically through the liquid in a steady continuous stream ('bubble train'), rising to the surface and radiating out to the edge of the glass to form the 'collar'. Sparkling wines made by the transfer process, the Charmat method, or by carbon dioxide impregnation will have coarser (large) bead, which is less persistent. An older sparkling wine made in the traditional way may lose a lot of its gas through cork drying or shrinkage, and will present a much slower bubble train with a very fine bead. Older champagnes may be served very cold in chilled glasses to preserve the bubbles as long as possible.

Interesting studies on the nucleation, formation and distribution of bubbles using high speed video photography has been carried out at the University of Reims Champagne-Ardenne. According to Liger-Belair (2004), bubble nucleation sites are not scratches in the glass, as popularly believed, but particles such as cylindrical cellulose fibers, which contain small gas pockets and adhere to the glass or float in solution. The gas pockets act as 'bubble guns' or nucleation points for bubble formation. Liger-Belair observed that in a completely clean container, carbon dioxide escapes only through the surface of the liquid and the wine appears still. Very few bubbles nucleate in a bottle of freshly opened sparkling wine because, over several years of storage, most of the as pockets within the liquid have become wet, and therefore no longer function as nucleation sites. Yeast autolysis products affect bubble stability and flavor. Proteins act as surfactants and lipids reduce surface tension (Jackson, 2000c). Gauging optimum levels of protein in the wine is a matter of experience. It has been determined that many of the premium champagnes have a higher protein level than other sparkling wines, probably as a result of time spent sur lie as well as possible cuvée nitrogen constituents. It is also recognized that champagne with a high proportion of Chardonnay in their composition have better foaming properties than those with high levels of Pinot Noir or Pinot Meunier (Zoecklein, 2002). Research at the University of Reims has observed a link between infection of the grapes with *Botrytis cinerea*, and the foaming properties in champagne, with a 40% infection of grapes reducing 'foamability' by as much as 70% (Jeandet, 2006; Cilindre *et al.*, 2007).

The release of carbon dioxide significantly magnifies the odorous components of the wine. An overview of sparkling wine production using the traditional method is shown in Figure 2.9.19.

Cultivars for Champagne Production

As previously noted, grapes used in the Champagne region are almost exclusively Pinot Noir, Chardonnay and Pinot Meunier (Ribereau-Gayon *et al*., 2000), with yields. Different styles require different cultivars, for example, Blanc de blanc is made from white grapes (usually pure Chardonnay), and blanc de noir is usually made from Pinot Noir. Rosé champagne may be made by allowing some skin contact prior to pressing, and then 'bleeding off' (saignée) free run juice from the crushed red grapes, or by adding a small amount of red wine to the white base wine later (Robinson, 2006a). Champagne is the only Appellation d'Origine Contrôlée where such a practice is authorized. Each of the cultivars adds an essential component to a blend, and the origin of grapes will affect the quality and style of the final product. This is usually as much of a secret as the carefully guarded information concerning the blends and additions for each house. Chardonnay is reputed to give finesse, freshness, floral notes and ageing potential to the cuvée. Originally planted on the east facing slopes of the Côtes des Blancs, a region south of Epernay, Chardonnay is now far more widely planted. Robinson (2006a) suggests that Chardonnay imparts austerity and elegance to the young wine, but is long lived, and gives good fruitiness in older champagne. Zoecklein (2002) noted that great care should be taken to avoid using mature (ripe) Chardonnay grapes for premium sparkling wine production in warmer climates, as

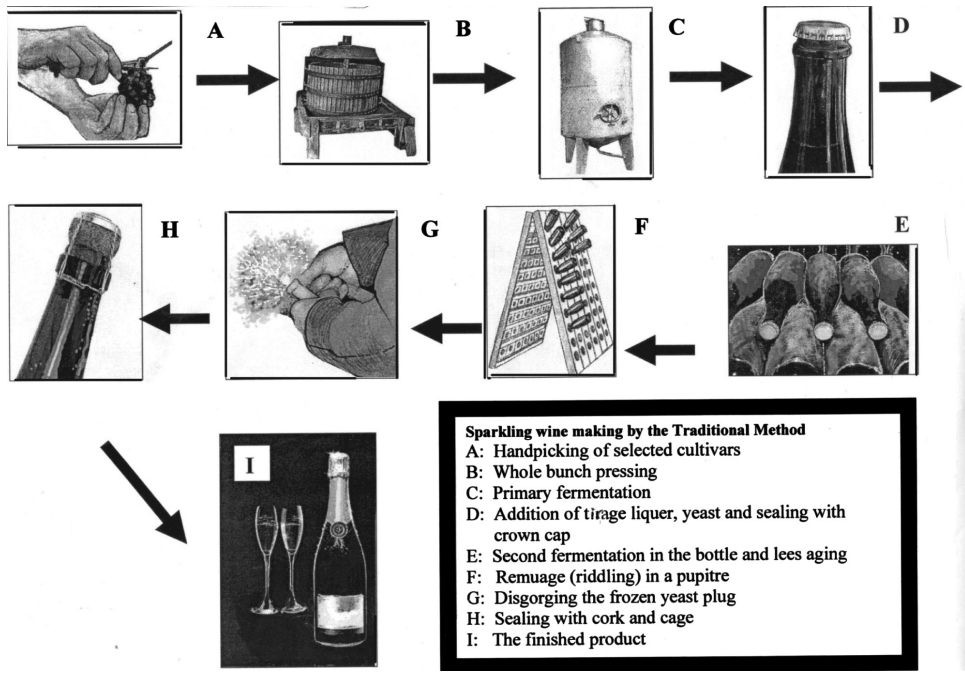

Figure 2.9.19 *An overview of sparkling wine production by the traditional method*

these can produce an aggressively varietal character. Pinot Noir adds body, complexity and structure, and is planted in the Montagne de Reims mainly on north facing slopes and in the Aube in the south. Pinot Meunier is found mainly in the Vallée de la Marne and is generally neutral, but also has spiciness and roundness (Jackson, 2000). The latter cultivar ages more quickly than Chardonnay, but helps to add fullness, body and length to the finish (Zoecklein, 2002). It usually has a lower titratable acidity than Chardonnay, and is harvested earlier in the season. Other varietals that may be suitable for base wine production include Chenin de la Loire, Ugni Blanc and Mauzax de Limoux, as long as the grapes are at the right acidity level (Ribereau-Gayon *et al.*, 2000) Outside of Champagne, AOC regulations will determine proportions and blending of cultivars within each appellation.

Harvest Procedures

Grapes for sparkling wine production are picked earlier in the season than those destined for still wine (Jackson, 2000c) in order to avoid the stronger varietal aroma associated with ripe fruit. Robinson (2006a) noted that traditionally champagne was made from grapes from a number of different vineyards within the appellation (major firms can use the produce of between 50 and 200 communes in their blend), but nowadays a fair number of producers make wines from a single vineyard.

In the finished product, the fermentation and autolysis bouquet are regarded as primary indicators of quality rather than fruit character, and therefore the Comité Interprofessionnel du vin de Champagne (CIVC) encourages harvesting when sugar to acid ratios are between 15 and 20. This means grapes reach optimum maturity for base wine production at only 14.5 to 18 °Brix, for a target alcohol from the first fermentation of between 10.5 and 11.5% v:v. Titratable acidity is high, around 12 to 18 g/l, with malic acid making up as much

as 50–65% of the total acid content (Zoecklein, 2002), which has implications for the microbial stability of the base wine. Harvesting is done by hand into small trays, selecting out rotten grapes. Selecting out rotten bunches and berries by hand, although very labor intensive and expensive, is done by some houses in order to avoid the physicochemical effects of fungal metabolites on foaming properties and yeast activity in the wine. Low levels of sulfur dioxide are used in base wine production. Low flavonoid phenol content is desirable and so grapes are harvested cool to avoid excessive phenolic extraction, which may introduce astringency, color and bitterness to the base wine. High temperatures may also encourage microbial or oxidative spoilage of fruit which reduce ageing potential, and form off flavors such as aldehydes and volatile acidity.

Pressing the Grapes

Whole bunch pressing in traditional basket presses (sometimes known as Coquard presses after the original manufacturer) is usually carried out for the production of champagne or other premium sparkling wine (Robinson, 2006a). Membrane and tank presses can also be used. The advantages of the more modern presses are that they are more efficient, fairly gentle and give protection against oxidation. The traditional press held 4000 kg of grapes, a quantity that became known as '*marc*,' and a standard unit of measurement in Champagne. Nowadays, the word is more usually associated with the fermentation cap or press cake from red wine macerations.

Skin contact is usually minimized in order to avoid extraction of color, tannin and fruit character into the base wine. Pressing of whole bunches of grapes is carried out, a slow process which involves a high level of manual labor, and exposes the juice to oxygen if carried out in traditional vertical basket presses. No destemming occurs before pressing, as stems give a better pressing efficiency at lower pressures, forming channels within the press cake along which the juice can escape. By AOC law, 4000 kg batch of grapes, pressed at around 1 bar, are only allowed to yield around 2600 l of juice if the juice is to be used in champagne production. The first 512 l/tonne (2050 l in total) constitute the *cuvée* portion. This is the least fruity, highest in acidity and sweetest of the fractions and is usually reserved for the *vin de cuvée* (top quality base wine of a specific batch) (Robinson, 2006a). The next 410 l are pressed at less than 1.2 bar and are known as the 'premiere taille' (51 l/tonne – fruitier, less fresh and less elegant than the cuvée), and 206 l of 'deuxieme taille', extracted by pressing up to 1.4 bar, which may be discarded (Jeandet, 2006). Later press fractions are not allowed to be included in the cuvée due to high pH, excess color, high total phenolic content, excessive varietal character, harshness and higher insoluble solids. The different fractions are usually kept separate until assemblage (blending).

Combining press fractions can affect such things as the fullness and flavor of the *cuvée*, as press fractions can be separated on the basis of their titratable acidities (later fractions have lower acidity). For red varieties such as Pinot Noir and Pinot Meunier, care is taken to avoid excessive color extraction and astringency by pressing fruit cold and separating pressing fractions. Short, cold skin contact periods of crushed grapes or carbonic maceration may be used to enhance color without adding to astringency and tannins. In some cases the juice is deliberately exposed to oxygen in order to remove color through polymerization and subsequent precipitation.

Additions

Sulfur dioxide is never added directly into the press in order to avoid extraction of phenols from the skins. Jackson (2000c) noted that an addition of 40 to 60 mg/l sulfur dioxide added to juice, is normal in Champagne, but the dose will depend on the condition and levels of rot in the grapes. Up to 80 mg/l may be added to press fractions if there is grey rot present.

A standard addition of 5–10 g/hl of diammonium phosphate is widely used for nitrogen adjustment, and between 10 and 25 g/hl of bentonite can be added during the primary fermentation of the cuvee (Zoecklein, 2002). Additions of up to 150 g/hl of a bentonite/casein mixture are often added to the '*tailles*' when a significant amount (greater than 15% of the berries) of rot is present, and the first taille may also receive 60–70 mg/l SO_2. Press juice fractions with turbidities of between 200 and 400 NTU (Nephelometric Turbidity Units) (Section 4.6.3) may be treated with pectolytic enzymes and are usually cold settled for 18 to 24 h at cold temperatures (10 °C) or centrifuged to reach a solids level of between 0.5 and 2.5% prior to fermentation. Settling decreases levels of proteins, pectins, and cations including iron (Jeandet, 2006).

The base wine should be relatively low in free sulfur dioxide content or the yeast may struggle during the second fermentation, and malolactic fermentation may not start.

Yeast (for First Fermentation)

The yeast employed maybe the same for the primary and secondary fermentation, frequently strains of S*accharomyces bayanus* (Jackson, 2000c), as this has a slightly better tolerance than *S. cerevisiae*. Sparkling wine yeasts are selected for their ability, among other things, to produce esters, but care needs to be taken if seeking a traditional Champagne style to avoid overproduction of fruity, floral characters. The same yeast can be used for both primary and secondary fermentations, but, as noted by Zoecklein (2002), care is taken to avoid the selection of a strain that produces high levels of esters in order to avoid a product that is too fruity and floral. A producer may choose to use an appropriate dried commercial starter culture developed by the (CIVC), or a strain selected from the yeast collections that large Champagne houses maintain. Winemakers will usually do some in house testing to determine the merits and deficiencies of the strains within their own blends. Traditionally the *champenois* used small wooden barrels to ferment all or part of the cuvée, which added structure ('carpentry') to the wine, but nowadays the primary fermentation is frequently carried out in stainless steel tanks with a capacity of 50–1200 hl (Robinson, 2006a). Krug and Bollinger ferment the entire vintage slowly at low temperature in oak vats, which is consistent with their full flavored, mature style (Jeandet, 2006). For product consistency, and to achieve the house style, a producer may choose to add a proportion of the previous year's cuvée (reserve wine) to the fermenting juice. Reserve wine can also be added during *assemblage* or blending and may be a component of the *dosage*, based upon production and vintage dating considerations. Some producers choose to ferment their *cuvées* warm to reduce the floral intensity, thus making a more austere product. Higher fermentation temperatures are desirable if malolactic fermentation is sought, and 25–30 °C is not uncommon.

According to Ribéreau-Gayon and coworkers (2000) higher crop yields and pHs after the 1950s meant that during the 1960s a number of wine losses occurred in Champagne as a result of bacterial contamination during the bottle fermentation. Wines became 'ropy,' riddling was difficult, there were numerous stuck fermentations and high volatile acidities in the wine. With the exception of Lanson and a number of other Champagne houses, most producers now prefer to 'play it safe,' and induce a malolactic fermentation before the second fermentation. This helps to reduce varietal character and ensures microbial stability. Some c*hampenois* use malolactic fermentation of all or part of the *cuvée* to improve the finish and flavor through raising the pH and increasing complexity. Producers will keep their sulfur dioxide levels low in their base wine in order to encourage the malolactic fermentation and thereby prevent it happening in the bottle, as bacteria are almost impossible to remove by riddling. If malolactic fermentation is desired, it will be induced with an inoculation of malolactic bacteria (*Oenococcus oeni*) at a concentration of around 10^7 cells/ml. Because of the difficulty of initiating the malolactic fermentation, especially in highly acidic wines such as Champagne wines, studies have focused on the nutritional requirements (namely amino acids) and the metabolism of lactic acid bacteria under wine conditions. In particular, studies performed at the University

of Reims Champagne-Ardennes demonstrated that aspartic acid inhibits the growth of lactic acid bacteria by modifying the transport of glutamic acid (an amino acid essential for bacterial growth) into the bacterial cell (Jeandet, 2006).

Protein based fining agents such as isinglass and gelatin can be used to lower the phenolic content of the base wines. A mixture of bentonite and casein may be added to the *taille* fractions to assist in precipitating tannins. The base wine will be racked off the lees after the fermentation. The clarified wine after malolactic fermentation is sometimes referred to as '*vin clair*.'

Gauging optimum *cuvée* protein is a matter of experience, and producers of sparkling wine must manage their protein levels so that there is minimal protein precipitation in the bottle, but enough retained to ensure good bubble stability. While sugar diminishes CO_2 solubility and may therefore decrease bubble stability, free amino acids and proteins can help to retain dissolved carbon dioxide in the medium (Descoins *et al*., 2006). Those using bentonite as a riddling aid should avoid further fining of the base wine, as additional protein will be removed during disgorging.

Assemblage

Blending or 'assemblage' is the blending of wines from different vineyards, vintages or cultivars after the first racking and before the second fermentation, and is one of the most crucial steps in the making of champagne. A number of important decisions are made during the assemblage, for example, whether the cuvee is vintage or not, and if it is of sufficient quality for second fermentation in the bottle, as the carbon dioxide produced during the process will enhance any flaws in the aroma. Nonvintage champagnes rely completely on product consistency and usually require vin de reserve (cuvees from previous years) to be added to the blend in order to minimize any distinctive characteristics. Rosé wines can be obtained by mixing a white wine with a red wine (Côteaux champenois) (e.g. in the case of the Dom Pérignon Rosé; Vintage of Veuve Clicquot) in a proportion of 10 to 15% red wine (Jeandet, 2006). Rosés de Saignée can be obtained by a short period of maceration of the fermenting grape juice with the grape skins, where anthocyanins (the red pigments of grapes) are extracted (e.g. in the case of the Champagne Rosé from Krug). The brut nonvintage and the demi-sec champagnes are usually a blend of wines from several years, from different grape varieties and a number of crus. The brut style, especially, is a product that is very typical of the wine producer. Vintage champagnes are produced exclusively from the wines of a single harvest.

As stated previously, producers may use a number of different wines from different vineyards (as many as 200 communes may be included in the blend) within an appellation, as well as between 10 and 50% of reserve wine during *assemblage* (Robinson, 2006a). According to one source, Champagne is the only AOC where red and white wines may be blended. The goal is to produce a *cuvée* that is clean and neutral, but has enough structure to support the additional alcohol and bouquet from the second fermentation. *Assemblage* is also carried out to increase the complexity, balance and subtlety of the base wine, as it is rare for a single wine from a single vintage to be perfectly composed for premium sparkling wine production. The selection of the base wine components also needs to ensure the production of a sparkling wine of consistent flavor and style (the house brand) in sufficient quantity to be economically viable, so another important consideration is the amount of press wine to include in the *cuvée.* The inclusion of later press fractions makes economic sense, but may have implications for the quality of the final wine. The winemaker must blend a wine that produces a reliable bouquet during second fermentation, that withstands ageing well, and that may only be consumed (even decades) in the future. Some producers prepare *cuvée* blends prior to stabilization, because as the base wine is blended with other wines of different vintages, cultivars and origins, potassium bitartrate and protein precipitation can occur. Cellar treatments such as fining and filtration can also affect potassium bitartrate stability, and it is normal for protein and bitartrate stability be evaluated just prior to bottling.

Preparation for the Bottle Fermentation

Prior to the introduction of the yeast for the second fermentation, many producers cold stabilize their base wine at –4 °C in either a static contact process, or a continuous process, to precipitate potassium bitartrate. The wines are then filtered with diatomaceous earth in order to remove residual crystals and other particles that may cause gushing during degorgement, undesirable microorganisms and to present a clean 'canvas' to the yeast. If malolactic fermentation has been completed, it is sufficient to carry out a pad or diatomaceous earth filtration, but if not, a membrane filtration will is necessary. Some producers, for example, Krug, do not filter, but clarify with isinglass (Zoecklein, 2002). Barrel-fermented wines are generally not filtered, as they are naturally clarified by the combination of oak tannins and yeast mannoproteins during and after fermentation. Work has been done to research whether the very expensive treatment of wines with artificial cooling could be advantageously replaced by the addition of inhibitors of the potassium hydrogen tartrate (KHT) crystallization process such as metatartaric acid or carboxymethylcellulose (CMC). Such inhibitors increase the width of the supersaturation field of KHT in the wine, thus delaying tartrate salt precipitation in the bottle (Jeandet, 2006). Inhibitors for tartrate crystallization have not yet been authorized for winemaking. The later compound is an unstable ester that hydrolyzes with time and increasing storage temperature, and may actually pose more of a problem to the stability of the wine in the long term.

Tirage

At the bottling line, a mixture of selected, rehydrated wine yeast, water, dissolved sugar, sulfur dioxide, riddling aids and nutrients known as the 'liqueur de triage' is added to each bottle in order to produce the second fermentation.

The temperature of the second fermentation is said to affect the quality of the mousse, as well as yeast autolysis, and is kept fairly low (between 10 and 15 °C). In many of the older production houses, this is not monitored, but the second fermentation takes place in *caves* (underground cellars) where it is likely the temperature remains a constant 12 °C. Wine will be aerated slightly prior to the second fermentation to encourage growth of the yeast (Amerine and Singleton, 1977).

Yeast (for the tirage)

The second fermentation places extraordinary physical demands on yeast cells. A species needs to be tolerant of low temperatures, tolerant of high pressure and should possess the ability to ferment to dryness without producing foam, in the presence of high concentrations of alcohol. The yeast should not produce any off odors or sulfur dioxide, and should also die and flocculate after fermentation. Many firms use their own 'in house' yeast strains, and new producers will experiment to assess the performance of different yeasts under their own conditions. The yeast should also impart a positive fermentation and autolysis character to the wine. 'Epernay' is a good example of a highly flocculent yeast with good riddling ability, but it has an assertive character and is therefore usually not employed to carry out both the primary and secondary fermentation. 'Pasteur Champagne' (UCD 595) is also a popular yeast for secondary fermentation and is available in dehydrated form (Zoecklein, 2002), as are DV10, 10 C and Levuline CHP strains (Jeandet, 2006). Some sparkling wine producers use cultures containing a mix of yeast strains for the secondary fermentation believing that such a procedure adds complexity. Generally, 2 to 3% by volume of active starter culture is used (Amerine and Singleton, 1977), or around 15 g/hl dry yeast, which is then rehydrated giving a cell concentration of around 10^6/ml.

One of the important characteristics of yeast used for the second fermentation is the ability to form aggregates, which can be easily dislodged during riddling and removed by disgorging. There is significant

variation in the agglutination ability of yeast. Yokotsuka *et al*. (1997) produced bottle-fermented sparkling wines using *S. cerevisiae* immobilized within a double layer of calcium alginate beads and strands. Beads contained greater numbers of immobilized yeast cells, and were also considered by the authors to be more useful for commercial sparkling wine production as they were more easily removed from the wine than the strands during disgorging. A study by the same workers compared wines made with the immobilized yeast and traditional freely suspended yeast, which showed that there were no chemical differences between the wines. The authors also investigated factors affecting leakage of viable cells from the gel into the wine during fermentation and ageing. Fewer free yeast cells appeared in the wines with higher initial numbers of immobilized cells and those wines with higher ethanol concentrations.

Riddling aids in the tirage

In the traditional bottle fermentation of sparkling wines, the riddling (remuage) and disgorging (dégorgement) process are time consuming, labor intensive and can be accompanied by significant loss of wine, thus adding considerably to the costs of production. Most modern producers add riddling aids (usually fining agents) before the second fermentation to assist in sedimenting the yeast into a compact, granular deposit that is relatively easy to shake down the bottleneck prior to removal. The development of smoother glass in bottles also helps to make the process easier than previously. Riddling aids include sodium and calcium bentonite, commercial bentonite preparations like Clarifying Agent C, Adjuvant H, isinglass (e.g. Colvite) tannin (e.g. Botane), gelatine and diatomaceous earth (Zoecklein, 2002), with some producers using alginates (proteins derived from wheat, pea or alfalfa). The choice of riddling aids is based upon the expected time sur lie, and the age and composition of the wine. The effects of riddling aids on the yeast deposition are not predictable, and may in some cases be detrimental to the wine composition. Overdosing bentonite, for example, can adversely affect bubble formation and retention by stripping out protein, and using too much of any of these agents can actually make riddling and degorgement more difficult (Zoecklein, 2002).

Other components of the tirage

The amount of sugar is regulated to give the required increase in the alcohol concentration and CO_2 level, and the individual recipes used depend on the individual house. Sucrose, sugar syrups of various compositions and beet sugar are used, with different producers using various sugar sources for the second fermentation. This information is key to the 'house style' and is privileged. If there is residual sugar in the base wine, the amount of sugar added will need to be adjusted or excessive pressure may result as it ferments. Amerine and Singleton (1977) note that 4 g of sugar per liter of wine will produce one atmosphere of carbon dioxide pressure, and that for a total of 6 atm, around 24 g/l of sugar will need to be present at the start of refermentation. This equates to between 6 and 8 l of carbon dioxide per liter of wine, which is also the amount that can be safely contained by a crown cap or cork with a wire cage (Robinson, 2006a). The actual yield of gas is less than this due to production of small amounts of aldehydes, volatile and fixed acids, glycerol and other yeast by-products. The refermentation will also produce between 1 and 2% (v:v) additional alcohol. A small percentage of citric acid may be added with the sugar. Some producers add around 15 to 20 mg/l of sulfur dioxide to the tirage liqueur, which helps to protect the wine from oxidation and activity by microorganisms other than yeast during the ageing period. As stated previously, the free sulfur dioxide level is kept low (preferably $<$20 mg/l) in order to avoid yeast inhibition.

Yeast assimilable nitrogen compounds are essential for the growth and development of yeast, especially under the difficult conditions of refermentation. Diammonium phosphate additions of between 50 and 200 mg/l are not uncommon, and apparently favor the production of esters and diminish the production of fusel oils

and sulfites. The yeast growth stimulator biotin may also be added at a concentration of around 0.5 mg/l (Zoecklein, 2002).

After the cuvée has been mixed well, it is transferred to heavy glass bottles that are specially designed to withstand the pressures produced by carbon dioxide released during the second fermentation. The bottles will often have a push up or punt at the bottom for added strength (Amerine and Singleton, 1977). However, if the fermentation temperature is too high, the dosage of sugar incorrect or the glass is defective in any way, the bottle may break during fermentation, and the wine will be lost. In the event that a batch of bottles suffer from a production fault, this can be significant. The fill level will be based on estimations of loss during disgorgement, and the desired dosage volume. A 'bedule' (hollow polyethylene cup) is inserted into the neck, which helps to seal the bottle and prevent the metal crown from making contact with the wine. Following this, a stainless steel or aluminium crown cap closure is placed on the bottle.

Bottle Fermentation (Prise de Mousse)

Following crown capping, the bottles are placed horizontally on laths ('sur lattes') or into crates on their sides in a cool (10 to 15 °C), dark area such as in the traditional limestone *caves* underground in Champagne, for the second fermentation. The rate of the second fermentation is a function of yeast strain as well as temperature, pH, phenolic content and sulfur dioxide concentration. Complete fermentation and pressure generation can take 6 to 8 weeks, after which the bottles may be moved to a cooler location (around 10 °C) where they will remain undisturbed for the maturation period. The period between the initiation of the second fermentation and disgorging is usually around 15 months.

The rate of the secondary fermentation is a function of the yeast strain, yeast numbers, the ambient temperature and cuvée chemistry, but generally the process takes around two to three months. The rate is increased by high pH, high yeast nutrients, a low phenolic content, a low alcohol concentration, low sulfur dioxide levels and low carbon dioxide pressure. If the secondary fermentation temperature is too high, it is believed to result in coarse bubbles that less persistence and finesse (Ribéreau-Gayon *et al.,* 2000). Other factors affecting bubble retention include the yeast strain, whether the wine has been fined with bentonite (which will affect the levels of protein in the cuvée) and the length of time under pressure in contact with yeast. The pressure due to the carbon dioxide produced by the yeast builds steadily during the fermentation, and has an inhibitory effect on the fermentation, which can be counteracted by nutrient supplements in the triage and by using a high yeast dose. After the fermentation has finished, the wine must stay on the lees for a minimum of 15 months for nonvintage champagne and a minimum of three years for vintage champagne, according to the appellation rules. Some wines will age sur lie even longer than this.

On lees bottle maturation (sur lie)

Méthode traditionelle bouquet is a result of yeast autolysis and ageing. Sur lie (on lees) ageing takes place in the period after the second fermentation, and can vary, depending on the type of champagne, between one and a half, and eight years. Immersed in the wine, the internal membranes of the yeast give way and release enzymes that gradually break the cells down from within (autolysis). After a few months, the cell walls collapse and the cell contents are released into the wine. As a result of storing wine in contact with autolyzing yeast, there is an enrichment of the wine with amino acids through execretion or diffusion (Ribéreau-Gayon *et al*., 2000) as well as esters, proteins, fatty acids, peptides and terpenoids. The yeast layer protects the wine from oxidation phenomena as it is a source of reducing compounds such as glutathione. Products of yeast autolysis and ageing not only improve flavor, bouquet, complexity and depth, but perhaps also CO_2 retention and bubble size. The concentration of amino acids increases significantly between the 12th and the 43rd month sur lie (Zoecklein, 2002). Autolysis is dependent upon such parameters as pH, ethanol concentration,

and temperature. Higher pH values significantly increase the rate of autolysis, as does ageing bottles at elevated temperatures although this may a detrimental effect on both bubble retention and flavor of the wine. During sur lie, the wine may develop a yeasty smell and taste, the result of photodegradation of cysteine and methionine conjugates to methional, methanthiol and dimethyldisulfide (see Faults in Sparkling Wine, below). The difference in amino acid constituents of the *cuvée* as a result of sur lie ageing contributes to the character and complexity of Méthode Traditionelle wines and explains the sensory differences between these and sparkling wines produced by other methods. The development of what some call a 'yeasty' character ('le goût champenoise') does not refer to yeasty fermentation aromas, but to a toasty or biscuit note that is the result of ageing and yeast autolysis (Zoecklein, 2002).

Wines that are designed for long-term ageing undergo 'poignetage' or shaking once a year before riddling. This helps dislodge sediments and avoid crusting and staining of the bottle with the yeast lees.

Riddling (Remuage)

When the winemaker considers that his wine has matured for a significant length of time sur lie, the process of removing the sediment is started. Remuage is the process of encouraging all the particulate material (yeast cells, protein material, bitartrate crystals and riddling aids) in the wine to move into the neck of the bottle, eventually ending up as a compact plug against the bedule. The bedule helps to insure that the yeast pellet will be ejected uniformly during disgorging and that no yeast residue will be left in the bottle.

The riddling process is started by shaking the bottles to dislodge the lees layer, and then the bottles are transferred to a special A-shaped sloping rack known as a 'pupitre' (Figure 2.9.20) where they twisted several

Figure 2.9.20 *Sparkling wine in pupitres at the start of the remuage process at J.C. Le Roux, South Africa.* Photograph by courtesy of Paul Gerber

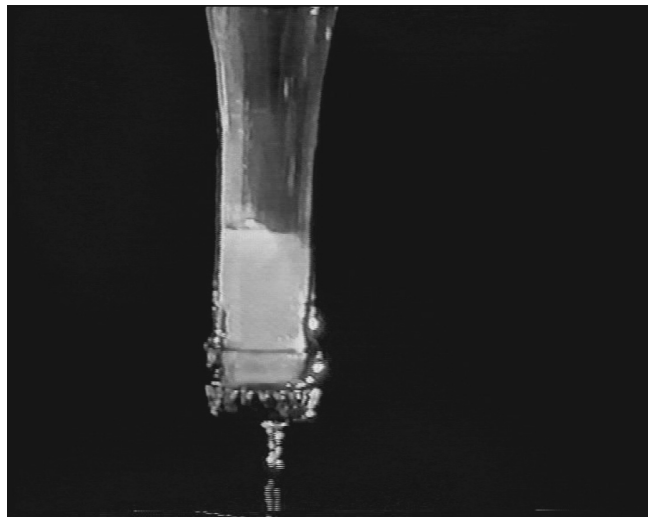

Figure 2.9.21 *The yeast plug compacted in the neck of the bottles*. Photograph by courtesy of J.C. Le Roux, South Africa

times a month. The bottle is placed in a more vertical position each time it is rotated so the yeast deposit gradually moves down the neck.

Eventually the bottles in a particular pupitre will all be upside down (sur point), ready for disgorging. The difficult work of riddling was traditionally done by hand, and a skilled riddler ('remueur') may do tens of thousands of bottles per day. However, riddling racks occupy large amounts of space in the cellar, and the process was highly labor intensive, so nowadays, in both Europe and the USA, the whole process is often done mechanically, on large, programmable 'gyropalletes.' Using this technology, riddling time is shortened to around a week, but most producers will still employ a riddler to attend to difficult wines, as it is widely acknowledged that hand riddling is more effective at compacting lees. Many wines appear to be easier to riddle shortly after fermentation and again after about 12–14 months sur lie (Zoecklein, 2002). The longer the yeast has been in contact with the wine, the more homogeneous is the sediment. Nowadays, economic pressures require shortened remuage times (two to four days at most) so immobilized or agglomerating cells may be used. Agglomerating yeasts or yeast immobilized into gels assist in the riddling process by being easier to dislodge and move into the bottleneck (see above). The disadvantage of shortening the riddling time is that the wines obtained sometimes still contain particles in suspension termed voltigeurs, which have been shown to be of mineral origin (probably bentonite added in the liqueur de tirage) (Jeandet, 2006).

When the sediment is compacted in the neck of each bottle (Figure 2.9.21), and the wine is clear, the bottles are ready to be disgorged.

Disgorging ('Dégorgement')

Dégorgement is the removal of the plug of sediment from the neck of the bottle, a process Robinson (2006a) rightly refers to as 'cumbersome.' Prior to this step, the wine is usually chilled to about 5 °C in order to prevent significant loss of carbon dioxide or wine during disgorging. The process should not cause loss of more than 2% of the volume of the bottle, but this can only be achieved if the wine is very cold, and the carbon dioxide better contained. If disgorging is carried out properly, only about 0.5 to 0.8 bar of carbon dioxide pressure

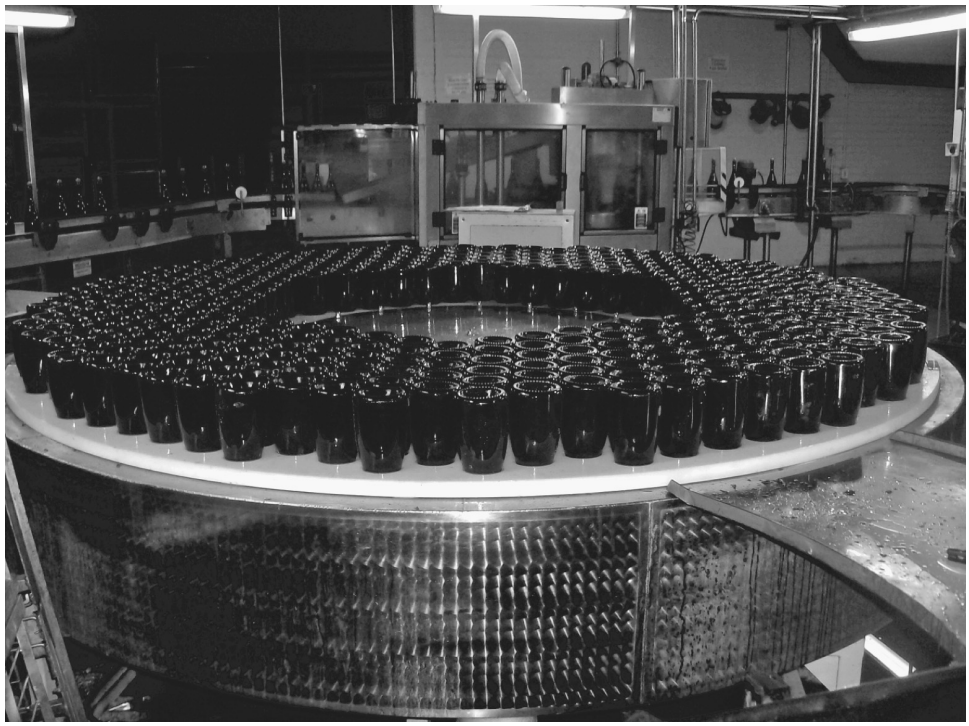

Figure 2.9.22 *The glycol brine bath at J.C. Le Roux, South Africa*. Photograph by courtesy of J.C. Le Roux

should be lost (Jeandet, 2006). One person disgorging manually may be able to complete around 2000 bottles per day, and an automated system will handle the same amount in an hour, so many larger concerns have automated.

Bottles of higher capacity such as magnums, jeroboams and methusalems, are still disgorged manually.

After cooling, but while still 'sur point.' the bottlenecks are carefully placed to a depth of about two to three inches into a very low temperature ($-15\,^{\circ}C$ to $-30\,^{\circ}C$) brine of calcium chloride or a glycol solution (Figure 2.9.22), which freezes the sediment and a small portion of the liquid in the bottle neck.

The frozen portion (around an inch) of liquid in the neck helps to form a barrier to the wine and carbon dioxide beneath it, which assists in preventing loss of product. If too much liquid is frozen, disgorging will be very difficult, as some carbon dioxide pressure is needed in order to eject the plug.

Just prior to disgorging, the bottle is rinsed and held upright, at about 45° off the vertical. The crown cap is removed briskly, and the bedule, yeast plug and a little frozen wine are ejected (Figure 2.9.23). The disgorger then places his thumb over the bottle mouth to avoid any further loss of pressure or liquid, and wine is evaluated for clarity and off odors. If too many yeast cells are left in the bottle, refermentation may occur after the sugar containing 'liqueur d'expédition' is added during dosage. Wines that are not yeast free, and tainted wines, are usually discarded, but clean, clear bottles will placed on a carousel apparatus ready for the dosage. Only a few bottles are ever opened at a time, and if there is any sort of delay in the process, they may be temporarily capped to minimize gas loss.

At this point, the final manipulations to the composition of the wine must be made by adding the liqueur d' expédition before the bottle is corked. The main adjustment is usually the sweetness, as the base wine

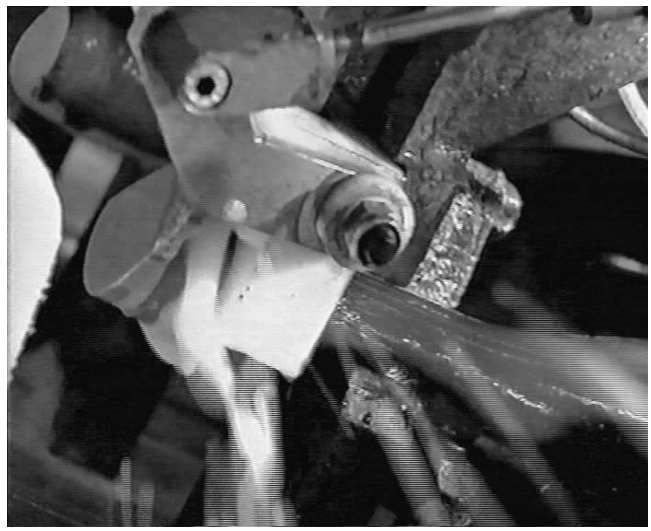

Figure 2.9.23 *Disgorging machine in action.* Photograph by courtesy of J.C. Le Roux, South Africa

has high acidity and champagne with no added sugar may be unpleasantly tart. Robinson (2006a) noted that sur lie ageing and the accompanying yeast autolysis can have a mellowing effect, and may be an 'excellent substitute' for dosage, with older wines having progressively less need for sugar. Some champagnes are made with zero sweetness (see Table 2.9.1), but generally speaking, the liqueur d'expédition will contain sugar, invert sugar, or sugar syrup, some vin de reserve or deionized water, sulfur dioxide, and possibly brandy to mimic age in young wine (up to 3% Cognac may be used) (Zoecklein, 2002). The liqueur is prepared according to a closely guarded secret recipe used by each house, and may have been aged for some time before use. Levels of sweetness are adjusted according to the style of wine, and the liqueur will be filtered brilliantly clear before use to avoid gushing.

The addition of recent reserve wine or low levels of citric acid (up to 500 mg/l may be added in the dosage to provide freshness in older wines, a little red wine would contribute depth and brightness to the color of sparkling rosés, and oak aged wine can be used for depth and complexity if these are needed (Zoecklein, 2002). Some producers add ascorbic acid (up to 90 mg/l), in conjunction with sulfur dioxide as an antioxidant, and copper sulfate may be included in very low doses ($<$0.4 mg/l) to counteract reductive aroma development.

Refermentation of the sugar in the dosage is unusual. Residual carbon dioxide pressure in the bottle is normally too high (up to 4 atm) for yeast metabolism, even after disgorging losses, and the alcohol concentration will have increased due to the second fermentation. Sulfur dioxide is thought to reduce the quality of the product, but will be added if the bottle ageing period is under nine months, and there is a chance there may be viable yeast cells present.

A manual dosage machine adds the liqueur and will then top up each bottle to the required fill level with a measure of the same wine from another bottle set aside for the purpose. Following the dosage, corking and caging of the corks, bottles are shaken to distribute the dosage liqueur.

After dosage and corking, many producers lay wines down for a time in order that the wine and dosage 'marry' prior to release, in a process known as empilage. During this time, the corks will assume their characteristic shape, and leaks can also be detected. At the time of disgorging, the reductive, protective effect of the lees layer is no longer present and oxidation of the wine begins. Zoecklein (2002) noted that by the time champagne is exported, distributed and finally consumed, it may be excessively oxidized, and prove

Figure 2.9.24 *The release of foam and carbon dioxide on opening.* Photograph by courtesy of J.C. Le Roux, South Africa

quite disappointing, as most sparkling wine is released for immediate consumption (Figure 2.9.24), and does not benefit from ageing.

Faults in Sparkling Wines

The appearance of sparkling wine, especially the presence and quality of bubbles, is a very important quality feature. Bubble trains are ideally small and continuous, with great persistence. The collar of the wine (the collection of bubbles or foam around the rim of the glass) should last, ideally, until the glass is almost empty. The liquid should be brilliantly clear (other than the bubble trains), and color should be typical of the age and style of the wine (pale straw in young wines, deep yellow and gold in older wines, pink, blush or onion skin in blanc de noir or rosé styles).

Gushing, the excessive frothing on opening the bottle, as discussed previously, is a sporadic problem due to particles (yeast cells, potassium bitartrate crystals, cork or packing dust) within the wine acting as nucleation sites. If an entire cuvée has the problem, it may be due to excessive CO_2, a lack of cold stabilization or excessive tannins (Ribéreau-Gayon *et al.,* 2000a).

D'Auria *et al*., (2003) conducted an experiment in which champagne was analyzed using solid phase microextraction (SPE) (Section 4.2.4) before and after UV irradiation. They noted that significant modifications in the composition of the flavor were observed, and ester profile of the wine after the irradiation was completely modified. Ethyl acetate, ethyl butanoate, ethyl 2-hydroxypropanoate, 3-methyl-1-butanol acetate, ethyl hexanoate and ethyl octanoate were significantly reduced. Cheese, vegetable and/or shrimp-like aromas in sparkling wine may be caused by the breakdown of methionine or cysteine in the presence of ultraviolet light at around 370 nm to methional and methanethiol, with subsequent dimerization to dimethyl disulfide (Jeandet, 2006). These components are responsible for a fault known as *goût de lumière* ('light struck' taint). Using dark green glass (which does not transmit light at wavelengths below 450 nm) should help with preventing this problem (Ribéreau-Gayon *et al.,* 2000a), but even limited exposure to light can result in the production of unwanted aroma, so it is important to store bottles in the dark.

Cork taint (2,4,6-trichloroanisole) is less usual in champagne than it is in still wines due to high positive pressure within the bottle. The CIVC tests for the fault regularly, and figures for affected bottles are put at between 0.5 and 2% (Jeandet, 2006), which is still very high, and involves considerable financial loss for producers. Presumably in response to these unacceptably high figures for cork taint, in 2009 entrepreneurial producers capped their bottles with aluminium tops for the first time in Champagne's 350 year history (Wallop, 2009). Until recently, this was not thought possible due to the carbon dioxide pressures involved. Duval-Leroy, a Champagne house, which produced more than 6 million of the 320 million bottles made in 2008, capped a limited number of bottles of Duval-Leroy's Clos des Bouveries range with aluminium to test market reaction. As screw caps on still white wine bottles have only recently been embraced by consumers, it is foreseen that the new technology will take decades to penetrate markets worldwide, and producers will have to live with losses due to taint for a while yet.

In conclusion, the process of champagne production is complex, labor intensive and prolonged, and the resulting product is usually expensive. Amerine and Singleton (1977) pointed out that up to 120 hand operations may go into the production of one bottle of champagne, and the production process involves a high measure of skill, risk and higher taxation on the wine, justifying its sometimes hefty price tag.

Other Methods of Sparkling Wine Production

The sparkling wine market is growing rapidly worldwide, particularly among young adult consumers. An estimated 2150 million bottles were produced in 2008, of which around 25% were produced in France (Theron, 2009a).

Sparkling wines, by definition, are wines that contain a visible excess of carbon dioxide on pouring, and they are usually classified on the basis of production or the source of the gas within them. There are four basic methods of preparation. The first is carbonation of the wine by injection of 'artificial' carbon dioxide (CO_2) under pressure. The other methods of sparkling wine production (bottle fermentation, tank fermentation and the transfer method) rely on 'trapped' carbon dioxide generated through fermentation of sugar by yeast. According to Theron (2009a), yet another method, the continuous process, has been developed in Russia, and is now used in Germany and Portugal.

Despite their differences, all the methods of sparkling wine production require a base wine of relatively good quality, as gas release in the final product will exaggerate any faults. In most cases of sparkling wine production, the alcohol content of the base wine should be between 10% and 12% (from an original sugar concentration in the grapes of between 18 and 19.5 °Brix), a limited amount of SO_2 should have been used during production, the pH and polyphenol content should be fairly low and flavor should be neutral, unless the style specifies a particular character. Theron notes that an important point in any sparkling wine production, over and above the method of production of carbon dioxide within the wine, is that the grapes should be selected or harvested with the style of wine in mind.

Carbon Dioxide Impregnation (Carbonation)

The simplest and cheapest method of adding bubbles is carbonation. Carbonated wines are generally recognized as being of a different quality to bottle-fermented sparkling wines and are usually priced more cheaply. The base wines will have fresh fruity styles with moderate alcohol concentrations, and there will be no increase in the alcohol content from a secondary fermentation as in the bottle-fermented products. The choice of base wine is important as it directly affects the character and quality of the final product. Impregnated sparkling wines may be dry, but are often semi-sweet or fully sweet, in which case the fermentation will be terminated prematurely by yeast removal or cooling in order to retain sugar. Base wines are often made from cultivars that have higher levels of terpenes, such as the muscats, which suit the sweeter styles of wine. The

yeasty, toasty character due to autolysis in the bottle is usually absent, unless it was present in the original base wine. Nowadays, a number of producers are avoiding malolactic fermentation as it changes the character of the wine, and destroys fruit flavor and varietal character. Instead, they will dose their wine with carbon dioxide after sulfuring.

There are a number of different ways of impregnating wine with gas. A suitable still wine is exposed to high pressure carbon dioxide either in a tank or in line at very low temperature (−4 °C) to enhance dissolution of the gas within the solution. When the temperature of the wine is allowed to increase to ambient, the gas pressure in the bottle will increase to the required level, and bubbles will result when the bottle is opened. With tank carbonation the wine is stirred under pressure in a CO_2 atmosphere, and there is little control over the quantity of carbon dioxide, which dissolves in solution. In line carbonation is more precise. The wine is passed through a column in a thin stream, and the gas flows in the opposite direction through it. The temperature, flow rate of the liquid and gas pressure can be controlled to give a known amount of carbon dioxide in the wine.

A characteristic feature of carbonated wines is that the gas bubbles are inclined to be larger than those of the other types of sparkling wines and that they lose CO_2 more rapidly once the bottle has been opened. The retention of gas bubbles is influenced by various factors, including a lack of particles in the wine, which can act as a core for bubble formation, and protein content. As carbonated wines are usually filtered before gas impregnation, and seldom experience any time on the lees, it seems self-evident that bubble formation and retention would be affected. Although no scientific evidence correlates the quality of a sparkling wine with bubble size, people nevertheless believe that the two are inversely proportional, i.e. the smaller the bubble, the higher the quality of sparkling. It is usually given that the transfer and Charmat wines have larger bubbles that do not last as long as those of Méthode Traditionelle. In work carried out by Liger-Belair *et al.*, (2003), the experimental diffusion coefficient of CO_2 molecules in five carbonated beverages (a high quality champagne well known for the fineness of its bubbles, a low quality sparkling wine, a beer, a soda and a fizzy water) were accurately determined by using the nuclear magnetic resonance (NMR) technique. The author concluded that the differences in the bubble size between the beverages could not be explained by differences in their diffusion coefficients, which were very similiar. The differences were more likely to be due to differing CO_2 concentrations between them, or significant differences in the pool of surface active macromolecules, which adsorb on the surface of a rising bubble, modifying its surface state.

Impregnated wines make up the highest volume of the sparkling wine market, and include a wide range of styles from Vinho Verde, to an ever increasing variety of flavored sparkling wines and fruit flavored coolers. In the Vinho Verde (meaning ‘green wine’), Portugal’s largest wine-producing region, wines are characterized by fruit flavors, good acidity, astringency and low alcohol, as well as a slight pétillance originally derived from the malolactic fermentation, but now added by most producers by means of bulk carbonation. The wines are designed to be drunk young (‘green’). Other aromatic types of sparkling wine include Asti style Muscat based wines, Spumante and Crackling.

As long as the base wine is of a sufficient quality and a pure source of carbon dioxide is used, the product need not be inferior. The wine can be produced at any time of the year on demand as the production process is far quicker and cheaper than the labor intensive bottle-fermented methods. The consumer is assured of an affordable product of consistent quality. Carbonated wines are not designed to age in the bottle after impregnation, and are best drunk fairly soon after purchase.

Tank Fermentation (The Charmat Process)

The origins of the bulk method for making sparkling wine using ‘natural’ carbon dioxide generated by yeast during fermentation are controversial. Some texts state that it was originally developed in the early twentieth century by Frenchman Eugène Charmat, but others note that Charmat copied an earlier method by the Italian,

Frederico Martinotti, who carried out controlled fermentations in pressurized stainless steel 'autoclaves.' There may be substance to the latter claim, as Martinotti used his pressurized tanks in 1895 in order to produce Asti Spumante, a *Denominazione di Origine Controllata e Garantita (DOCG*) sparkling white wine from Piedmont. Present day tank fermentations are modifications of the original method in which the interconnecting tanks retained the pressure created by the production of carbon dioxide during fermentation. Nowadays, around 7–8 atm is maintained throughout the production process.

The fermentation tanks for bulk sparkling production represent a significant investment for a winery, as they are fairly 'high tech' pieces of equipment, able to withstand very high pressures. They are fitted with temperature gauges, pressure release valves and 'jackets' in which to circulate cooling water for temperature control. Capacities are relatively small (less than 100 000 l) due to the need for pressure and temperature control. Since excess gas can escape from the tank, the regulation of sugar in the dosage is not as critical.

Depending on the style of wine being made in the tank fermentation process, the primary fermentation in the base wine may continue to dryness or be terminated to keep residual sugar if the alcohol levels warrant it. The wine will have sugar added to it if necessary, followed by yeast and nutrients. The tirage liqueur will not contain bentonite or other riddling agents as these are not necessary – the yeast lees will be filtered off under pressure rather than removed through riddling. In Asti Spumante production, 'refermentation' is probably more accurate term to use than 'second fermentation,' as the wine goes through one fermentation, which is 'paused' and then restarted. The first phase finishes at around 7% alcohol, whereupon the wine is transferred to a second autoclave in which it referments for about two to four weeks to form 8–9% alcohol. The wine is cooled to –4 °C and transferred to a third autoclave for bottling. In recent times, a derivation of the Charmat method known as *charmat lungo* has been devised for sparkling wines made from Chardonnay and Pinot Noir. This is a longer process which gives a drier product that has contact with the lees or '*fecce*' in the tank for three months to a year to duplicate some of the effects of the classic method. When refermentation is complete, the wine is cold stabilized under pressure to precipitate tartaric acid crystals, which are removed. The wine is then clarified by centrifugation or filtration under pressure, and this is maintained as the wine is bottled and corked. Wines made by the tank fermentation method are usually sold soon after bottling, though some *charmat lungo* wines seem to benefit from a few months of storage.

Tank fermentation enables winemakers to produce inexpensive sparkling wines within three months of harvest, compared to the much longer and more expensive bottle fermentation. This process works well with sweeter styles as it suits wines that rely on varietal rather than ageing character, like those produced from aromatic cultivars (in Italy good quality grapes of the cultivars Moscato, Prosecco, Malvasia and Brachetto are used to produce Spumante). In the sparkling style of Lambrusco production (from northern central Italy), the grapes are crushed, then moved into tanks where they are allowed to ferment with the skins to extract color and aroma compounds. During fermentation, wine is circulated through the marc (or cap of skins) in a process that is quite oxidative. The wine is then pressed under pressure, before the end of fermentation, and the rest of the winemaking process is conducted under pressure. Prosecco, a dry white sparkling wine from the Veneto region of Italy, also produced using the Charmat method, has recently gained enormous popularity globally as one of the less expensive alternatives to Champagne.

In the USA, wines will be labelled 'charmat process,' in France 'cuve close' and in Italy 'metodo charmat' or 'autoclave.' This process is used in Germany for sekt wines, which must stay in the tank on yeast lees for at least nine months to allow yeast autolysis to occur. This autolysis and dissolution of the yeast contents are assisted by the tanks being agitated periodically. Tank fermentation is also used in New Zealand and Australia to make spumante type sparkling wines, and wines of reduced carbon pressure like 'Cold Duck' (Jackson, 2000c).

Although wines produced this way are generally regarded as superior to those made through carbonation, they are not as highly esteemed as those produced by Méthode Traditionelle.

The Transfer Process

The transfer process (which does not have a proprietary name, and is known as *méthode transfert* in France) was developed in the 1940s in Germany as a means of avoiding the low quality associated with the bulk process and the expense of manual riddling. Since the development of automated riddling and yeast encapsulation, some of the advantages of the transfer method have been negated (Jackson, 2000c), and as the equipment required is expensive and there is a large requirement for refrigeration this process is only used by large producers nowadays. The preparation of wine up to the riddling is essentially identical to that prescribed for the traditional method. The bottles are stored neck down in cartons, and after ageing on the lees, the wines are chilled to 0 °C, the bottles are opened by a transfer machine and the wine is poured into pressurized receiving tanks to retain the dissolved CO_2. The wine is sterile filtered and then sweetened and sulfured with the dosage prior to rebottling with a counterpressure filler.

An important point is that although sparkling wine made by the transfer process follows the same procedure as Méthode Traditionelle, the secondary fermentation does not take place in the actual bottle sold to the customer. This can be confusing for consumers, especially as labeling can be deceptive. For example, of wines sold in the USA, the label statement 'Fermented in this bottle' means Méthode Traditionelle, whereas the statement 'Fermented in the bottle' refers to the transfer process.

There are advantages to the process, as the complicated rémuage, riddling and dégorgement steps of the Méthode Traditionelle are done away with. As well as being less expensive, the transfer method is also far less time consuming than the traditional method. The period from harvest to bottling can be as little as three months, and as long as a year, which is still a great deal faster than the conventional alternative. The mixing of the wine allows for a more consistent product, which is a very important consideration for consumers' brand loyalty. Although some would say the transfer process strips flavor and aroma, many Champagne makers commonly use this method to produce any size bottle smaller than 750 ml standard or larger than 1.5 l, as their facilities are not set up to produce these volumes in the traditional manner. The future of the transfer process is questionable, however, as it is still more labor intensive than the Charmat method, and does not really provide a better product.

Continuous Production

Another method for producing sparkling wine, the continuous process, was developed in Russia, but the first wines made by the continuous fermentation of grape juice on a commercial scale were produced in California and in Argentina. Since that time both red and sparkling table wines have been made commercially by continuous fermentation in South America, the USA and Europe in a variety of proprietary fermentors. A considerable number of continuous single stage red wine fermentors are in operation, particularly in Southern Europe. In some incarnations of this process, grape juice is fed through a series of five or more multi (or reticulated) tanks of identical volumes and carbon dioxide pressures and the contents are gradually changed from juice, to base wine and finally to sparkling wine. In others, base wine is added to the first tank and undergoes second fermentation, with autolysis taking place in later tanks, and the wine emerging clear in the last tank, having spent three to four weeks in the system. Early studies by workers like Cahill *et al.* (1980) showed that Montrachet wine yeast (usually used in batch fermentations) would grow under continuous fermentation conditions. The onset of fermentation was delayed by carbon dioxide pressure of 0.6 atm (gauge) and there was a fourfold inhibition of growth rate with the final maximum cell concentration about half of the control, but the yeast were able to maintain steady state growth at each of the carbon dioxide pressures tested, in spite of the inhibitory effects. It was found that if the second fermentation begins when the concentration of alcohol is around 4%, undesirable microbial activity was virtually suppressed, and the retained carbon dioxide could be used to control the rate of growth of the cultured yeast thereafter. The second

and third tanks may also contain materials like wood shavings on which dead yeast cells can accumulate and stay in suspension in the wine, adding a limited autolysis character.

Continuous fermentations have advantages in commercial operations, which include the avoidance of lag periods in the starting of the fermentation, shortening of the time needed for 'shut-down' at the end of the fermentation, and the possibility of automation of the production. The new process is obviously much faster than the traditional one and the sparkling vines obtained are perfectly clear without showing quality faults. A large fermentor could produce about 2000 bottles per day if consumption required it, but higher concentrations of sugar mean the production of a much sweeter wine than would be acceptable to the most sparkling wine consumers.

2.9.4 Fining, Filtration and Clarification

The quality and haze stability (resistance to haze formation) of any commercially produced beverage are very important to consumers and there are many options available to the winemaker to enhance the natural color, flavor and aromas, while also improving the long-term stability of a product. For beer, cider and fruit wine clarification treatments see Sections 2.6.9, 2.8.5/6 and 2.11.3, respectively, and for a general discussion of filtration, see Freeman and McKechnie (2003).

Sources of Instability and Hazes in Wine

The particles left in solution after fermentation fall into three groups in terms of their size. Simple molecules such as alcohols, sugars and acids are less than 2 nm in size. These dissolve in the fermented product, are a necessary part of its chemical composition and remain through all treatments. Unless they are involved in a reaction or interaction, which causes a larger molecule to form a haze or precipitate, they are unlikely to cause problems. Large particles (>1000 nm) such as grape debris in wine, yeasts, bacteria and proteins, may contribute to the cloudiness of the fermented product. If required, these can be removed by sedimentation or filtration.

Certain substances known as colloids, exist neither in solution or suspension, but in a dispersion. These molecules range in size from 2 nm to 1 micron (or micrometer, 1 μm), and although they are considered large, they are not sufficiently large to be visible or to be removed by a filter. Indeed, filtration of wines containing high levels of colloids may lead to filter blockages and breakthrough, for example glucans (polysaccharides produced by yeast and *Botrytis cinerea*) are notorious for their ability to block filters.

Some colloids carry a charge and as long as conditions remain the same, they are kept in suspension by interactions with other charged particles in the wine. Examples of naturally occurring colloids in wine that are negatively charged are tannins, pectins, dextrans and glucans. Positively charged colloids in wine include colored phenolics and proteins. Changes in the redox state of the solution or conditions of temperature or light may lead to the molecules losing their charge, enabling them to clump together (flocculate). Flocculated material is harmless and tasteless, but can form an unattractive haze or deposit in the bottle. Even a product that has been sterile filtered will not remain clear for long if it contains a high level of colloids, as sooner or later these will flocculate, producing a haze.

Spontaneous Clarification: Initial Sedimentation

Cold settling of juice before (*debourbage)*, and after alcoholic fermentation is a batch process and is often used in small and medium sized wineries. Under the influence of gravity alone, turbid juice separates into

two phases: an opalescent juice and a layer of deposits (lees) varying in thickness. Clarification consists of separating (usually by racking) the clear juice or wine from the lees.

The factors affecting settling include the density difference between solids and juice, particle size, the attachment of bubbles to solids, temperature differentials in the holding tank, juice viscosity and colloid content. Tall, narrow tanks minimize the natural convection currents and provide better settling conditions, but a larger lees layer. Containers that are poor conducters of heat, like barrels, are also suited to sedimentation. Settling takes time, and if a wild fermentation starts during the settling period, it is often it is impossible to clarify the fermenting juice, which may lead to poor quality of final product.

In order to prevent spontaneous fermentation during the initial settling period, the juice should have an effective level of free SO_2, low pH and low temperature. Settling times can be up to 10 days (Morgan *et al.*, 2006), and both the yield of clear juice and degree of clarity depend on the settling conditions. If conditions are not ideal or the fruit was not healthy, the settling time should be reduced, the minimum settling period being around 12 h (overnight), and bentonite may assist in reducing oxidative enzymes (Jackson, 2000e). Settling overnight, below 15 °C, should reduce suspended solids to around 1 to 2%; clarification with pectolytic enzymes, followed by centrifugation or earth filtering will reduce solids to 0.1–0.5% (Morgan *et al*., 2006). The degree of juice clarity may be measured with a nephelometer measuring in NTU (Nephelometric Turbidity Units). Specific clarity objectives are advocated by some winemakers in order to reduce or eliminate the potential for alliaceous mercaptans and thiols associated with poor clarity (Ribereau-Gayon, *et al.,* 2000b). However, overclarification may cause yeast fermentation problems due to lack of fatty acid nutrients, giving rise to volatile acidity and hydrogen sulfide production. A turbidity range between 100 and 250 NTUs, which corresponds to 0.3–0.5% particles, is usually recommended for juice before alcoholic fermentation (Ribereau-Gayon *et al.,* 2000b).

The clear juice may be racked off the top of the solids, with a racking plate or through a racking valve, or lees may be run off from the bottom of the tank until the juice is clear. In all cases it helps to have a sight glass in the line. If necessary, juice may be recovered from the lees layer through filtration, or by centrifugation.

Fermented products may also be turbid after fermentation and should be clarified before bottling. The initial postfermentation clarification is usually carried out by gravity settling, and the gross lees layer (mostly dead yeast cells) should settle fairly quickly. Some winemakers claim that any other form of clarification, such as centrifugation and filtration, is detrimental to the quality of wine, particularly red wines aged in barrels, which are often clarified through sedimentation only. The big disadvantage of sedimentation is that it is a slow process, does not guarantee absolute clarity, and the lees produced are considerable. Once settling has occurred, the clear wine is racked into another container, leaving the lees behind. Racking can also be used to homogenize the solution, aerate it and remove carbon dioxide. Racking off the gross lees is normally carried out straight after the alcoholic fermentation unless yeast autolysis characters are a desired part of the bouquet. Further racking can be done three weeks later, and then every two months for wine in tanks, and every three months for wines in barrels (Morgan *et al.,* 2006), until the wine is either bottled or stored without racking. Traditionally, racking was carried out before the spring, to remove tartrate and protein deposits which had precipitated during the cold winter months. Racking is usually accompanied by a free sulfur dioxide level assessment and adjustment, and may be preceded by a stability test to see if the wine will stand aeration.

Centrifugation

Centrifuges work by speeding up the sedimentation of particles. An apparatus consisting essentially of a compartment spun about a central axis to separate contained materials of different specific gravities, or to separate colloidal particles suspended in a liquid. Gravitational acceleration is replaced by the centrifugal force generated by the very high speed spin of the centrifuge (often up to 10 000 rpm). Most centrifuges are now self-decanting (automatic extraction of lees), and those used for sparkling wines are

completely hermetically sealed. Their uses include rapid clarification of musts, removal of yeasts during fermentation to slow down the alcoholic fermentation, postfermentation clarification, and immediate clarification of fined wines. Centrifuging is particularly useful if juice is heavily laden with particulate matter (Jackson, 2000f).

Foster and Cox (1984) found the decanting centrifuge to be a valuable tool in white winemaking. According to the authors, it decreased the volume of fermentation lees, and lowered processing costs and losses due to lees filtration. It gave better fermentation control by eliminating the premature onset of fermentation due to wild yeast. It decreased the need for fining agents such as PVPP and Cufex, lowering labor and supply costs. The authors also stated that the method increased the overall quality of the white wines, through lowering the flavonoid phenol and iron contents, thus decreasing browning capacity.

Centrifuges are excellent for removing dense particles, such as bits of grape skin, but will only remove a proportion of them; they never lead to their complete elimination. They are also expensive and very noisy, but they are often used as they have a very high flow rate, and can handle quite high solid levels. If wine is not blanketed with inert gas in the centrifuge chamber, oxygen may be forced into the wine during the process, and lead to oxidative problems. The use of a centrifuge usually requires that a specific area is set aside in the winery, and trained personnel carry out the operation. Despite these disadvantages, automation combined with continuous centrifugation has improved efficiency and economy of the process to such an extent that in larger concerns, this is often a preferred clarification technique (Jackson, 2000f). Jackson, (2000e, g) also notes that by removing only suspended particles, centrifugation affects the chemical composition of wine very little, and this, together with the minimal juice loss, and speed of operation, have made it a fairly popular technique. The juices of Chardonnay and Colombard may show nitrogen limitation leading to a retarded fermentation if juice is overcentrifuged.

Fining

Fining is an ancient process of clarification that is used to prevent hazes and improve the balance of the wine (Bird, 2005). Fining can involve complex interactions, but the principle is simple. An introduced agent reacts with the specific wine component either chemically or physically, to form a new component (usually larger or heavier) that can be separated from the wine by precipitation and racking, or filtration (Margalit, 2004).

As previously stated, the colloids in wine usually remain in solution due to their electrostatic charge, but under certain conditions and over time, flocculation will occur due to changes in charge state, or through interaction with oppositely charged molecules. This will lead to haze formation, followed by precipitation. If this happens during bulk storage, the wines can be racked and filtered, but if it happens in the bottle, it is a problem. Winemakers will therefore add fining agents in order to 'force' reactions that would naturally happen over time. An example of a naturally occurring interaction in red wine is that between tannins and proteins (Figure 2.9.25), which has the beneficial effect of removing excessive tannins from solution and precipitating unstable proteins, resulting in a better balanced, softer and more stable wine.

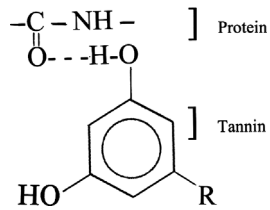

Figure 2.9.25 *General scheme for interaction between proteins and phenols*

Table 2.9.2 *Dosage and efficacy of fining agents (Morgan* et al.*, 2006)*

Wine	Agent	Dose rate (mg/l)	Properties	Clarity
White	Bentonite	250–500	Reduces protein, and associated copper complexes	++
	Gelatine	15–150	Reduces bitterness, astringency and off tastes	+++
	Casein	50–500	Reduces colour and oxidation	++
	PVPP	200–600	Reduces bitterness and browning precursors	+
	Milk	2–4 ml/l	Deodorizing, removes color	++
	Carbon	max. 1 g/l	Reduces color and off odours	+
	Silica sol	30–300	Flocculates proteins	+
Red	Gelatine	30–300	Reduces astringency, off tastes and color	+++
	Isinglass	10–100	Leaves wine brilliantly clear	++++
	Egg albumin	60–100	Reduces astringency	++

Bentonite, gum arabic and liquid silicon dioxide (also known as *kieselsol*) are negatively charged at wine pH. Proteinaceous fining agents are invariably obtained from natural sources, and at wine pH, carry a positive charge. When a fining agent is added to a wine it usually adheres to oppositely charged colloidal matter in solution and the colloidal groups agglomerate, flocculate and drop to the bottom of the vat as sediment. The flocculation of finings is faster at warm temperatures, but sedimentation is better at low temperatures.

To speed up naturally occurring processes and improve stability in wine, negatively charged fining agents can be added to remove unstable proteins or, alternatively, positively charged protein based fining agents can be added to remove tannins.

Fining agents are often used as blends, and the correct fining to use depends on the wine's chemical composition, and the nature of particles in suspension. Usually, comparative trials using small volumes of wine will be carried out in order to establish which fining agent, at which dosage, gives the best clarity for a particular wine. The selected fining should be the lowest dose to give the best quality of wine aroma and flavor, clarity, rapid sedimentation and result in the least lees volume. Table 2.9.2 gives some of the important agents used in fining in winemaking. Overfining is when some of the fining agent remains in solution. This may flocculate later with temperature changes, time or with tannins from barrels or corks, and so should be avoided. Overfining with protein fining agents is unlikely to occur in red wines due to their high tannin content, but can happen in whites, especially with gelatine.

Proteinaceous Fining Agents

Gelatin, a widely used fining agent, is essentially denatured collagen; it is made from collagen, the major structural protein in skin, tendon and bone, and has been used as a fining agent for the selective removal of phenols from wines for many years (Yokotsuka and Singleton, 1995). It is a polypeptide consisting of a number of different amino acids, with the main ones being glycine, proline and hydroxyproline. The concentration of these three amino acids, which can be as high as 56%, makes gelatine a good protein fining agent because their presence favors a flexible noncrystalline peptide chain with a high availability of hydrogen bond accepting carbonyl groups (Yokotsuka and Singleton, 1987). The industrial production of gelatine dates from the early eighteenth century and several different types are now available, produced by acid, alkaline and enzymic hydrolysis (Ribéreau-Gayon *et al.*, 2000c). Gelatine is usually added to wines to reduce astringency and bitterness, but also off flavors resulting from poor quality fruit. Fining with this protein eliminates tannin molecules that react most readily and are most astringent, and also removes molecules that contribute to the

impression of body and volume on the palate (Ribéreau-Gayon *et al.*, 2000c). To ensure the fining of the wine is not detrimental to the overall quality, fining trials must always be carried out prior to additions made in the winery.

Gelatine is available in various forms for its use with wine. It can be purchased in sheet, powder or liquid form and the choice is purely dependent on the preference of the producer, however powders and sheets may have the disadvantage that dissolution requires both heat and time and solutions can form gels on cooling, (Cole, 1986). Gelatine viscosities are grouped according to their bloom strength, i.e. the resistance to deformation of the gel made under specific conditions), which range in wine gelatines from 80–150 (Margalit, 2004). There are already various grades of gelatine available on the market for the use of fining wines from whites to heavily structured reds and with the ever improving technology and understanding of tannin–protein interactions the choice can only increase, with the specificity of the tannins removed a great possibility. As gelatine is extracted from animal bones or hides by boiling, there are ethical issues concerning its use, and winemakers should bear this in mind when labeling. The preparation should be odorless and colorless and is often sold as a powder, which requires dissolution in warm water (30 °C) into a 8–10% solution before use. In white wines, gelatine should be used in conjunction with enotannin (derived from grape pips and skins) or Kieselsol at a ration between 1:5 and 1:10 (Ribereau-Gayon *et al.*, 2000c). Thorough and immediate mixing is very important. In red wines fining with gelatine will also increase suppleness, but can also strip out some of the colored phenolics. There is no legal limit for gelatine addition to wine (Margalit, 2004), but usual additions range from 1.5–15 g/hl in white wines and 3–10 g/hl in red wines (Ribéreau-Gayon *et al.*, 2000c). Maury and coworkers (2001) found that protein molecular weight (MW) may be of importance in a gelatine fining treatment, as it correlates with the nature of precipitated tannins. Their experiments used a range of different gelatines to fine four different wines, and it was found that the protein having the lower molecular weight was more selective, probably due to its small size, which makes it more flexible and therefore more accessible to the tannins (Maury *et al.,* 2001) Sarni-Manchado and coworkers (1999), however, concluded that the similar behavior of different grades of gelatine was because although tannins differ greatly in their affinity for proteins, and proteins likewise differ greatly in their affinity for tannins, the difference encountered is more due to the composition of proteins then their size (Sarni-Manchado *et al.*, 1999). This is supported by Yokotsuka and Singleton (1995), who found that affinity for phenols is considerably influenced by the amino acid composition and structure of peptides rather then their molecular weights.

Gelatine is very subject to overfining in white wines as it is flocculated by tannins. There is no direct relationship between the levels of fining and the levels of tannin required to flocculate it – it depends on the pH and temperature. A sample of the wine should be tested for protein stability after fining either by heating (70 °C for 30 mins), or by adding 0.5 g/l tannin and looking for cloudiness after 24 h.

Isinglass

This is a proteinaceous fining agent originally derived from protein extracted from the swim bladder of sturgeon. More recently, it is manufactured from fish cannery waste (Ribéreau-Gayon *et al.*, 2000c). Previously, the preparation of isinglass was a long, arduous task, but nowadays it is prepared as fine chips, which are mixed with water as a 1% solution without heating. Isinglass flocculates on contact with wine due to the wine's tannin content, and falls to the bottom of the vessel, removing particles by screening and electronic attraction.

It is commonly used at doses of 1–2.5 g/hl for white wines, just before bottling. It gives a better brilliance than gelatine and is less detrimental to wine color and flavor, and is less prone to overfining, although it may require a little aeration to flocculate, and too much may result in a fishy nose and palate. Its disadvantages are that it produces small amounts of light, fluffy lees, which clog filters, is comparatively expensive and can

be difficult to prepare. There are also environmental and ethical issues concerning the use of products from endangered sources, and a number of winemakers prefer to use alternatives like alginates. Isinglass is widely used in the fining of cask-conditioned and other beers (Section 2.6.9).

Albumen

Albumen is a very old fining agent, and has always been presented as the only fining agent for really great red wines (Ribéreau-Gayon *et al.*, 2000c) It is produced from the white of chicken's eggs, and can be fresh, frozen or powdered. Dosing is between 100 and 150 mg/l if using powdered egg white, and this should first be mixed with water. If using raw egg, between three and eight fresh egg whites per barrel (225 l) are used depending on the astringency of the wine. In many New World wines, due to shorter maceration periods, as little as one egg white per barrel will suffice. Egg whites must first be diluted up to 250 ml with water, and a pinch of salt is often added to help flocculation (Morgan *et al*., 2006). Egg albumen is not suitable for white wines, as high levels of tannins are required for flocculation (Ribéreau-Gayon *et al.*, 2000c). It is the best fining for red wines as, although it clarifies the wine poorly, it removes the colloidal phenolics, and renders the wine supple without removing too much color or flavor.

Casein

This is the principal protein of milk. It is a good fining agent for white wine and removes excess color, oxidized character and reduces the iron content of the wine (Ribéreau-Gayon *et al.*, 2000c). It does not overfine, as its flocculation is mostly due to wine acidity. It is often used for the fining of Sherry wines (Section 2.10.2). It is most effective at 15–20 °C, and must be mixed thoroughly and rapidly, as it coagulates as soon as it mixes with the wine. Fining with whole milk is not permitted in the EU (Ribéreau-Gayon *et al.*, 2000c), but skimmed milk can help with color removal and deodorization. The recommended dose is 2–4 ml/l. The disadvantage with milk is that it can lead to overfining at very high doses, and provides a wide range of nutrients for bacterial growth.

Powdered blood

Fresh blood, generally from cattle, was used as a fining agent for many years, but has recently been banned on health grounds. The alternative is powdered blood, which is made by treating fresh blood with sodium citrate and centrifuging. The precipitate is dried, and mixed with carbon to remove its taste, and help it flocculate. It is either brown or yellow, and must be mixed into a paste with water before addition to the wine. This is a very high quality fining for white wines, as it is good at clarification, reduces astringency greatly, reduces herbaceousness, and softens bitter, stalky young wines (Ribéreau-Gayon *et al.*, 2000c). It does not strip color, and there is no risk of overfining at normal doses. It is expensive, and ethical considerations should be taken into account when using it, in particular it may be required by wine legislation that the presence of animal proteins be declared on the label.

Nonproteinaceous Fining Agents

Ribéreau-Gayon and coworkers (2000c) note that sodium alginate is a polymer of mannuronic acid extracted from phyophaceae algae, particularly kelp, by alkaline digestion. It is an odorless, tasteless preparation which, when mixed with water and added to wine at doses of between 4 and 8 g/hl, can help to clarify wine, though not as effectively as traditional fining agents.

Carbon (charcoal)

Charcoal is derived from burnt animal or plant matter and carbon fining is often used as a last resort to remove off odors and color. It is best used in conjunction with 50 mg/l ascorbic acid, as otherwise it may provoke oxidation. Often used at low doses for final pressings.

Tannins

Tannins are extracted from various sources for fining purposes, but a typical source is the insect galls on oak leaves (Jackson, 2000f). They are usually combined with gelatine, and form a network that helps to sweep excess grape tannins and proteins out of the wine.

PVPP

Polyvinyl polypyrrolidone is a resinous polymer that acts in a similar way to proteins to bind tannin (Jackson, 2000f). It removes lower molecular weight phenolics (particularly flavans, and mono and dimeric phenolics), and so is often used to reduce bitterness in wines, particularly white wines which have undergone skin contact. It has little effect on astringency, but can help to reduce pinking and oxidative browning caused by smaller phenolics in white wine. Unfortunately, it is also good at removing resveratrol, one of the components frequently associated with the 'French Paradox,' and health benefits in red wine (see Chapter 5.1, Sections 5.6.3 and 5.8.6). It functions well in wine conditions, and precipitates quickly.

Silica sol (Kieselsol)

This is an aqueous, colloidal suspension of silicon dioxide, used to help flocculate fining agents such as gelatine, or remove mucilaginous protective colloids (Jackson, 2000f). Because it is available in both positively and negatively charged forms, it can remove colloidal material in both charge states, but is most commonly used to remove bitter polyphenols from white wine. It does not remove much color, and produces less sediment than bentonite.

Bentonite

Bentonite is a montmorillonite clay widely employed as a fining agent. It exists in a negatively charged state at wine pH, and so removes positively charged colloids such as proteins, including enzymes such as oxidases, vitamins and amino acids, thus increasing microbial and heat stability. It also increases copper stability, as it removes proteins that may be involved in copper haze production (Jackson, 2000f). However, it tends to strip and turn red wine color brown (especially in young red wines), and so is usually only used in whites and rosés. In red wines the tannins present react with the protein, and precipitate out any excess, giving the wine stability. There are two types of bentonite, calcium and sodium bentonite, of which the latter is more commonly used in the United States (Jackson, 2000f). Bentonite usually needs swelling in approximately 10 times it own weight of water for 24 h before addition.

Fining Trials

Fining trials should always be carried out before fining wine. Fining agents are generally nonspecific and remove a range of compounds. It is important to assess the results of fining on the appearance, smell and

taste of the wine. The most suitable fining agent to try in a given situation is often chosen using experience gained of the style of wine and the fining agents available. It is also important to keep detailed records of all fining trials carried out even if the wine is not fined. The least amount of the fining agent that gives the desired result should be used to fine the wine. This is facilitated by the use of graduated levels of fining agent mixed with the wine, plus, importantly, a control sample with no added fining agent. By observing the level of deposit, degree of clarity and organoleptic effects in a quantitatively graduated series of test tubes or clear glass bottles, it can be ascertained when an increased level of fining agent has no further effect on the wine. Once the required level is determined, the actual fining procedure can be carried out. It is vital that fining agents are mixed thoroughly in the wine as soon as they are added. They are then left to settle before being racked and, if required, filtered.

Filtration

This involves the separation of liquid (wine) from any sedimented deposits or suspended particles through screening and/or adsorption mechanisms. The size and nature of the particles to be removed will determine which filtration system and grade is required. The two major mechanisms involved in filtration are outlined below, and illustrated in Figure 2.9.26.

Absorption (depth filtration)

This refers to the type of filtration where particles adhere to the filtering medium because of their opposing electrical charge. For instance, cellulose fibers have an overall positive charge, and so attract yeasts, which have an overall negative charge. In this type of filtration, the pore size is not as important as the bulk, type and surface area of the fibers. The flow rate remains constant (though it may drop due to screening caused by a bridging effect of absorbed particles), but the wine comes out progressively cloudier until saturation point when the filter no longer has any effect. This is also called 'depth' filtration. (see Section 2.6.9 for further discussion, with respect to beer).

Screening (surface filtration)

This type of filtration involves retention of particles by pores in the filter material (usually a membrane), which are smaller in diameter than the particles. The flow rate of a filter that uses screening exclusively decreases in proportion with the volume of liquid passing through. Only screening filters can be rated absolutely according to pore size (10 μm, 20 μm, etc.) – adsorption filters will only remove a proportion of particles larger than their rating. Depth filters are much more sensitive to 'break through' due to increased pressure, pressure surges or pulses, than screening filters. On the other hand, depth filters have a much higher dirt holding capacity than membrane filters (Morgan *et al.,* 2006), so as a general rule, screening filtration is carried out either on wines that are clear to the naked eye or have been treated already with adsorption filtration. Figure 2.9.26 outlines both the adsorption and screening mechanisms of filtration.

Filtration may be used at a 'coarse' or 'rough' level to remove yeast lees or fining sediment and at its 'finest' or 'tightest' level to remove bacteria. The former may be required throughout various stages of the wine making process using, for example, a coarse pad or a rotary vacuum drum filter. The latter may be required at the ultimate stage, bottling, to polish and 'sterile' bottle the wine, for example with a much finer pad or membrane cartridge system (Morgan *et al.,* 2006).

The efficacy of a filter is determined by the size of the pores, or the permeability of the filtering medium. The flow rate across a filter is proportional to the surface area, pressure and permeability of the filter, and

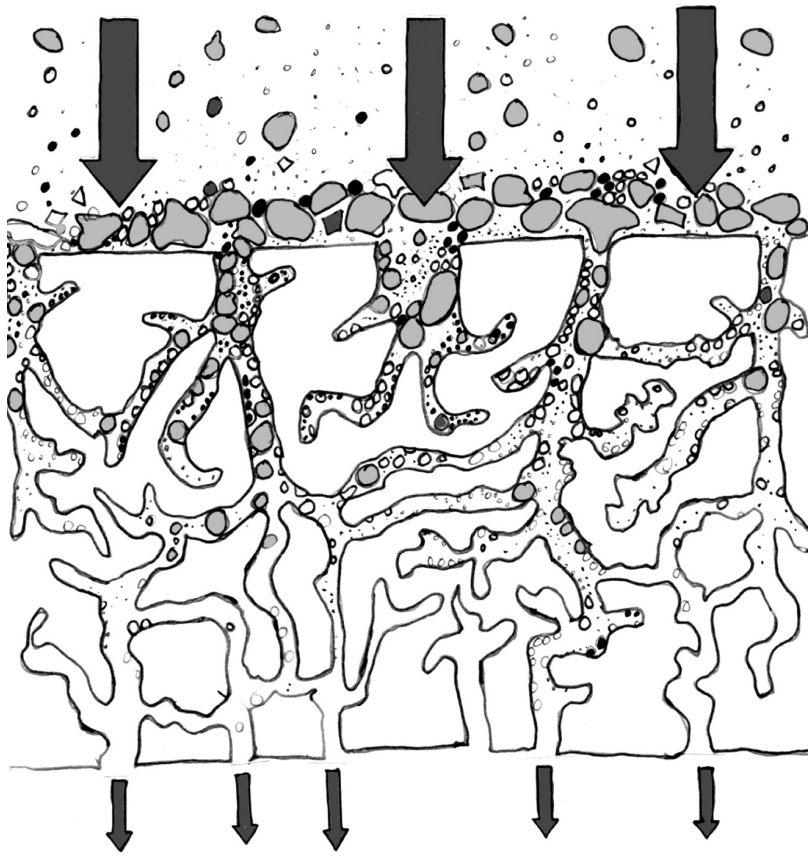

Figure 2.9.26 *Mechanisms of filtration showing screening (larger particles) and adsorption onto pore walls (smaller particles)*

inversely proportional to the viscosity and the thickness of the filtering medium. A filter is also defined by its efficiency, that is to say the volume of wine that can be filtered before the filtering surface becomes blocked. The ability of a wine to clog a filter depends not only on the percentage of solids that it contains, but on the nature of the particles, in particular, 'plastic' molecules such as gums and mucilages. Other particles that block filters easily are colloidal proteins, bentonite and isinglass. Bacteria clog more than yeasts, as they tend to agglomerate in groups, and so wines having undergone malolactic fermentation are more difficult to filter.

Filtering surfaces are defined according to their rating: nominally rated surfaces are rated according to their average pore size; absolutely rated surfaces are rated according to their maximum pore size.

Pad filtration

The wine is passed across a filter pad made of cellulose, cotton, diatomaceous earth (DE) or synthetic fibers such as polyethylene. This method uses adsorption and screening and also sedimentation, inertia and turbulence.

Figure 2.9.27 *Earth filtration system. Commonly used to filter cider and beer as well as wine.* Photograph by courtesy of Vigo Ltd., UK

Plate and frame filtration

This consists of a series of specially designed plates held in a frame. The sheets are fibrous material, which are packed between the plates and screwed tightly together. This type of filtration is known as depth filtration as the wine passes through a large depth of fibrous material. Different grades of filters are available, up to sterilizing grade. These filters are versatile and widely used. They can be expensive to install, but cheap to run. The operator needs expertise in operation of the filter as exceeding the limits of pressure and flow rate can cause breakthrough of the pads. An example of a depth (earth) filtration system for use in beer, wine and cider applications can be seen in Figure 2.9.27.

Diatomaceous earth filtration

Diatomaceous earth (DE, kieselguhr) is a filtration aid made from a sedimentary rock composed of the silicate skeletons of diatoms (microscopic algae) that lived 60–100 million years ago. The most important deposits are in Santa Barbara, California, and fine and coarser grades can be specified. Diatomaceous earth filtration is used extensively in winemaking for initial rough filtrations as it removes large quantities of mucilaginous material very effectively. Earth filtration is mostly by screening, though some adsorption takes place. Earth filters either have supporting plates or a rotating drum through which the wine is sucked by a vacuum pump. Normally, earth filtration takes place in two stages: firstly a layer of coarse grade earth (precoat) is deposited on a supporting screen made of nylon, stainless steel, ceramic or cardboard; then powdered, purified

diatomaceous earth is made into a thin slurry with water and fed continuously into the wine stream, where it builds up in a layer on the filter plate or pad, continuously providing a new filtration surface until the distance between plates is filled (Morgan *et al.*, 2006). With a rotary drum vacuum filter (RDV) the diatomaceous earth bed is laid down on the drum before filtration starts. The drum rotates through the wine, which dries on to the surface as a result of the internal vacuum and the dirty layer is automatically removed as the drum rotates.

Perlite

This filtration aid consists of the pulverized remains of heat-treated volcanic glass (vitreous rock, like pumice), and has a very fine structure (Jackson, 2000f). It is used using the same support and equipment as diatomaceous earth for musts and cloudy wines, but is coarser and more abrasive to pumps and metal pipes. It can also be incorporated into pads and sheets for use in different *filter housings.*

Cellulose filtration

Cellulose is the basic component of all cell walls. This filtration aid is prepared from pine, birch or beech wood which is powdered, chemically purified, washed and dried, and then mechanically broken down to different grades. It can be used as a powder during depth filtration or in pads to be incorporated into appropriate filtration housings. The cellulose used in filtration is relatively pure, but it will give a papery taste to the wine and is usually rinsed through with 1% citric acid first.

Membrane filtration

This most modern type of filtration uses a cartridge made of cellulose esters, polysulfonate, nylon, polypropylene or glass fiber inside a filtration unit. Although there are several versions of this technique, it works mostly by screening, with a little depth filtration. This method is used more for microbial stabilization than clarification, and is commonly the last filtration before bottling wine. A membrane filter consists of a thin membrane of perforated material with holes of a controlled size mounted in a housing. This is known as absolute or surface filtration and particles of more than a certain size are removed. The normal grade used in wineries is 0.45 μm, which removes most bacteria, but the pore size can go down to 0.2 μm. The equipment is relatively cheap, but cartridges are expensive and easily blocked. The wine must be clarified (preferably given an initial filtration) before reaching the membrane as it is the final guard filter immediately prior to bottling.

Cross flow filtration is an adaptation of membrane filtration, where the flow of liquid is across the face of the membrane rather than through it. The flow of liquid constantly removes deposits from the face of the membrane and the wine flows in a closed circuit.

The wine is passed along the surface of a porous membrane with sufficient pressure to force liquid through the pores. This parallel feed prevents clogging, but as the wine is being pumped around a partially closed circuit, the particle concentration increases. This method can be used for musts or wines with very high particle concentrations, and has also been developed for ultrafiltration (dealcoholization), and reverse osmosis (concentration) of wines and other alcoholic beverages (Section 2.13.3).

Ultrafiltration is a cross flow system using a membrane with a nominal molecular weight cut off (NMWC) of 10 000 Da. This will remove large phenolic polymers and proteins, thus increasing the stability of the wine, but unfortunately may also affect structure and color. It is therefore seldom used in red winemaking (Jackson, 2000f).

Osmotic distillation is used for the production of high quality grape juice concentrates. Juice is passed on one side of a polytetrafluoroethylene (PTFE or Teflon) membrane with high strength sodium chloride

solution on the other side. The membrane is gas permeable and so vapor can pass through. The differences in osmotic and hydraulic pressures cause water vapor to pass from the juice through the membrane and into the brine. The salt solution is being continually reconcentrated by a desalinator. The method is characterized by low operating temperature and pressure, long membrane life and no browning or oxidation of the product (Morgan *et al.*, 2006)

Reverse osmosis (RO) is used for dealcoholising wine (Section 2.13.3). Wine is passed along a membrane (cross flow) with very small pores, which will only allow small uncharged molecules such as water, methanol, ethanol, acetic acid, ethyl acetate and acetaldehyde. Any dissolved ions or molecules with a relative molecular mass of more than 200 cannot pass through. This pressure must be high enough to counteract the force of osmosis, which acts in the opposite direction. Dry wine has an osmotic pressure of 14 bar, and so RO systems can pump wines at up to 40 bar (Morgan *et al*., 2006). As the wine concentrates, its osmotic pressure increases, and so it is diluted with water so that as much alcohol as necessary can be extracted. This water should come from the original wine (extracted from the filtrate by distillation) for the wine to retain its designation of origin, grape variety and vintage. Total inert gas blanketing and low temperatures are used so the wine retains flavors. Systems used are quiet and fully automated.

Flotation

Flotation is used for clarifying musts, including some cider must (Section 2.8.5). Gas and fining agents such as gelatine, bentonite and silica sol are injected into the medium under pressure, gas is dissolved into the must under pressure, and then the pressure is released. The gas comes out of solution and adheres to the solid particles, thus making them rise to the top of the vessel. These solid particles can then be removed physically (e.g. by a vacuum) or decanted from the juice and passed through a press filter or RDV.

Practical Implications for Clarification

Fining before filtering improves the efficiency of a filtration, but some fining agents can cause filtration problems. Fining clarified wines often gives better results, and so fining is often carried out after an initial 'rough' filtering. The advantages of fining over filtering are that it requires little equipment, it improves wine stability; and it can have desirable quality effects (e.g. reducing bitterness) (Morgan *et al.*, 2006). However, filtration is more efficient in clarifying, can remove microorganisms, has few side effects, and if the right equipment is available, is quick and easy to carry out. In practice, however, the processes of fining and filtering are complementary and invariably carried out in succession (usually fining followed by filtering). The winemaker must have a clear overview of the processes he or she plans to consider for each wine. For example, it is obviously wise to protein 'fine' before bentonite additions, since these would require a second bentonite addition if subsequent tests showed up any 'overfining.'

2.9.5 Wine Maturation and Ageing

This section is divided into four parts: an introduction, a discussion of the factors affecting wine maturation and ageing, a discussion of the effects of ageing on wine, and a brief description of the process of accelerated ageing.

Introduction: The Need for Maturation

Maturation and ageing are two different concepts when applied to wine, although they are frequently used interchangeably. Maturation in winemaking terms is the time period, and associated changes, that occur in

a wine between alcoholic fermentation and bottling, while the wine is still in bulk storage in the production facility. This period may be anything from two to 24 months, or longer, depending on the style of wine being made, and may include processes such as malolactic fermentation, oak coopering, racking or sur lie (on lees) ageing in tanks or barrels, fining and filtration.

Chemical processes during maturation include the oxidation of phenolics and other substances, formation of aldehydes and esters and hydrolysis of glycosides and other components. Physical effects include salt precipitation, loss of carbon dioxide, evaporation of volatile substance and dissolution of oak components. Effects may include loss of brightness, changes to the color of the wine and character of the bouquet, and rounding and softening of tannins.

The effects of microorganisms during the maturation period may lead to the metabolism of malic and other acids and concomitant increases in by-products of these fermentations such as acetic acid and diacetyl. Yeast autolysis during the maturation period will release cell contents into the medium and yeast cell walls (hulls) can be involved in binding and removing substances (for example, α-ionone) from solution. Other physicochemical effects of maturation are linked to changes in the redox (oxidation–reduction) potential of the wine, and polymerization and flocculation of colloids during or after fining.

The term 'ageing' when related to wine, is often used negatively to denote a product that has been too long in the bottle, and is past its best. Strictly speaking, the period after bottling and before consumption in the life of a wine should be referred to as 'bottle ageing,' but for the purposes of this discussion, it shall just be termed 'ageing.' This is when the maturation of the wine continues with no, or very little, oxygen present, and includes the period when the wine is at its peak, and the time during which it loses quality and becomes unacceptable. The length of time that this process takes depends on the cultivar, vintage, wine style and storage conditions.

A successful ageing period will depend on the specific composition of the wine being matured, and will vary from weeks, (in the case of fresh, fruit driven white wines) to decades, for highly structured, tannic reds. It is generally recognized that the quality of a wine will increase during a period of maturation up to a certain point, after which it starts ageing and loses quality. Changes over time may be very subtle, or extremely obvious and unpleasant. Although some styles (usually red wine) are robust enough to withstand, and can even benefit from the associated volatile acidity and deepening color, obviously oxidized wine is normally perceived as overaged.

The wine ageing process is complex and there are very few rules that can be applied to maximize success. It is generally recognized that a slower maturation process at cool temperatures is correlated with higher quality for most wine (see Figure 2.9.28). It is also an advantage for ageing to take place in a dark, vibration free environment, with a relatively high humidity. This is why winemakers in chalk or limestone districts such, as Champagne, Burgundy and Vouvray/Montlouis in Touraine (Loire), often use cellars hewn out of the local rock for ageing their wines prior to sale.

The shelf life of wine is a primary concern of the wine industry, and wine will be 'engineered' by the winemaker to be consumed within a specified time period. Aside from problems caused by spoilage organisms, the shelf life of a wine is directly related to its resistance to oxidation, which in turn depends on the concentration of polyphenols in solution, the reliability of the bottle closure, dissolved oxygen levels and sulfur dioxide concentrations on bottling.

Factors Affecting the Maturation and Ageing Process

Oxygen

Oxygen plays a fundamental role in wine maturation and ageing. It is necessary for the maturation of young red wines, but detrimental to older reds and most white wines with the exception of ranciostyle

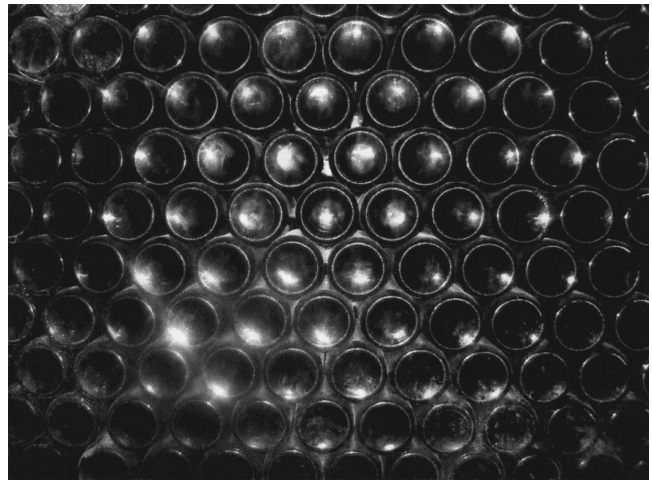

Figure 2.9.28 *Red wine bottles ageing in cool conditions, packed horizontally in a South African winery cellar*

wines (Sherries, Madeiras, some Vins Doux Naturels – see Chapter 2.10) where it is essential for flavor development. The effect of oxygen on the composition of wine has warranted many studies, a review of which was covered by Du Toit *et al.* (2006). Oxygen is involved in the transformation of components in the wine, and is also necessary for the growth and spoilage caused by acetic acid bacteria. At various stages in the maturation and ageing of the wine, the effects of oxygen can mask fruity and varietal character, prevent the development of a reductive bottle bouquet, and/or generate acetaldehyde and other odors associated with oxidation.

Conventional winemaking recognizes the effect of oxygen on wine quality, and accepts that the amount of oxygen that comes into contact with the processed wine at any given time can be managed, but seldom rigorously controlled. The solubility of oxygen in wine increases with increasing alcohol content, but decreases with increasing temperature. For instance, saturation is approximately 5.8 ml of oxygen per liter of wine at 20 °C and around 6.5 ml/l at 15 °C. When chilling wine (e.g. during cold stabilization), care should be taken as the cold liquid can absorb up to 12 ml/l at –5 °C, which may then go on to do all sorts of damage to sensitive components once the wine warms up to room temperature. If the wine contains carbon dioxide, oxygen dissolution is decreased, so freshly fermented and sparkling wines are less vulnerable. The free sulfur dioxide level has no effect on the oxygen dissolution process, but will affect the consumption rates of oxygen once dissolved, and will help to counteract negative effects of any reaction products of oxidation. After fermentation, due to the presence of alcohol and additions of sulfur dioxide, enzymic oxidation is reduced to virtually nothing, and chemical oxidation is responsible for any oxygen related changes. Even during bottle ageing, when the wine is totally protected from the air, there are reduction and oxidation reactions occurring in the wine, which cause the oxidation of certain components. As these reactions take place, the state of oxidation in the wine increases.

Metal ions, particularly copper and iron, are necessary to catalyze oxidation in wine, and along with other components, form intermediates in reactions. Danilewicz (2003) suggests that sulfite does not react with oxygen directly, but with products that result from catechol oxidation (i.e. quinones and hydrogen peroxide). During maturation and ageing, tartaric acid forms dioxymaleic acid (among other substances) which can be further oxidized to oxalic acid if exposed to too much oxygen, for instance in a bottle left open for too long. Some of the other compounds that have been associated with oxygen contact are products of the oxidative

degradation of unsaturated fatty acids, such as hexanal, *trans*-2-octenal, *trans*-2-nonenal and 1-octen-3-ol. Aromatic products of oxidation and ageing are further discussed in a later section in this chapter.

Oxygen can be added to wine 'by accident,' or deliberately, during the winemaking process. Dissolving oxygen in wine through aeration or sparging of a thin stream of gas, is a technique that is used frequently in modern wineries in order to reduce the susceptibility of white wine to later oxidation by deliberately oxidizing sensitive components in a controlled fashion. It may also help to reduce 'pinking' of susceptible wines like Sauvignon Blanc later on in the bottle. This process, known as microoxygenation, can also help to make wines better able to withstand the highly reductive conditions under screw cap, and avoid the reductive or vegetal taints associated with the development of disulfides and mercaptans later in the life of the wine. Microoxygenation can also help to soften harsh tannins and improve color stability in red wines, somewhat mimicking the effects of a lengthy barrel maturation period.

The normal (less controlled) exposure of wine to oxygen during the winemaking process has similar effects to microoxygenation, but may easily lead to oxidative taints in the wine if the amount of oxygen dissolved is too high. As previously noted, oxygen can dissolve in wine quite rapidly and the rate at which it is then used up in chemical reactions depends on a number of factors including phenolic content of the wine, its pH and temperature, and the rate of oxygen ingress. The total oxygen consumed by wines under normal acidic conditions ranges from about 30 to 100 mg/l, but phenols can have substrate, catalyst and buffer roles during oxidation, and their concentration will greatly influence consumption. Danilewicz *et al.* (2008) found that sulfur dioxide actually accelerated the reaction of oxygen in model wine conditions and in red wine, and proposed the increased rate was due to the reaction of bisulfite with quinones. The accelerating effect of SO_2 on oxygen consumption was also observed by these workers in red wine. The free SO_2 concentration was increased to 51.2 mg/l in one portion of the Beaujolais wine and removed entirely with hydrogen peroxide in a second. Both were saturated with aerial oxygen, and the consumption of oxygen was markedly slowed by the removal of sulfur dioxide.

de Beer *et al.* (2005) studied the effects of bottle ageing on the antioxidant activity of Pinotage, Cabernet Sauvignon, Chardonnay and Chenin Blanc wines, by storing wine at 0 °C, 15 °C or 30 °C for a period of a year. They found a significant decrease in both the total antioxidant activity and the total phenol content of the wines. The total anthocyanins in the red wines decreased significantly over the year at all temperatures except for storage at 0 °C, while the flavanol content of the Pinotage, Cabernet Sauvignon and Chardonnay wines increased up to nine months storage with a subsequent decrease to 12 months. The stabilization of flavonols and anthocyanins in wines seemed important in protecting the wine against loss of total antioxidant activity. As wines are not normally consumed directly after production and a decrease of between 18% and 50% in total antioxidant activity could occur even under favorable storage conditions (15 °C) during one year, the use of total antioxidant activity values to market wines should be treated with caution. The authors noted that understanding the complexity of these reactions may provide clues for preserving the antioxidant ability of a wine without losing the beneficial effects of bottle ageing.

Wine is capable of absorbing the effects of very small quantities of oxygen over longer periods of time with few negative effects, but rapid oxygen ingress for even short phases will lead to a loss of aromas and the flat taste associated with the presence of acetaldehyde and ethyl acetate. Slow, light aerations (e.g. barrel ageing) mean that the beneficial oxidation intermediates formed are weakly reactive and perform best at low redox potentials. Although it is generally agreed that postbottling oxidation is usually detrimental to wine, Jackson (2005) highlighted the fact that a little in bottle oxygen ingress may have some benefits. Some wines, such as Sauvignon Blanc and Shiraz, can suffer from the rotten egg smell of hydrogen sulfide, and circumstantial evidence indicates that oxygen slowly negates this, as well as helping to remove the burnt rubber smell of 2-mercaptoethanol in affected wines. The author added that whether slow or intermittent oxygen ingress aids, or is essential to, the formation of a desirable aged character in older red wines is unknown from a purely scientific perspective at this stage.

Free sulfur dioxide

The phenomenon known in the wine trade as 'bottle shock' or 'bottle sickness' is a temporary condition in which there is a loss of varietal aroma and fruit flavor, and an increase in harsh, flat characters due to the adjustment of the chemical composition of the wine to the bottling process. In the past, bottle shock was attributed to the production of a small amount of acetaldehyde by oxygen contact at bottling, but as most commercial wines are bottled under anaerobic conditions, it is more generally associated these days with the dose of sulfur dioxide that a wine is given just before bottling, and usually affects lighter, delicate styles of wine. It lasts for a few weeks after bottling, during the transport of wines between producer and point of sale, and goes unnoticed by most consumers. In the event that the loss of primary aroma and flavor is obvious to people other than the winemaker and wine experts, or continues for a longer period than a few months, it should be considered that the problem is more severe than bottle shock, and may due to excessive doses of sulfur dioxide, or higher levels of dissolved oxygen (depending on the bottling conditions).

The antioxidant effect of sulfur dioxide on wine is well known, but a full understanding of this mechanism of action has yet to be achieved. Concerns over health issues related to sulfur dioxide during recent years have led to the maximum levels of sulfur dioxide permitted by law being systematically reduced by producers, with knock on effects on the longevity of their wines.

The multitude of reactions in which sulfur dioxide can be involved in wine include antimicrobial, antioxidasic, carbonyl binding (e.g. binding of acetaldehyde formed by the oxidation of ethanol) and antioxidant mechanisms. These are discussed in more detail in Sections 2.5.2 and 2.5.3. It had been previously suggested that sulfur dioxide protects wine from oxidation by reacting directly with molecular oxygen dissolved in the wine, but most authors now agree that although this reaction occurs in industry in the presence of metal catalysts, it is not particularly relevant at wine pH, as the reaction with molecular oxygen is not favored by the electron configuration of the oxygen in its ground (triplet) state. Studies have provided evidence as to the catalytic importance of iron and copper in the autoxidation, not only of polyphenols, but also of sulfur dioxide in a wine model system (Danilewicz, 2007). The studies indicated that nonmetal catalyzed pathways were so slow that they were unlikely to play a significant part in oxidative processes in wine, and that the autoxidation of sulfur dioxide is a radical chain reaction in which powerful intermediate oxidizing radicals (including hydrogen peroxide) are produced.

Hydrogen peroxide, by way of the Fenton reaction, will oxidize ethanol, but is intercepted by radical scavenging polyphenols, which break the radical chain process. The sulfate radical is another powerful oxidant that can oxidize bisulfite to regenerate the sulfite radical. This regeneration of the sulfite ion means that the oxidation of bisulfite will continue as long as there is oxygen available, and for this reason, bisulfite appears to consume oxygen dissolved in wine. Radicals formed during the process are obviously capable of oxidizing other wine constituents, so sulfur dioxide exerts its main protective effect through scavenging these reactive species, and protecting sensitive wine components from their effects. Waterhouse and Laurie (2006) stated that SO_2 acts in other important ways to limit oxidation. These include the ability to bind reversibly to acetaldehyde, as well as other aldehydes and ketones, and to reduce reactive quinones back to phenols.

Within the European Union, the maximum permitted level of total sulfur dioxide in dry red wines is 160 mg/l. In dry white, dry rosé and sweet red wines, 210 mg/l is permitted, and in sweet white and rosé wines where higher levels of sulfur dioxide are needed to inhibit possible fermentation of the residual sugar, the permitted level goes up to 260 mg/l. Certain styles with a high sugar content like the sweet white Loire wines, Trockenbeerenauslese and Ausbruch from Germany and Austria are allowed up to 400 mg/l sulfur dioxide, which goes some way to explaining the extreme longevity of such wines. The maximum level permitted in Australia was reduced to 250 mg/l in the 1990s, except for wines with 35 g/l or more residual sugar for which up to 300 mg/l sulfur dioxide is permitted (Robinson, 2006b).

Certainly the search has been going on for a number of years to find a replacement for sulfur dioxide as a preservative for wine, but so far alternatives have been elusive. From permitted levels of up to 500 parts per million (ppm) in 1910, which again may help to explain the excellent preservation of some of the wines made around this time, legal maxima had dropped to half this amount around the world by the end of the twentieth century, largely in response to public health concerns about the effect of high doses of sulfur on asthmatics and other sulfur sensitive individuals.

Researchers continue to try to find alternatives to sulfur based winemaking preservatives which have antibacterial and antioxidant properties, but it is rare to find both in one compound. Lower levels of sulfur can be used in combination with other antioxidants like ascorbic acid for protecting wine during ageing, but no other single substance manages to combine all the attributes that sulfur dioxide does. In a recent study, sulfur dioxide and mixtures of glutathione and caffeic acid or gallic acid were tested as inhibitors of the decrease of isoamyl acetate, ethyl hexanoate and linalool (positive wine aroma contributors) during storage of a model wine medium (Roussis and Sergianitis, 2008). Model wine samples containing 0, 20, 40 or 60 mg/l free sulfur dioxide were analyzed and it was found that isoamyl acetate, ethyl hexanoate and linalool generally decreased during storage of the model wine medium, but sulfur dioxide protected the three volatiles at 20 (isoamyl acetate), 40 (ethyl hexanoate) and 60 mg/l (linalool) respectively. Mixtures of glutathione with caffeic acid or gallic acid were also protective – more so at higher than lower levels. A combination of glutathione and caffeic acid was more effective than glutathione and gallic acid. Unsurprisingly, the presence of sulfur dioxide at 40 mg/l increased the protective effect of the mixtures. The results indicated that higher concentrations of sulfur dioxide protected wine aroma volatiles, but that mixtures of glutathione and caffeic or gallic acid were also effective, and their efficacy was boosted by sulfur dioxide.

Some attempts to produce wines without any addition of sulfur dioxide have been reasonably successful (especially in the still red wine category), but sweet wines are particularly prone to oxidation and attack by wild yeast and bacteria, and usually require pasteurization if they are to 'survive' without SO_2. Preserving wines with alternatives like natamycin leads to complications when shipping to countries where this preservative is forbidden – even adding small amounts of sweet reserve in the final stages of winemaking can elevate the natamycin concentration to unacceptable levels.

Sulfates are natural components of fermentable substances and it is normal to encounter small amounts of sulfur dioxide in fermented products such as bread and wine as by-products of yeast metabolism (Robinson, 2006b). Indeed, anecdotal evidence suggests that the levels of sulfur dioxide found in salad bars in restaurants, as well as in packaged foods, far exceeds that found in wine.

Compulsory labeling information is now required on wine bottle labels in various countries, usually just a small legend to the effect that the wine 'Contains sulfites,' but Australian labels must state that sulfur dioxide, or 'Preservative (220),' has been added. Within the European Union (EU), sulfur dioxide is known as E220, but it does not need to be specified on wine labels.

pH and acidity

Cilliers and Singleton (1990) also observed that the rate of autooxidative reactions in *o*-dihydroxyphenols like caffeic acid and caftaric acid can be slowed substantially by operating at low pH and low oxygen concentration. Any increase in pH (i.e. decrease in hydrogen ion concentration), the authors noted, will greatly increase the rate of this oxidative reaction, and that high pH during ageing is the reason why so many 'hot-country' wines 'fall apart' too soon. In his earlier review of oxygen with phenols, Singleton (1987) also suggested that lowering the pH as early as possible would improve the maturation rate and staying power of wines from over-ripe grapes from warmer seasons and regions and improve otherwise flat tasting wines. Certainly winemakers are starting to take cognisance of the fact that a lower pH will help to preserve a wine for a number of different reasons (better sulfur dioxide efficacy not least amongst them). Methods of increasing

acidity have come full circle in recent times, with winemakers now practicing differential harvesting (picking at staggered times during the ripening period) and fermentation, with subsequent blending of the wines to achieve the desired pH and titratable acidity, as used to be done in the times before relatively cheap tartaric acid was available on demand.

Singleton (1987) noted that the negative charge of the phenolate ion is delocalized through the benzene ring, lending about 8 kcal extra resonance stabilization to the anion compared to the protonated phenol, and therefore phenolic oxidation in wine is faster at higher pH as the removal of an electron is much easier from the phenolate anion than from the protonated phenol. The phenolate ion concentration at pH 3.5 is very low (about 0.004%) of the total, but this ion is so reactive that oxidative reactions will still take place as equilibrium will replace any phenolate ion consumed. du Toit, *et al.* (2006) in a review of the role of oxygen in wine, stated that the oxidation rate of ascorbate decreases as pH decreases, becoming very low at pH 2, as at lower pH phenolic molecules tend to be protonated and less easy to oxidize. Danilewicz (2003) stated that the pH of the solution determines the position of equilibria involving ionizable species such as phenols, and hence their reduction potentials. The protonated species of the quinone radical anion is remarkably acidic as it is an electron deficient system. It has a dissociation constant pK = 5.0, so that at wine pH (3.0–3.6), the semiquinone will be protonated. At wine pH, electron transfer rates were lowered, but still remained appreciable, and it was possible that equilibria would still exist for the more easily oxidizable components, depending on the stability of the phenoxy radicals generated. As pH rises, the proportion of phenols in the reactive phenolate (negative) state increases, enhancing potential oxidation and decreasing the ability of the wine to withstand the ageing process.

During his studies on pH effects, Singleton also observed that wines that are made alkaline will rapidly consume a lot more oxygen, reaching saturation quickly. The total amount of oxygen consumed, however, under 'slow' acidic conditions was much higher – and ranged from 1.4 to 18 times as much in the same wine under alkaline conditions. From a practical viewpoint, slow oxidation did not exhaust the original oxidizable substrates of wine as rapidly as fast oxidation, and suggested to the author that additional, slower reactions occur which augment the pool of substrates. He also stated that fast oxidation does not lead to the same 'good' result in wine ageing, but that there is not a lot of data available to substantiate this statement.

In apparent contrast to received wisdom, Silva Ferreira *et al.* (2002) found that bottled wines subjected to extreme conditions (45 °C temperature, and oxygen saturation) for three months seemed to experience more off lavor formation at pH 3 than at pH 4. They showed that synergistic effects of increasing temperature and oxygen levels at lower pH were significant, both on the decrease in levels of terpene alcohols and norisoprenoids (which impart floral aromas), and on the development of off flavors such as 'honey-like,' 'boiled potato' and 'farmfeed' associated with the presence of phenylacetaldehyde, methional and 1,1,6-trimethyl-1,2- dihydronaphthalene (TDN).

As wine is such a complex medium, and the equilibria in solution dependent on so many factors, it is unsurprising that seemingly conflicting reports are written on the sensory effects of various treatments. Wine pH, so fundamental to the chemistry of the solution and therefore the flavor and aroma of the product, is certainly an area that deserves far more attention than it has so far received in enological laboratories and wine cellars.

Phenolic compounds

Because of the different techniques used to produce white and red wines, the concentrations of phenolic compounds vary greatly between them. Phenolic compounds play a major role in red wine quality, since they contribute to sensory characteristics like color and astringency, and exert a strongly protective influence on the wine during processing and maturation due to their antioxidant and antimicrobial properties. As white wines contain few phenolics to protect them, they require higher levels of free SO_2, and are usually made in a

way that minimizes exposure to oxygen unless the alcoholic fermentation needs to be stimulated, or hydrogen sulfide needs to be removed.

As discussed in Section 2.9.2, there are two major classifications of phenolic compounds in grapes: flavonoids and nonflavonoids. Nonflavonoids (smaller, less complex phenols) are concentrated in the pulp cell vacuoles and are present in all juices. White wines contain relatively low levels of total phenols and the majority of these are nonflavonoids like caftaric acid (an ester of caffeic and tartaric acids). The flavonoids (complex, larger phenols including anthocyanins and tannins) are usually concentrated in the skin, seeds and stems of red grapes. During the maturation and ageing of red wines, the concentration of grape anthocyanins, initially responsible for color, decreases because they progressively react with other phenolic compounds, particularly flavanols (Singleton, 1987). This phenomenon results in the color change from the purple tone of young wines towards the brick red color of matured wines, as well as in the decrease of wine astringency observed during ageing.

At wine pH values, anthocyanins exist as two forms in equilibrium, namely the red flavylium cation and the colorless hydrated hemiketal form, the latter being predominant (Fulcrand and Cheynier, 2006). Various pathways involving both anthocyanin forms have been proposed to explain the conversion of anthocyanins to new, more stable pigments in mature wines. The first process is a direct reaction between flavanols (F) and anthocyanins (A), leading to two kinds of products, denoted A-F and F-A, according to the position of the anthocyanin moiety. Recent work has revealed the presence in wine of both types of compounds, which respectively arise from addition of tannins onto A and from addition of AOH to the carbocation formed by acid catalyzed cleavage of proanthocyanin interflavanic bonds.

The second pathway concerns the reactions between anthocyanins and flavanols mediated by acetaldehyde, a product of the oxidation of ethanol during ageing. This mechanism starts with condensation between acetaldehyde and a flavanol leading to a carbocation intermediate, which reacts in turn with either another flavanol or the hydrated form of an anthocyanidin. The effect of unlimited exposure to oxygen and the associated acetaldehyde addition reactions is an initial increase in color density and polymeric pigments, followed later by a decrease in color and formation of a colored precipitate. Eventually most of the color in the wine will be in the form of dark brown, black or brick red precipitated aggregates (often combined with potassium bitartrate crystals), and the wine itself will be thin, oxidized and pale brown in hue.

The third type of reaction established in wines is a cycloaddition process between anthocyanins and some yeast metabolites possessing a polarizable double bond, for example, vinyl phenol and pyruvic acid, which leads to more stable pigments, structurally similar to pyranoanthocyanins, with excellent stability and resistance to sulfite bleaching.

As stated previously, oxidation in wine occurs faster at higher pH levels because electron removal is easier from phenolate anions than it is from the neutral, or positively charged forms of phenols. Phenols are very weak acids with pK_as between 9 and 10, so the higher the pH, the greater the extent of dissociation, and the more phenolate ions there are. The fact that the hydroquinones formed from oxidation have a lower redox potential than the phenols, and therefore are more oxidized, means that they serve to protect some of the original wine phenols from oxidation, so providing a buffering effect from oxidation (Singleton, 1987). As noted in the previous section, the slower the rate of oxidation, the more the pool of oxidizable phenols is augmented by regenerative polymerization. If oxidation occurs rapidly and most available phenols are oxidized to quinones, there will be less consumption of oxygen because less regenerative polymerization can take place, but greater production of oxidized products. Rapid oxidation of a wine may therefore be deleterious to its potential longevity, but slow oxidation, such as that which occurs during intermittent racking of barrels, has far fewer negative effects. The way in which a wine of a particular phenolic composition responds to oxygen depends on the redox potential of the wine, which is influenced by pH, its phenolic composition, the presence of ascorbic acid and sulfur dioxide concentration.

Phenolics are discussed further later under the heading ‘effects of ageing on color.’

Temperature

In recent work, it has been found that out of a range of possible factors affecting the ageing potential of wine, temperature has the greatest affect on the consumption of oxygen, decrease in sulfur dioxide concentrations and oxidation of phenols (McKay *et al*., 2008).

It is well recognized that prolonged exposure to higher temperature will degrade quality due to the increased rate of reactions within the bottle, and associated reaction products. In the case of oxidation this is especially relevant; the same amount of dissolved oxygen is consumed by reactions in three months at 3 °C as in three days at 30 °C. The effect of storage temperature on oxidation processes of fino wines was investigated by Macias *et al.* (2001). The degree of oxidation was found to be much greater at high (27–45 °C) than at lower temperatures (20 °C).

If oxygen is completely excluded (for example if the wine is bottled under screw cap, with a very small headspace), low storage temperature will help to preserve aroma and prevent other degradation reactions – for example, acetate esters will hydrolyze very slowly at 10 °C but rapidly at 30 °C. Temperature also has a marked effect on age induced changes in terpenes. Conversion of carbohydrates to furfural and pyrroles will be favored by increased temperature, and they may also undergo Maillard and thermal degradation reactions leading to baked flavor ('madeirized') and brown color. Color is also adversely affected by high storage temperatures during maturation and ageing. Dallas and Laureano (1994) investigated the effects of various parameters on the storage of red table wine and found that there were significant decreases in concentrations of individual and total anthocyanins at higher temperatures (30–40 °C) during ageing, which effect was ameliorated by sulfur dioxide additions. Malvidin-3-glycoside was the only phenolic under study that was not affected by temperature, but was more influenced by the time of storage.

In the event the wine is under cork, it becomes even more crucial that storage temperatures are kept stable or the seal between bottle and cork will loosen due to continuous expansion and contraction. Rapid changes in temperature also affect wine volume, and freezing should be avoided as the expansion of the volume in the bottle may even force the cork out. Mayen *et al.* (1996) subjected wines to accelerated browning at 50 °C under aerobic and anaerobic conditions, and found decreases in procyanidin contents with simultaneous increases in flavonol concentrations, due to the hydrolysis of oligomeric derivatives at this temperature. Villamor *et al.* (2009) studied storage conditions on the chemical and sensory properties of young bottled Cabernet Sauvignon and Merlot wines. Low and high tannin wines were stored at 23 °C, 27 °C and 32 °C for 0, 40, 55 and 70 days. In both low and high tannin wines, storage at 32 °C resulted in significant increase in small polymeric pigments with a corresponding decrease in anthocyanin concentrations over time, which was most pronounced in Cabernet Sauvignon. In both varieties, high tannin wines contained more large polymeric pigment (LPP) than the low tannin wines. Generally, titratable acidity and pH were not affected by storage treatments. A trained sensory panel gave higher astringency ratings to high tannin wines than low tannin wines and there was an increased perception of bitterness associated with storage at 32 °C storage for 70 days. The authors stated that results indicated that storage temperature and storage time contributed to changes in the chemical composition of typically ageing red wines, but did not impact perceived astringency.

Vivas de Gauljac *et al.* (2001) showed that concentrations of quinones formed through oxidation of (+)catechin and (–)epicatechin were higher at 40 °C than 4 °C, but the kinetics of quinone formation did not change: levels were close to their maximum values after 30 minutes, indicating that even short exposure times at high temperature can have negative effects for wine. de Beer *et al.* (2005) showed that white wines exhibited a decrease of between 5.7 and 17.2% in their total phenolics during storage at different temperatures. Storage at higher temperatures caused a faster decrease in phenolics with significant differences between wines stored at 0 °C and 30 °C. Decreases for Chenin Blanc wines were faster than those observed for Chardonnay, presumably as a result of Chardonnay's more robust phenolic profile. Chardonnay is also often given barrel

fermentation or maturation treatment, which enhances the phenolic profile of the wine and gives it better ageing potential.

Although sulfur dioxide offers some protection against the ravages caused by high temperatures, it can only do so in a limited fashion. In an early study carried out by Ough (1985), white and red table wine samples were subjected to simulated transit or storage conditions, and held at five different temperatures between 28 and 47 °C with low and medium sulfur dioxide levels for 21 days. The problems caused by minimal SO_2 usage increased dramatically with increasing temperature. SO_2 and color changes were related to temperature, with greater changes and subsequent losses of quality found at higher storage temperatures. Red pigment was lost for the red wine at about the same rate the white wine browned for the low SO_2 wines. The loss in SO_2 was more rapid with increasing temperature for the red wine than for the white.

The result of all the observations around the effects of heat on wine during ageing emphasize the importance of keeping wine in low (10–15 °C), stable temperature conditions if it is to be stored for significant periods. Even in the event that wine is subjected to high temperatures for short periods, damage may be done to the aroma and color. Wine in transit, particularly on large container ships, may experience temperatures up to 50 °C for hours at a time, and this has large implications for the quality of the product being delivered. Even refrigerated containers are not immune to temperature fluctuations of between 10 and 30 °C over a 24 h period, and winemakers need to be aware that the product that left the winery may be entirely changed by the time it reaches its destination due to the effects of heat during transport.

Light

It has always been known that storing wine in light, bright places will alter its color and chemistry over time. For hundreds of years wines have been stored away from light and heat in cool, dark cellars. The scientific rationale behind doing this only been investigated relatively recently. Timberlake and Bridle (1976) examined reactions that occurred between phenols in tartrate buffer solution at pH 3.5 at room temperature in air under darkness and light. Several reactions occurred simultaneously. The anthocyanins and phenolic compounds reacted very slowly, with eventual formation of yellow xanthylium salts. Procyanidins were partly transformed to epicatechin and polymers, the reactions being catalyzed by daylight. The addition of acetaldehyde to mixtures of anthocyanins and phenolics caused rapid and spectacular color augmentation with shifts toward violet, with extent of the shift varying with the type of component. Later, Singleton (1987) observed that exposure of wine to light, especially sunlight where there may also be heat involved, increases the rate of oxygen consumption and the establishment of a low 'rest potential' (or ageing capacity) in bottled wine. Carbon dioxide is generated as the wine is oxidized (under certain conditions) – possibly from the condensation reaction between catechol and pyrogallol derivatives, and the proportion of CO_2 generated to O_2 consumed is far higher in light than in dark conditions.

Concentrations of highly hydroxylated compounds such as gallocatechin also increase if wines are oxidized in light. The author noted that oxygen can be activated to two singlet forms which are then able to react with most organic molecules (which are also singlets). The most active form of oxygen has a very short half life and decays to form the more stable delta activated singlet oxygen, which is 97.8 kJ/mol (23.4 kcal/mol) in energy above the ground state triplet. The delta form has a 2 μs half life in water, which is an adequate time for many reactions to take place. This form can be reduced to yield the superoxide ion. Singlet oxygen is produced by UV light in the presence of photosynthesizing pigments and by certain chemical and enzymic reactions.

Mattivi and coworkers (2000) noted that exposure to ultraviolet and blue light (wavelengths 300–500 nm) will cause heating, and the radiation itself may activate some oxidation reactions, one of which is the well known shrimp-like, skunky fault of champagne called 'light struck' ('goût de lumière'). According to these workers, the photogeneration of thiols (methylmercaptan and hydrogen sulfide) and dimethyldisulfide in wine

exposed to light of wavelengths below 450 nm is caused by photodegradation of methionine and cysteine in the presence of free riboflavin, which acts as a photosensitizer and oxidising agent in wine. The higher alcohol 2-methylpropanol has also been implicated in goût de lumière, as well a number of esters. Attempts to control light struck flavor in wine include the use of copper sulfate, tannin and bentonite. It has been reported that free riboflavin concentration can be a good index of the likely degree of deterioration in the flavor of still and sparkling wines on exposure of bottles to light.

Vivas de Gaulejac *et al.* (2001) showed that the effects of temperature and UV light on the oxidation of phenolic compounds caused the concentration of quinones to increase with increasing temperature. More quinones were formed in the presence of UV light than in its absence, but UV light did not affect the kinetics of the reaction. The authors concluded that while temperature and UV light affected the quantity of quinones formed, they did not affect the rate at which they appeared. The authors stated that wine storage management greatly influences wine ageing and cited temperature and light as being the two best known storage conditions affecting the success of maturation. The authors emphasized the importance of (an absence of) heat and light in the conservation of wines as these factors lead to higher quinone formation with concomitant impact on sensory qualities in white and red wines.

Grape derived aroma components are also affected by light. The alkyl methoxypyrazines (MPs) are grape and insectderived odor compounds responsible for 'green,' 'capsicum' and 'vegetative' aroma in wine. At higher concentrations, MPs are detrimental to wine quality, but at lower concentrations, they are responsible for 'grassy,' 'fresh' smells that are better suited to the style and aroma profiles of white rather than red wines. Blake and coworkers (2010) examined the influence of light and temperature during cellaring on MPs and other impact odorants. Riesling and Cabernet Franc wines were stored at ambient temperature (22 °C) under fluorescent lighting, in the dark at ambient temperature, or in the dark at 12 °C. Additionally, the wine exposed to light was stored in clear, green or amber bottles, the most common glass for wine, which transmit 95%, 50%, and 10% of 350–550 nm light, respectively. Isobutylmethoxypyrazine decreased over a 12 month period by around 30% under all conditions in both cultivars. Acetate esters also decreased with time, regardless of light or temperature conditions, while phenethyl acetate and isoamyl acetate decreased faster at 22 °C than they did at 12 °C. Retention of free and bound sulfur dioxide was higher in light excluded conditions and influenced by bottle hue. Browning in white wine was inhibited by SO_2 and reduced in light exposed conditions and suggested to the authors that the combination of clear bottles and elevated storage temperature was not optimal for protecting against premature browning and other negative quality indicators in white wine. Practices such as bottling in dark colored glass containers and protecting from bright light help to protect the wine in the short, as well as the long term. These results should assist winemakers in selecting bottle hues, and assist in selection of optimum storage conditions for preserving wine quality in both retail and cellar environments.

Vibration

From the anecdotal evidence of the changes in wine that happen during periods of transit (particularly by road), it has long been suspected that wine 'does not like' vibration, and reacts with differences to the flavor and bouquet. According to Chung *et al.* (2008), vibration disturbs the delicate sediments in fine wine and the process of biochemical evolution, which can cause undesirable flavor and taste development. There is very little scientific research on the subject, so Chung and coworkers studied the effect of vibration on some physicochemical characteristics of a commercial red wine. The wine bottles were placed in a specially designed vibration rack, and aged for 18 months under controlled dark conditions with a constant temperature of 20 °C. There were four different 'degrees' of vibration (1, 5, 10 and 20 cm/s^2 or 'Gal'). The pH of the wine was 3.4 before storage, and it did not change significantly during storage. The authors found that although the total acidity increased slightly with ageing up to nine months, especially at the highest vibration level

(20 Gal), the amounts of tartaric and succinic acids, and levels of tannins, decreased during storage. The refractive index increased during the first three months and thereafter it remained constant. The propanol and isoamyl alcohol contents were higher in the wine stored at low levels of vibration. In the initial period up to three months, the lightness significantly decreased (the wine became darker in hue), and then remained relatively constant afterwards. The authors did note that various reactions including oxidation, condensation and polymerization may have resulted in the color changes observed, rather than the vibration.

Closures

Goode (2006) cited cork as the 'prime culprit' in an overview of premature oxidation among white Burgundies as this was the only factor that varied amongst the wines that were studied. He suggested a number of reasons why corks might be responsible, which includes the use of peroxide as an alternative sterilising agent to chlorine containing bleaches associated with trichloroanisole and cork taint. Residual traces of the peroxide in some corks could have led to the random postbottling oxidation observed. However, the scale of the problem and the fact that so many cork suppliers were involved seemed to negate this as the only contributing factor. Goode's suggestion is probably based on work done by Fabre (1989), who demonstrated the presence of peroxide in corks treated with oxygenated water, peracetic acid or sodium peroxide, and showed that peroxide was associated with premature ageing, a drop in SO_2 content, darker coloration and loss of organoleptic quality in wines. The author noted that corks treated with peroxide did not necessarily lead to the presence of oxidizing residues within corks, but use of corks containing peroxide residues was not recommended. Later work by Waters *et al.* (1996) at the Australian Wine Research Institute (AWRI) demonstrated that oxygen permeation through cork was just one mechanism of oxidation affecting bottled wines, but that it was a significant defect for a cork to possess. They cited the example of a wine held for three years under a permeable cork, and noted that up to 36 mg/l of sulfur dioxide was consumed by oxygen ingress and that unlike residual oxidant activity which decreases with time, permeation will continue for the life of a bottled wine. Data gathered in the study also indicated that oxidative damage could result from cork containing oxidants, which might result in losses of sulfur dioxide of up to 73 mg/l in six months. The authors also stated that effects observed for oxidant activity and permeability were highly variable across the corks examined in this study, and that the samples used in the investigation were not representative of corks in the wine industry as a whole, as the wines were from batches that had already shown a sporadic oxidation problem and the corks were thus defective.

Goode suggested that there was a decrease in cork quality in line with large demands for cork during the 1990s, leading to corks with lower integrity and more physical faults being used. Low humidity levels during storage may also cause drying and deforming, exacerbating any physical defects in the corks. If the cork shrinks, cracks or loosens, air will enter the bottle and accelerate oxidative changes. On the other hand, a high humidity level (above 80%) can create the risk of mildew formation on the cork, and possible moldy odors being transferred to the wine.

Goode noted that the theoretical maximum of 11.36 mg of oxygen incorporated on bottling can react with 45.5 mg of SO_2 assuming a reaction ratio of one oxygen molecule to four sulfur dioxide molecules. Danilewicz (2006) suggests a ratio of 1:1 or 1:2). Goode goes on to say that if total loss of SO_2 in a 750 ml bottle exceeds 45 mg then the loss cannot be explained by oxygen entrained at bottling, and must be due to oxygen ingress through the closure. Lopes *et al.* (2006) also stated that bottle ageing of wine (presumably successful bottle ageing) is extremely dependent on the oxygen barrier properties of closures. These workers measured the oxygen ingress through different types of closures using a nondestructive colorimetric method and found that rates of oxygen ingress were dependent on closure type and independent of bottle storage position. Closures that performed best were screw caps and technical corks, with synthetic corks showing the highest levels of oxygen entering the bottle, and conventional natural corks an intermediate level. In another study by the AWRI carried out on wine closures, including cork, cork substitutes and screw caps, it was found that screw

capped wines retained their delicate characters and showed no oxidation or corky off odors. However, screw caps did show rubbery or other sulfur related off odors (Jackson, 2005). Generally speaking, closure type will not dictate whether a wine will receive a gold medal for quality in an international competition. However, it has been regularly observed that closure type affects the types of defects observed in faulty wines: typical defects for wines under cork include fungal, musty, oxidative and 'atypical ageing' notes, while for screw caps defects include sulfide, 'stinky' and vegetative notes. Cork and screw caps therefore have their detractors and fans in equal portions. Jackson (2005) noted that those favoring cork closures argue that limited oxygen ingress (associated with cork use) neutralizes hydrogen sulfide and other reduced sulfur compounds which exist in the wine before bottling. Cork critics might state that the presence of reduced sulfur odors in the wine indicates a lack of understanding of the conditions in the bottle on the part of the winemaker and that the problem is not the 'fault' of the screw cap. It should be noted that reduced sulfur odors can certainly occur (though they are less common) in bottles sealed with a cork. There are certainly broad rules that can be applied to winemaking for either closure. Independent studies on screw caps have demonstrated that Riesling wines can retain their fruity character for upwards of 30 years, but whether the same can be said for red wines (with their greater phenolic content and lower redox potential) remains to be seen.

Effects of Ageing on Wine

Color changes

For white wines, ageing can contribute to quality defects such as browning and to a lesser extent the pinking phenomenon. In young red wines, as described in the section on phenols earlier in this chapter, both anthocyanins and tannins participate in the coloration of the wine. As the wine ages, the anthocyanins polymerize with themselves or copolymerize with proteins, polysaccharides, tannins, ethanol and tartaric acid. Anthocyanin/protein and anthocyanin/polysaccharide copolymers are poorly soluble, and tend to flocculate and precipitate out. Anthocyanin polymers are moderately stable, but flocculate and precipitate out during maturation as a deposit in the bottle. Anthocyanin/tannin copolymers are the most stable. It is well known that barrel ageing a red wine will help to stabilize its color. This is due to the production of a limited amount of acetaldehyde, which activates the formation of the latter small complexes. Not only do these complexes protect the anthocyanin chromophore (part of the anthocyanin molecule that generates color), but they also increase color depth and reduce color loss by enhancing solubility. The yellow-orange xanthylium compounds also significantly contribute to the color shift in red wines towards a tawny red. These reactions help to explain why red wines, which are high in anthocyanins and low in tannins (e.g. from thermal extraction) are poorly color stable, and why sulfur dioxide does not decolorize old wines, as tannin/anthocyanin copolymers are not bleached by sulfur dioxide.

Some of these reactions are accelerated by the presence of oxygen, but they will still occur in a wine protected from oxygen due to the presence of other catalysts like metals and acetaldehyde. The speed of these reactions increases with temperature.

While browning has already been explained as the result of condensation products from quinones, pinking is believed to be caused by the fast conversion of flavenes to red flavylium salts in the presence of oxygen. When white wines (particularly Sauvignon Blanc) are made under highly reductive conditions in order to preserve their aromas, oxidation sensitive phenols are never exposed to oxygen and either precipitated out through polymerization, or preventative treatments included the addition of active carbon, casein, milk powder or polyvinylpolypyrrolidone (PVPP) for the removal of the phenolic compounds, but due to the nonselective nature of these fining agents, they were always regarded as a last resort. In the past years, the use of oxygen in a controlled manner for the removal of phenolic compounds has been received attention. In studies concerning the sensory effects of hyperoxidation on musts and wines, there is general agreement upon improved color stability of wines treated. Although initial color intensity (determining the brown hue at A420) is often

slightly higher than in the controls obtained by conventional winemaking practices, browning capacity during oxidative ageing is significantly reduced or eliminated.

Browning under accelerating conditions is only the visual indication of further profound flavor and odor alterations to expect during oxidative ageing. Development of bitterness and astringency can be avoided or at least drastically reduced by must oxygenation. Kallithraka *et al.* (2009) studied the effects accelerated browning on the polyphenol content, antioxidant activity, reducing power and color changes during storage over nine months in bottles in selected white varietal wines. The results showed that the contents of most of the individual phenols diminished with time, with the exception of caffeic, ferulic and *p*-coumaric acids, the concentrations of which probably increased due to hydrolysis reactions. Antioxidant activity did not show any significant change, but reducing power decreased during the browning test. Absorbance at 420 nm was significantly increased after accelerated browning, as could be expected.

It has also been found that the decrease of wine color during the ageing period is less in red wines that have been made in a more oxidative way (in open fermenters, with punching down and pumping over during fermentation, for example). Anaerobically vinified samples (for example, those made in enclosed fermenters), have a lower free anthocyanin degradation rate initially and a greater percentage of the colorless hydrated form (AOH), but more of the color will precipitate out in the long term. It is fairly common knowledge now that oxidative winemaking generates more stable pigments than nonoxidative winemaking.

Red wines initially deepen in color after fermentation, but subsequently take on a brick red hue. Vivas *et al.* (2008) described the formation and diversity of new compounds resulting from nucleophilic reactions in wine, and which included dimers, trimers and polymers. The research focused particularly on the color properties of the released products and their potential impact on the color of white wine. After 50 to 60 days, the color of the solution was mainly due to soluble polymeric forms, and there was a color shift towards brown. Temperature directly affected the rate of polymerization, and the authors suggested that mild heating might be used to stabilize color. White wines took on yellow gold and eventually brown shades, generally darkening in color.

Color is also an issue for rosé wines. Most rosés are designed to be drunk soon after release, and they do not age well, losing color and fragrance within a few years (Jackson, 2005). In a study conducted by Blanchard *et al.* (2004), results indicated that phenolic fractions derived from grapes (anthocyanin and catechin) influenced the evolution of 3-mercaptohexanol (an important fruity, 'rhubarb,' 'grapefruit' aroma in rosé wines) content in a model solution in the presence of oxygen. The disappearance of 3-mercaptohexanol with catechin in the presence of oxygen was demonstrated in the study, as well as the fact that this mechanism can be inhibited by adding sulfur dioxide. A synergistic effect of sulfur dioxide and anthocyanins in the stabilization of the compound was found. In a model wine, the combination of anthocyanins and sulfur dioxide reduced the oxidative decrease of this aroma constituent significantly. The effect is, however, limited and large doses of oxygen would negate it completely. The protection provided by anthocyanins results from their antioxidant properties, and unfortunately oxygen consumption by the molecules results in their color changing, and gradually the pink color of the wine will go orange. As outlined in the next section, the presence of certain polyphenols (see tannins, below) may actually speed up degradation of odor. Jackson suggests that the use of screw caps may help in limiting the color degradation.

All the reactions and processes listed above may influence the color and color stability of wine, as well as astringency, but their relative importance, as well as the structure of the end products, will depend on the initial wine composition, and also on the presence of yeast metabolites and on oxygen exposure.

The development of tertiary aromas

The oxidation of juice is much more complex than the simple elimination of readily oxidizable phenols, since oxygen can affect other wine constituents, and as such, reports on olfactory changes generated by

hyperoxidation and other oxygen exposure studies in wine are occasionally conflicting. Generally speaking, the oxidative degradation of white wines leads to a loss of their sensorial qualities as primary and secondary aromas degrade, and tertiary aroma compounds increase in concentration. Primary aroma constituents (e.g. terpenes, damascenone and mercaptopentanones) are often changed by oxidation, and so winestyles in which these components are critical will seldom benefit from the effects of time and oxygen, even if well protected by ascorbic acid and sulfur dioxide. Monoterpenes, important in the aroma of Muscat and aromatic cultivars like Gewürztraminer) evolve in the bottle to form products with quite different characters. For example, nerol (with a citrus aroma) will degrade to hydroxynerol with a more resinous odor. The decreases in geraniol (fruity, berry aroma), linalool (sweet, floral) and citronellol (citrus) are usually significant over time. The oxides that form from these terpenes are generally waxy and eucalyptus-like in their odors, so the fresh, floral bouquet of the young wine will be replaced by a 'heavier,' more complex aroma profile in the older wine. Some terpene glycosides can hydrolyze slowly under bottle conditions and offset the loss, lending further complexity.

Flavor loss in white wines is also associated with changes in ester content, although the importance of these compounds in a wine's long-term bouquet is questionable. The esters originating from the berry are highly volatile and unstable, those resulting from microbial activity are often unfavorable, and those resulting from ageing are nonvolatile. There is no direct relationship between the total concentration of a wine in esters and the quality of its bouquet. Esters are formed by the condensation of an acid and an alcohol, are part of the primary aroma, and it cannot be argued that a great number are produced during fermentation and generate the fresh, fruity bouquet of young whites, for example, the ripe banana quality of Pinotage is undoubtedly due to the formation of isoamyl acetate during fermentation. Once yeast is removed, the equilibrium will slowly shift back to normal and esters hydrolyze back to their acids and alcohols. Yeast hydrolysis during lees contact increases the wine's esterase content, which may explain why wines undergoing lees contact have a more pronounced bouquet. Certain ethyl esters such as ethyl tartrate and ethyl succinate are synthesized in the bottle in a slow, nonenzymic reaction between ethanol and the primary fixed acids in wine. They participate only very slightly in the wine aroma, as they are poorly volatile, but can cause a decrease in total acidity of up to 10%, thus 'softening' the wine.

The transformation of norisoprenoid precursors and diterpenes into vitispirane and trimethyl dihydronaphthalene (TDN) will also lead to resiny, kerosene-like characters, particularly in Riesling from warmer regions and vintages. The aroma of oxidized white wine is largely due to the Sherry-like, nutty odor of acetaldehyde, the primary compound produced on oxidation of ethanol. With further time, and oxidation, the acetaldehyde will itself be oxidized to acetic acid, and will also react with other compounds in solution. The acid catalyzed dehydration of residual carbohydrates in the wine may occur rapidly at higher temperatures leading to 'baked' notes. Even at low temperatures, other reactions involving degradation of carbohydrates occur in time, to give products like hydroxymethylfuraldehyde (from fructose) which has a 'camomile' odor, and furfural which has a 'sweet, burnt' aroma. The Maillard reaction between amino acids and residual sugars can also generate a range of melandoin products which deepen the color of white wines, and impart caramelized flavors through the production of compounds such as hydroxymethyl furfural, glyoxal, methylglyoxal and diacetyl. In addition to this, ageing will also affect any reduced sulfur compounds that happen to be present in the wine, very seldom with positive consequences for the product. At low levels, dimethyl sulfide acts as an enhancer of fruity aromas, and even at levels above detection (30–40 mg/l) it has been correlated with a desireable aged bouquet. As soon as it exceeds this level, particularly in delicate white wines that do not have the complex, aromatic 'background noise' of red wine, it becomes detrimental and its odor is sometimes described as 'shrimp-like.' Pisarnitskii (2001), in a review of minor aroma components in wine, noted a 'saprogenic, fecal, wineskin' tone in wine is usually due to the presence of low molecular weight sulfur containing compounds. Hydrogen sulfide (H_2S) is the most important of these 'reductive' sulfur compounds, formed from sulfur containing amino acids, primarily methionine. It has a characteristic rotten egg odor, easily detected and

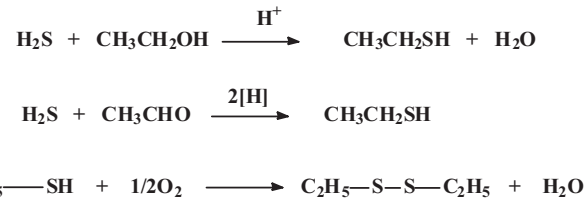

Figure 2.9.29 *Production of some odiferous organosulfur compounds from H_2S during wine maturation*

identified by most consumers. The reaction of H_2S with acetaldehyde or ethanol produces ethyl mercaptan (Figure 2.9.29), a compound also associated with 'reductive' conditions in wine, which has an 'alliaceous' or 'garlic' odor and a threshold concentration between 0.02 to 2 mg/l. In time, contact with oxygen favors condensation of ethyl mercaptan into diethyl sulfide, a foul-smelling compound, which is extremely difficult to remove or disguise.

Methyl mercaptan may similarly undergo condensation into dimethyl disulfide (Figure 2.9.29), a foul smelling compound with a threshold concentration of between 0.1 to 12 mg/l, depending on the matrix of the solution. Dimethyl sulfide may well present as the 'metallic' flavor sometimes associated with wine under screwcap, especially if it is in combination with ethyl methionate. These sulfur compounds are most commonly associated with wines under screw cap (i.e. in conditions where oxygen has been effectively excluded from the ageing process), but it is important to note that these compounds can develop in wine even in nonreductive conditions, at which stage further oxygen exposure may result in turning a smelly wine into a smelly oxidized wine (Goode, 2006b). Equating the term 'reduced' with the presence of volatile sulfur compounds is therefore an oversimplification.

The identification of the most important descriptors related to aged or oxidation affected wines include 'honey-like,' 'farmfeed,' 'hay' and 'nutty.' By gas chromatography olfactometry analysis three aromatic zones related to these descriptors in the oxidation spoiled white wines could be determined. Sotolon (4,5-dimethyl-3-hydroxy- 2(5 *H*)-furanone), was been found to have an important impact on the flavor of botrytized sweet wines (such as Auslese wines and Sauternes), Sherry-like wines and also aged white wines. Other aromatically important contributors to an aged bouquet include 3-(methylthio)propionaldehyde, phenylacetaldehyde, and TDN (1,1,6-trimethyl-1,2-dihydronaphthalene) (Jackson, 2005).

Flavonoids have been proven to induce odor degradation under conditions of accelerated oxygen consumption, although they are not volatile themselves. Schneider (1998) observed that when a low flavonoid wine was enriched with catechin or other flavanols extracted from grape seeds, negative aroma attributes like mushroom, earth and straw increased strongly within five months under normal bottle storage conditions, whereas the control had higher ratings for fruity attributes. During accelerated oxygen consumption, the flavonoid enhanced sample consumed more oxygen, lost more sulfur dioxide and produced more acetaldehyde than the control. All research conducted on this issue stresses that further research is needed to evaluate the reasons behind the differences occurring on different varieties, and to understand the effect of oxygen contact on the evolution of nonphenol flavor compounds.

A lot of recent research has been conducted on the atypical ageing phenomenon (ATA or UTA 'untypical ageing') in white wines. Bell and Henschke (2005) noted that these wines lose their varietal character and begin to exhibit atypical aromas/flavors such as 'acacia blossom,' 'floor polish,' 'naphthalene' (moth balls) and 'wet towel.' These characters are quite distinct from the kerosene-like odor, attributed to 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN), that some white wines, notably Riesling, display as they age in bottle. The taint was first found in German wines in 1988 and has since been observed in South African, American and other European wines. One of the compounds implicated in atypical ageing is *o*-aminoacetophenone (*o*-AAP).

It is a nitrogen containing compound, which is of interest because it appears that it has a relationship with yeast assimilable nitrogen (YAN) concentration in the wines. It has been postulated that the formation of ATA is the result of the grape berries' response to growing under conditions of stress, for example, with insufficient water and low nitrogen supply in dry seasons. The precursor of *o*-AAP is the phytohormone indole-3-acetic acid (IAA), which, following fermentation, is oxidatively degraded in the presence of sulfur dioxide to *o*-AAP. Workers observed a significant increase in the free IAA concentration after fermentation of wines from stressed vines. Although ATA was not measured in the wines, the precursor concentrations were reportedly sufficient to form tainted wines. It is possible that yeast might play a role. Comparison of free and conjugated IAA concentrations after fermentation carried out in the presence or absence of diammonium phosphate (DAP) supplements showed that the concentration of both the free and conjugated forms of IAA were higher in the DAP supplemented fermentations. This may discourage winemakers from adding DAP as a matter of course, without first checking assimilable nitrogen levels as well as yeast requirements to see if supplementation is actually necessary.

Taste and mouthfeel

Red wines are known to substantially improve through moderate oxygen contact, such as during barrel maturation or racking. They become more harmonious and acquire greater stability and bouquet.

Many wines, especially reds, are rough and astringent in their youth. There is usually a decline in bitterness and astringency during wine ageing due to polymerization of tannins and anthocyanins, although the initial effect may be an increase in astringency associated with increase in number of medium sized tannins. Eventually the progressive association of smaller, more bitter tasting tannins into large complexes, as well as the reaction of hydrolyzable and condensed tannins with proteins will lead to loss of more bitterness and astringency. Because of the difficulty in isolating and characterizing these types of molecules, only limited studies of their structures and mouthfeel properties have been made to date. In a sensory study of red wine tannins in model wine solutions, Vidal *et al.* (2004) established that neither anthocyanins (in their glucoside or coumaroylated forms) nor pigmented tannin-like polyphenolic compounds influenced either astringency or bitterness. The authors suggested that the pigmented tannin-like polyphenolic compounds that are formed during winemaking and upon storage may decrease astringency in red wine, provided they are present in sufficient levels. This could occur through the transformation of part of the astringent material in the wine into pigmented polyphenolic compounds rather than astringent ethyl bridged flavanols. The authors emphasized that research efforts were needed for the structural characterization of compounds formed during vinification and ageing, as not much is known about the process or structures involved.

What is well known, however, is that over time, aggregated tannins and color will precipitate from red wine (forming sediment in the bottle), leaving a more refined mouthfeel. It is suggested that the formation of tannin–polysaccharide or tannin–protein complexes in the wine decreases their ability to react with taste receptors in the mouth. The stable proteins in wine (that is, those not involved with haze production) may provide winemakers with a new measure of how well a wine will age. It may also supply an additional means of regulating wine quality (Jackson, 2005).

As far as the effects of ageing on other components in wine go, there is also limited knowledge available. Although glucose and fructose react with other constituents and undergo structural rearrangement, the losses do not affect sweetness perceptibly. Ageing of wine may also induce small losses in acidity due to formation of esters and precipitation of acids in with polymers and as potassium bitartrate.

Accelerated Ageing

Commercial pressures have encouraged many winemakers to look at methods to accelerate the ageing process in wines. Ultraviolet and infrared radiation and ultrasonics have not had much success, but aeration and wide

temperature differences (to recreate summer and winter conditions) have been used with some effect. For instance, in the 'Monti' process, red wine is taken through several cycles of saturating with air at low temperatures, heating to 20 °C, cooling, then resaturating. This type of handling is never used for premium wines, and is mostly used in fortified wines, as it tends to modify color more than taste.

An accelerated ageing process may produce more unpleasant than pleasant effects, as wine is such a complex medium, so predicting the results of reactions and the outcome of such treatments is difficult and financially risky when dealing with large volumes. It is generally accepted that a slow, cool ageing without temperature fluctuation or exposure to light is best for the production of good quality wine.

2.9.6 Some Current Trends in Wine Production

Viticulture 'Going Green'

The concept of farming in an environmentally friendly, sustainable way rather than just to maximize profits is receiving increasing amounts of attention in winegrowing areas. In South Africa, to give just one example, the BWI (Biodiversity in Wine Initiative) (Biodiversity in Wine, 2010) is a pioneering partnership between over 150 wine producers, and the conservation sector. The goals are to minimize loss of threatened natural habitats in the Western Cape, and to contribute to sustainable wine production through the adoption of biodiversity guidelines by the South African wine industry. One of the strategies of the BWI is to identify and enlist interested producers as members or champions of the initiative, who will implement the biodiversity guidelines, conserve critical ecosystems and incorporate a biodiversity facet into their winery. Farmers who subscribe to BWI principles are involved in conservation projects, clearing alien vegetation, and farming with as little impact on the local biosphere as possible, with the aim of encouraging indigenous vegetation and vineyards to flourish in the same soils. Studies into 'green tourism' in the Western Cape and elsewhere indicate that visitors are looking for a restorative and recuperative experience in a rural environment which contributes in a meaningful way to communities they are visiting, and that farms that are adding value to their surroundings by subscribing to the principles of initiatives like the BWI are preferred destinations.

As discussed in Section 1.3.12, biodynamics, a 'super-charged' version of organic farming, is gaining popularity with wine farmers around the world in line with the current global trend for lower impact agriculture and environmentally sustainable methods of production. One of the common denominators amongst biodynamic practitioners is the importance of developing a healthy microbial population in the soil. Anything that is going to be added to the soil, even conventional supplements, is done via the compost heap, which will typically contain waste material from the winery (such as the grape seeds, skins and stems), plus cow manure and a range of special biodynamic preparations added to the heap (Goode, 2010). Compost is added to the soil sparingly so as not to promote vigorous growth, which is not conducive to wine quality. Working the soil in order to break up superficial roots and encourage deep root systems is also encouraged, and a return to the 'old ways' of ploughing using horses has also become part of the biodynamic landscape.

Currently biodynamics in viticulture still has an esoteric, cultish image without any real scientific underpinning of the practices so far being put forward in the literature. Rigorous research on biodynamics faces a number of obstacles, not the least of which is a lack of funding. The studies that have been carried out seem to suggest that biodynamics does enhance soil quality, with more organic matter content and microbial activity (Reganold, 1993). The results of a long-term study in Central Europe comparing organic and biodynamic farming with conventional agriculture by Mäder *et al.* (2002) showed that while biodynamic farming resulted in 20% lower crop yields, the input of fertilizer and energy was reduced by 34 to 53% and pesticide input by 97%. Enhanced soil fertility and higher biodiversity found in organic plots seemed to render these systems less dependent on external inputs.

So, while detractors of the biodynamic system of farming would highlight a lack of scientific evidence to back its claims of improving wine quality, point out the dubious advantages associated with applications of manure fermented in cow horns by moonlight and ascribe the whole business to the worst form of cynical marketing exercise, proponents can point to the improved soil structure and texture, and enhanced microbial activity in the soil. One thing that cannot be argued is that farming sensitively, with respect for local wildlife, can only benefit a region in the long run.

Other techniques that have been tested in order to reduce the application of chemical sprays include successful trials on the control of molds on fruits or vegetables by applications of natural saprophytic yeasts. However, their use is often limited because production on an industrial scale is very difficult, or even impossible. For example, a study has now examined the potential reduction of microbial diseases on damaged grape berries by spraying industrial *S. cerevisiae* yeasts (readily available in large amounts) onto the grapes (Salmon, 2010). Two species of fungal disease were selected: *Botrytis cinerea* (invasive disease fungus) and *Aspergillus carbonarius* (responsible for production of the toxin ochratoxin A), as well as an invasive bacterial species (*Gluconobacter oxydans*). Ochratoxin A (OTA) is a secondary metabolite of molds that contaminate food and feed (Section 5.11.4). OTA is nephrotoxic, hepatotoxic and immunotoxic in experimental animals, and due to its carcinogenic properties, the International Agency for Research on Cancer (IARC) has evaluated OTA as a possible carcinogen in humans (2B group).

It was demonstrated that the spreading of *S. cerevisiae* at the surface of previously damaged grape berries contaminated with different microbial species was very efficient for reducing fungus mycelium growth after 48 h of incubation. This was not the case for bacterial *G. oxydans* contamination, where no effect was observed. The authors noted that the yeast spraying should be done about 2–5 days after initial infection by the fungi in order to obtain an optimal antagonistic effect. The effect of yeast spraying on *A. carbonarius* development on the grape berries was particularly significant, indicating that yeast spraying before grape harvest could represent a biological alternative for limiting the occurrence of *A. carbonarius* in the vineyard. The reduction of the spread of *A. carbonarius* was accompanied by a significant reduction in the final level of ochratoxin A in the corresponding wines. The chemical and sensory properties of the final wines were not detrimentally affected by the yeast spraying (Salmon, 2010).

Precision Viticulture and Spectral Vineyard Imaging

High spectral and spatial resolution airborne sensors are increasingly being used for the assessment of the health and vigor of crops, including grapevine. The spatial resolutions available nowadays enable the capture of fine features in plantations such as the vine rows in a vineyard as well the means to analyze the health status of plants through characterizing the spectral reflectance of the plants at different stages of phenology. Advances in global positioning system (GPS) technology and geographic information systems (GIS) mean that input can be used for the application of fertilizers, herbicides, insecticides and seeding in general agricultural, horticultural and viticultural practices (Lamb *et al.*, 2004). Optical remote sensing can provide a synoptic view over entire vineyards offering viticulturists and winemakers a management tool of enormous potential with red grape varieties, especially if canopy architecture can be linked to production of phenolics in ripe grapes. Given the practice of differentiation in pricing between grapes based on quality attributes like color and total phenolics, accurate and reliable data that describe grape quality is particularly useful.

Atmospherically corrected high-resolution imagery is used to produce a number of image maps which can either individually or collectively help vineyard managers and winemakers alike to make more informed management decisions regarding the high value vineyard plantations (Arkun, *et al.*, 2001). Attributes that can be monitored include:

Vine vigor (greenness) for better targeting of vineyard practices such as irrigation, fertilization, spraying, pruning and harvesting

Crop condition, so that the winemaker can harvest segments of a vineyard block at optimum ripeness, which also avoids the mix of riper grapes with the less ripe ones increasing the overall value of the harvest
Differentiation between cultivars, ensuring varietal purity at crushing by avoiding the harvesting of inappropriate vines or rows
Plant species discrimination based on chlorophyll a, chlorophyll b, carotenoids and xanthophylls
Regional mapping of vine varieties, which can be used for planning or inventory purposes
Digital elevation models to map features across the topography and existing plantation areas and other features of interest (e.g. dams, vacant blocks, future plantation or improvement sites etc.)

Enology 'Going Green'

In the same way that biodynamic principles are moving into the vineyard, they are also moving into the cellar. Fermention in 'concrete eggs' or 'biodynamic fermenters' is being trialled at a number of establishments around the world According to enthusiastic converts, the shape of the fermenters create a vortex during fermentation, keeping the marc and juice moving, and maximizing contact and extraction without harsh punching down. However, a great number of winemakers have lined their old sunken concrete fermenters with fiberglass or stainless steel because of sanitation and concerns around the level of extraction of minerals from the porous concrete, and these are still valid issues inside the more modern versions. The concrete eggs are also hard to shovel out, and controlling the temperature of the fermentation inside the eggs is almost impossible, with wine needing to be pumped through heat exchangers if there are problems. Other features of biodynamic winemaking are that the use of preservatives is kept to a minimum, filtration is sometimes avoided, and cellar operations are occasionally carried out according to a lunar calendar.

Carbon Footprinting Wineries

Another aspect of 'greener' production trends is highlighted by Theron (2008) in a discussion on carbon footprinting to quantify the impact of environmental pollution by wineries. Theron noted that businesses may in future be compelled by law to reveal their carbon footprint and that the wineries will have to calculate this on a regular basis, and be shown to be making improvements over time if their footprint is too large. The method of calculation, which is very complex, consists of various sections that address specific winery usages or activities. The most important of these include fuel consumption of vehicles, consumption of electricity and other sources of energy, the use of carbon dioxide in the cellar, the use of fertilizers and chemicals, disposal of liquid and solid winery waste, packaging materials such as containers, bottle closures and wood products, and the impact of transportation of wine to the various markets. The wine industries of Australia, California, New Zealand and South Africa have collaborated to develop a method by which a winery may calculate its carbon footprint. The details may be obtained on the websites www.wfa.org.au or www.ipw. co.za. Theron noted that if cellars are expected to make use of this method, it requires serious attention to make it more user friendly, but that it was disconcerting to learn that a number of cellars in South Africa were still unaware of even the basic data such as their own fuel and energy consumption. During 2007, students at Stellenbosch University in South Africa calculated the carbon footprint of three local wineries as a project, using the International Wine Carbon Calculator (2010). The pressing capacity of the cellars ranged from 170 to 11 400 tons and the carbon footprint varied from 0.1 to 1.0 tons of carbon dioxide per ton of grapes pressed. The concept of food miles contributes to the carbon footprint of any product, as it implies that the further the required distance to transport the product, the bigger the carbon footprint. However, this idea is simplistic and studies undertaken in the United Kingdom on New Zealand dairy products, lamb and apples showed that the carbon footprint for these products is four times smaller than similar products produced in the UK, even taking into account the transport, by ship, of those products to the UK (Müller, 2007). Shipping transport should

be used more frequently than air transport for moving goods over long distances to reduce the associated impact on the carbon footprints of products. A Californian entrepreneur, for example, is developing yacht transport for wine, in view of the fact that conventional transport of wine is one of the biggest contributors to the carbon footprint of wineries. Californian Clark Beek intends to use his 40 foot yacht to transport wines from sustainable or biodynamic production from the Napa and Sonoma wine regions to the San Francisco Waterfront. Such transport, combined with his tourism activities, provides a service to ecologically minded wineries and consumers (Theron, 2009b)

Alternatives to Sulfur Dioxide

Sulfur dioxide is fairly ubiquitous in winemaking due to its effective antimicrobial, antioxidant and antioxidasic activities, but is still seen as a necessary evil because it is an additive, and certain individuals are sensitive to its effects. Based on EC Regulation 1991/2004, sulfites must be declared on the label if their concentration in the wine is higher than 10 mg/l. There are alternative practices and additives that can be used in reducing the use of sulfites in winemaking, but the complete elimination of sulfites is improbable. Winemakers have still not yet quantified by how much is it possible to reduce sulfur dioxide levels without risking taste and quality degradation, or increasing microbial contamination or oxidation during vinification or storage. Hyperoxygenation, a massive addition of oxygen or air with the purpose of completely oxidizing all the unstable substances, is another alternative, as is hyperreduction with ascorbic acid or other antioxidants to protect the must from oxidative reactions, but both these methods have associated disadvantages and the possibility of the production of off flavors that may result from their use. Conservation under inert gases such as nitrogen or argon can be useful in the management of the wine level inside steel tanks, but obviously has a cost associated. These gases (as opposed to others such as carbon dioxide) show a low solubility in the wine itself and are able to significantly reduce the concentration of oxygen in the headspace, minimizing the risk of oxidation. The recently introduced practice of coinoculating yeast and lactic acid bacteria permits an effective and simultaneous management of both alcoholic and malolactic fermentation without the need for long periods after fermentation with little sulfur present waiting for the malolactic fermentation to start. An alternative to sulfites is lysozyme (a family of enzymes which affect bacterial cell walls) Around 500 mg/l of this albumin derived protein has the same effect on unwanted lactic bacteria as 40 mg/l of sulfur dioxide. However, as lysozyme is a protein, its use should be carefully considered due to possible interactions with phenolic compounds which may lead to color loss in red wines. It may cause protein instability in white wines, and it can cause allergic reactions.

The use of recently developed electrodialysis bipolar membranes allows acidification to a required pH value, and thus potentially decreases the amount of sulfur dioxide required during winemaking. The bipolar process was successful at inhibiting *Brettanomyces* growth, notably with no or a very low sulfur dioxide addition (total about 10 to 20 mg/l) when the level of acidification was high. The use of the electrodialysis is not yet permitted in commercial wine production (Cottereau, 2010).

An appropriate combination good acidity, antioxidants and antimicrobial agents may help to reduce the amounts of sulfur dioxide necessary for wine protection.

New Methods of Monitoring Oxygen Uptake and Consumption

The importance of oxygen ingress through closures in the formation of oxidized aroma has long been known, and the reliability of closures has been the subject of innumerable studies, notably those by the Australian Wine Research Institute. Previously, oxygen ingress could only be measured through destructive techniques with oxygen sensitive electrodes (Section 4.5.2), but new technology developed by Nomacorc means that a ‘light reactive’ dot can be inserted into a bottle before closure. The dot consists of a substance that reacts

with dissolved oxygen in solution, is then illuminated, and the fluorescence measured. This correlates directly with the amount of oxygen in solution. This way, oxygen consumption or ingress in a closed bottle can be monitored almost indefinitely. The system provides rapid readings of total oxygen content in wine when measuring either high or trace amounts of oxygen and has applicability as a tool for controlling quality at every step in the winemaking process from crushing through postbottling aging. Although the method can only work if the 'dots' are inserted before the bottles are filled, and therefore assume a large measure of preplanning and organization. Research partners, wine producers and analytical laboratories have validated the accuracy and value of this system. See also Section 4.4.3 for further discussion.

Biotechnology in Winemaking

Changing wine styles and consumer demands for better quality products mean that winemakers are constantly on the lookout for new products and techniques to enhance their usual ranges. Using different yeast strains for different winemaking objectives has become routine practice in most establishments with a range of products on offer, for example researchers are currently looking at developing yeast that are able to produce lower levels of alcohol during fermentation from grapes with higher sugar content (Hart and Jolly, 2008). Other yeast producers are attempting to isolate, select and microencapsulate enological native to or indigenous yeasts from several European wine producing regions (Rioja Alavesa, Bordeaux, Chianti and Vinho Verde), in order to allow wineries to control the fermentation process and ensure production of high quality wine while maintaining the typical sensory properties and the aroma profile of each wine area. The usual method employed to improve yeast strains is yeast breeding. However, because of the generalized and uncoordinated way that the genetic material is rearranged during the mating process, many new strains will have none of the desired characteristics and some may even exhibit a few unwanted traits (Styger, 2008). The process of developing yeasts by natural selection and breeding is also time consuming. Second generation biotechnological procedures entail the generation of better biological agents to perform the reaction, through the so-called classical microbiological techniques, such as breeding, mutagenesis and directed evolution. Numerous laboratories around the world are working on the genetic modification of yeast strains with the specific aim of enhancing fermentation performance, facilitating wine processing, manipulating the physicochemical structure of wine and the enhancement of organoleptic qualities (through the intentional loss of negative or gain of positive characters). Novel traits have also been considered, such as the possibility that transgenic yeast may elevate resveratrol or antioxidant concentrations in wine. However, despite the rapid and successful development of genetically modified yeasts, the route to commercialization for transgenic yeasts has been slow. Their future use remains unclear as the negative attitudes of consumers towards GM products has remained unchanged for at least a decade in spite of the fact that research seems to suggest that GM yeasts have very little impact on the environment (Styger, 2008). The whole process of winemaking, using yeast to convert sugar in the form of grape juice into ethanol in the shape of wine, is in fact one of the world's oldest biotechnological processes. Despite this, biotechnology does not have a very good reputation in conservative winemaking circles, and it may be a very long time before they are able to accept that GM products are more beneficial than harmful.

Dealcoholization

It is generally accepted that low to moderate consumption of wine is beneficial to health (Section 5.6.3), but it is still not clear how much the alcohol and the nonalcoholic compounds in the wine contribute to these benefits. Owing to the obvious disadvantages associated with excessive alcohol intake, the partial or total removal of alcohol from wines and other fermented beverages has gained importance in recent times (Ligouri, 2007). The definition of a low alcohol beverage varies between countries. The content for consumers is declared as volume of alcohol per volume of beverage. According to the European Commission, drinks

are described as 'low alcohol' if they contain less than 0.5% alcohol, and 'alcohol free' if they contain less than 0.05% alcohol. A 'wine' needs to contain at least 9% alcohol, and if less than this, the beverage needs to be referred to as a 'wine based drink.' In contrast, the South African Wine and Spirits Board, advises that a 'light' wine should have an alcohol level of less than 10% v:v. In the United States, a low alcohol wine contains 6–7% alcohol. According to the Australian Food Standards Code, a 'low alcohol' beverage must contain no more than 1.15% alcohol by volume (Blackhurst and Marais, 2009).

In a winemaking context, dealcoholization is used for adjusting the alcohol content when grapes have been harvested very ripe, for producing lower alcoholic wines for the growing market, or during the production of nonalcoholic beverages. Winemakers will often pursue the flavor characteristics associated with a high degree of ripeness, and a small adjustment in the alcohol content, between 1 and 2%, is carried out in order to bring the wine into balance, so that high alcohol does not entirely dominate the palate. Although earlier harvesting, and cooler climates can limit the alcoholic content of wine, consumers have become increasingly concerned about health, spawning some interest in low alcohol wines. The decrease in the annual per capita wine consumption in the French, from 120 l in 1959 to 43 l in 2008 (Blackhurst and Marais, 2009), may thus be reversed if palatable, healthier beverages are available. Fermented beverages from which the alcohol has been removed after fermentation theoretically offer traditional beverage flavors without the health risks and side effects of the alcohol, but in practice are often found inferior to their higher alcohol counterpart. The perception that that lower alcohol wines are 'undrinkable' may also result from the fact that wines with higher alcohol content (some containing alcohol concentrations of as high as 16%) are often highly acclaimed by critics.

In the case of wine with moderate reductions, however, it seems that consumers were not able to differentiate between the taste of standard wines with 13–14% alcohol and those with a moderate reduction of alcohol to 10–11% (Blackhurst and Marais, 2009).

There are several methods available for removing or reducing alcohol in wines, like evaporation, cryoconcentration and vacuum distillation. Each process has its advantages and disadvantages in terms of cost and product quality. Technologies such as adsorption on zeolites and supercritical fluid extraction, as well as filtration, using specialized membranes, reduce the ethanol content under mild conditions, so the other organoleptic features of the wine are affected less.

European Union legislation precludes the use of recognized enological practices such as reverse osmosis, distillation, nanofiltration or centrifugation for lowering alcohol concentrations. These practices are allowed in South Africa, Australia and California, but wines may not be exported to the EU. Recently in the UK, the Wine Standards branch of the Food Standards Agency banned an 8% alcohol wine because an unauthorized alcohol lowering process was used**.** Paradoxically, similar beverages made in the USA using these practices may be sold in the EU owing to an EU/US bilateral agreement**.** There is a paucity of information on health benefits of low alcohol wines. The current evidence seems to indicate that ethanol is not vital for providing the health benefits in moderate wine drinking, and therefore reducing the ethanol in wine would not diminish the potential health benefits whilst enabling safer consumption. Genetic modification has the potential to create yeasts that give lower alcohol yields, but natural selection and breeding of yeast with lower sugar to alcohol conversion rates is the route currently used and therefore alcohol reduction is only in very small increments. Additional hybrid breeding and selective screening are ongoing in an attempt to decrease the sugar to alcohol conversion rate in subsequent generations (Hart and Jolly, 2008).

Dealcoholization is discussed more generally in Section 2.13.3.

Wine Packaging

For hundreds of years, glass bottles have been the container of choice for wine, and it is generally agreed by most producers that aluminium, bag in the box (BIB) or polyethylene terephthalate (or PET, thermoplastic

polymer resin) bottles are not appropriate for the presentation of premium wines. Consumers are increasingly aware that if wine is to be transported across the world, emissions of greenhouse gases will be associated with this transport, and that bulkier products involve higher emissions. Industry bodies in several countries have set goals to reduce such emissions and the use of lighter glass and recycled bottles are part of the strategy. Recycling of bottles in California, increased to 28.1% in 2007 compared to 23.5% in 2006 (Theron, 2009c). Bottling bulk wine at the distribution points in the destination country is another strategy that has been adopted widely, and the use of plastic containers for wine has recently met with some consumer approval. PET bottles weigh far less than glass bottles (120 g compared to 550 g), have the same shelf appearance as glass bottles and can be recycled. Glass bottles themselves have decreased in weight considerably, with 750 ml wine bottles closed with screwcaps weighing only 350 g becoming fairly standard in the South African wine industry, for example. The average weight of bottles sealed with corks has also reduced from 570 to 460 g.

The reduction in the weight of the bottles should reduce the carbon emissions created during the transportation and export of bottled wine bottles through lower fuel consumption, but the export of wine in bulk containers is also a fuel efficient alternative used by a number of producers.

Another adaption being taken on by wine producers is to package still wines in bottles without a 'punt' or concave base. This feature is used to strengthen the bottle in the case of sparkling wine (where it will in all likelihood remain a permanent feature), and to help with collection of sediment in red wines. If wines are not going to be under pressure, are not heavy reds likely to drop phenolics or tartrates and are not going to be aged, the feature is superfluous, and a great weight saving can be made by bottling in a flat bottomed bottle.

There is an increase in BIB packaging of wine but although the outer cardboard casing can be recycled, the inner foil bag cannot. TetraPak is an aseptic packaging container consisting of layers of pressed cardboard, an aluminium isolation layer and plastic covering. Recycling of TetraPak differs among countries and may range from 5 to 27% (Theron, 2009c).

To some wine producers, new market requirements or regulatory prescriptions can be restrictive and frustrating, and many fight against considering alternatives to their heavy glass bottles. But to proactive wineries or distributors, such requirements represent opportunities to gain a market advantage, and lighter bottles and alternative packaging ideas are embraced as part of a larger strategy to 'go green.'

2.10
Fortified Wines and Liqueur Wines

There are as many characters of Port as of people, as many colours as races of mankind, and a good Port lives to be as old as a man.

—Antonio da Silva

2.10.1 Overview and Scope

A fortified wine is one to which an alcoholic spirit (usually grape spirit or brandy) has been added at some point in its production, so that its alcohol content is not derived solely from fermentation. Many fortified wines, such as Port (Section 2.10.7), the sweeter Bual and Malmsey Madeira wines (Section 2.10.5) and the liqueur Muscat wines of France (vins doux naturels, Section 2.10.9) and Australia, are made by adding brandy to the fermenting must, thereby arresting fermentation, increasing the alcohol content and leaving a residual sweetness from unfermented sugar. At what point in the fermentation spirit is added, for a given final ethanol content, determines the degree of sweetness of the finished wine and the volume of spirit that needs to be added: early addition requires much spirit and results in a sweet wine; late addition needs less spirit, but gives a drier wine. At one extreme of this general theme, some fortified wines are made by addition of spirit after fermentation has finished. Sherry and the drier Sercial and Verdelho Madeira wines are examples of this type. Sweeter Sherries are made by addition of 'sweetening wine' (Section 2.10.2) to the fortified dry wine. At the other extreme, fortification involves the addition of wine spirit to the unfermented grape juice. These beverages are known as vins de liqueur (Section 2.10.10), the best known being Pineau de Charentes (Cognac region) and Floc de Gascogne (Armagnac region). Some Australian Muscat Liqueur wines are made with brandy added at a very early stage in the fermentation. There is an equivalent of vin de liqueur in the world of apples and cider: pommeau (Section 2.8.5). One of the original reasons for fortifying wine with spirit was to increase the robustness of the wine, to make it less sensitive to unfavorable environmental factors, thus increasing its life span. In particular, fortification enabled the wine to withstand the rigors of a long journey while still in cask. Nowadays, transport is easier and much faster, and additionally much wine is shipped in bottle rather than in cask, so that much of the original necessity for fortification has vanished. Nevertheless, during the course of evolution of fortified wines, several features of their production gradually resulted in elevated status for many of the wines, which have not only thrived (taking into account fluctuations in the market and fashion), but are still evolving. For example, the development of flor (Section 2.10.3) on the

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass

surface of fino and manzanilla type Sherries, the heating process ('estufagem') used to produce Madeira (Section 2.10.4) and the gentle, but constant agitation of fermenting Port must before mixing with spirit (Section 2.10.5) are all essential to the production of the best fortified wines of those styles. To these can be added the solera system of ageing and blending for Sherry (Section 2.10.2), some Madeira and other wines, the use of fortified or concentrated must for sweetening and adding color to oloroso type Sherries and many other fortified wines and the use of oxidative ageing in the production of certain types of fortified wines, such as oloroso Sherry, Madeira, tawny Port, Marsala and others.

This section reviews the methods of production and salient features of the greatest fortified wines: Sherry, Madeira, Port and the liqueur wines of France, Australia and other countries. Also reviewed here (but more briefly) are a number of other wines, notably Marsala, vin jaune, Vernaccia di Oristano and the wines of Montilla-Moriles and Málaga. Many of these are technically unfortified, but they are considered alongside the fortified wines because they share many of their characteristics. Thus vin jaune and fino Montilla wines (unfortified) share some characteristics with fino Sherry and Vernaccia di Oristano (fortified), because formation of flor velum ('biological ageing') is common to them all. For a fairly recent account of fortified wine, see for example Reader and Dominguez (2003).

2.10.2 Sherry and Other Flor Wines

Sherry is produced in a small area around Jerez de la Frontera, in the province of Cadiz, which lies at the southwestern edge of Andalúcia. The area and methods of production (Denominación de Origen) are controlled by the Consejo Regulador. There are over 11 000 ha of vineyards, which can be increased, provided that stocks held by the many Sherry houses or companies (bodegas) are not diminished by more than 40% in any single year. This is a regulation that is intended to prevent the dominance of quantity over quality. Figure 2.10.1 defines roughly the area of Sherry production: between the towns of Rota, Sanlúcar de Barrameda, Trebujena, Jerez de la Frontera and Puerto Real. This area is divided into a number of subareas (pagos), some of which are shown in Figure 2.10.1, with the Zone of Superior Sherry (Zona de Jerez Superior) forming a rough triangle with Sanlúcar, Jerez and Puerto de Santa María lying at the corners. The soil in this area is recognized as being responsible for the finest Sherry. It is a white highly calcareous soil (known as 'albariza') that not only reflects much sunlight, helping the grapes to ripen, but also bakes hard in the hot summer sun and hence prevents the escape of moisture from the soil around the vine roots (Lichine, 1982a). The pagos of Añina, Balbaina, Carrascal, Macharnudo and Miraflores are mostly in the Superior Zone, having largely albariza soil. Outside the Superior Zone, barro (sand/chalk/clay) and arena (sandy soil with alumina and silica) soils tend to dominate.

The major grape variety for the making of Sherry is the Palomino, although it is known by many synonyms, even in the small area around Jerez. Pedro Ximénez and Moscatel are also grown, mostly for coloring and sweetening, and other varieties include Albillo, Cañocaza and Mantúo. The grape harvest is in September, when midday temperatures are often still around 30 °C, with very little chance of rain; the harvest around inland Jerez starts a few days before that of Sanlúcar, which is closer to the sea. The natural sugar content of Palomino grapes is often about 26 °Brix (or 110 °Oechsle), giving a wine of 14–14.5% alcohol (v:v), when fermented to dryness. Grapes destined for the more delicate fino style wines (Figure 2.10.2) are crushed and pressed soon after gathering, but those meant for the heavier oloroso types are spread out on esparto grass mats to dry in the sun, protected at night by plastic sheets, so that the grapes are not affected by the morning dew (Halliday and Johnson, 1992). Sometimes grapes that are to make fino or manzanilla are dusted with 'yeso' (gypsum, $CaSO_4.2H_2O$) in order to increase the acidity of the must and to encourage the formation of flor, so essential for the production of these Sherry styles (Section 2.10.3). Pedro Ximénez grapes are often exposed on mats to the sun until they shrivel to dark raisins. They are then macerated with brandy to give a

Figure 2.10.1 *Sketch map of Sherry country and list of some notable producers (shippers)*

very dark, sweet liquor known as 'PX,' which is used to add sweetness and color, especially in the formulation of blends for export, such as the dark cream Sherries and brown Sherries. Palomino and other grapes treated in a similar manner give a paler sweet liquor that is used for blends such as pale cream Sherries. It will be seen later that Sherry is a naturally dry wine – the Spanish like it that way and the sweetened blended Sherries are mostly exported.

The many wineries of the Sherry area (most of the big ones are in Jerez) are owned by the Bodegas (Bodegas de Crianza y Expedición, or Sherry shippers). At present (2008) there are 64 of them on the register

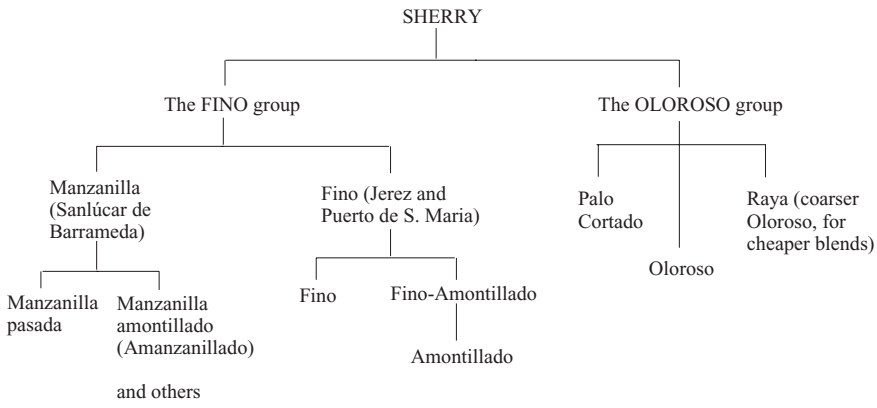

Figure 2.10.2 *The Sherry family. All sherry is naturally dry. Some are sweetened and/or colored for certain brands or styles, mainly for export*

of the Denominación de Origen's regulatory council. Depending on the shipper, the winery is used for the full winemaking process, or as a cellar (or nursery: *crianza* in Spanish) for ageing, the wines having been fermented elsewhere, often in far houses, close to the vineyards. The wineries vary markedly in style, from converted mosques and convents to tall cathedral-like buildings. The latter are preferred for the production of fino and manzanilla, because of the special microclimate and ventilation that are given by that style of architecture (see Figure 2.10.6).

The grapes are tipped onto conveyor belts on arrival at the winery, where they destemmed, gently crushed and then pressed (Figure 2.10.3). Acidity may be increased by the addition of gypsum, which reacts with potassium hydrogen tartrate in the grape must (Figure 2.10.4). Nowadays, tartaric acid is often added in place

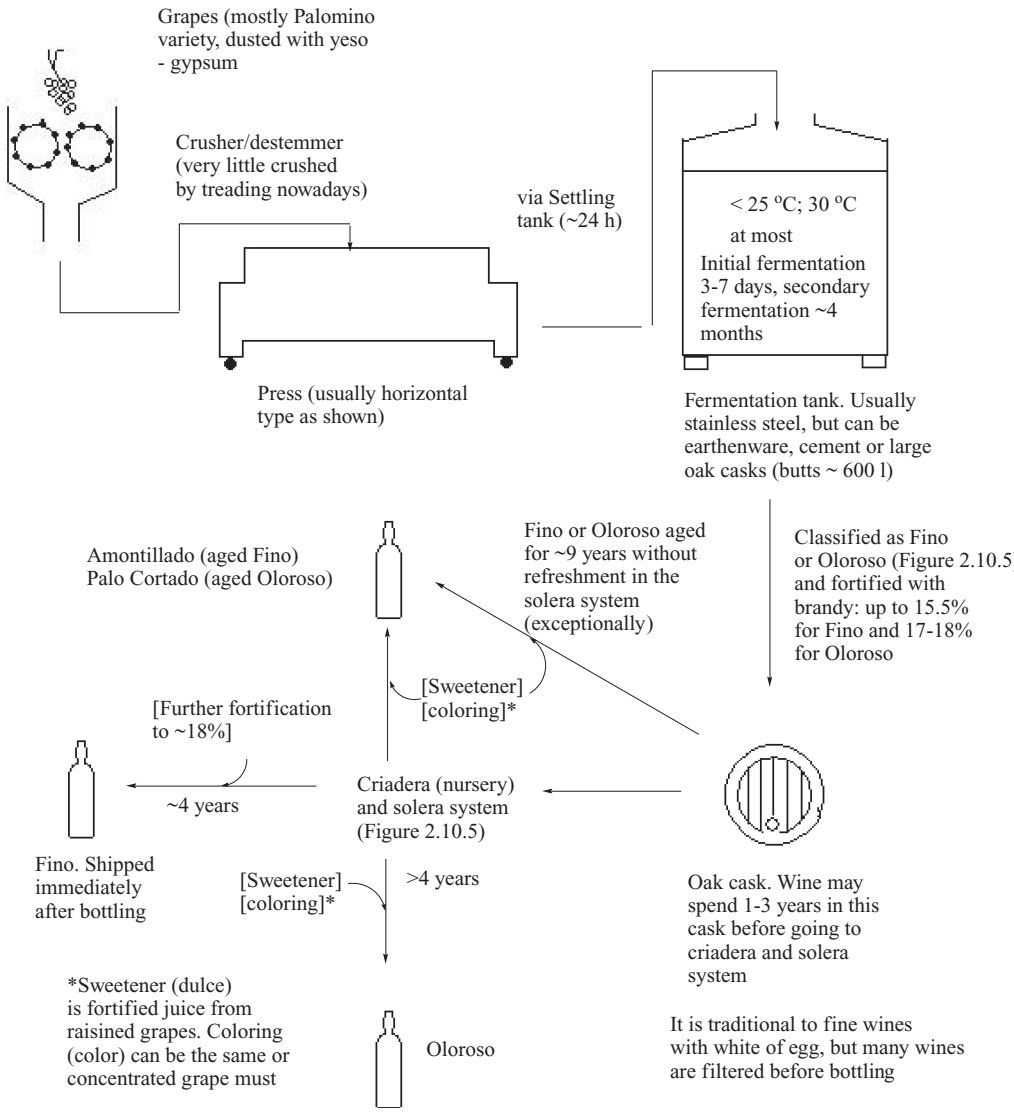

Figure 2.10.3 *Making Sherry: a summary. Square brackets indicate optional processes. Not to scale*

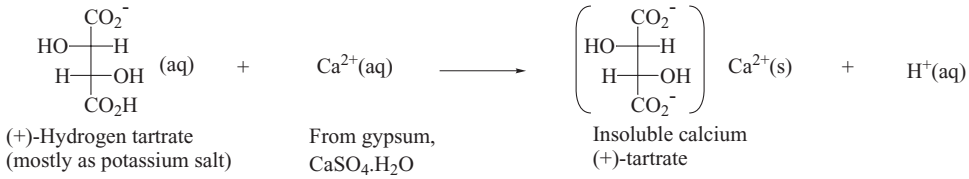

Figure 2.10.4 *Increasing the acidity of Palomino must by addition of gypsum ('yeso')*

of gypsum. Only the first pressing ('mosto de yema') is used for making Sherry (700–750 l per 1000 kg of grapes); the other pressings are used to make wine for distilling into grape spirit, an important part of Sherry. The must ferments vigorously for a few days at ~22 °C for fino and ~27 °C for oloroso. Most Sherry is fermented in stainless steel vats that can be temperature controlled, thus allowing the winemaker a chance to direct production to fino or oloroso for a particular vat. Some shippers still use the traditional method of conducting the first in new oak butts ('botas' ~600 l), the casks being used again later, in the criadera/solera system (Section 2.10.3). After the first stage of fermentation, where ~90% of the grape sugars has been used by the yeast, the wine is racked into oak butts for the gentler second stage of fermentation that lasts until December. Some winemakers allow fermentation to be carried out by wild yeasts in the bloom on the grape skins, using a minimum (if any) sodium or potassium metabisulfite. However, nowadays most winemakers carry out mild sulfiting and then add cultivated wine yeast, which for fino production includes flor yeast (Section 2.10.3). Thus by choice of initial fermentation temperature and yeast strains, the winemaker can direct production of fino and oloroso with reasonable confidence: a process that used to be more or less random. In December, the wines are tested by smell, taste and appearance and are classified as fino (light, floral, pale wines with flor formation) or oloroso (heavier wines with little or no flor formation) (Figure 2.10.3). The wine is then racked off its lees into fresh oak butts that are marked according to the destiny of the wine: fino or oloroso. The casks are filled to only 5/6 of their capacities, after fortifying with grape spirit (~95% ethanol), gradually to avoid shock, up to 15.5% alcohol (v:v) for fino and up to ~17% for oloroso. The vast majority of these casks enter the criadera/solera ageing and blending system, but some shippers produce single vintage (añadas) wines from a few casks that do not enter the solera system. A good example of this is Añadas of Gonzalez Byass. Thus nearly all Sherry is a nonvintage blend of wines of differing ages and also usually of different vineyards, although Valdespino Ynocente comes from a single Macharnudo vineyard (see Figure 2.10.1).

During the maturation of fino Sherry, a characteristic crust or film, known as flor (Section 2.10.3) forms on the entire surface of the wine, usually of 2 or 3 cm thickness. This flor velum protects the wine from oxidation and promotes certain reactions that add to the complexity and quality of the wine. It should be present during the whole of the fino's maturation in the criadera/solera system (four or five years usually). If the flor on a wine in a particular fino cask dies after more than three years maturation in the solera system, the wine becomes rather darker and more pungent due to extra oxidation, and is designated amontillado. This name is derived from Montilla, whose wine it resembles (Section 2.10.4). This cask is no longer included in the fino solera system, instead being blended with similar wines from other casks and usually further fortified with grape spirit. Alternatively, the winemaker can choose to divert a fino to amontillado by increasing the degree of fortification to ~17% ABV, which kills the flor. If the flor dies at an earlier stage in the maturation process, the wine will probably end up in a rather anonymous medium blend (which may actually be called amontillado!), as it is unlikely to be suitable as either a fino or genuine amontillado.

Oloroso wines do not develop a crust of flor because this yeast will not grow in a medium with more than 17 or 17.5% ethanol (v:v); 15.5% ABV is just about the limit. The wine in some oloroso casks may

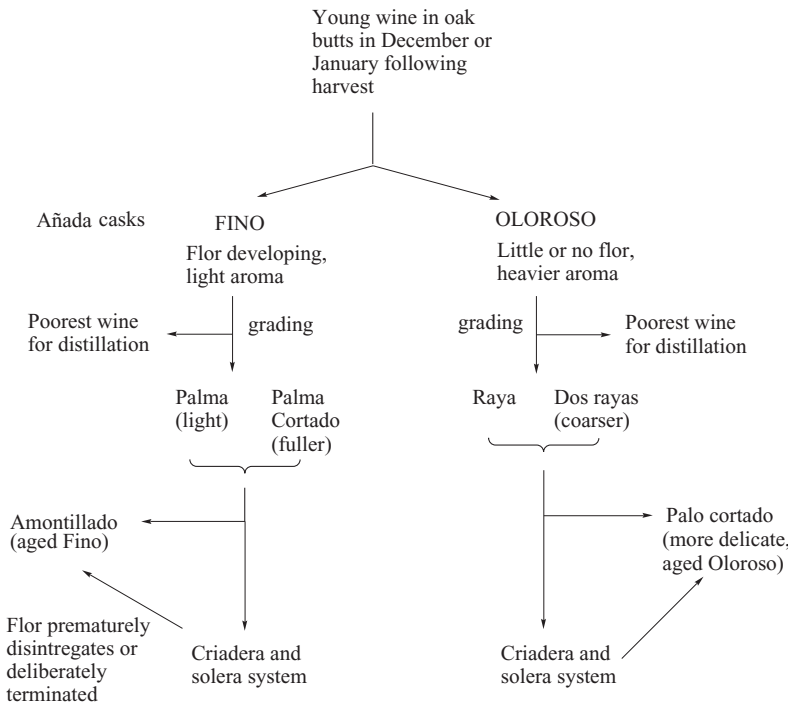

Figure 2.10.5 *Origin of Sherry types. The number of grades of fino and oloroso is higher than that shown. Only four are included here, for clarity*

well have developed a thin velum of flor at the first classification (in December following the harvest), but this is killed by fortification with spirit up to ~17.5% ABV. The lack of flor velum during maturation has two consequences for oloroso wines. Firstly, they are more oxidized than fino wines, having a more pungent and resinous character, as well as being darker. Secondly, through preferential evaporation of water, oloroso wines actually increase in alcoholic strength with age. It is not unknown for oloroso wines that have been in the solera system for more than seven years to have ethanol contents well in excess of 20% (v:v) (Lichine, 1982a). For the same reason old amontillado wines can also have high ethanol contents. In contrast, a film of flor prevents evaporation and, moreover, actually metabolizes a small amount ethanol during its lifetime. Consequently, many fino wines are further fortified (up to 16 or 17% ABV) before being bottled for export. At home in Spain, they are preferred at their natural strength (~15% ABV).

Before wines in the añada casks are entered into the criadera/solera system, they are further graded (Figures 2.10.3 and 2.10.5) according to their likely qualities, after inspection by skilled tasters. This means that the wine in a particular añada cask will enter a solera system (in a particular bodega, there will be many of these) judged to be of similar quality and characteristics. Thus, fino wines may be graded as palma (light and floral) through to tres palma (exceptionally delicate). Heavier finos are classed as palma cortado. Similarly, oloroso wines may be classified as raya (the best) and dos rayas (less good) (Lichine, 1982a). Some lighter, but high quality olorosos with a nutty character may be classed as palo cortado. Tasters play an important role in the production of Sherry: firstly, they grade and classify añada wines to match those already in the solera system and secondly, they are responsible for formulating the blends that eventually go into bottle, particularly for export.

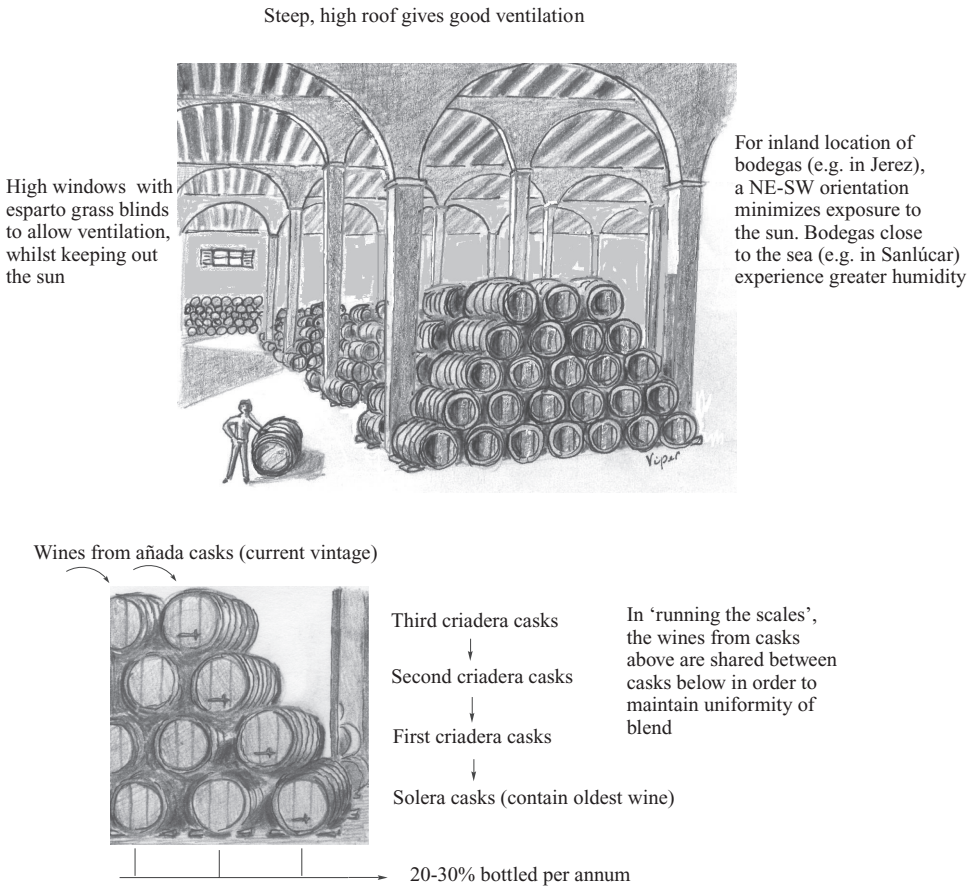

Figure 2.10.6 *Typical Sherry bodega and solera/criadera system*

The solera system is a dynamic ageing method that continuously blends wines of different vintages. Older wines are refreshed from time to time by quantities of younger wines. This ensures that the noble characteristics of the older wines are passed on to the younger wines, whilst at the same time enabling a consistent quality and character. The butts in a solera are arranged in rows (scales), one on top of the other, usually four or five casks high (Figure 2.10.6), but solera systems have more rows than this. The bottom row (on the floor) is known as the solera (the name solera is a corruption of suelo, meaning ground) and the casks here contain the oldest wine. The row of casks resting on the solera casks is called the primera (first) criadera; these butts contain the next oldest wine in the system. The top row of casks, therefore, contains the youngest wine in the system.

Wine for bottling is drawn from the solera butts in such a way that no more than about 20% (~100 l) is taken from each butt at any one time, usually once a year. The ullage in the solera butts, caused by removal of wine for bottling, is replaced by transfer of a similar volume of younger wine from the primera criadera casks immediately above the solera butts. This starts a cascade replenishment/refreshment process known as 'running the scales.' The youngest wines in the top casks are refreshed with wine from the añada casks (the wine from the latest vintage). For consistency of quality and character, a little wine from each cask in a

higher row is added to all the casks of the row below it. In a fino solera system, transfer of wines is carried out using a 'canoe' and 'sprinkler,' which ensure a gentle of trickle of wine, so that the all important layer of flor is undamaged. In oloroso solera systems, this precaution is unnecessary.

In this way, a solera system may be kept in operation for many years, even over a century. It is possible to determine the average age of the solera wine at a particular bottling by knowing the number of scales (rows of casks) in the system, the percentage of wine transferred at each bottling, the frequency of this operation and when the solera was laid down. At the discretion of the regulatory council of the Denomination of Origin, after strict analysis, a shipper may be allowed to state the average age on the labels of certain wines from especially old solera systems. The minimum average age of Sherry is three years, and a typical fino or manzanilla will have had four or five years in the solera system before bottling. Amontillado, oloroso and palo cortado wines are aged longer; upwards of seven years in a solera system is not unusual. The añada wines (fresh wines from the latest vintage) are subject to three possible destinies. Much is used to refresh the wine in the top rows of existing solera systems, some is used to lay down a new solera system and (depending on the shipper) a little is statically matured in cask for the production of a single vintage (añada) wine. The solera system originated in Jerez in the early nineteenth century, but it is not unique to that area. Solera systems of varying kinds are used in Madeira, Malága, Marsala, Montilla-Moriles and in countries that produce Sherry style wines, such as Australia, Cyprus, South Africa and the USA (California).

Sherry is a naturally dry wine and many are bottled as such. Fino and manzanilla are always dry as are many of the best amontillado, oloroso and palo cortado wines. A dry Sherry nowadays often undergoes clarification (often with egg whites) as well as filtration, cold stabilization and then in line sterile filtration as it is bottled under an inert gas to prevent extraneous oxidation. Sulfur dioxide (i.e. metabisulfite) is never used at this stage. Once they are drawn from the solera butts, fino and manzanilla wines have lost their protective velum of flor and hence it is imperative that these wines are not exposed to oxidation. The best way to prevent oxidation is to drink the wines 'young' (i.e. fresh from the cask); indeed to sample the best fino or manzanilla wines directly from the cask is one of the greatest wine experiences. Once in bottle, fino and manzanilla wines should not be kept for more than a few months, and once the bottle is opened, its contents should be consumed within a few days. That is why half bottles (375 ml) of these wines are popular in Spain.

In contrast, amontillado, oloroso and palo cortado wines will keep for many years in bottle and remain vital for a long time after the bottle is opened. Many wines of the oloroso type are sweetened and maybe colored before being bottled, as there is still a considerable demand for sweet Sherry in countries such as the UK and USA.

Apart from the Sherry shippers (bodegas de crianza y expedición) in the Sherry area (Jerez de la Frontera), El Puerto de Santa Maria and Sanlúcar de Barrameda, see Figure 2.10.1), there are smaller companies that make and mature wines in private cellars exclusively for sale to the shippers. These firms are known as bodegas de crianza y almacenado or simply as 'almacenistas.'

Sherry style wines are made all over the world, especially in regions with similar hot climates, such as Central Valley, California; Cyprus; New South Wales and South Africa. Often grapes of local varieties are used, rather than Palomino or Pedro Ximénez grapes. Examples include Gordo Blanco (New South Wales), Flame Tokay and Mission (California), Steen, also known as Chenin Blanc (South Africa) and Xynisteri (Cyprus). The emphasis is on medium to sweet oxidatively aged and moderately priced wines of moderate or even modest quality. A common practice of accelerating the ageing process for Sherry style wines in California is to heat the wine in bulk (up to 60 °C) and then leave it to mature in small casks in the cellar. Another way, practiced in Cyprus, is to expose casks of wine to the sun for two or three years. However, higher quality wines are being inceasingly made from Palomino grapes with flor formation, biological ageing and solera methods of maturation and blending. Notable amongst these is Llords and Elwoods (San José, California), Keo (Cyprus) and Cavendish (South Africa). In South Australia (Barossa), the Seppelt winery

produces flor Sherry style wines (a fino and amontillado type) and an oloroso style wine from Palomino grapes, using solera systems. These wines have a fragrance, nuttiness and rancio character (respectively) that are reminiscent of Jerez wines, despite differences in climate and soil types. Similarly, the Quady winery (San Joaquin, California) makes a solera aged amontillado style flor wine from Palomino grapes. Presumably this wine is produced by a period of biological ageing under a velum of flor, followed by oxidative ageing after removal of the flor, as in Jerez.

2.10.3 Flor and Oxidation in Sherry Wines

Flor is the name of the layer (velum) that can form on the surface of white wines, provided the alcohol content does not exceed about 15% (v:v). It is essential for the production of fino and manzanilla Sherries, Montilla Moriles wines, Vernaccio di Oristano and vin jaune. Wines like these that are aged under a layer of flor, protected from oxygen, are said to 'biologically aged.' In contrast, most other wines are aged in the presence of oxygen (albeit in a controlled manner) and are said to be oxidatively aged. In this section, the oxidatively aged wines include oloroso Sherry, Madeira wines, tawny Port wines, Marsala and vins doux naturels. The velum of flor not only protects the wine from extraneous oxidation and spoilage by microorganisms such as *Acetobacter*, but produces certain attractive aroma/flavor compounds, notable amongst which are Sherry lactones, like solorone. It also reduces the ethanol content somewhat, because ethanol forms a small part of the metabolism of the flor yeast. Under the same conditions, the same white wine without flor would undergo enzymic and nonenzymic browning, and infection by microorganisms may also occur. Flor is killed at ethanol concentrations greater than 15–15.5% (v:v), so oxidatively aged wines are usually fortified to 17–18% ABV. Under these conditions, *Acetobacter* and other spoilage organisms are inhibited, but oxidation results in browning and the formation of pleasant characteristic aroma and flavor compounds.

Fino and manzanilla Sherries can spend four years or so under a velum of flor. If the velum begins to grow thin or shows signs of dying before the end of the maturation period, the cellarmaster in many Bodegas may increase the alcoholic strength to 17–18% (v:v) by adding grape spirit. Ultimately, this produces an amontillado Sherry, a bit darker and more oxidized than a fino, because of a number of years of ageing without the protection of the flor velum. During the ageing of fino Sherries, the dead flor yest cells are continuously shed and fall to the bottom of the cask, being replaced by younger cells in the velum; the life cycle is similar to that described in Chapter 2.1. The layer of dead cells gradually release peptides and glycoproteins, providing nutrients for the living cells in the velum and inhibiting crystallization of tartrates. Many species of the genus *Saccharomyces* are able to form flor layers; most of these are races of *S. cerevisiae*, but *S. bayanus* can form a flor velum, albeit a rather thin one (Mauricio and Ortega, 1997). In the making of fino Sherry wines, the main races of *S. cerevisiae* are beticus, cheresiensis and montuliensis (Martinez *et al*., 1998). The first two mentioned produce flor velum rapidly and hence tend to predominate in young wines, whereas the last mentioned, which produces higher acetaldehyde concentrations, appears in older wines in the solera system (Martinez *et al*., 1998). These *S. cerevisiae* races usually make up the bulk of some 1126 different microorganisms that been identified in fermenting Sherry (Esteve-Zarzoso *et al.*, 2001), but *Candida stellata*, *Dekkera anomola*, *Hanseniaspora guilliermondii*, *H. uvarum* and *Issatchenkia terricola* have also been identified in frequencies higher than 2%. Most bodegas use inoculation of commercial flor yeast strains rather than rely on the wild yeasts for the formation of fino type Sherries, so that whatever strain is used dominates the microflora of the solera system (Esteve-Zarzoso *et al.*, 2001). In this way, the organoleptic qualities of the wine can be controlled up to a certain point (Martinez *et al.*, 1997).

Molecular characterization of flor strains by karyotype and mitochondrial DNA (mtDNA) restriction analysis usually indicates high polymorphism, but with certain patterns predominating (Mesa *et al.*, 2000),

usually corresponding to a small number of genotypes. Flor yeasts give different mtDNA restriction patterns to nonflor yeasts (Esteve-Zarzoso *et al.*, 2001). Further to this, a restriction analysis of the 5.8S ITS region from a large number of *Saccharomyces* flor strains (isolated from the velum of Sherry wines from different wineries) indicated that they all had the restriction patterns using endonuclease cfo I, thus suggesting the universal presence of the 24-bp deletion (Fernandez-Espinar *et al.*, 2000). The above results suggest the genetic origins for the observed adaptive mechanisms shown by flor yeast strains compared with nonflor strains. These are expressed as morphological, physiological and chemical characteristics, which are discussed next.

Flor yeast cells show differences in their cell shape, size and hydrophobicity compared with nonflor strains of *S. cerevisiae*. Hydrophobic interactions between cell surfaces allow the cells to cluster into colonies that are less dense than the wine, especially because of the buoyancy caused by trapped CO_2 bubbles released by metabolic processes (Martinez *et al.*, 1997). The population consequently floats and grows on the surface of the wine. Flor yeast strains are tolerant of ethanol concentrations of up to about 15.5 % (v:v) and are also tolerant (to a greater or lesser degree) of acetaldehyde and acetic acid (often known as 'volatile acid'). Different strains have different tolerances of these components: the cheriensis race is less tolerant of ethanol and acetaldehyde, but is more tolerant of acetic acid than the beticus strain (Mesa *et al.*, 2000). The race montuliensis is likewise more tolerant of acetaldehyde than the race cheriensis. These generally high tolerances of metabolic products have been shown to be the result of an especially efficient antioxidant defence system of flor yeasts, which is related to their generally high superoxide dismutase activity (see also Section 5.8.4) (Castrejon *et al.*, 2002). This confers a high resistance to oxidative stress in general and a tolerance of ethanol and acetaldehyde in particular.

The growing cells in a flor velum obtain most of their energy requirements from aerobic metabolism, during which specific nutrients from the wine are required. A modest amount of ethanol is used as a carbon source, but there is high uptake of acetic acid, ethyl acetate and glycerol (Berlanga *et al.*, 2006). Thus, the ethanol content decreases somewhat (by about 0.5–1.0% v:v) during biological maturation of a fino Sherry and there is a significant level of acetaldehyde in the mature wine. Dissolved oxygen in the wine is depleted during growth of the flor velum, but once this has gone, nitrogen compounds (mainly amino acids and ammonium salts) are taken up by the yeast cells and used as nitrogen sources or as electron acceptors. Amino acids are metabolized to more reduced amino acids (especially (*S*)-leucine), carbonyl compounds and alcohols, including acetoin (2,3-butanediol), 1-propanol, isoamyl alcohol and isobutanol (Martinez *et al.*, 1998; Mauricio and Ortega, 1997; Berlanga *et al.*, 2006). Some of these metabolic products make important contributions the aroma and flavor of fino Sherry. The amino acids in wine are of diverse origin: some come from the original must, others are synthesized by yeast during growth and yet others are released by yeast cell autolysis or by redox regulation (Berlanga *et al.*, 2006). The principal source of nitrogen for growing flor yeast cells is (*S*)-(or L)-proline (Mauricio and Ortega, 1997). The general metabolism of flor yeast cells may well be regulated by the most efficient balancing of redox potentials, coenzyme reoxidation pathways (e.g. $NADH \rightarrow NAD^+ + H^+ + 2e^-$) being used as alternatives to the electron transport chain (Section 5.8.3). It has been found that supplementation of amino acids led to an enhanced release of certain metabolic end products, depending on the supplement. Thus, all supplements led to the release of L-leucine, L-glutamate led to enhancement of ethyl acetate, L-leucine to isoamayl alcohol and L-valine to isobutanol. 1,1-Diethoxyethane was also produced (Berlanga *et al.*, 2006).

The concentrations of characteristic odor compounds in fino Sherries depend not only on the amount of nutrients present, but also on the status of biological ageing; indeed the concentrations of certain aroma/flavor compounds can be used as an indicator of the extent of biological ageing (Zea *et al.*, 2007). By using statistical analysis of concentrations of aroma compounds in fino wines of different biological ageing (1, 3 and 5 years), it was found that sotolon, 1,1-diethoxyethane and 2-whisky lactone were the best indicators of biological ageing (Moreno *et al.*, 2005).

Ageing of oloroso Sherry wines occurs in oak butts in the absence of flor velum; it is often known as oxidative ageing and leads to a darker product due to 'browning' and to a different aroma profile to corresponding biologically aged wines. Oxidative browning mechanisms have been reviewed recently (Li *et al.*, 2008). Browning is undesirable in most white wines, including fino Sherries, but forms an essential part of the ageing process for oloroso Sherries and certain other wines, such as Madeira (Section 2.10.5) and the 'rancio' styles of vins doux naturels (Section 2.10.9). The major cause of browning in wine is the presence of many phenolic substances, especially flavan-3-ols, which are able to undergo regenerative coupled oxidation reactions, as well as nonoxidative browning reactions (polymerizations) (Li *et al.*, 2008). Nonenzymic browning appears to be prevalent in wine, whereas enzymic browning tends to be more important in grape must. Both general mechanisms require the presence of Fe^{2+} and Cu^{2+} ions. Polyphenol oxidase is a copper containing enzyme and peroxidase contains iron (Section 5.8.4); these and tyrosinase (catecholase) are the major agents for enzymic browning. Nonenzymic browning mechanisms involve Fe catalyzed oxidation of flavan-3-ols to *o*-benzoquinones, ethanol to acetaldehyde, and (+)-tartaric acid to glyoxalic acid. The quinones can form polymer pigments by reaction with phenols and it is known that both acetaldehyde and glyoxylic acid can be involved in flavan-3-ol polymerization (Li *et al.*, 2008, Lopez-Toledano *et al.*, 2004).

Although browning is an essential feature of the ageing of oloroso wines, it is most undesirable in biologically aged wines, such as fino Sherries and fino Montilla-Moriles wines. In order to stabilize browning, by the removal of flavan-3-ols, these wines are fined and often filtered before bottling. Fining agents include activated charcoal, PVPP and a mixture known as Riduxhigh™: these all remove most of the flavan-3-ols after initial fining with casein or bentonite (Barón *et al.*, 2000). Dehydrated baker's yeast cells have been used for a similar purpose, the cells absorbing many brown compounds and flavan-3-ol derivatives (Razmkhab *et al.*, 2002). Likewise, yeast cells immobilized on carageenan gel were effective in reducing the concentration of browning compounds, without drastic modification of the wine's sensory properties (Lopez-Toledano *et al.*, 2004).

Oloroso wines have different aroma profiles to fino and similar wines, whereas amontillado wines possess profiles that are intermediate between those of fino and oloroso wines. The differences in profiles have been linked to the differences in the extents of biological versus oxidative ageing for wines of the Montilla-Moriles region, which are similar to Sherry (Zea *et al.*, 2001). Thus, fino wines were richer in acetaldehyde, acetoin, carboxylic acids and lactones, whereas oloroso wines were richer in ethyl acetate, other acetate esters, fusel alcohols, diethyl malate, diethyl succinate and ethyl lactate (Zea *et al.*, 2001). More specifically, the aroma compounds that best distinguished fino wines were butanoic acid, 3-methylbutanoic acid, γ-butyrolactone, pantolactone, γ-decalactone, farnesol and octanal. On the other hand, compounds that distinguished oloroso wines included 1-butanol, 2-butanol, methyl acetate, ethyl acetate, butyl acetate, hexyl hexanoate, hexyl lactate, isobutanoic acid, furfural and methionol. The contribution of flor yeasts and oak to the aroma profile of fino wines can be organized into eight ordorant series: balsamic, chemical, empyreumatic, floral, fruity, spicy and vegetable (Zea *et al.*, 2001). During biological ageing, the fruity series (related to flor yeast activity) and spicy series (related to release of oak compounds) most closely represented the changes in aroma.

Maintaining wines in the criadera/solera systems for at least four years, despite the advantages that have been described, is a costly business, making it impossible to reduce the price of Sherry or similar wines, such as those of Montilla-Moriles. For this reason, there has been some interest in methods of accelerated biological ageing and experiments have been conducted with fino style wines on laboratory and pilot plant scales. Recently, experiments involving periodic and controlled microaerations of fino wines (without disturbing the flor) produced, in a few months, wines that had similar aroma profiles to cellar aged wines (Muñoz *et al.*, 2007). Thus biological ageing time can be shortened by controlled periodic microaerations in stainless steel tanks, followed by a period in oak cask.

2.10.4 Other Flor Wines

The fino style wines of the Montilla-Moriles region, near Córdoba, are the other great flor wines of Spain. This area, being some 170 km northeast of Jerez and well away from the influence of sea breezes, experiences even hotter summers than the Jerez area. Pedro Ximinez is the major grape variety, rather than Palomino, and the grapes are usually harvested in early, to mid August. Although Montilla-Moriles wines have a distinctive character that sets them apart from Sherry wines, their methods of production are similar to those of Sherry and the family resemblance is clear to those who taste the wines. Similarities of production include biological ageing for fino wines, oxidative ageing for oloroso wines and the use of criadera/solera systems, so much that has been written in Section 2.10.3 applies to the wines of Montilla-Moriles. Indeed, production similarity is such that there is much discussion of these wines, alongside Sherry wines, in Section 2.10.3. The major differences include main grape variety, climate, terroir and the fermentative organisms, especially the flor yeasts. The Pedro Ximinez grapes are harvested some weeks earlier than Palomino grapes in Jerez. After drying in the sun for some time, they can make a wine containing up to 16% ethanol (v:v), thus removing the need for fortification with grape spirit for the fino style wines. The amontillado and oloroso wines, like their Jerez equivalents, are fortified up to about 18% ABV. Another interesting difference (although one which probably has little bearing on organoleptic differences between the wines of Montilla and Jerez) is the occurrence of fermentation in earthenware jars (tinajas), in the more traditional bodegas. However, many bodegas, like their Jerez counterparts, now use stainless steel fermentation vessels. Ageing is carried out in oak butts arranged in a criadera/solera system, as in Jerez. Also, like Sherry, the wines of Montilla-Moriles are naturally dry, but can be sweetened and given a deeper color by the addition of dolce and vino de color, respectively. Montilla-Moriles wines do not have such a strong export tradition as Sherry, probably because of the relative remoteness of the vineyards from the sea. They do, however, enjoy a great reputation in Spain. Principal bodegas include Alvear, Carbonell and Montuila.

Veranaccio di Oristano is a flor wine of about 15% ABV made on the island of Sardinia from Vernaccio grapes. Traditionally, the flor is formed after the first vigorous fermentation by wild yeasts in the bloom of the grapes. This was rather haphazard and led to variations in style and quality. In the past few decades, inoculation of the lightly sulfited must with flor forming yeast strains (mainly *Saccharomyces bayanus*, *S. cerevisiae* var. *prostoservodii* or *S. cerevisiae* var. *rouxii*) has become common for biologically aged fino style wines (Galletti and Carnacini, 1996). Inoculation accelerates the biological ageing process and makes it easier to control. *S. cerevisiae* var. *prostoservodii* was generally more successful at producing desirable ester components than *S. bayanus*, but inoculation with either led to a wine richer in desirable aroma components than a corresponding wine aged under sterile conditions (Carnacini *et al.*, 1997). Fortified liquoroso type Vernaccio di Oristano wines, with ethanol contents up to ∼18% (v:v) are also made. Wines aged for a minimum of four years in oak casks are called Riserva, provided that the ethanol content is at least 16% (v:v). Three year old wine (again oak cask aged) of at least 15.5% ABV is called Superiore. Major producers include Cantina Sociale della Vernaccia, Carta, Contini, Puddu, and Sella and Mosca.

Vin Jaune is a flor wine made from grapes of the vine variety Savagnin (called Gewürztraminer or traminer elsewhere) in Château-Chalon and L'Étoile, two small areas in the Jura region of France, between Burgundy and Switzerland. The grapes are harvested late, giving a must of high sugar content, which is fermented to dryness, producing a wine with up to 15% ethanol (v:v). The wine is stored in incompletely filled oak casks, whence a velum of flor develops and promotes the type of biological ageing described in Section 2.10.3. The wine remains in these casks undisturbed for up to six years, after which time it is bottled. Although it has its own unique character, vin jaune is rather like a cool climate version of fino or manzanilla, perhaps with the nutty aroma more reminiscent of an amontillado. The distant similarity with Sherry must result from biological ageing under a velum of flor, since most other factors are different: soil, climate, grape variety and static maturation, as opposed to to the dynamic criadera/solera system of maturation.

Table 2.10.1 *The main vine varieties of Madeira and the styles of wine they produce*

Variety	Main pseudonyms (probable or *possible* origins)	Type of wine produced	Approx. alcohol content in % v:v (and residual sugar in ° Brix) after final fortification
Sercial	White Riesling, Rheinriesling, Esganinho (Rhineland)	Sercial (dry)	17 (0.9–2.7)
Verdelho	Gouveio, Vidonia (Portugal)	Verdelho (medium dry) and 'Rainwater'	17 (2.7–4.5)
Bual	Boal (Portugal)	Bual (medium)	17 (4.5–5.5)
Malmsey	Malvasia (Turkey)	Malmsey	17–18 (5.5–12)
Tinto Negra Mole	(Iberian Peninsular)	Malmsey*	17–18 (5.5–12)

*Since 1986, must be minor component of Malmsey (<15%)

2.10.5 Madeira

Madeira wine is made from the grapes of five principal *Vitis vinifera* varieties growing mostly on terraces on the steep volcanic hillsides of the island of Madeira (57 km × 23 km), lying some 575 km off the coast of Morocco and some 850 km distant from Lisbon. Madeira and its neighboring islands, Porto-Santo and the Desertas, belong to Portugal and so production of its wines, like those of the mother country, is governed by European Union regulations. The volcanic soil of Madeira is very rich, indeed enriched by the ashes of thousands of trees that were burnt by the explorer João Gonçalves ('Zarco') in the early fifteenth century. Small clusters of trees from the ancient forest still grow around the island, amongst the vines and many other agricultural crops. The rich soil and moist warm climate influence the quality of the final product, but a greater influence is exerted by the grape varieties and the altitudes at which they are grown, together with the highly specific ways in which Madeira wines are made, especially the heating process known as estufagem.

The main varieties are all of the species *V. vinifera* and are described in Table 2.10.1. With the general exception of Tinta Negra Mole, Madeira wines are varietal and bear the name of the variety: Sercial, Verdelho, Bual (Boal) and Malmsey (Malvasia). Tinto Negra Mole (the 'soft black' grape) is now recognized as a good, but not classic variety for Madeira wine production. It used to be a substantial, even major part of the island's sweet Malmsey wines, along with Malvasia, which gives the wine its name. This has changed since Portugal entered the European Union in 1986, whose wine laws state that wines named after a specific grape variety must contain a minimum of 85% of that variety. Nowadays, most Tinta Negra Mole vines are grown at low altitudes, where they ripen early (from mid August onwards). Much of their fruit is made into the cheaper Madeira wines that are so popular for cooking, by an accelerated estufagem process (Section 2.10.6). This was once the role of Jacquet or Black Spanish, a hybrid (*V. vinifera* x *V. aestvalis*, probably) that produces black skinned and red juiced grapes. The vines on Madeira were especially badly affected by *Phylloxera vastatrix* in the early 1870s and so hybrids like Jacquet, Canica (Cunningham) and Isabellinha played important roles both as rootstocks for the *V. vinifera* varieties and as direct producers of wine. Today, they are all on the wane, since the European Union generally forbids the use of hybrids or non-*vinifera* species for the production of quality wine. Table wines for local consumption still originate from hybrid vines and also from minor *V. vinifera* varieties, such as Barrete de Pedre, Carão de Moca, Listrão, Terrantez and Triunfo. Newer, but still

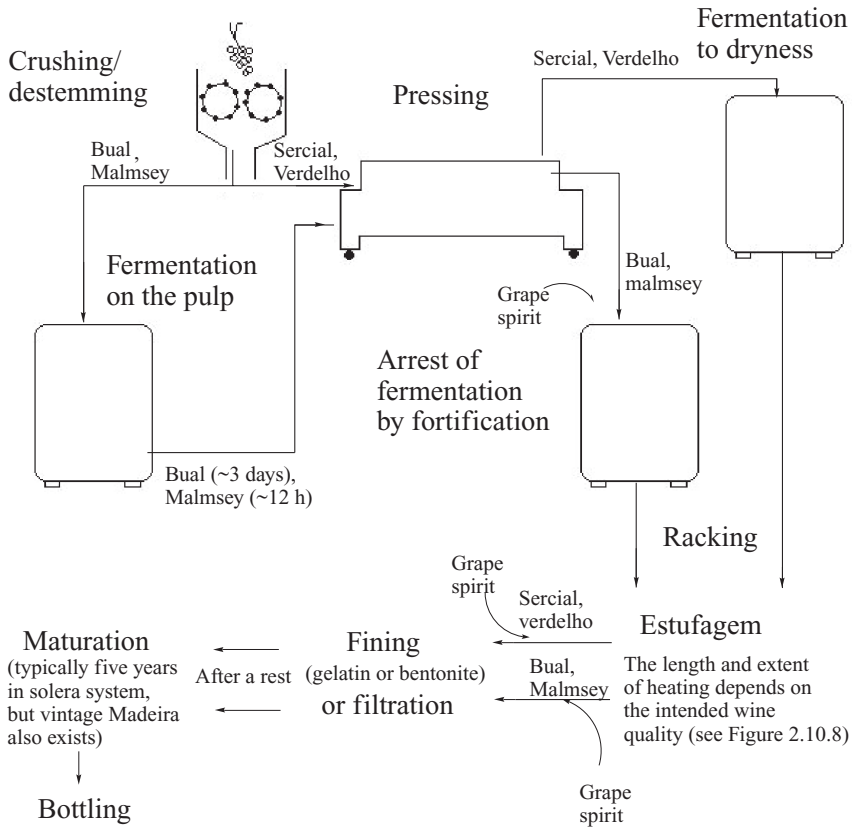

Figure 2.10.7 *Making Madeira wine. Not drawn to scale*

minor varieties used for Madeira wines include Complexa and Tinto de Madeira. The vineyards of Madeira stretch from sea level up to ~700 m or so above sea level. This, and the five varieties having different natural ripening times, necessitates many different harvest times on the island. The first grapes, Tinta Negra Mole grown at low altitude are picked in early August. The last grapes to be picked are usually those of Sercial vines growing around the 600 m or 700 m contours, often harvested in late October.

The traditional method of crushing grapes by foot in lagares (large wooden troughs) is uncommon now; most grapes are crushed and destemmed in an electrically powered crusher/destemmer (see Section 2.9.1). Sercial and Verdelho grapes are pressed (separately) immediately after crushing and destemming and are fermented to dryness (Figure 2.10.7). Bual and Malmsey grapes, on the other hand, are fermented on the pulp (again separately) for a period of time (Figure 2.10.7): until 50% of the sugar is fermented for Bual and for Malmsey until only 25% of the sugar has been used up. At these points, the fermentation is arrested by the addition of grape spirit, either before or after pressing, depending on the winery practices. After this, all the varietal wines are treated in similar ways, as indicated in Figure 2.10.7. They all go through a heating process known as estufagem and they are all fortified with grape spirit to bring their ethanol contents up to 17–18% (v:v). Some Verdelho wines are also colored and sweetened with vinho surdo, a mixture of concentrated unfermented must and grape spirit. Tinto Negra Mole grapes that are destined for the cheapest cooking Madeira wines, are treated somewhat differently from those shown in Figure 2.10.7. They are crushed and

pressed immediately, their musts are fermented to dryness and the wines are sweetened and fortified up to ~17% ABV by addition of vinho surdo, which is most likely made from Tinto Negra Mole must anyway. The wines are then given an accelerated estufagem (Section 2.10.6) in concrete vats, heated to 50 °C by a heating coil for three months.

After emerging from the estufa and having had 12–18 months rest (including fining and filtration), most young Madeira wines of medium to best quality are entered into a fractional or dynamic blending and ageing system, like the solera system of Jerez (Section 2.10.2). A few special wines are statically matured to produce a vintage Madeira wine, sometimes residing in the same cask for 30 or more years – but these wines are very rare. The really original part of Madeira wine production is the heating process known as estufagem. It is this process that gives the wines most of their special characteristics.

2.10.6 Estufagem and Cask Maturation of Madeira Wine

Like Sherry, the wines of Madeira were originally given fortification with grape spirit to preserve them on long sea voyages in cask to Great Britain or much further afield to the American continent and the Caribbean islands. It was found that these voyages, sometimes lasting six months or so, improved the wine quality remarkably. The high temperatures and wide fluctuations in temperature encountered on these long journeys, followed by a long period of rest (still in cask) at ordinary cellar temperatures, transformed the wines into something altogether better than those that started the journey. So, up until the latter half of the nineteenth century, Madeira wines were deliberately shipped around the world before landing at their destinations, often back home in Madeira, because more and more of the wine was being bottled on the island. However, nowadays, the wines in cask undergo a process known as estufagem in the wine shippers' lodges, mostly in Funchal, the island capital. Estufagem is intended to simulate the temperature conditions experienced by a wine that has been taken on a long sea voyage through tropical or subtropical zones. There are several versions of estufagem, in terms of heat intensity, fluctuation and duration, and which regime is chosen depends on the intended quality of the finished wine, as outlined in Figure 2.10.8. The majority of wines are subjected to the two regimes at the bottom of Figure 2.10.8, both of which involve the application of heat. The better quality wines are racked into 650 l casks (pipes), which are stacked in a building known as armazen de calor. The building is centrally heated by hot water ducts that maintain a temperature of around 40 °C for 6–12 months.

cis- and *trans*-5-Hydroxy-2-methyl-1,3-dioxane

Figure 2.10.9 *Heterocyclic acetals in Madeira wines. Câmara* et al. *(2003)*

Wines destined to be the most basic are pumped into 500 hl ceramic lined concrete vats, where they are heated at 50 °C for about three months by electrical immersion coils. Wines that have been heated naturally, in south facing winery lofts or in large glass carboys kept outside in the sunshine (Figure 2.10.8) are called canteiro. Some of the best Madeira wines, including rare vintage wines, are produced by the canteiro method. Whatever the estufagem method, the wines are gradually allowed to cool to ambient temperatures over a period of a few weeks, whereupon they are fined and/or filtered, allowed a 12–18 month rest (estágio) and the best wines are entered into a solera system for four or five years, whereas the more basic wines may be blended and bottled after estágio (Figure 2.10.7).

During estufagem the relatively high temperatures and the presence of oxygen promote caramelization, Maillard reactions (Section 2.6.2) and oxidation, resulting in profound changes in aroma and flavor. Notable amongst these changes are enhanced concentrations of furans (Ho *et al.*, 1999). In particular, 5-hydroxymethyl-2-furaldehyde (5-HMF) was found in far greater concentration (361 mg/l) in 10 year old Madeira than in Banyuls, Port, Sherry and Tokay wines (average 61 mg/l) that had received long cask maturation times. However, the presence of many other volatile substances is more likely attributable to extensive cask ageing than to estufagem itself. Included here are heterocyclic acetals (1,3-dioxolanes and 1,3-dioxanes). In a study of Madeira wines of varying cask ages, Câmara *et al.* (2003) found a good linear correlation between the concentrations of the *cis*-1,3-dioxolane (I) and the *cis*-1,3-dioxane (II) (Figure 2.10.9) and cask age. These heterocyclic acetals are well known to be formed from acetaldehyde and glycerol, and similar ratios of *cis:trans* isomers have been found in Port wines. Concentrations of all four heterocyles were not significantly affected by the extent of estufagem. Similarly, an excellent correlation between the concentration of *cis*-oak lactone and the length of cask ageing of Madeira wines, was found by Alves *et al.* (2005).

Oxidized non-Madeira white wines have been found to possess enhanced levels of methional (3-thiomethylpropanal) and this compound has been demonstrated to be responsible for a cooked vegetable off flavor. Methional is thought to originate from the α-amino acid methionine by Strecker degradation, probably brought about by *o*-benzoquinones (oxidized polyphenols, probably flavan-3-ols) (Escudero *et al.*, 2000) (Figure 2.10.10). Recent studies of Madeira wine aroma profiles using the highly sensitive solid phase microextraction (SPME) and stir bar sorptive extraction (SBSE), followed by GC/MS (see Sections 4.2.4 and 4.3.2) (Alves *et al.*, 2005) have revealed only low levels of methional. This may indicate that extended exposure to temperatures in excess of 40 °C and extended ageing in oak casks result in the loss of methional by evaporation and/or degradation. Phenylacetaldehyde is another Strecker aldehyde that has been found in oxidized white wines (da Silva Ferreira *et al.*, 2007), presumably produced by the Strecker degradation of phenylalanine. Moreover, da Silva Ferreira and coworkers (2007) were able to detect α-keto-γ-(methylthio)butyric acid and β-phenylpyruvic acid, as their quinoxaline derivatives, in Madeira wines by HPLC with UV/fluorescence detection (Section 4.3.3) in concentrations up to 5.7 mg/l and 9.6 mg/l, respectively. Thus, for the first time, these α-ketoacids were detected in wine and are presumed to be Maillard intermediates, and in particular intermediates of Strecker degradation (Figure 2.10.10). Other Maillard products have been found at trace levels in Madeira wines from all the major vine varieties. In particular,

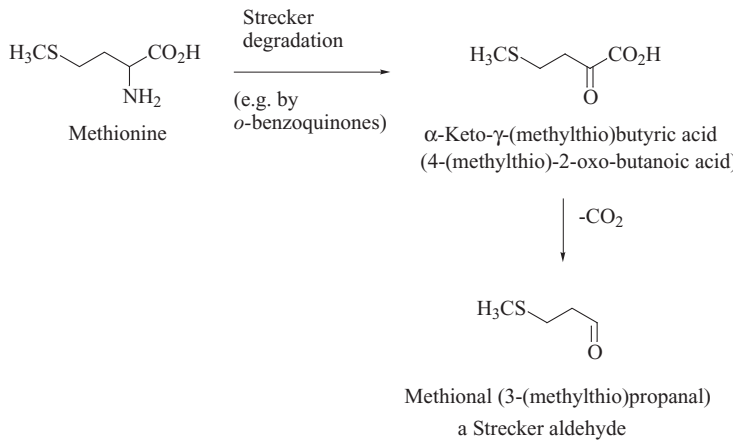

Figure 2.10.10 *Formation of methional during maturation of Madeira wine via Maillard reaction/Strecker degradation. da Silva Ferreira* et al. *(2007)*

low levels of 5-hydroxyfurfural and 2,3-dihydro-6-methyl-4*H*-pyran-4-one (DDMP) have been found, using SBSE-GC/MS (Alves *et al.*, 2005). This highly sensitive technique was able to detect trace amounts of *cis*- and *trans*-oak lactones in some young wines and at quantifiable levels in older wines.

Apart from the Maillard products mentioned above, analysis of the volatile components of young Madeira wines has revealed the presence of many compounds that have been found in other wines (Alves *et al.*, 2005; Câmara *et al.*, 2007). Prominent amongst these were esters, with the most abundant being ethyl hexanoate, diethyl succinate, ethyl octanoate and ethyl decanoate (the last named not in Tinto Negra Mole wines). Tinto Negra Mole wine also had high levels of ethyl butyl 3-methylbutanedioate. The C_{13} norisoprenoids, β-damascenone and β-ionone, were also present. Interestingly, phenylacetaldehyde diethyl acetal was detected in all young varietal wines. Presumably this is formed from phenylacetaldeyde (a Strecker degradation/Maillard product) and ethanol.

2.10.7 Port

Port is the generic name for the fortified wines of the Upper River Douro, in northeastern Portugal, close to the border with Spain (Figure 2.10.11). The vineyards and wine estates ('quintas') are situated on the hills (often on terraces on steep slopes) that line the Upper Douro and its tributaries, such as the Pinhão, the Torto and the Tua. The best vineyards are to the east of the town of Peso da Regua, with some of the very best being around the town of Pinhão. Some of these vineyards are owned by the big Port lodges (Port wine companies), whose cellars are concentrated in the small port of Vila Nova de Gaia (Figure 2.10.11), across the river from Oporto. Others are owned or run by small companies or independent families who sell their grapes to the various Port lodges. In these vineyards, the granite and fragile schist soils, the hot, dry climate and the numerous grape varieties all contribute to the basic wine. Different vinification and maturation methods are then responsible for producing the range of Port wines, from white, through tawny to red, with the latter two being the most important.

The black grape varieties include Alvarehão, Bastardo, Sousão, Tinta Amarella, Tinta Barroca (the same as the Spanish Tempranillo), Tinta Cão, Tinta Fransisca, Tinta Miuda, Touriga Fransesca and Touriga Nacional.

All these varieties contribute different character to the wine, but the general opinion is that Tinta Cão, Touriga Fransesca and Touriga Nacional generally produce the best wine. The major white varieties are Esgana-Cão, Folgasão, Malvasia Fina, Rabigato, Verdelho and Viosinho. The grapes are mostly harvested by hand, mechanization being difficult on the steep and wild terrain of the vineyards. They are taken to the nearby quintas for vinification, where nowadays electrically driven crusher/destemmers and pneumatic presses do most of the work (Figure 2.10.12). Traditional crushing by foot in lagares (large, shallow troughs made of granite or hard slate) is relatively rare, but is still used in the best years for small quantities of the finest wines in some quintas (Halliday and Johnson, 1992). Once the grapes are crushed, fermentation of the pulp begins very soon and is allowed to occur with skin contact, as for standard red wines (Section 2.9.2). The difference with Port wine is that the pulp fermentation will be brief, soon to be halted by mixing with grape spirit, so to achieve maximum extract, continuous agitation of the must is required during fermentation. Traditionally, this is done in lagares by the relatively gentle motion of many treading feet, which continuously break up the pulp and submerge it. The large surface area of a lagar ensures fermentation at temperatures a little below 30 °C. Much more common these days are the open tank vats with pump over to keep the pulp cap moist. Also common are closed system autovinifiers, where the must is forced up and over the cap because of the build up of pressure caused by the CO_2 evolved during fermentation. Efficient as these pump over and autovinifier systems are, they lack the facility to extract that little bit of extra color and flavor that traditional manual treading was able to achieve from the skins and pulp. In recent years, the company of W. & J. Graham have

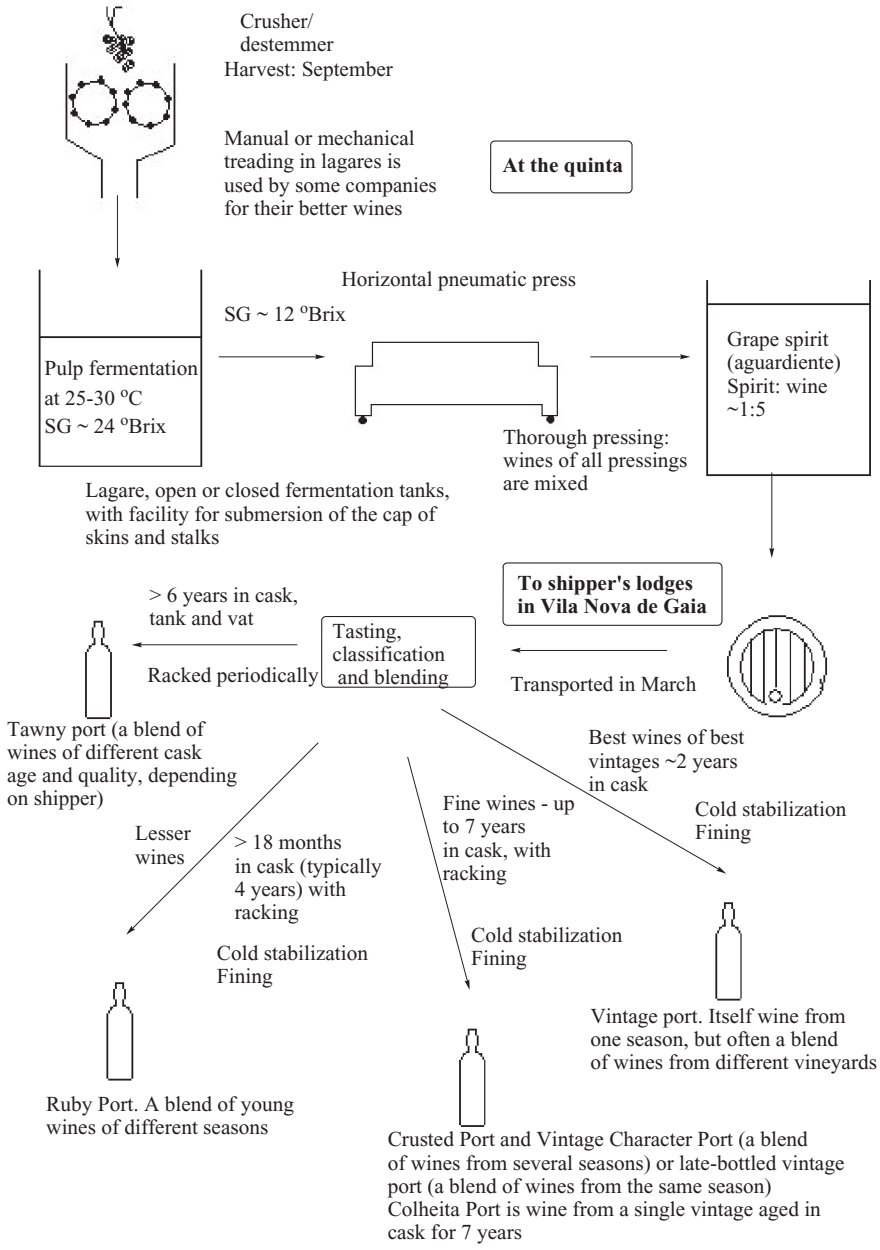

Figure 2.10.12 *Making Port wine from black grapes. All port wines are made from grapes of several varieties. Most are blends of wines from dif ferent sites and many are blends of wines of dif ferent vintages*

built and operated automated treading machines at Quinta dos Malvedos. These machines use pistons whose gentle up and down motion simulates the action of the human foot by pressing the grape skins and pulp gently against the floor of the lagar. The system has the added advantage of good temperature control.

At some point, whilst considerable unfermented sugar still remains in the must, fermentation is arrested by pumping the must into a tank one quarter filled with grape spirit (aguardiente) of about 76% ABV, so that the must to spirit ratio is about 5:1. The timing of this fortification step is important; it is based on calculations made from charts or tables that relate volume and ethanol content of the wine and spirit, initial sugar concentration, concentration required at the time of fortification (measured using a hydrometer) and the final ethanol concentration required. The winemaker's intuition and experience may also play a part in the fortification step. Generally, fortification occurs when approximately one half of the sugar content has been fermented, leaving about 12 °Brix of unfermented sugar. After fortification and subsequent processing, Port wines have typically ∼20% ethanol (v:v) and ∼8 °Brix of unfermented sugar. The pulp is then pressed thoroughly and the wine is transferred to 523 l casks ('pipes'), which are then transported by rail and/or road to Vila Nova de Gaia, where the Port lodges are situated. This journey used to be done down the River Douro on special sailing boats known as barcos rabelos; a romantic, but hazardous journey because of the rapids and strong river currents. This practice stopped after the Douro was damned for hydroelectric power, but the boats are still used for fishing.

Like Jerez and Madeira (and Marsala, initially), the modern day Port wine styles owe much to the enterprise and perseverance of British merchant companies, most of which are still prominent, although often amalgamated (e.g. Dow, Graham, Offley, Taylor, Warre and many others) (see Figure 2.10.11). The Dutch also have a footing (e.g. Burmester, Niepoort, for example) and, of course, there are many Portuguese lodges (Barros, Noval, Pocas, Sousa and others). Some companies, like Croft, Gonzalez Byass and Sandeman are also Sherry shippers, having bodegas in the Jerez area (see Figure 2.10.1 and Section 2.10.2). Originally (in the seventeenth and early eighteenth centuries), the wines were shipped unfortified, but were not popular in England as alternatives to red Bordeaux and other red wines (Lichine, 1982b). Fortification was found to improve the wine quality, by curing the travel sickness. However, the wines were still generally rather harsh and of course dry, so the merchants gradually moved to sweeter wines and the practice of arresting the fermentation was more or less in full favor by the late eighteenth century. As with Sherry and Madeira, high quality grape spirit (in the sense of fine old Cognac or Armagnac) is not necessary for the production of the best wines (Halliday and Johnson, 1992); the rough, high strength (∼77% ABV) grape spirit used even for the best Port (vintage Port) is made by distillation of basic wines from the Douro region or southern Portugal, without either the dilution or long cask ageing usually afforded to brandy (Section 3.6.1) and pomace spirits (Section 3.7.2). To emphasize this, shortage of grape spirit for the very good 1904 Port vintage meant that many lodges had to buy German potato spirit, but the resulting vintage Port wines were of high quality (Halliday and Johnson, 1992). Nowadays, the Port lodges choose their grape spirit according to aroma quality and price (Pissarra *et al.*, 2005), with most winemakers preferring a neutral spirit. The spirit aroma is due mainly to aldehydes, higher alcohols and esters, the major aldehydes being acetaldehyde, but with propanal, 2-methylbutanal, 4-methylpentanal, methylglyoxal and benzaldehyde having significant concentrations. Decreased levels of grape anthocyanins, coupled with increased hue angle (yellowing effect) and increased chromaticity (color saturation) of Port wine were positively correlated with the aldehyde content of spirit used for fortification (Pissarra *et al.*, 2005). Grape spirit with high aldehyde content gave Port wines with more intense colors and flavors; it is probable that aldehydes, especially acetaldehyde, participate in vitisin type anthocyanin formation, as well as in copolymerization between anthocyanins and flavan-3-ols (Figure 2.10.13). These aspects and the color of Port wine are discussed in the next paragraphs.

As with other red wines, the initial anthocyanin pigments of Port wine undergo progressive copigmentation reactions with other wine components, notably phenols, during maturation, so that after ∼2 years very little of the original anthocyanins remain (Romero and Bakker, 2000). The result of prolonged red wine maturation

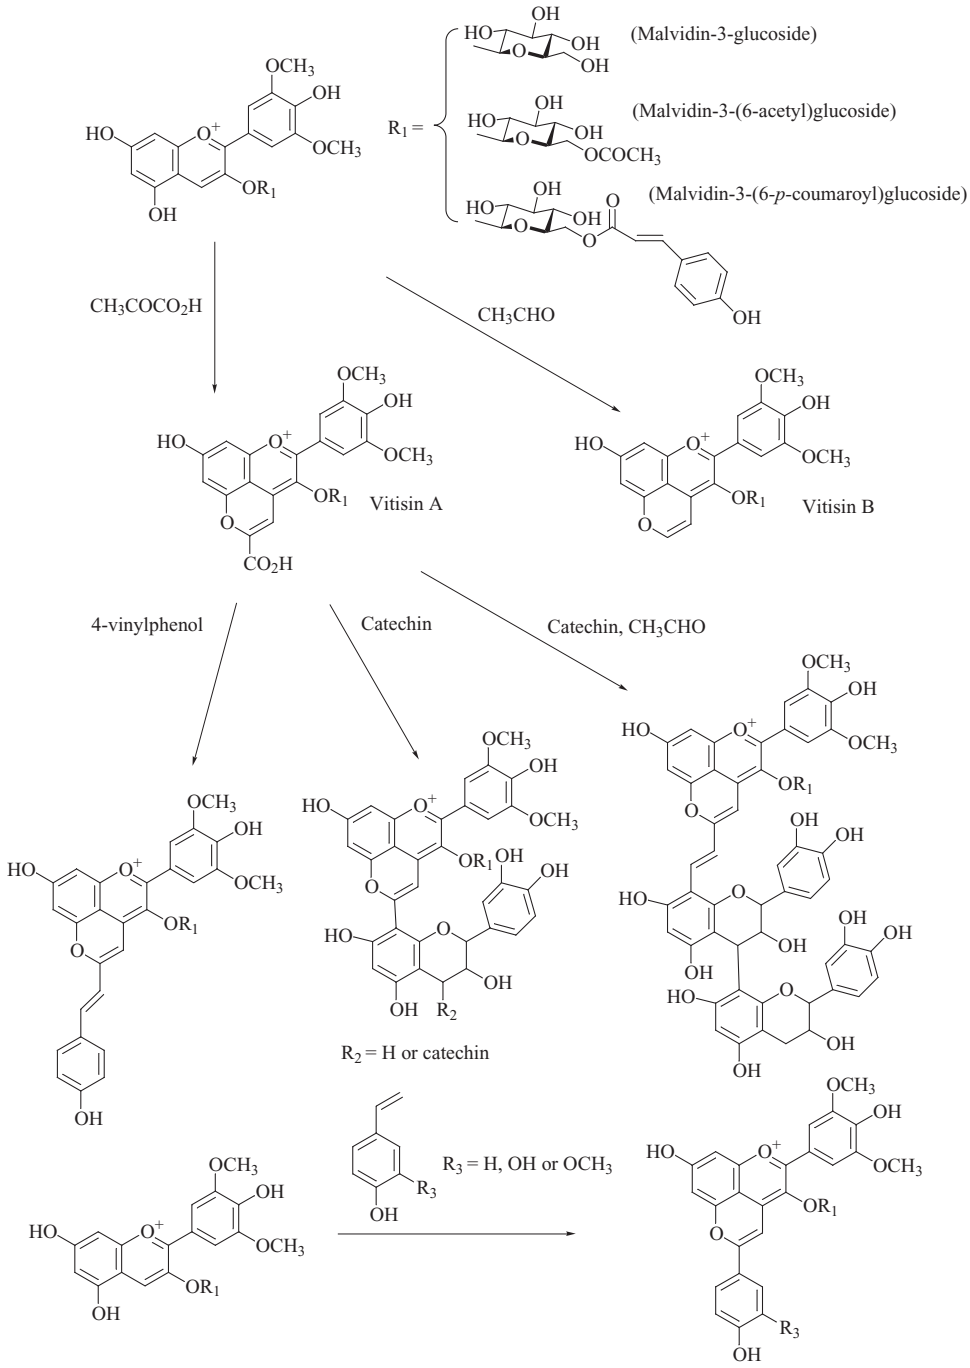

Figure 2.10.13 *Formation of pigments in maturing Port. Mateus* et al. *(2006) and Tempranillo wines, Morata* et al. *(2007)*

is a gradual shift of color from purple (~528 nm) through various hues of red to tawny, given enough time and the right conditions. This corresponds to the formation of new pigments with lower wavelengths of absorption (see Section 2.9.5) (actually lower λ_{max} values – see Section 4.4.3). Initially, the relatively labile anthocyanins, mainly malvidin-3-glucoside and its acylated derivatives, react with pyruvic acid and acetaldehyde to give pyranoanthocyanins, vitisin A and vitisin B, respectively (Figure 2.10.11) (Romero and Bakker, 2000). This occurs during the first two years of maturation, alongside other reactions, including some with flavan-3-ols to produce proanthocyanin polymers (Section 2.9.5). Acetaldehyde is a product of alcoholic fermentation and of ethanol oxidation, whereas most pyruvic acid is produced during malolactic fermentation. Acetaldehyde, along with other aldehydes, is also present in the grape spirit used in fortification. Vitisin concentrations have been increased by the addition of pyruvic acid (Romero and Bakker, 2000). Similarly, both vitisin A and vitisin B concentrations have been increased by addition of pyruvic acid and acetaldehyde, respectively, to young non-Port wines made with grapes of Tempranillo (itself one of the many Port varieties – known as Tinta Barroca) (Morata *et al.*, 2007). Vitisin A has also been produced in model wine solution by reaction between malvidin-3-glucoside and pyruvic acid, its formation being favored by low pH, high concentration of pyruvic acid, absence of acetaldehyde and low temperatures (10–15 °C) (Romero and Bakker, 1999). At wine pH (~3), the vitisins are characterized by both higher color intensity (large ε_{max} values – see Section 4.4.3) and somewhat lower λ_{max} values than those of the original anthocyanins; their colors are slightly to the red side of purple. The vitisins are less reactive and are relatively unaffected by SO_2, whereas the original anthocyanins are readily bleached by this widely used preservative (Ribereau Gayon *et al.*, 2000b; Bakker and Timberlake, 1997). However, on further maturation of the wine, the vitisins gradually undergo polymerization reactions with flavan-3-ols (with and without acetaldehyde bridges) and simple phenols, such as 4-vinylphenol (Figure 2.10.13) (Mateus *et al.*, 2006). The products of the latter reaction are known as vinylpyranoanthocyanins; that formed from vitisin A and 4-vinylphenol actually has a color on the bluer side of purple (λ_{max} ~538 nm) than malvidin-3-glucose (λ_{max} ~528 nm) at wine pH. This compound was characterized by mass spectrometry, NMR spectroscopy and by synthesis from authentic vitisin A and 4-vinylphenol at pH 2.6 (Mateus *et al.*, 2006). It also appears that malvidin-based anthocyanins react directly with vinylphenols to give pyranoanthocyanin-like adducts, as discovered in wines made from Tempranillo (Figure 2.10.13) (Morata *et al.*, 2007). These have colors rather on the red side of purple (λ_{max} <520 nm).

The polymerization reactions that lead to the gradual change of color from ruby to brown occur more rapidly in the presence of oxygen. Port wine matured in incompletely filled oak casks is transformed into tawny Port in less then 10 years, especially if racking with forced aeration has been carried out. Compared with this, vintage Port, with only 18 months cask maturation and stored in well sealed (waxed) bottles can take well over a century to reach a similar color to tawny Port. In a study of the vessel type on the changes in color and phenolic composition during the early stages of Port wine maturation, it was shown that wine maturing in oak casks developed more rapidly than those matured in stainless steel or glass vessels (Ho *et al.*, 2001). The cask wines had higher dissolved oxygen concentrations and higher redox potentials than tank or glass carboy wines. Furthermore, racking with forced aeration over a period of 15 months appeared to have an accelerating effect on the rate of maturation.

Flavonoid phenols and other colorless phenolic compounds are important in red wines, because of their copigmentation reactions with anthocyanins and vitisins (Figure 2.10.13), their contribution to the wine's bitterness and their contribution to the wine's antioxidant properties. Although there is information on these phenolic compounds in wine (Section 2.9.2), fruit wine (Section 2.11.2), cider (Section 2.8.2) and beer (Section 2.6.9), there appears to be limited data for Port wine grape varieties and Port wine (Andrade *et al.*, 2001). In a preliminary study of some major port varieties, Andrade *et al.* (2001) identified 12 phenolic compounds: five flavonols, (+)-catechin, (–)-epicatechin and the tartrate esters of caffeic acid, coumaric acid, *p*-coumaric acid, ferulic acid and syringic acid. The flavonol heterosides were predominant in most of the varieties, except Tinta Cão and Rufete, where (–)-epicatechin was predominant. The major flavonol

heteroside was found to be isorhamnetin 3-glucoside for most varieties, with myricetin 3-glucoside being the predominant flavonol in Tinta Roriz. Kaempferol 3-rutinoside was the least abundant flavonol.

Carotenoids in Douro grape varieties and port wines are of interest because of their antioxidant value and because they are precursors of C_9-C_{13} norisoprenoids, some of which are important flavor compounds. Certainly, carotenoids are biochemical precursors of aroma active norisoprenoids such as β-damascenone, α-ionone and β-ionone in grapes (da Silva Ferreira and Guedes de Pinho, 2004). It is possible that carotenoids are gradually degraded in maturing Port wine to the above norisoprenoids, plus 2,2,6-trimethylcyclohexanone (TCH) and 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN) (Mendes-Pinto *et al.*, 2005). Some 13 carotenoids and three chlorophyll derived compounds were found in the Douro grape varieties Tinta Cão, Tinta Roriz, Touriga Francesca and Touriga Nacional (Mendes-Pinto *et al.*, 2005). Port wines were found to have 19 carotenoids or chlorophyll derived components, but chlorophyll b was not amongst them. The latter, present in grapes, appears to be degraded during the winemaking process to pheophytins and other products. The youngest wines generally had the highest levels of total carotenoids (up to 720 μg/l), with β-carotene and lutein being the most abundant. Of the varietal wines, Tinta Roriz showed the highest carotenoid content, while Touriga Francesca had the lowest. Mendes-Pinto and coworkers (2005) showed that aged wines had higher β-carotene:lutein concentration ratio than young wines, suggesting that lutein degrades more rapidly than β-carotene in maturing Port wine.

Of the many grape varieties used to make Port wine, Touriga Nacional is thought by many to be the finest, giving a wine that is characterized by herbal floral aromas, often described as citrus, bergamot and violet. Correspondingly, Touriga Nacional wines were found to have higher total terpenoid contents than the other major Port varieties (Guedes de Pinho *et al.*, 2007). The compounds largely responsible for bergamot notes were found by GC-O ('sniff GC'), GC-MS and aroma dilution analysis to be linalool and linalyl acetate (de Pinho *et al.*, 2007). This was supplemented by a study of bergamot essential oil, where it was found that linalool, linalyl acetate and α-pinene were the major aroma contributors. Although these studies were carried out on table wines, it is not unreasonable to suppose that the results should relate to Port wine, where Touriga Nacional usually forms a significant part of the blend.

Most recent studies on Port wine aroma compounds have focused on the influence of ageing, winemaking and technological factors on the aroma profile. As with many wines, norisoprenoids, such as β-damascenone, β-ionone, TCH, TDN and vitispirane make important contributions to Port wine aroma. The first two compounds contribute flowery and violet notes, respectively, TCH is responsible for 'rock rose' aroma, whilst TDN and vitispirane contribute 'kerosene' and 'tea leaf' notes, respectively. These compounds are of particular interest in Port wine because the short fermentation (stopped by fortification with grape spirit) results in the presence of carotenoids and other grape material in young wines. da Silva Ferreira and de Pinho (2004) have shown that young wines were richer in β-damascenone and β-ionone, whereas old cask aged tawny Ports had TDN levels some 15 times higher than in young Port wines. TCH and vitispirane were also present at higher levels in old oak aged wines. Furthermore, these authors demonstrated that pH, temperature, free SO_2 concentration and dissolved oxygen concentration all had influences on the norisoprenoid levels in young Port wines as they were stored over a period of 54 days. In particular, TCH and TDN (initially at very low levels in young wines) were formed during storage time, especially at low pH and high temperatures ($\geq$45 °C). Oxygenation increased the concentrations of all the norisoprenoids after a short storage time, but thereafter their levels fell drastically. The concentrations of β-damascenone and β-ionone were maintained by the presence of SO_2, although this compound had the effect of retarding the formation of β-damascenone. Thus, it is possible to rationalize the very different aromas of old vintage Port wines and old tawny Port wines on the basis of their different norisoprenoid compositions.

Many other changes in aroma and flavor occur in Port wines as they are aged for long periods in oak casks. The enhanced nutty, spicy notes that are characteristic of tawny Port wines have been attributed to the presence of sotolon (3-hydroxy-4,5-dimethyl-2(5*H*)-furanone) (da Silva Ferreira *et al.*, 2003a). This compound was

found in concentrations of up to 958 μg/l in old wines, and since its odor threshold value (OTV) in Port wine is only 19 μg/l, it was concluded that it made a significant contribution to the aroma of all the old tawny Port wines studied. Indeed, there was a linear correlation between sotolon concentration and cask age. Sotolon is a common wine compound, being found in Sherry wines (Section 2.10.3), vins doux naturels (Section 2.10.9), vins jaunes (Section 2.10.4) and various botrytized wines, such as Sauternes, as well as Asian rice 'wines' (Section 2.7.1).

It is probably produced in flor wines by aldol condensation between acetaldehyde and 2-oxobutanoic (2-ketobutyric) acid, which itself is derived from threonine by flor enzymic action. However, this mechanism may not be possible in Port wines, so a Maillard reaction origin for sotolon formation in these wines has been suggested by da Silva Ferreira and coworkers (2003a). It can be produced by the condensation of butane-2,3-dione (diacetyl) and hydroxyacetaldehyde. This suggestion is compatible with the observed high correlation between sotolon and 5-hydroxymethylfurfural (5-HMF, another Maillard product) concentrations and poor correlation between sotolon and 2-oxobutanoic acid levels in tawny Port wines.

Volatile sulfur compounds often exhibit unpleasant odors, even when present in very low concentrations, and hence they are often regarded as wine spoilage compounds. Compounds such as methional, methionol and 2-mercaptoethanol contribute aromas of cooked vegetables, cauliflower and burnt rubber, respectively, if present in wine at concentrations close to their OTVs. Other sulfur compounds, like dimethyl sulfide (DMS), provide pleasant odors (truffles or quince for DMS) if present at levels close to (but not exceeding) their OTVs. In general, sulfur compounds are much less in evidence in tawny Port wines than in young ruby Port types (da Silva Ferreira *et al.*, 2003b), so it has been suggested that the long oxidative ageing in oak casks experienced by many tawny Port wines leads to depletion of sulfur compounds. In controlled storage experiments with young Port wine at varying pH, temperature, SO_2 content and dissolved oxygen content, it was found that high O_2 content in particular led to depletion of methionol and 2-mercaptoethanol and build up of DMS and the odorless dimethylsulfone ($(CH_3)_2SO_2$). No methional (with cooked vegetable notes) was formed, nor could dimethyl sulfoxide ($(CH_3)_2SO$) be found (da Silva Ferreira *et al.*, 2003b). It also appears that 2-mercaptoethanol (burnt rubber notes) is converted under these oxidative ageing conditions to the odorless bis (2-hydroxydiethyl) disulfide. In wine, DMS and dimethylsulfone may have the same (as yet unknown) precursor, whereas in beer, the major precursor of DMS is known to be *S*-methylmethionine (SSM) (Section 2.6.2). These experiments explain generally why tawny Ports never suffer from sulfur compound off flavors and also why truffle or quince notes often feature in the aroma of such wines.

Young ruby Port wines often possess almond or hazelnut notes amongst the floral, fruity, herbal, vinous and other aromas. It has been found that 1,3-dimethoxybenzene (*m*-DMB) was responsible for sweet, medicinal, hazelnut notes in young ruby Ports (Rogerson *et al.*, 2002). This compound was present in concentrations up to ~20 μg/l, and although its OTV in Port wine is 47 μg/l, it was considered to contribute to the wine aroma. 1,3-Dimethoxybenzene is thought to be originate partially from the grapes and partially from the grape spirit (aguardente): it was found in Douro grape musts and Port wines, but not in unfortified Douro table wines, where the much longer fermentation process appears to result in degradation of this odorant (Rogerson *et al.*, 2002).

Many different styles of Port wine (except for white Port) are summarized in Figure 2.10.12. As with Sherry and many other fortified wines, blending is of prime importance for most Port wines to ensure consistency of quality and character from year to year. Blending is performed on the basis of the advice of experienced expert tasters who are familiar with the shipper's general wine styles and with the character of the base wines from year to year. Even most vintage Ports are blends of wines from different vineyards, although there are many single vineyard Ports, such as Calem's Quinta de Foz, Quinta de Noval, Offley's Boa Vista and Taylor's Vargellas (see Figure 2.10.11). Vintage Ports are generally reckoned to be the greatest products of the Douro. They are produced in the best seasons only, as decided by the numerous shippers (in theory) independently. Not all shippers 'declare' a vintage Port for a particular good season; a shipper's judgement is based on the

developing quality of the young wines of that season in cask, compared with the quality of previous recent declarations and the projected quality of newer harvests. Vintage Ports are all matured in cask at the shippers' wine lodges in Vila Nova de Gaia for 18 months to three years, with two years being typical. It is shipped in bottle for sale; not long ago, some vintage Port was shipped in cask to be bottled abroad, especially in England. Vintage Ports continue to mature slowly in bottle and may take many decades to develop their full potential. In doing so, they 'throw' a heavy dark, powdery deposit (crust), composed mostly of tannins and tartrate salts, and hence these wines need careful decanting before drinking.

High quality Port wine that was tentatively put down as a vintage wine, but for one reason or another was not declared, is aged in cask for another 2–3 years to become late bottled vintage (LBV) Port. Alternatively, it can be blended with wine of similar quality, but of different ages and bottled as crusted Port, sometimes after extra cask maturation. Although generally of lesser quality than vintage Port, crusted Ports are held in high esteem and will throw a sediment after some time in bottle. Vintage character Port is similar, but the average time in cask is less than that of crusted Ports. All the aforementioned styles (like the basic ruby Port style) are a rich ruby color at the time of bottling; careful racking and topping up of casks ensures a lack of oxidation. The red Port wines generally have 20% ABV and ∼6 °Brix (∼24 °Oe) of residual sugar. They generally have around 3–5 g/l of acidity, expressed as tartaric acid.

Tawny Port is held by many to be the other great product of the Douro, although it is totally different in style to vintage Port. As discussed earlier, oxidation is encouraged by a long maturation in cask and vat, and also by forced racking (Figure 2.10.12). The art is to strike a balance between oxidative ageing and fruit character, something that requires great skill and experience on the part of winemaker and blender. Tawny Ports are usually sweeter than ruby Ports, often having about 9 °Brix (∼36 °Oe) of residual sugar, but this is balanced by a higher acidity, sometimes almost 6 g/l, expressed as tartaric acid.

White Port is a relative newcomer. It is generally made from white grapes without skin contact, from varieties such as Códega, Malvasia Fina, Rabigato and Viosinho. White Port is usually a bit less alcoholic (18–19% ABV) than ruby or tawny Port wines (∼20% ABV) and also slightly less sweet (∼5 °Brix or ∼20 °Oe of unfermented sugar); it is enjoyed as an aperitif in many European countries.

Port style wines are made in many countries, but notably Australia (especially South Australia) and the USA (California, particularly). In South Australia, companies such as Burge, Château Reynella, Hardys and Penfolds make ruby, tawny and vintage style wines from Rhone varieties, particularly Grenache, Mourvedre and Syrah (Shiraz). Especially impressive are the tawny wines, many of which have average ages (most are blended) of over 20 years. Also in South Australia, Seppelt Winery makes a 100 year old 'Liqueur Tawny' wine with an alcohol content over 23% (v:v), almost certainly the result of a long rest in cask. The same company also uses Touriga varieties, along with Grenache and Shiraz, for vintage Port style wines. The tawny wines have the characteristic intense nutty flavors and rancio character associated with the real article, although they tend to be less sweet, typically having ∼3 g/l of residual sugar, as opposed to the more typical value of ∼9 g/l for tawny Port wines.

In California, Port style wine (and other fortified wine) production is concentrated in the hotter Central Valley regions, with some of the best coming from the San Joaquin Valley, especially from Madera County. Here, Ficklin Vineyards use Tinta Cão, Touriga Francesca, Touriga Nacional and other Douro varieties to make wine in the Portuguese style. Likewise, Quady (a winery that specializes in fortified wines – see Sections 2.10.2 and 2.10.9) makes its 'Starboard' brand from Douro varieties in the Douro style. As the producers suggest, differences in character between San Joaquin and Port wines arise from differences in climate (San Joaquin is hotter!), terroir, cask ageing (in 267 l casks, rather than in 623 l 'pipes') and in spirit used for fortification. The same argument could be used for the Australian Port style wines, with different varietals being added to the list.

Elsewhere in California, Port style wines are more likely to be made from the grapes of varieties such as Carignan, Grenache, Syrah, Zinfandel and others; indeed, the Quady winery made its first Port style wine

from Zinfandel grapes. These wines are all made in modern wineries (e.g. Fairbanks-Gallo) with emphasis on quick maturation. They tend to be considerably sweeter than the corresponding Port wines, in contrast to many Australian Port style wines.

2.10.8 Marsala and Málaga

Marsala is a DOC (Denominazione di Origine Controllata) wine of Italy and is that country's most famous fortified wine (see also Vernaccia di Oristano, Section 2.10.4). The vineyards are situated around the city of Marsala, on the west coast of Sicily. The grapes used include Catarratto, Damaschino, Grillo and Inzolia (white), as well as Calabrese, Nerello, Mascalese, Pingatello and Perricone (black). These varieties are also used to make unfortified white and red wines in Sicily and Southern Italy. The best grape for Marsala wine is considered by many to be Grillo. Like Madeira, Port and Sherry, British wine merchants played an important early part in developing the style of Marsala. In this case, it was a Liverpool merchant John Woodhouse who first fortified the wines for export to Great Britain and distant parts of the British Empire in cask, originally, then in bottle. The wine became so popular that he set up a winery in Marsala, where the general style of production of Marsala wine was established. Unlike Madeira, Sherry and Port, British influence in Sicily has gone, but modern methods of production owe much to Woodhouse. Like Sherry, all Marsala is fortified and there is wide variation in sweetness, color and quality, indeed some wines are maturated using a solera system. Unlike fino and amontillado Sherry, there is no formation of flor and Marsala wines therefore undergo oxidative maturation like oloroso Sherry, to which they have a distant resemblance. All Marsala is initially dry, containing some 14% ABV (minimum ethanol content is 12% (v:v)). Depending on quality level and style, the base (or young) wine is fortified with grape spirit and supplemented with musto cotto – grape must that has been concentrated to a syrup by heating. Alternatively, sifone, a blend of sweet wine made from semi-dried grapes and grape spirit, can be added. Just as likely a mixture of cotto and sifone (concia) may be used produce medium and sweet wines, depending on the blend of cotto and sifone.

The three basic styles of Marsala are seco (dry), made with added grape spirit only; semiseco (medium) and dolce (sweet), made with concia, cotto and spirit, or sifone. The styles and quality types of Marsala wine are summarized in Figure 2.10.14. The highest quality levels are vergine riserva and vergine; these are unsweetened seco wines which have undergone long cask maturation. Fine is the most basic quality level, with cask maturation for up to one year. This is followed by superiore and superiore riserva with longer time

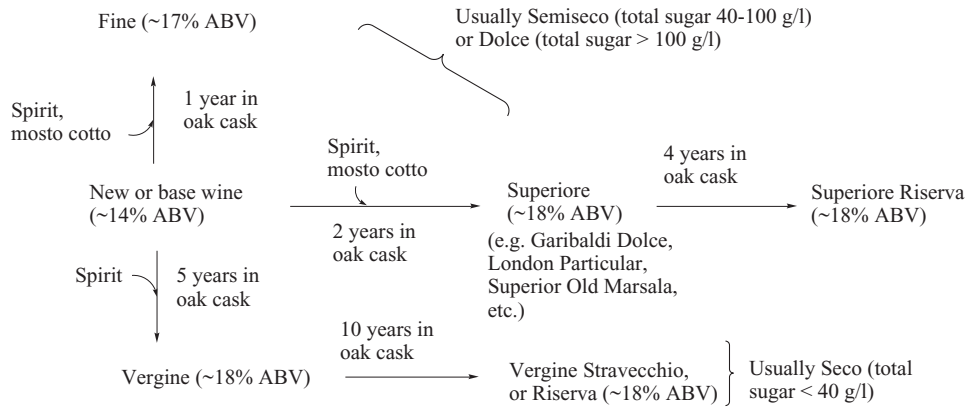

Figure 2.10.14 *Quality levels and styles of Marsala wine*

in cask. These wines are either semi-seco or dolce (i.e. sweetened), but seco superiore riserva wines exist too. The vergine wines are golden (oro) or amber (ambra), but the other quality wines are usually amber, the depth of color depending on the quality and depth of color of the concia used in the winemaking. The amber colors originate not only from the physical concentration of the grape must, but also from caramelization of sugars and Maillard reactions that occur during must heating. Less common are the ruby (rubino) Marsala wines, made from black grapes.

The grapes are harvested in August and September. Most are vinified to give the base wine, but some are semi-dried, fermented and converted to sifone by addition of grape spirit. Yet others, mostly Catarratto, are crushed, pressed and converted to musto cotto. Most Marsala wines are aged statically in oak casks (~450 l typically), which are stacked in rows to the winery ceiling. Blending is a highly skilled business – achieving consistent and high quality from a large number of wines of different ages, degrees of color, density, flavor and alcoholic strength. A few wineries are reputed to still use a solera system of dynamic aging/blending, like that of Jerez. Major producers are Vito Curatolo Arini, Florio, Di Guiseppe, Carlo Pellegrino, Diego Rallo and Scia-Scia.

It may well be difficult for amateurs to differentiate the various categories of Marsala by organoleptic analysis, but recently canonical discriminant analysis (CDA) of analytical results allowed classification according to phenolic compound and heavy metal compositions (La Torre *at al.*, 2008). Highest discriminant power was found with caffeic acid, catechin, kaempferol, lactose, procyanidin B1, quercetin, rhamnose and tyrosol, as well as copper, lead and zinc.

Málaga is a port on Spain's Mediteranean coast, situated east of Jerez and directly south of Montilla – Moriles. The strong wines of Málaga were once as famous as those of Jerez, but the area has never recovered from the ravages of *Phylloxera vastatrix* in the 1870s and now produces a small fraction of its former volume of wine. The best vineyards are found to the north of the city (Zona Norte), where Pedro Ximenez, Moscatel and Airen are the main vine varieties. The wines are often blends of wine from the above varieties, but varietal wines are also made from Pedro Ximenez or Moscatel grapes. Málaga wines are made in a range of styles from dry (seco) to sweet (dulce) and most are fortified. Like Marsala, the cheaper Madeira wines and sweet Sherry wines, Málaga wines are given a range of color and sweetness by the use of sweetening and coloring 'wines,' Arrope is must that has been reduced in volume by two thirds during heating. Vino de color (or pantomina) is an even more concentrated and viscous cooked must. Vino maestro and vino borracho are blends of grape must and grape spirit. To achieve the desired color, sweetness and alcoholic strength, a combination of the sweetening and coloring 'wines' is used to give blanco (white), dorado (golden), rojo-dorado (tawny), osuro (dark) and negro (black) Málaga wines. Very sweet wines were once made from the free run press juice (labelled Lagrima, which means tears). The best Málaga wines are matured in solera systems like those of Jerez. To qualify as Málaga DO (Denominación de Origen) wine, the wine must be made from grapes of specified varieties growing in four designated areas around the city and must be matured in bodegas in the city. Major shippers include Vinícole Andalucía, Hijos de A. Barceló, Luis Barceló, Felix Garcia Gómez, Flores Hermanos, López Henmanos, Scholtz Hermanos, Carlos J. Krauel, Larios, Campañia Mata, Morón, Juan Mory & Cía, Manuel Pacheco, Casa Romero, José Garijo Ruiz, Guillermo Rein Segura, Pérez Texeira and Hijos de José Suárez Villalbe.

2.10.9 Vins Doux Naturels, Liqueur Muscat and Similar Wines

Vins doux naturels (VDN) are French fortified wines made in 12 locations (appellations) in the south of the country, bordering or close to the Mediterranean Sea (Figure 2.10.15). Like all Appellation Contrôlée Wines, their production is strictly regulated from vineyard to bottle. For example, each appellation has its own defined territory, with certain grape varieties being grown, harvested in well defined yields, at well defined

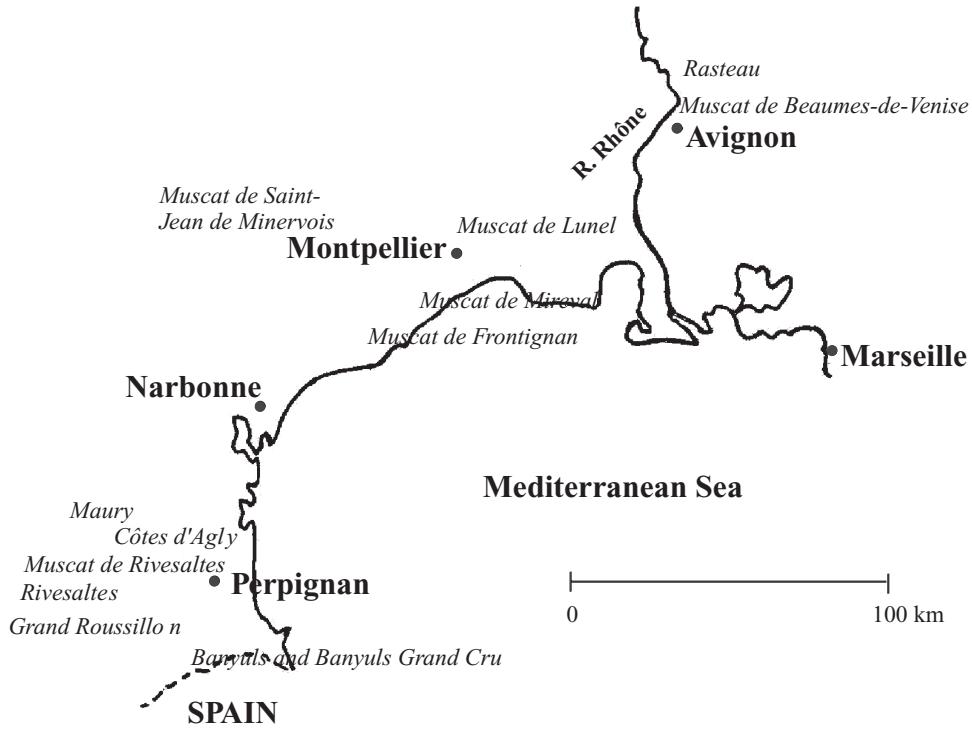

Figure 2.10.15 *Approximate locations of French vins doux naturels production*

maturity (Riberean-Gayon *et al*., 2000a). For example, yields must not exceed 30 hl/ha and the juice must contain in excess of 253 g/l of sugar (about 14.5% potential alcohol by volume). Permitted grape varieties include Grenache Blanc, Grenache Gris, Maccabeo, Malvoisie, Muscat d'Alexandrie and Muscat a Petits Grains (all white), along with Grenache Noir (black). The three major regions of VDN are Roussillon, Hérault and Vaucluse, all in the south of the country. The best areas within these regions have their own restricted appellations. In Roussillon, there is Banyuls and Banyuls Grand Cru on the rugged coastal hills very close to the border with Spain (Catalonia). Further inland are the Côtes d'Agly and Maury Appellations. All of these are well known for their VDN made from nonaromatic (non-Muscat) varieties. Also in Roussillon, just north of Perpignan, Muscat de Rivesaltes is made from Muscat d'Alexandrie and Muscat à Petits Grains. In Hérault, Muscat de Frontignan, Muscat de Lunel and Muscat de Mireval are made from the Muscat varieties near Montpellier and close to the mouth of the Rhône. A bit further inland, a smaller amount of VDN is made at St. Jean-de-Minervois. In Vaucluse, north of Avignon and close to Orange, Muscat VDN is made at Beaumes de Venise and non-Muscat VDN is made at nearby Rasteau, mostly from Grenache Noir.

Because of their different locations, grape varieties and details of winemaking, the VDN of southern France are of quite diverse character. However, they are all sweet and contain around 20% ABV, as required by the appellation laws. Some details of their production are summarized in Figure 2.10.16. Most of the Muscat wines are made by pressing the crushed grapes immediately, and fermenting the clear juice until the desired gravity has been reached, for fortification with grape spirit (mutage): usually 5–12 days.

A few Muscat wines are still made by either rough pressing or by allowing a short maceration period (fermentation on the pulp) before pressing and mutage. The greater extraction of aroma compounds, mainly

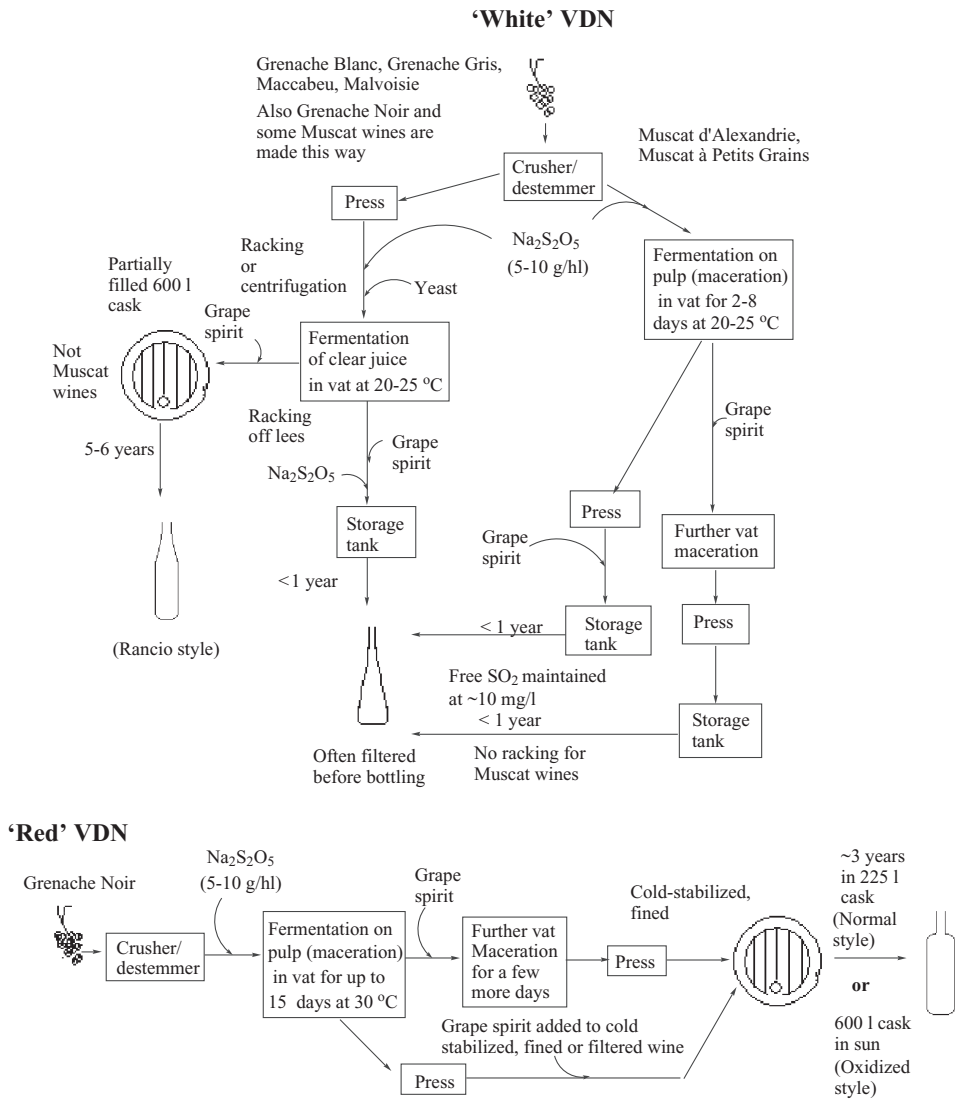

Figure 2.10.16 *Summary of methods for the production of vins doux naturels. White VDN is full gold to caramel, red VDN is brick red to dark amber*

alcohols, esters, norisoprenoids and terpenoids, give a wine with a more pronounced Muscat 'nose.' Muscat VDN are aged for up to a year in concrete or stainless steel tanks with minimal racking and with sufficient free SO_2 to prevent oxidation and preserve the bouquet. They tend to be bottled and sold in the spring or early summer following the harvest, whereas a few decades ago, two or three years maturation was not unusual for Muscat de Beaumes de Venise, for example. The Muscat VDN are the most floral and delicate wines of the type and should be consumed while still fresh – after three or four years in bottle. Muscat à Petits Grains is the more important variety in Beaumes de Venise, but this variety is subservient to Muscat d'Alexhndrie in most of the other Muscat VDN appellations (Frontignan being an exception). Although Muscat à Petits Grains is

classed as a white grape variety (its full name is Muscat Blanc à Petits Grains), there are clones that produce berries of colors ranging from greenish-yellow through pink to purple. The last type (grains noirs) are not dark enough to give a red wine but they do impart a copper color that can be found in some Muscat VDN.

Non-Muscat vins doux naturels are also made by a variety of methods (Figure 2.10.16) with immediate pressing/fermentation being used for most white wines and with the (less common) red wines being made by an extended pulp fermentation (maceration). Many non-Muscat VDN are matured in oak casks for 2–3 years, after being subjected to cold stabilization and fining, following mutage. Racking is performed as necessary and levels of free SO_2 are kept at about 10 mg/l by sulfiting. These VDN are typically golden-brown (nonmacerated) or red-brown (macerated). A few wines, at Rasteau and Maury in particular, are given an oxidative maturation in oak casks for 5–6 years, whence they take on the 'rancio' character of oloroso Sherry or tawny Port; Rasteau Rancio is an example of this. Maturation occurs in 600 l casks that are partially (~5/6) filled. Either a certain volume is removed from the casks each year, the volume being replaced with newer wine (a kind of simplified solera/blending system) or the wine from the rancio casks is bottled all at once (essentially a vintage wine). A few decades ago at Rasteau, it was not unusual for rancio wine to reside in casks for 10 years. Rancio wines tend to be brown in color and have a roundness of flavor and character that are reminiscent of oloroso Sherry (Section 2.10.2) or tawny Port (Section 2.10.7).

Some red VDN, after fining and cold stabilization, are placed in 600 l casks and exposed to the sun for a period of time, rather in the style of estufagem (Section 2.10.6). Oxidation and the heating cooling cycles ultimately give brown wines with characteristic rancio and toasted aromas rather like Madeira wines (Ribéreau-Gayon *et al.*, 2000a). The traditional making of oxidized style VDN, using loosely stoppered large glass carboys (bonbonnes) for maturation has almost disappeared, but some Banyuls is still made this way, mostly from Grenache Noir grapes. As with other fortified wines, the fortification process (mutage) used for VDN production is crucial. The moment of fortification must be chosen correctly to give a final unfermented sugar content in accordance with both the legislature pertaining to the appellation and the style of product required. Either grape spirit (~90% ABV) or mistelle, a mixture of grape spirit and unfermented must, is used. Fortification can be achieved in one go or at intervals over several hours, but the timing of fortification is based upon the fermenting wines' gravity; the minimum residual sugar content is between 95 and 125 g/l, depending on the appellation. The quantity of spirit added at the time of mutage is required to be between 5 and 10% of the fermenting wine volume and the final product must contain between 15 and 18% ABV and at least 21.5% total alcohol (v:v). Total alcohol content is the sum of actual alcohol content and the potential alcohol content remaining in the residual sugar (= residual sugar concentration in g/l divided by 17) (Ribéreau-Gayon *et al.*, 2000a). Fortification tables exist to help the winemaker perform the mutage correctly (as in other regions where fortified wines are made, like the Douro); these are based on volumes of wine and spirit, residual and original sugar content, and appellation requirements.

Non-Muscat VDN have characteristic odors that depend on the ageing process. Typical description include cocoa (or chocolate), caramel, coffee, dried fruits, prunes, jam and spice. It has been found that nonoxidatively aged red Maury VDN made from Grenache Noir have a standard range of acids, esters, lactones and volatile phenols, with perhaps somewhat elevated levels of carbonyl compounds and lower levels of fusel alcohols, possibly resulting from the mutage spirit (Schneider *et al.*, 1998). On the other hand, oxidative ageing in ullaged casks or in carboys exposed to the sun, led to increased levels of acetals, acids, esters, lactones and phenols. GC sniffing experiments indicated that ethyl 2-hydroxyglutarate (chocolate), 4-carboxy-γ-butyrolactone (coconut) and ethyl pyroglutamate (honey) made considerable contributions to wine aroma. These were found in nonoxidized wines, but were present in much higher levels in oxidized VDN (Schneider *et al.*, 1998). Certain other compounds, notably diethyl and monoethyl succinate, diethyl malate and ethyl lactate were also found at higher levels in oxidized wines. Interestingly, sotolon (3-hydroxy-4,5-dimethyl-2(5*H*)-furanone), with its curry or spicy notes, was found in only nonoxidized Maury VDN, and even then below its OTV. However, sotolon has been found at elevated concentrations in white non-Muscat Rivesaltes

Table 2.10.2 *Some major producers of Vins Doux Naturels*

Region	Producers
Roussillon	Les Vignerons de Maury, Mas Amiel (both Maury). Les Vignerons des Côtes d'Agly, SA Destavel (Banyuls and Rivesaltes), Cellier de Templiers (Banyuls and Banyuls Grand Cru), Société Coopérative l'Étoile (Banyuls), SCV Le Dominicain (Banyuls), Cave de l'Abbé Rous (Banyuls Grand Cru). Ch. de Canterrane, Ch. Las Collas, Ch. Pradel, Domaine Mounié, Domaine Rancy (all Rivesaltes, some Muscat de Rivesaltes).
Hérault	Ch. de la Peyrade, Ch. de Stony (both Frontignan). Les Vignerons du Muscat de Lunel, Ch. de la Devèze, Ch. Verargues, Ch. Tour de Farges (all Muscat de Lunel). Domaine du Mas Rouge, Domaine du Mas Neuf, Caves de Rabelais, Ch. Exindre, Domaine de Capelle (all Muscat de Mireval). Domaine Barroubio, Domaine Montaluc, Val d'Orbieu (all Muscat de Saint-Jean-Minervois)
Vaucluse	Coopérative Intercommunale des Vins et Muscats, Domaine Durban, Domaine des Bernadines, Domaine de Coyeux, Domaine St.-Saveur (all Muscat de Beaumes-de-Venise). Domaine de Char-à-vin, Domaine de la Grangeneuve, Francis Vache (all Rasteau).
Corsica	Domaine Gentile (Muscat du Cap Corse and Muscat de Patrimonio)

Source: Grand Roussillon Appellation is not shown. Roussillon information from www.vivexpo.org

VDN that had been aged in oak casks (especially if new) in a non-air-conditioned winery, where temperatures varied between 8 °C and 33 °C (Cutzach *et al.*, 2000). It was above its OTV, and hence made a significant contribution to odor, in all cask aged samples and also in a non-air-conditioned vat aged sample, after just 30 months maturation time. 5-Ethoxyfurfural and cis/trans-methyl-γ-octalactones were also found at higher levels (above their OTVs) in cask-matured wines from non-air-conditioned wineries. These results support the idea of a Maillard reaction origin for these compounds, as suggested by da Silva Ferreira *et al.* (2003a) for Port wines (see Section 2.10.7). It is not clear why sotolon was not detected in oxidized red VDN (Schneider *et al.*, 1998), a possible reason being that in this study, a four year old cask aged wine was kept at a constant cellar temperature of 17 °C and the sun exposed wine was matured in demijohns for only a year. Hence, it appears that the spicy character of red Maury VDN can be enhanced by cask ageing in a warm (or fluctuating) environment. Principal producers of VDN can be found in Table 2.10.2, including Muscat wines produced further east on the island of Corsica.

Both Muscat and non-Muscat are made around the world in the VDN style (i.e. via mutage). In the eastern Mediterranean there is Moscato di Pantelleria, the sweeter versions of which (liquoroso and passito) are fortified. Pantelleria is a small island, viticulturally and administratively linked to Sicily, but geographically closer to Tunisia. The sweet Muscat wines are reckoned by many to be amongst the best in Italy. The annual production of all Moscato wines on Pantelleria is around 1 000 000 l and the biggest producer is Agricoltori Associati di Pantelleria. The grape variety is Zibibbo, a clone of Muscat of Alexandria, and the wines usually have around 22% ABV after fortification. Further north, on Sardinia, some Malvasia di Bosa is fortified (called liquoroso), although not all of it by mutage. There are also fortified versions of Moscato di Sorso-Sennori and Cannonau in northern and eastern Sardinia, respectively. In Portugal, the well known Moscatel de Setúbal is made from Muscat of Alexandria grapes in the VDN style.

The Australian liqueur Muscat dessert wines are made like VDN, by stopping the fermentation with grape spirit. The best wines are made from Brown Muscat grapes, from vines that are strains of the darker skinned fruiting clones of Muscat à Petits Grains, responsible for the finest VDN. They are made in the hot, dry country of northeastern Victoria (especially Rutherglen), not far from the border with New South Wales. Here, there is usually no problem in achieving musts from raisined grapes with sugar concentrations of at

least 29 °Brix (~125 °Oe). Cultured yeasts are used and fermentation may be stopped early (which then requires a greater volume of spirit for balance) or when there is about 14 °Brix (~57 °Oe) of unfermented sugar still in the must. A kind of solera system is used, the wines being aged for four or more years in old oak casks that are stacked high in the winery or in the roof space. The fluctuating temperatures subject the wines to an oxidative heat treatment, rather like the estufagem used for the best Madeira wines (Section 2.10.6). The result is an intensely flavored deep colored dessert wine that has the nutty characteristics and balancing acidity associated with tawny Port and Malmsey Madeira wines. The best known liqueur Muscat wines are probably those of Brown Brothers and Campbell wineries. The lower quality Gordo Blanco (Muscat of Alexandria) grapes, along with Palomino, Pedro Ximénez and Sultana, are used in making Sherry style fortified wines, usually sweet or semi-sweet (Section 2.10.2). An interesting difference between Australian liqueur Muscat wines and European fortified wines is that the former is often made from relatively mature cask aged brandy, rather than more neutral and less refined grape spirit. This can give the Australian wines an extra dimension of spiciness, derived from the oak aged brandy.

Interesting fortified wines are made by the Quady winery in San Joaquin Valley of California. The Orange Muscat wine, made from grapes of that name, is relatively lightly fortified (~15% ABV). The Red Muscat dessert wine is unusual (for California, at any rate) in being made from Muscat Hamburgh grapes that have fully ripened (25 °Brix). At this ripeness, Muscat Hamburg grapes produce wine with strong Muscat notes, whereas this character is muted or even absent in the wine of less ripe grapes.

2.10.10 Vins de Liqueurs and Similar Beverages

Vins de liqueurs are defined as alcoholic beverages made by the addition of grape spirit to grape must. Thus, all the alcohol is derived from the added spirit. By French law, vin de liqueur must have 15–22% ABV, but in practice, the majority have around 17.5% ethanol (v:v). Another name for them is ratafia, as used for the vins de liqueurs of the Burgundy and Champagne regions. Vins de liqueurs are different from fruit liqueurs (or fruit liqueur wines), where crushed (or sometimes whole) fruits are soaked in spirit (not necessarily grape spirit) with added sugar and sometimes for extended periods of time (Section 3.9.2). Vins de liqueurs are made in several regions of France, each production being governed by the specific regional Appellation d'Origine Contrôlée. The main beverages are summarized in Table 2.10.3.

The best known vin de liqueur is probably Pineau de Charentes, reputedly discovered by accident in 1589 when a winemaker added grape juice to a cask that he thought was empty, but which in fact contained a considerable volume of Cognac. Being vintage time, the winemaker was very busy and simply put the cask aside to get on with other jobs. After two or three years in cask, the drink was found to be very palatable and was soon produced at each vintage, becoming known as Pineau de Charentes. Today, Pineau is made in the départements of Charente and Charente-Maritime from Ugni Blanc, Folle Blanche, Colombard grapes and sometimes Semillon and Sauvignon Blanc grapes (white) or Cabernet franc, Cabernet Sauvignon and Merlot Noir (rosé). The rosé version is less common. For the white version, the grapes are destemmed, crushed and then pressed heavily. The must is mixed immediately with Cognac (60% ABV) and aged in oak casks for at least a year, but usually longer; five years is not uncommon. The Cognac itself will have had a minimum of one year in cask, and the must and spirit are added in proportions to give about 17.5% ethanol (v:v). The rosé version is made in a similar manner except that it is given a short maceration time to extract some color. Floc de Gascogne is probably the next best known vin de liqueur. It is made in the Armagnac region of Gascony, in the département of Gers mainly, but also in a few cantons (parishes) in Lot-et-Garonne and Landes departments. The grapes are Colombard, Gros Manseng and Ugni Blanc (white version), Cabernet Franc, Cabernet Sauvignon and Merlot Noir (rosé version). The method of production is similar to that of

Table 2.10.3 *Vins de liqueur*

Type (AOC)	Allowed grape varieties	Type of grape spirit used	% Ethanol (v:v)	Ageing in cask/ years	Producers or brands
Pineau des Charentes	Colombard, Folle Blanche, Sauvignon Blanc, Semillon, Ugni Blanc; Cabernet Franc and C. Sauvignon, Merlot	Cognac	17–18	>2 years	H. Bergey, L. Bouron, Dom. Estève, Gautier, Otard, Remy Martin
Floc de Gascogne	Colombard, Gros Manseng, Ugni Blanc; Cabernet Franc and C. Sauvignon, Merlot	Armagnac	18	~2 years	Dom. de Bilé, Ch. La Grangerie, Dom. de Joÿ, Dom. de Pujo, Ch. de Sales
Ratafia de la Champagne	Chardonnay, Pinot Meunier and P. Noir	Fine or Marc de Champagne	18	>2 years	Boulard, Dumont, Geoffroy, Moutard, Vranken
Ratafia de Bourgogne	Aligoté, Chardonnay; Gamay Noir, Pinot Noir	Fine or Marc de Bourgogne	17–18	1.5–2 years	Cartron, Defaix, Lejeune, Trenel, Védrenne
Macvin de Jura	Chardonnay, Savagnin; Pinot Noir, Poulsard, Trousseau	Marc de Jura	17	>1 year	Ch. Gréa, Dom. de la Pinte, Dom. de la Tournelle
Cataroise de Béziers (Picardin Doux)	Bourboulenc, Clairette, Grenache Blanc, Maccabeu, Marsanne, Picpoul, Rolle, Roussane, Viognier; Cinsault, Grenache Noir, Mourvedre, Syrah	Local eau-de-vie de vin	18	>1 year	Comte de Fontserrane, Douce Nuit

Pineau de Charentes and is made under similar regulations: the grape must and Armagnac brandy must come from the same vineyard, and the Floc resides in cask for about a year before being tasted by a committee of experts and given Appellation d'Origine Floc de Gascogne status. Additionally, the grape must should have enough sugar to give 10% ABV – although this ethanol will never be produced as such in Floc de Gascogne, because of the mutage. This rule ensures that ripe grapes are used, so giving a well balanced product, with some sweetness. Like some Pineau de Charentes, Floc de Gascogne is fined, filtered and cold stabilized before bottling.

The other vins de liqueur are mostly consumed locally, but can also be found outside their region of production. Macvin de Jura may well be the first documented example of a vin de liqueur (fourteenth century). Pommeau is a drink made from apple must and Calvados and homemade (noncommercial) liqueur

wines are made in Deux-Sèvres département (Pineau) and in the Vendée département (Troussepinette), although the latter is flavored with pine.

2.11
Fruit Wines and Other Nongrape Wines

I am always happy making wine and writing about it, and if people would only grow fruit to be eaten or drunk it would help them achieve and maintain good health.
—Peggy Hutchinson, 1959

2.11.1 Overview and Scope

The word 'wine' has more than one definition and means different things in different parts of the world. The most restrictive definition, and probably the original and most widely accepted one, is 'the fermented juice of freshly crushed and pressed grapes.' This demonstrates the domination of the grape over other sources (fruits particularly) in the production of alcoholic beverages. In many countries alcoholic beverages made from fruits other than grapes enjoy a significant economic standing and a good reputation, although they often have to contend with deep seated prejudices against them, in favor of grape wine. Alcoholic beverages can be made from any source of fermentable carbohydrates: fruits, vegetables, cereals, roots, honey, sap, leaves and flowers, with or without the use of adjuncts. In English speaking countries, these beverages are often known generally as country wines and those made from fruits are often simply called fruit wines. This is the terminology that will be used in this section and the emphasis here will be on fruit wines, although others will be mentioned and mead has a separate section (Section 2.11.5). Cereal based fermented drinks are dealt with under the headings Beer (Chapter 2.6) and Rice 'Wines' of Asia (Section 2.7.1). Similarly, cider and perry are treated together in Chapter 2.8. In many cases, the driving force behind the production of nongrape alcoholic beverages is the conversion to spirits by distillation. This includes the following conversions: 'grain or cereal wines' to Akvavit (Aquavit), gin, vodka, whiskey or whisky, 'rice wine' to soju or shochu, fruit wine to fruit spirit and Schnaps, potato and other 'wines' to aquavit or vodka, and sugar cane or molasses 'wine' to rum. These and others are discussed in Part 3. Many of the fruit based alcoholic beverages of Asia (such as those produced from green plums, yellow plums or blackberries in China, Japan and Korea) that have names that are loosely translated into English as 'wine' are technically not wines at all. Instead they are best classed as infused liqueurs, since they are usually made by extraction of the fruit with a sweetened spirit base that is derived from vegetables (such as sweet potatoes) or cereals (such as rice, sorghum or wheat). These beverages, which include maeshilju (Korea) and umeshu (Japan), are discussed in Section 3.9.2.

Table 2.11.1 *Sugar and acid content of crushed fruit used to make fruit wines. These are typical values in % w/w of fresh fruit, assuming fully but not overripe fruit*

Fruit	Apple	Apricot	Banana	Bilberry/ blueberry	Blackberry	Blackcurrant	Cherry
Sugar content	14	14	17	11/10	8	10	14
Acid content	1.0	1.5	0.3	0.8/0.3	1.2	3	1.0
Fruit	Crab apple	Damson	Gooseberry	Grape (wine)	Grape (table)	Loganberry	Mulberry
Sugar content	16	14	9	20	14	11	10
Acid content	2.0	2.0	1.5	0.5	0.3	2.0	1.0
Fruit	Orange	Pear	Plum	Raspberry	Strawberry		
Sugar content	11	16	15	11	8		
Acid content	1.0	0.6	1.2	1.5	1.2		

2.11.2 Comparison of Fruit for Winemaking

The most successful grape varieties are used as a yardstick for suitability of all other fruits for winemaking. This is because, when fully ripe, wine grapes give the optimum volume of juice (per mass of fruit) with the best balance of sugar and acidity. Additionally, grape must is usually low in protein and pectin content and hence it generally leads to wine that is easily clarified. In normal seasons, grape must requires little or no adjustments by way of adjuncts (sometimes called additives in country winemaking circles), including dilution with water. Table 2.11.1 shows some typical sugar and acid contents of fruits that are commonly used to make wine. Here it can be seen that ripe wine grapes are just about the only fruits that give a good yield of must, that can be fermented to produce an alcoholic beverage of acceptable alcoholic strength (say ~12% or more) and acidity (say pH ~3.2 or higher) without some kind of adjustment. Apples and pears give beverages of lower alcoholic content (5–9% ABV), but higher acidity and tannin content may partially compensate for this. All other fruits yield either too little juice or one that is deficient in sugar (which means a low alcohol content) and usually with excessive acidity. Some fruits, such as banana, although high in sugar content and of reasonable (if low) acidity, give musts that are both low in yield and are difficult to clarify. The majority of most other fruits would give musts that would result in a wine of low alcohol content (3–8% ABV) and high acidity.

Despite these deficiencies, some fruit wines (as well as cider and perry) are produced commercially from their fruit musts without any or with only little adjustment. The majority, however, are made by methods that involve extraction of ingredients from the fruit into water, and involve adjustment of the extract by addition of sugar, acid and other adjuncts (Section 2.11.3). 'Other adjuncts' often includes a source of polyphenols (loosely called tannins), since despite the fact that many fruits and berries (e.g. damsons, elderberries, mulberries and others with dark skins or flesh) possess high total phenolic contents (TPC), these are considerably diluted by the extraction winemaking process.

Table 2.11.2 lists some polyphenols and anthocyanins (along with some typical concentrations) found in fruit that are commonly used to make fruit wines. Some of these, such as bilberry, elderberry, huckleberry and mulberry have TPC and/or anthocyanin contents that rival those of black grapes, but the polyphenol or anthocyanin profiles are quite different. The differences lie not only in the relative proportions of the aglycones (cyanidin, delphinidin, malvidin, pelargonidin, peonidin and petunidin), but also in the nature of

Table 2.11.2 *Total phenolic content and anthocyanin content of some fruits commonly used to make fruit wines. Unless stated otherwise, in mg gallic acid equivalents/100 g fruit weight and in mg cyanidin 3-glucoside equivalents/100 g fruit weight, respectively*

the carbohydrate moieties (e.g. galactose, glucose, rafinose, xylose, etc.). In black grape must and young red wine, the dominant anthocyanin is malvidin 3-glucoside, whereas in most other musts of dark skinned or dark fleshed fruits, the major anthocyanins are cyanidin-based (Table 2.11.2). Thus adulteration (such as the use of elderberry pigments to deepen the color of red wine) is often readily detected by chromatography (Bridle and Garata-Viguera, 1996). Figure 2.11.1 shows some prominent anthocyanins and polyphenols of dark fruits. Polyphenol profiles of fruits used in winemaking also vary widely, although this variation has been less frequently used to detect adulteration or fraud.

Ellagic acid derivatives (Figure 2.11.1) are found mostly in seeds and pips (embryos), as well as in more woody parts of plants. Thus they tend to be more prominent in the must of berry fruits such as blackberry, raspberry and strawberry, where normal winemaking practices of crushing/infusion/pressing causes some leaching. As with grape must, flavonols (especially quercetin and kaempferol derivatives) are present in fruit juices. Likewise, flavan-3-ols (–)-epicatechin and (+)-catechin are found in many fruit musts,

although often in low concentrations (Siriwoharn and Wrolstad, 2004; Seeram *et al.*, 2006a). Advances in technology, especially LC/MS/MS (Sections 4.3.3 and 4.4.5), have significantly widened the scope of natural phenolic compound analysis, so that not only are minor components being newly reported, but more reliable structural information is obtained for more complex components (including condensed molecules), and in some cases correcting earlier structural assignments (Seeram *et al.*, 2006a; 2006b). Similarly, GC/MS in SIM (selected ion monitoring) mode (Section 4.3.2) has been able to detect and quantify the derivatized stilbenes, resveratrol, pterostilbene and piceatannol (Figure 2.11.1) in blueberries (*Vaccinium* spp.) (Rimando and Cody, 2005).

Simple phenolic acids are present in fruit juices (often as glycosides); these include chlorogenic acid, cinnamic acid derivatives and neochlorogenic acid in huckleberries (*Vaccinium* spp.) (Lee *at al.*, 2004), neochlorogenic acid and *p*-coumarylquinic acid in sweet cherries (Usenik *et al.*, 2008), and chlorogenic acid and neochlorogenic acid in sweet rowanberries (Hukkanen *et al.*, 2006). Mattila *et al.* (2006) have determined the phenolic acid composition of a very wide range of berry fruits, where caffeic acid was found to be particularly concentrated in bilberry, blueberry and sweet rowanberry, protocatechuic acid in bilberry and blackcurrant, *p*-coumaric acid in bilberry and sweet rowanberry, *p*-hydroxybenzoic acid in strawberry, cinnamic acid in cloudberry (*Rubus chamaemorus*), and gallic acid in raspberry and strawberry. This study has provided much information on berry fruits that are not readily available outside specific areas of the world, especially northern Europe.

The major acids (other than phenolic acids) in fruit are malic and citric acids, as opposed to tartaric and malic acids in grapes. In cherries (as in apples and many varieties of pear – see Section 2.8.2) malic acid in predominant, but in many berry fruits, such as blackberry, raspberry and strawberry, citric acid (or isocitric acid lactone) is significant or predominant. As a result of this, malolactic fermentation may not be required (or may even be undesirable) in the production of certain wines made from berry fruits such as strawberry.

Like grapes, the major sugars present in fruit are the reducing sugars fructose and glucose, but unlike grapes, low concentrations of sucrose are also present. For example, bluberry, raspberry and strawberry sucrose contents are typically 10%, 20% and 10% (respectively) of the total sugar content. Additionally, sugar alcohols (especially sorbitol) are minor components of many fruit musts, as they are for grape, apple and pear juices.

Each kind of fruit has its own characteristic aroma compounds; in many cases over 100 such compounds have been detected, and often quantified, mainly by gas chromatography (Section 4.3.2). For a particular fruit, many of these compounds are present in concentrations that are well below their odor threshold values (OTV) (Section 4.7.2) yet they may be essential for the full (true) aroma of that fruit. Likewise, many of these compounds individually possess odors that are not reminiscent of the fruit aroma. However, there are often individual compounds or a combination of small numbers of compounds that obviously contribute most to the actual fruit aroma; their odors are a simplified essence of the whole fruit odor. Examples of such compounds are given in Table 2.11.3, where it can be seen that the majority are alcohols, carbonyl compounds, esters, terpenoids and norisoprenoids. Although the aroma profile of a particular fruit is altered during fermentation and other processing events, many of the characteristic aroma compounds persist, so that the resulting wine may often be strongly reminiscent of the original fruit. This is especially the case if no heat treatments (e.g. hot water infusion or boiling) are used in the winemaking processes.

2.11.3 Making Fruit Wines

There are two basic styles of fruit wines. The first, which is the more common, strives to maintain the fruit character of the base ingredient, giving it emphasis over all other aromas and flavors in the finished product. The second style aims to create a fruit wine that has a general resemblance to grape wines or even

Table 2.11.3 *Characteristic aroma compounds of some fruits*

Fruit	Characteristic aroma compounds
Apricot	Benzaldehyde, linalool, 2-phenylethanol, 4-terpineol and α-terpineol
Blueberry	Ethyl 3-hydroxybutanoate, hexanol, (*E*)-2-hexenol, linalool
Raspberry*	1-(*p*-Hydroxyphenyl)-3-butanone ('raspberry ketone'), (*Z*)-3-hexen-1-ol, β-ionone
Lychee†‡‡	(*Z*)-rose oxide, β-damascenone (rose-floral), dimethyl disulfide, dimethyl trisulfide, 2-methylthiazole and other sulfur compounds
Elderberry‡	Dihydroedulan, β-damascenone, 1-pentanal (fruity), 1-nonanal (flowery), 1-hexanal (grassy), 1-octen-3-ol (mushroom)
Banana§	Pentan-2-one, isobutyl and isoamyl acetates and butanoates
Peach**	Hexalactone, γ-decalactone
Strawberry††	2,5-dimethyl-4-hydroxy-2H-furan-3-one (DMHF)
Pineapple	Allyl carboxylate esters, ethyl and methyl 2-hydroxybutanoates and 2-hydroxyhexanoates
Cherry	Acetophenone, benzaldehyde, benzyl alcohol

*Fuganti *et al.* (1996); †Ong and Acree (1999); ‡Jensen *et al.* (2001) – many other compounds contribute to fruity, flowery, grassy and mushroom notes; §Salmon *et al.* (1996); **Tamogami *et al.* (2001) – determined as enantiomeric composition; ††Mura and Zabetakis (2002); ‡‡Mahattanatawee *et al.* (2007).

a resemblance to a specific wine type, such as Port or Champagne. The making of fruit wines is generally very similar to winemaking (Sections 2.9.1, 2.9.2 and 2.9.3), the major differences being at the early stages of the process, as outlined in Figure 2.11.2. Some fruits, such as apples, pears (see Chapter 2.8), peaches and some berry fruits give sufficient juice when crushed and pressed, with a reasonable balance between acids and sugars. After perhaps addition of sugar syrup to improve the acid:sugar ratio, or perhaps the addition of a little water, these juices can be fermented without any further additions or adjustments. This process seems to be best for wines of the first of the two aforementioned styles; the wines produced this way are often intensely fruity and are immediately recognizable as strawberry or peach or whatever. In order to accentuate the fruit

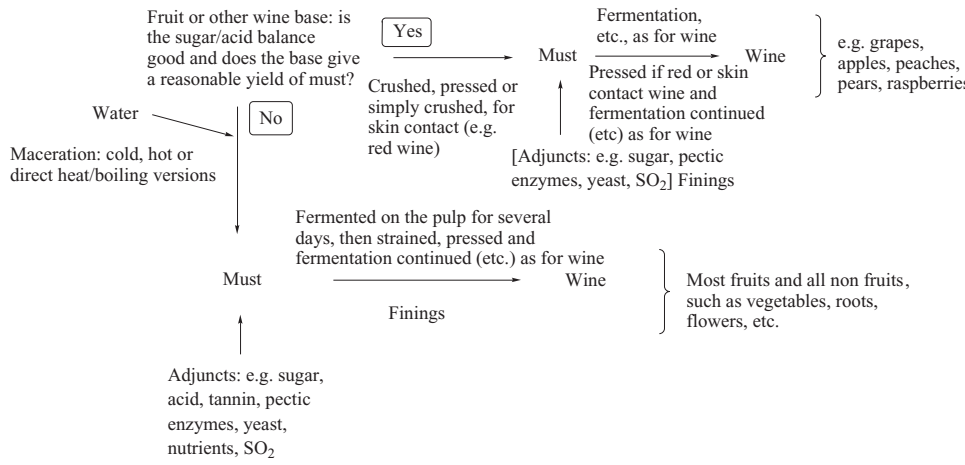

Figure 2.11.2 *Summary of processes used to make fruit wines and country wines. Optional items are indicated in square brackets*

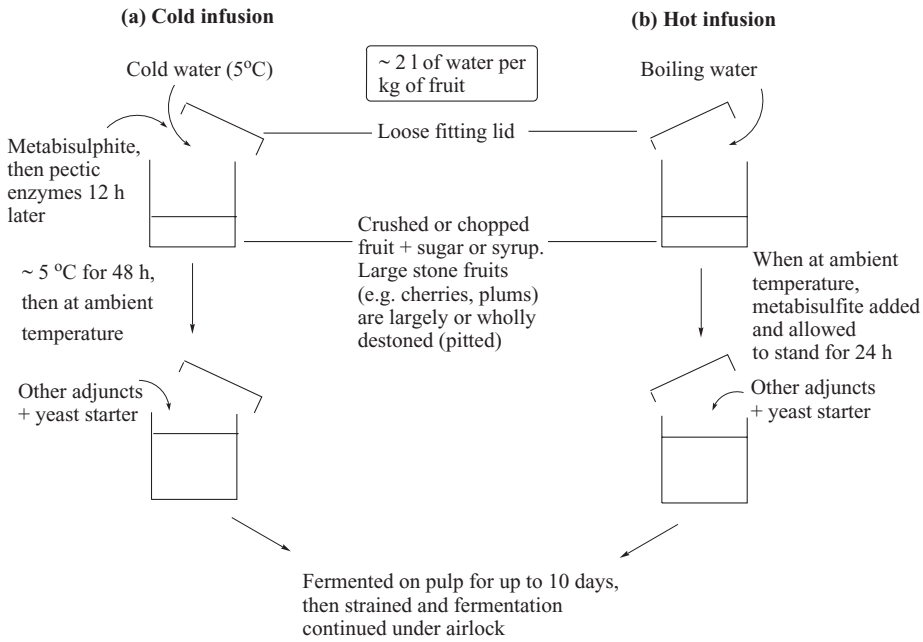

Figure 2.11.3 *Infusion techniques for making fruit wines*

character and also to balance the usually high acidity, they are often made semi-sweet or sweet. This process, shown at the top of Figure 2.11.2, is similar to the making of wine, cider or perry. The alternative process – basically an infusion technique with water, followed by incorporation or readjustment of components by use of adjuncts – is essential for fruits that produce too little juice or juice with poor balance of acids and sugars. The cold and hot infusion versions are generally preferred over the direct heat or boiling version, as the last named technique leads to the loss of volatile components and the formation of 'cooked' flavors (via Maillard reactions, presumably). The hot infusion technique (Figure 2.11.3) involves mixing the crushed or whole fruit with boiling water and allowing the mixture to cool at ambient temperature.

Some adjuncts are usually added straight after mixing, but enzymes such as pectolases are added when cool. Adjuncts include sugar or invert sugar syrup, acids, yeast nutrient, pectic enzymes, grape concentrate, grape tannins, sodium or potassium metabisulfite and oak chips. Many wineries may only use a selection of these adjuncts, depending on the desired nature of the final product. The cold infusion technique is somewhat gentler than the hot method, but probably gives similar results. The hot water helps start the leaching process that is an essential part of the initial fermentation period, by breaking cell walls. It also aids sterilization before fermentation starts, although metabisulfite plays the bigger role in this respect. If not already crushed, the fruit is macerated with a mechanical or electrical device, such as the one shown in Figure 2.11.4. After adding and mixing of sodium or potassium metabisulfite, the must is allowed to stand for 24 h. Most wineries then add an activated pure yeast starter culture at this stage and fermentation on the pulp commences after a few hours. Fermentation on the pulp is an important part of the process – it allows and indeed facilitates continuation of the leaching process via breakdown of cellular wall tissues. The rapidly increasing ethanol concentration during this period helps extract flavor compounds and pigments from the fruit tissues. The presence of pectolytic enzymes also helps in this respect. In this way, the hot or cold infusion methods can produce wines that are almost as overtly fruity and (for rosé and red wines) as deeply colored as those made by the direct crushing and pressing method.

The overall character of the wine can be influenced markedly by the nature of the adjuncts used in the infusion techniques. Apart from sugars and metabisulfite (and in some cases pectic enzymes), the most essential adjuncts are acids and tannins. In former times, amateur country winemakers in Britain used (maybe some still do!) lemon juice and cold tea as a source of acid and tannin, respectively. Nowadays food grade organic acid and grape tannin have largely taken their place. As the dominant organic acids of fruits other than grapes are either malic or citric acids, tartaric acid may be the best acidity regulator for use in the making of most fruit wines. The acid strengths of the common fruit acids are malic acid ($pK_a(1) = 3.40$) < citric acid ($pK_a(1) = 3.13$) < tartaric acid ($pK_a(1) = 2.98$). Whatever acid (or mixture) is used, care in taken to keep the

pH of the final must (i.e. before addition of the yeast starter) between 3.0 and 3.4, in most cases. The weight of sugar used to make a particular volume of fruit wine is determined by experience, according to the type of wine desired (i.e. its % ABV and degree of residual sugar); the winemaker will measure the original gravity of the must before adding the yeast starter. If incorrect, the original gravity can be altered by the addition of more sugar syrup or more (sterile) water. Grape concentrate can be used in place of some (or all) of the sugar. Its main advantage lies in the better balance it often imparts to fruit wines, along with a certain increased vinosity that underlies, but does not dominate, the finished wine. The major disadvantages are the extra cost and the fact that, according to the particular country's food labeling regulations, its presence will need to be indicated somewhere on the label. The presence of all other adjuncts will also need stating on the label in some countries (e.g. the USA), a situation that may deter certain kinds of consumers. Wines made by the hot or cold infusion technique with a grape concentrate adjunct tend to have more vinous character, at the expense of overt base fruit character. Indeed, with careful choice of base fruit, adjuncts and yeast strain, fruit wines can be made to resemble certain commercial grape wines. Commercially, this style of fruit wine is in a minority, although it is very popular with amateur winemakers in the UK. Probably the most commercially emulated grape wine style is Champagne or sparkling wine – witness the sparkling (and even bottle-conditioned) cider and perry (Sections 2.8.5 and 2.8.6) and sparkling wine made from nongrape bases such as green gooseberry, rhubarb, peach or elderflower (Section 2.11.4).

Oak chips can be added just before pitching the yeast starter. As with wine (Section 2.9.5 – see also Section 2.8.7), this is an inexpensive way give the wine oak character and it makes possible the emulation of well known commercial grape wines, such as Rioja. Experience has shown that highly toasted oak chips tend to be much more successful than low toasted types, but care must be taken to avoid overoaking, especially with white fruit bases. The generally recommended amount is 100 g of oak chips to 100 l of must; the 7–10 day pulp fermentation for red wines (less for white wines) should then give about the right level of oak flavor, as the oak chips are filtered off with the pulp and debris during the straining and pressing processes. Of course, oak chips can be added at the maturation stage and there are also oak extract materials (both solid and liquid versions) that can be used in the place of oak chips. In the experience of many fruit winemakers, however, the best oak flavors are obtained after the fruit wine has been subjected to a maturation period in an oak cask. As with wine, the larger the cask, the longer the maturation period that is possible. The very slow and controlled ingress of oxygen through the wood pores into the wine results in a modest amount of oxidation, something that is not possible with wines stored over oak chips in non-porous containers. Furthermore, malolactic bacteria are present in the wood pores and if the conditions are favorable, MLF will occur during the maturation period in wood, provided that there is sufficient malic acid in the wine. These factors probably make up the biggest differences between oak matured and oaked red fruit wines. Indeed, using a base like elderberries or blackberries (or a mixture), it is possible to make a red fruit wine that bears a striking resemblance to Rioja or other high quality oaky red wines.

Pectolytic enzymes are useful not only for hydrolysis of natural pectins, but also for the degradation of fruit cell walls, thereby improving the efficiency of extraction of flavor compounds and pigments. The natural pectolytic enzymes of fruit will be largely denatured by the hot infusion technique and so enzymic adjuncts are added when the must is at ambient temperature and some 12 h following the addition of metabisulfite, since this acts as an inhibitor. Commercial pectolytic enzymes are of fungal origin and can be purchased as liquid formulations or powders.

Choice of yeast can influence the style of a fruit wine, and the winemaker has a wide range from which to choose. Many companies (Gervin, Lallemand, Red Star, Wyeyeast, Young – to name but a few) produce several cultured yeasts, some of which are recommended for specific results (e.g. delicate white, robust red, sparkling white, sweet white) or for particular types of fruit bases. Examples are shown in Table 2.11.4, but it should be kept in mind that there is quite a lot of tolerance and it is possible to use a particular yeast strain to satisfactorily ferment quite different fruit (or even nonfruit) musts. It is also possible to purchase dried

Table 2.11.4 *Possible cultured wine yeasts for production of fruit wines*

Fruit base	Wine style	Possible wine yeast (with comments)
Black stone fruit (plums, cherries, damsons and sloes) and black/red berry fruit (e.g. blackberry, blackcurrant, blueberry, elderberry, mulberry)	Full-bodied red (long maceration time) Medium-bodied red	Lalvin RC212 (varietal aroma enhancer) Lalvin B45 (Brunello di Montalcino strain) Gervin No. 2 or Red Star Montrachet strain (UC Davis 522 strain) Gervin No. 1 (Fermivin; Bordeaux 7013 strain) Red Star 904 (Institute Pasteur strain) (varietal aroma enhancer)
White or pale fruit (e.g. apple, citrus fruit, gooseberry, pear, white currant)	Full-medium (dry-sweet) wines, with enhanced aroma	Lalvin ICV D-47 Lalvin 71B-1222 (reduces acidity due to ability to metabolize ~30% of must malic acid content) Lalvin EC-1118 (not for sweet wines), Red Star 904 (Institute Pasteur strain)
	Delicate, light, fruity wines	Gervin No. 5 (GVN) (good for low temperature fermentation) Gervin No. 9 (CC)
Acidic white fruit (e.g. some apples, gooseberries, plums)	Sparkling wine	Red Star 750 (Geisenheim strain), Red Star 796 (*S. bayanus*; good for restarting stuck fermentations), Gervin No. 6 (*S. bayanus* 8906 strain)
General	General	Lalvin 71B-1122, Lalvin K1-V1116 (highly tolerant of conditions), Red Star 595 (Institute Pasteur strain)

cultured yeast, nutrient and bentonite (finings) mixtures, so that a certain amount of clarification of the wine can take place during the early stages of the winemaking process.

Straining and processing the wort is carried out after 3–10 days of pulp fermentation, depending on the desired final result (especially with regard to depth of color for rosé and red wines). Rack and cloth presses (as used for cider and perry – Section 2.8.3), basket wine presses and pneumatic wine presses are all used by various commercial procedures. Thereafter, the fruit winemaking process is similar to that for cider and perry (Sections 2.8.4 and 2.8.5) and wine (Sections 2.9.1–2.9.5).

The chemical reactions (both enzymic and nonenzymic) that occur during fermentation and maturation are similar to those that have been described for wine (Chapters 2.2, 2.3 and Section 2.9.5). A large number of volatile aroma compounds are produced as end products of various yeast metabolic pathways and the aroma of these is superimposed on those of the surviving characteristic fruit aroma compounds (i.e. those that have not been degraded or otherwise lost during fermentation). As with most alcoholic beverages, the major aroma compounds are higher alcohols, esters, terpenoids and norisoprenoids.

Strawberry wine is reported to have several esters (amyl acetate, ethyl hexanoate, ethyl octanoate, ethyl 9-decenoate and ethyl cinnamate) as the major flavor compounds (Kafkas, *et al.*, 2006). As may be expected, limonene is a flavor component of clementine (*Citrus reticula* Blanco) wine, as are a number of esters, higher alcohols and an assortment of furfurals (Selli *et al.*, 2004).

In the making of red fruit wines, the anthocyanin pigments undergo a number of changes that are likely to be similar to those reported for red grape wines (Section 2.10.7). Thus, after fermentation and maturation, a substantial proportion of the fruit anthocyanins exist as derivative pigments: pyranoanthocyanins, acetaldehyde (and other aldehyde) mediated anthocyanin-flavan-3-ol condensation products and direct

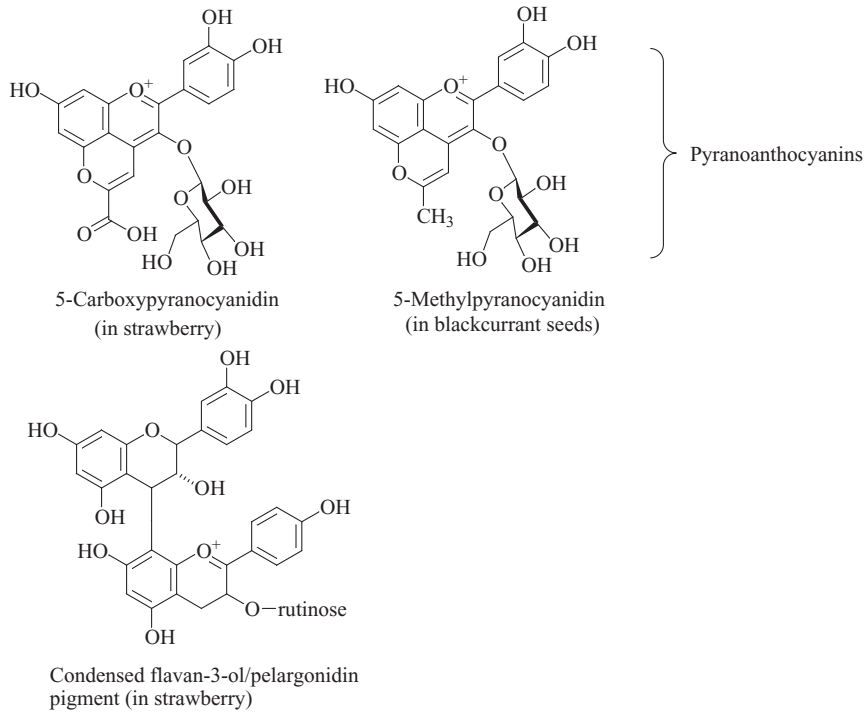

Figure 2.11.5 *Some anthocyanin-derived pigments in soft fruit. Gonzalez-Paramas* et al. *(2006) and references therein*

anthocyanin–flavan-3-ol condensation pigments (Figure 2.11.5), although it is claimed that some of these pigments are present in the original fruit (Gonzalez-Paramas *et al.*, 2006).

Apart from the changes outlined above, any winemaking process that involves a significant amount of heating (i.e. the hot infusion and especially the direct heat method) is potentially responsible for a certain amount of degradation of anthocyanins. Sadilova *et al.* (2006) have shown that exposure of pigment isolates from elderberry and strawberry to heat at 95 °C for 1 h leads to loss of ∼ 19% and 17% of anthocyanins, respectively. Furthermore, they showed that cyanidin sambubioside (glucosylxyloside), a major anthocyanin of elderberry, degrades via deglycosylation to the aglycone cyanidin, which then decomposes to protocatechuic acid and phloroglucinaldehyde. Similary, pelargonidin3-glucoside of strawberry is degraded to phloroglucinaldehyde and 4-hydroxybenzoic acid (Figure 2.11.6). These results were obtained using isolated purified pigments from commercial concentrates after dilution with water, but it is reasonable to suppose that similar reactions would occur in elderberry or strawberry must during winemaking procedures that use heat.

2.11.4 Country Wine Styles

Country wines, and fruit wines in particular, are made throughout the world. The largest producers appear to be Canada, the USA, the UK and France, although in the last named country most of the fruit wine in distilled to give the corresponding spirit (Chapter 3.8). The emphasis is generally on intense fruit character, with winemakers tending to use a high fruit load per volume of finished wine. Sugar syrup or water are added

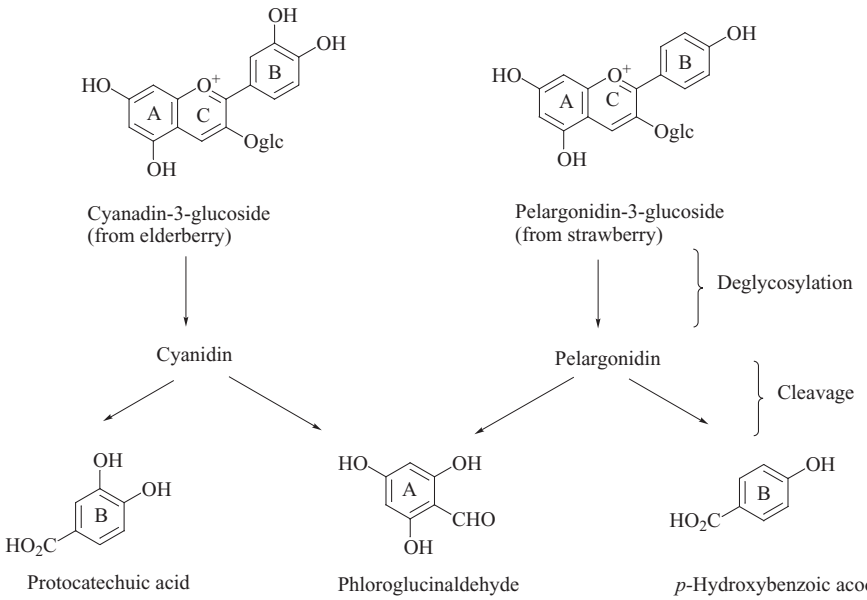

Figure 2.11.6 *Thermal degradation of anthocyanins from elderberry and strawberry. From Sadilova* et al. *(2006)*

in cases where sugar content of the juice is too low or the acid content too high, respectively. There is also a tendency to ferment to 9–11% ABV, in order to preserve maximum fruit character, a common opinion being that 12–14% ABV (or higher) detracts from the fruit character. These wines rely on a delicate balance between sweetness and acidity and because of their strongly fruity character, they are used as social wines, dessert wines or mixers. The lighter styles can be used as aperitifs and the drier styles as dinner wines, but these appear to be in a minority. Some wineries use first grade (i.e. eating quality) fruit, whereas others use 'culls' or 'seconds,' as long as no rotten fruit is included. Other wineries use at least a proportion of concentrate (e.g. cherry or raspberry) and some use frozen fruit, so that wine can be made at different times of the year, rather than just at harvest time (see Section 2.8.6). Freezing also helps to break down fruit cellular tissues, thereby making the extraction of a clearer juice easier. Nevertheless, pectic enzymes are extensively used throughout the fruit wine industry, as is fining (bentonite and gelatin being most popular) and filtration. Many fruit wines are given a polish pad (sterile) filtration immediately before bottling. The majority of these fruit wines are made from a single fruit type, although some mixed fruit or 'formula' types are made. Fermentation and maturation vessels are typically of stainless steel or fiberglass, and residence times are often less than six months, so that bottling is achieved with maximum retention of fruit character. Oak characters and lack of malolactic fermentation are of little consequence for most of these wines (but see later for exceptions).

In the USA, fruit wine production is concentrated in the Midwest and in the northern states of both the Atlantic and Pacific seaboards. The states of Illinois, Michigan, Minesota, Missouri and Ohio possess many fruit wineries, such as Diamond Ridge (Minesota), Lynfred Winery, Illinois Cellars (both Illinois), Chateau Grand Traverse (Michigan), St. James Winery (Missouri) and Wyandotte (Ohio). Some of these wineries specialize in fruit wines, whilst others also make wine from grapes (e,g. Diamond Ridge) or cider (Illinois Cellars). Further west, the Prairie Berry Winery of South Dakota makes an oak barrel aged wine from chokeberries (*Aronia arbutifolia* and *A. Melanocapa* – giving red and black fruit, respectively), as well as grape and other fruit wines. On the Pacific coast, famous (grape) wineries, such as Oak Knoll Winery (Williamette Valley, Oregon) and Bonny Doon Vineyard (California) make intensely flavored raspberry wines,

called Frambrosia and Framboise, respectively. The latter is made to resemble Crème de Framboise from Alsace, Burgundy and other European locations, and so is a fortified fruit wine. There are also fruit wineries in the eastern states, although many of these also produce grape wines, such as Chateau Renaissance (Finger Lakes, New York) and Sand Hill Berries (Pennsylvania).

At present (2009) only grape wines are allowed by the Alcohol and Tobacco Tax Bureau to carry a vintage indication on the bottle, provided at least 95% of the wine in the bottle is derived from grapes harvested in the stated year. Since the presence of a vintage year on the bottle is a common perception of superiority and given the fact that fruit and other country wines, like grape wines, have a wide range of ageing capabilities, it would be a very useful step to change the regulations regarding statement of vintage to nongrape wines.

In Canada, the National Fruit Wine Committee was set up to oversee fruit wine production quality and standards in the regions where fruit wines are in commercial production (Ontaria, Quebec, British Columbia and Atlantic Region). Regulations were drafted to help producers achieve high and consistent standards of quality for export markets. The biggest concentration of fruit wineries is in Ontario, but there are many wineries in other Canadian provinces, with the exception of the most northerly ones. Sunnybrook Farm Estate (Ontario) has a very big range of fruit wines including ice wine made by gently pressing frozen fruit, and unusual blueberry and chocolate wine. In British Columbia, Forbidden Fruit and Kermode Wild Berry Wines are well known for their produce, including fortified wines. East of B.C., Field Stone Fruit Wines (Alberta), Rigby Orchards Ltd (Killarney, Manitoba) and Cypress Hill Winery (Saskatchewan) make a good range of fruit wines, the first – named using wild Choke Cherry (*Prunus virginiana* – 'bird cherry') for some of its products. Fruit wineries also exist in Quebec, Nova Scotia and Newfoundland, Rodrigues Markland Cottage Winery (Newfoundland) being an example. In Australia and New Zealand, there are fruit wineries that concentrate on wines made from indigenous or tropical/subtropical fruit, making wines that are probably made nowhere else in the world. Barossa Fruit Wines (South Australia) produce wine from Quandong (Australian national peach or *Santalum acuminatum*), as well as from apricot, blueberry and mulberry. Even more exotic is Paradise Estate (Queensland); here tropical fruit wines are made from mangosteen, banana, coconut and pineapple (white), and red mango, dragon fruit and banana (red). Fruit wine production is quite extensive in New Zealand (especially North Island). Examples of wineries include Lothlorien (Ahuroa), Manaku Blue (Rotorua), Riverhead Estate Winery (Kumeu) and Sentry Hill (Taranaki). Lothlorien and Sentry Hill make wine using feijoa (*Feijoa Sellowiana*: pineapple guava or guavasteen) and the latter produces several styles of red wine from boysenberry (a loganberry-dewberry-*Rubus ursinus* cross), quite rare in the fruit wine world.

In the UK, the two largest fruit wineries are probably Broadland Wineries (Norfolk) and Lurgashall Winery (West Sussex). The former produces a range of fruit wines and fortified wines from concentrate (British Wines), as well as mead. The latter makes around 500 000 bottles of fruit wines, liqueurs and mead. The fruit wines are made from fresh fruit by the cold infusion method (Section 2.11.3), but both wineries produce elderflower wine and Lurgashall also makes a wine from rose petals and one from silver birch sap.

Dedicated fruit wineries also exist in Scotland, the best known are probably Cain O'Mohr (between Perth and Dundee) and the Orkney Wine Company. Both companies concentrate on fruit wines (from both wild and cultivated fruit), including blaeberry (bilberry) and cranberry, rare for UK fruit wines. They also produce wines from leaves (oak) and flowers (hops, gorse), which may well be unique to the UK. Apart from these few dedicated country wineries, some English vineyards produce fruit wines, notably Avalon (Somerset), Carr Taylor (East Sussex), Kemp's Wine (Suffolk), Rosemary Vineyard (Isle of Wight), Sascombe (Suffolk) and Sedlescombe (East Sussex). Additionally, Old Walls (Devon) makes Elderberry and Regent, a mixed fresh fruit-grape wine, possibly unique in the UK at the time of writing (2009). Several of the above-mentioned vineyards, along with other English vineyards, make cider (Section 2.8.8), mead and liqueurs (Section 3.9.2). Most UK fruit wines are probably made by cold infusion methods; alcoholic strengths vary from ~10% (v:v) to nearly 20% (v:v) for some fortified country wines.

2.11.5 Mead

Mead is basically honey wine; in its simplest form it is an alcoholic beverage made by the fermentation of a solution of honey in water. Since honey, along with grapes, fruit and malted cereals, was a source of sugar for early man, mead probably has as venerable a history as beer, cider and wine. The first mention of mead is probably in the books of Rigveda, of the ancient Vedic religion of India (from the seventeenth century BC). Since then, mead is known to have been produced as a popular beverage in all three continents of the Old World, especially in Ancient Greece, and the Celtic and Germanic kingdoms of northern and western Europe, in the early centuries after the birth of Christ. For a variety of reasons, the popularity of mead waned in many parts of the world, in favor of beer or wine. It maintained some popularity in the Baltic States and some Slavic countries (especially Russia) and recently has undergone a revival of popularity in western Europe, like cider and ale. Likewise, its production in Australia, New Zealand and the USA has increased along with the number of craft breweries and wineries during the last two decades.

Like other alcoholic beverages, mead can be produced by natural yeasts (spontaneous fermentation) or by the use of cultured wine yeasts, the latter method predominating nowadays. However, some meads produced by craft brewers and specific types, such as Tej are made by spontaneous fermentation. Tej is home processed, but commercially available honey wine in Ethiopa. In a study of 200 samples of this beverage, it was found that over 25% of the yeast isolates belonged to the *Saccharomyces cerevisiae* genus along with *Kluyvermyces bulgaricus* (16%), *Debaromyces phaffi* (14%) and *K. veronae* (10%) (Bahiru *et al.*, 2006). The lactic flora consisted of *Lactobacillus*, *Leuconostoc*, *Pediococcus* and *Streptomyces* species, with the first named being the most abundant.

The aroma and flavor of simple mead originates from original honey flavor compounds, along with yeast fermentation and products. Also, many varieties of mead are made with adjuncts (herbs, spices, fruit juices, etc.), which will contribute to aroma and flavor – these are discussed later. The honey aroma compounds will be a mixture of those derived directly from blossoms and those synthesized by the bees. Since simple meads are immediately recognizable as being derived from honey, it is reasonable to assume that the aroma characteristics of mead are similar to those of the honey from which they were derived. There is a lack of information in the literature on mead aroma compounds, but there is much on honey aroma (see Alissandrakis *et al.*, 2007 and references therein), so this will be discussed next.

Honey aroma varies according to the source of nectar, although aroma differences are often subtle, suggesting that, despite the aroma profiles being different, honeys from different blossom sources may have many common aroma compounds (Moreira and De Maria, 2005; Alissandrakis *et al.*, 2007; Tanaki *et al.*, 2007 and references therein). Common compounds include *p*-anisaldehyde, benzaldehyde, benzoic acid, (*E*)-β-damascenone, decane, heptanal, linalool, linalool oxides, nonanal, phenylacetaldehyde, 2-phenylethanol, octane and octanal. Nevertheless, it is possible both to select marker compounds (compounds that are unique to or are in high abundance) and major contributors to aroma of particular honeys, according to their source of nectar. This is particularly the case with blossom honeys, but is not so easy with pine honeys (it requires statistical Kohonen self-organizing map – KSOM analysis), where aroma compounds are dominated by saturated, aromatic and terpene hydrocarbons. For example, lilac aldehyde isomers have been suggested as markers for citrus honey (Allisandrakis *et al.*, 2007) and 3-carene as a marker for Turkish pine honey (Tanaki *et al.*, 2007). Similarly, benzaldehyde, benzonitrile, methylbutanoic acids and 2-phenylethanol have been identified as major aroma contributors of cambará (*Gochnatia velutina*) honey (Moreira and De Maria, 2005), phenylacetaldehyde and coumarin of lavender (*Lavandula augustifolia*) honeys, and *p*-anisaldehyde, linalool, phenylacetaldehyde and 2- phenylethanol of haze (*Rhus Succedanea*) honeys (Moreira and De Maria, 2005 and references therein). Honey displays a wide range of radical scavenging activity according to its floral origin (Baltrušaitytė *et al.*, 2007), with phenolic compounds apigenin, chrysin, *p*-coumaric acid and kaempferol playing a major role. Additionally, honey is known to be rich in enzymic and nonenzymic

antioxidants, including ascorbic acid, amino acids, carotenoids, catalase, flavonoids, glucose oxidase, Maillard reaction products, phenolic acids, proteins and various organic acids. Common flavonoids appear to be chrysin, galangin, kaempferol, luteolin, pinobanksin, pinocenbrin and quercetin (Baltrušaitytė *et al*., 2007). Although antioxidant properties of honeys and honey extracts have been determined by many different methods, such as the $ABTS^{+\bullet}$ and $DPPH^{\bullet}$ methods (Section 4.4.3), there is once more a lack of data for mead. However, it is likely that a considerable number of honey antioxidants will survive fermentation and other winemaking processes, although some of the proteins and phenolic substances may well be removed by fining agents or filtration. Also, mead recipes that call for prolonged boiling or excessive heat treatment will not only alter the antioxidant activity of the honey, but will also cause changes in the aroma profiles, by loss of natural aroma compounds and the production of extra Maillard products. In particular, enzymes are denatured (reversibly or irreversibly, depending on the temperature and duration of heating), so that diastase activity is impaired and hydroxymethylfurfural (HMF or 5- hydroxyl methyl) furan-2-carbaldehyde concentration increases (Tosi, *et al.*, 2008).

Strictly, mead is the product of fermentation of a honey based medium, although different names are often used, depending on the adjuncts used. Wine flavored with unfermented honey is not mead at all, but commercial examples are available under the name of 'meade'; an older name is malsum. Unfermented honey can also be used to flavor liqueurs, such as Drambuie (Chapter 3.8). Plain mead – produced from honey and water – is nowadays given the name traditional mead. Meads in Latin countries are based on the name hydromel, e.g. hidromiel (Spanish), hidromel (Portuguese) and idromele (Italian).

The Slavic countries (except Poland and Russia) have medovina and medica. In Poland, meads are named according to the honey/water ratio: Czworniak, Trojniak, Dwojniak and Poltorak, in order of increasing honey content. Mead is often made with adjuncts, especially fruit juices. The general name for these is melomel, but specific names can be used to indicate particular fruit juices used – e.g. cider (apple), morat (mulberry) and pyment (grape). Metheglin is traditional mead with added herbs and spices, such as cinnamon, cloves, coriander, ginger, mace, nutueg, orange (or other citrus) peal, rosemary, sweet briar, tea and vanilla. In eastern Slavic countries, such as Croatia and Slovenia, these are given the name gverc, from the German Gewürz (spice). Mead brewed with malt wort adjunct is known as braggot; not to be confused with honey beer (Section 2.6.13), in which the honey is an adjunct. Like other fermented alcoholic beverages mead can be distilled or freeze distilled, but such drinks are uncommon.

Mead (mostly traditional, metheglin and melomel types) are made all over the world, often by companies or wineries that also produce fruit wines or grape wines, although there are many companies that produce mead (and honey products) only. In Europe, mead is frequently made by companies that produce other foodstuffs, such as juices, syrups and wines. Some companies use pasteurized honey, some filter the honey/water liquor prior to fermentation, some use sulfites and sorbates and many filter the product prior to bottling. The label or company information (e.g. at the website) will tell much about the product, and the presence of sulfite or sorbates needs to be stated on the label in many countries, and there will certainly be strictly monitored legal limits. Mead is a popular drink in many African countries, notably Ethiopia (already mentioned) and South Africa. A major producer in the latter country, Makana Iqhilika Meadery, makes mead based on an ancient recipe from honey, water and the roots of a local herb, called imoela. Perhaps unique to the world of mead, Makana uses a continuous fermentation process (Chapter 2.6). In Australasia, well known mead producers include Bemrose Estate, Celtic Winery (both New Zealand) and Maxwell Wines of McLaren Vale (South Australia). In the USA, there are meaderies from Alaska (Ring of Fire) to Hawaii (Volcano Winery), but the highest concentrations are in the Pacific States and Colorado – indeed in the last named state, there is an annual mead festival. The emphasis of many of these companies is on melomel styles of mead, using fruit juices from blackcurrant, raspberry and others.

Bargetto Winery (California) matures some mead in redwood vats. Notable mead produces in the USA, apart from the ones mentioned above, include Mountain Meadows (California), Chateau Lorane (Oregon),

Sky River (Washington), Redstone Meadery (Colerado), Trapper Creek Winery (Montana), Pirtle Winery (Missouri), New Day Meadery (Indiana) and Montezuma Winery (New York).

The mead producers in Canada include Intermiel (Quebec), Munro Honey and Meadery (Ontario), and Middle Mountain mead (British Columbia). Mead producers are scattered all over Europe, with particularly strong representations in Slavic and Baltic countries, including Krkonosska Mead (Czech Republic), Pasicka Maceij Jaros (Poland), Tenczynek (Poland) and UAB Lietuviskas (Lithuania). The last named company makes some interesting flavored meads, using acorn, cloves, hops, juniper and linden blossom, amongst others. Other well known mainland European mead producers include Zaubertrank (Hamburg, Germany) and Chouchen (Brittany, France). The former company also makes a range of fruit wines and ciders, whilst the latter makes some oak cask matured traditional mead. In the UK, the two largest mead producers are Lurgashall Winery and Broadlands Winery, both of whom also make fruit wines (Section 2.11.4). Mead is also made by the Orkney Wine Company and by a few English vineyards, such as Avalon.

2.12
Aromatized Wines

There is something about a Martini,
A tingle remarkably pleasant,
A yellow, a mellow Martini;
I wish I had one at present. . .
—Cyril Ray, 1984

2.12.1 Introduction and Brief History of Aromatization of Wine

Aromatized wines are wines that have been flavored by the addition of aromatic substances of plant origin. This is performed by extraction of flavoring substances from bark, berries, flower heads, leaves, seeds or skins (peel) of plants, sometimes with the aid of heat (even distillation) and usually with the help of grape spirit for efficient extraction. Sugar syrup or mistelle (a mixture of grape must, sometimes concentrated by heating, and grape spirit) is added to many of these wines, such as vermouth (Section 2.12.2) and hence many are slightly fortified. The original purpose of aromatization, like fortification, was to preserve the wine from microbiological or oxidative spoilage. Nowadays, with vastly improved winemaking techniques, materials and equipment, the original purpose has been lost, but the taste for aromatized wines remains strong in many parts of the world. This is especially true of retsina, wine flavored with pine resin, which comprises close to 50% of wine production in Greece (Lichine, 1982a). The ancient civilizations of Egypt, Greece and Rome are all known to have used pine resin, usually smeared on the internal surfaces of earthenware wine jars. Some early wine jars may have been unglazed, so the film of pine resin performed the duel role of infusing preservative and antioxidant substances into the wine and keeping extraneous oxygen out by inhibiting the slow ingress of air into the wine through the porous earthenware.

The flavoring of alcoholic drinks with herbs and spices (known as botanicals) also has a long history and many of these beverages have survived to the present day, although in most cases, probably not in their original forms. These beverages include beer (Chapter 2.6), mead (Section 2.11.5), gin (Section 3.4.2), vodka (Section 3.4.3), absinthe and related drinks (Section 3.5.6), many liqueurs (Chapter 3.8), some Asian liqueur wines and spirits (Sections 2.7.1 and 3.4.4), vermouth and similar wines flavored with herbs and spices.

Vermouth is wine flavored with herbs, the combination and proportions of which are closely guarded secrets of the various manufacturers around the world. The term ‘vermouth’ was first used by a Piedmontese

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

winemaker and tavern owner named Antonio Carpano in the latter half of the eighteenth century. One of the main herbs was a species of wormwood, other species of which were already being used to flavor wine in Germany (Wermuth) and the spirit absinthe in France. Originally, vermouth was an alcoholic concentrate of herbs intended for addition to wine in measures called punti (points), according to the wishes of the customer. A popular measure in Carpano's tavern was one and a half points (punt e mes in the Piedmontese dialect of the eighteenth century). The first preblended vermouth was produced in 1786 by Carpano, in Turin; it was based on the same measure and was named 'Punt e Mes.' Vermouth rapidly gained popularity; many manufacturers sprang up in Piedmont and surrounding areas and many established wine and spirits companies tried their hands at vermouth. Such companies include Cinzano, Gancia, Martini and Rossi, and Stock. The proximity of several large ports, particularly Genoa, Livorno and Venice ensured that vermouth was soon being exported to many countries.

In the early nineteenth century, winemakers in the Midi began production of their own vermouth from local wine and herbs, in response to the influx of wine from Italy. Thus, Noilly Prat was established in 1813 in Marseilles, again convenient for export. A few years later (1821), a distinctive vermouth was being made by Dolin at Chambéry, Savoie. The Chambéry vermouth, originally a dry white version, was made from local high altitude wines and herbs, and was lighter and more delicate in flavor than the heavier vermouths of the Midi and Piedmont. Nowadays, vermouth is made in many wine producing countries: white, red and rosé, dry and sweet, and with a variety of herbal mixtures. Several techniques are used in winemaking, according to the manufacturer. These points are all discussed next.

2.12.2 Vermouth

As has been pointed out, the production of vermouth originally became established in Piedmont (southeast of Turin in northern Italy), followed by the Midi and Savoie (both in France) a few years later. In each of these regions there was a ready supply of white wine and aromatic or bitter herbs. The original purpose of infusion of herbal flavors into wine was to mask faults in the latter, particularly overoxidation, a common characteristic of white wines made in warm climates. The early attempts gained rapid popularity, to such an extent that deliberately oxidized white wine bases are still used by some vermouth manufacturers (e.g. Noilly Prat), although many other features have changed over the years, such as the botanical recipes and the methods of production. Oxidation occurs when the wines are stored in large casks in the open air, subject to sunlight and fluctuating temperatures. The main areas of original vermouth production are shown in Figure 2.12.1. It can be seen that, except for Chambéry, these areas are close to busy ports, making export relatively easy.

Dry, neutral white wine is the usual base for vermouth, with an ethanol content of 10% (v:v) upwards. A bland background is considered best for bringing out the herbal flavors, and besides, a well flavored, subtle white wine would be wasted on vermouth. Some of the original Piedmontese vermouths were made with Moscato wine, but this is no longer the case. Red wine can be used to make vermouth, but is not favored by commercial enterprises because the bitter herbal compounds, combined with red wine polyphenols ('tannins') can produce a wine that is altogether too coarse. Amateur red vermouths are sometimes made with red wine, and red wines are used as bases for other aromatized apéritif wines (Section 2.12.3). Red and rosé vermouths are generally made by including herbs in the botanical mixture that provide red pigments. Also, orange-brown colors can be imparted to the wine by the inclusion of caramel.

Originally, the white wine base was the product of local vineyards, but nowadays the source of wine is usually more prolific vineyards that produce cheap wine, which is transported (often over considerable distances) to the vermouth winery. Thus, most of the wine for Italian vermouth comes form Apulia or Sicily (Anderson, 1980) and the wines for Chambéry vermouth are mostly from the Midi and southwest France.

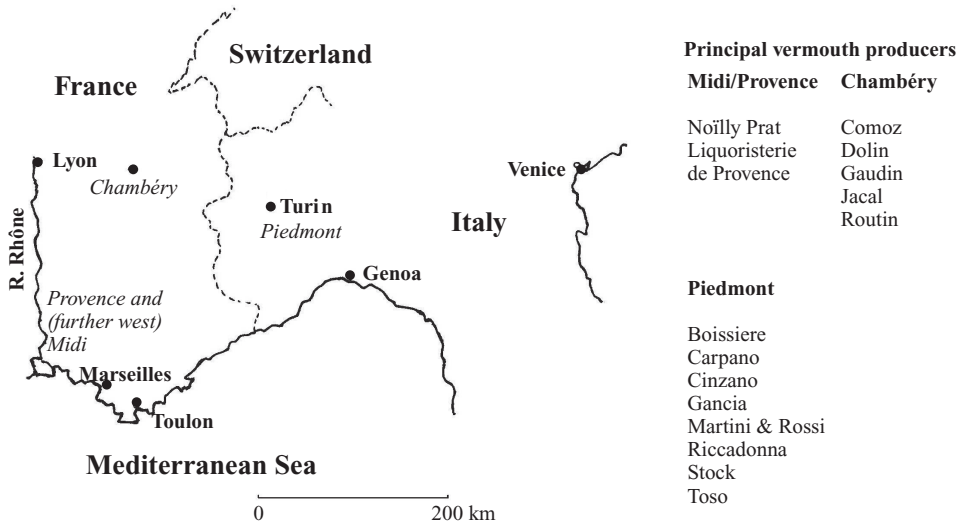

Figure 2.12.1 *Sketch map of earliest vermouth production and list of notable manufacturers*

Thanks to the success of the original vermouth producers in Piedmont, the Midi and Savoie, virtually all wine producing countries or regions make some vermouth nowadays, notable amongst which is California (e.g. Gallo and Tribuno).

Although there are many methods for the making of vermouth, most of these will have basic similarities to the two methods shown in Figure 2.12.2. Basically, vermouth is a fortified and sweetened wine that has been infused with herbal and spicy flavors. The various methods differ in details of the production process and each manufacturer has its own botanical recipe (the selection and quantities of herbs and spices used). Probably the most common methods are based on that labeled 1 in Figure 2.12.2; this is the basic method that has long been favored by northern Italian vermouth producers. Maceration in grape spirit (as opposed to wine or water) gives a more efficient extraction of flavor compounds, some of which are of low polarity (many are hydrocarbons – see Figure 2.12.4). Constant agitation of (e.g. by mechanical stirring, shaking or by ultrasound) is desirable for a week or so, and extraction is more efficient from milled herbs, which have a bigger surface area. Some companies and some amateur vermouth makers extract flavor compounds by simmering the herbal mixture in a sample of wine base. Others use distilled essences or essential oils of certain botanicals, along with the standard herbal infusion method. In the extreme, there are several commercially available clear ethanolic vermouth essences that can be added to bulk fortified and sweetened white wines. The clarified herbal extract is added, with stirring, to the wine in large vats, along with grape spirit and sugar, or mistelle. Caramel can also be added for red vermouth, giving an orange-brown mature tint, but the red pigments are from herbs (such as rose petals) or from permitted colorants (such as cochineal, E20). After a period of time, allowing the flavors to 'marry,' the wine is processed and bottled according to standard methods.

In the Midi and Savoie, rather more time consuming processes are used, similar to method 2 in Figure 2.12.2. Typically, herbs are macerated in a sample of the matured wine base (to which mistelle has been added) for many months to give a highly alcoholic, strongly flavored liquor. This is then racked off the debris and blended with the rest of the base wine and fortified with grape spirit.

The quantity of sugar syrup or mistelle determines the sweetness of the vermouth, which varies from extra dry, through dry to sweet. Dry vermouths (mostly white) normally have less than 30 g/l of sugar,

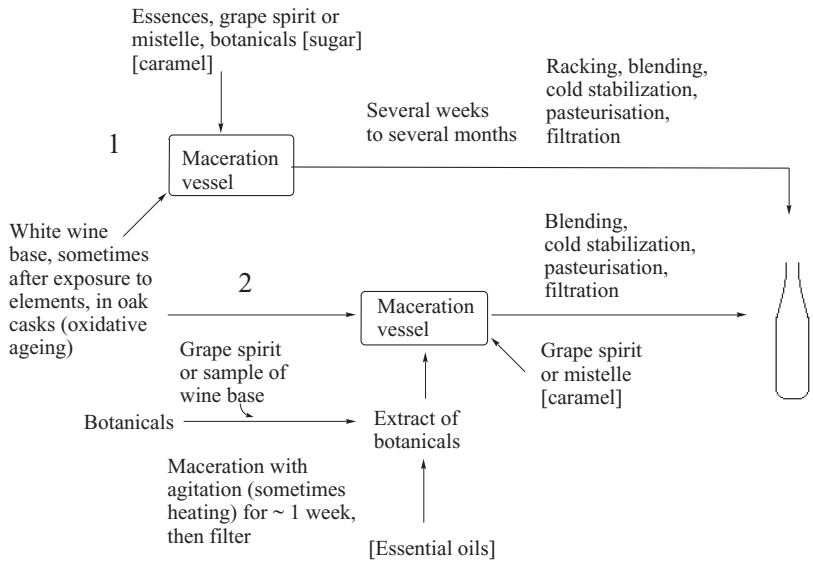

Figure 2.12.2 *Two methods for the manufacture of vermouth. In practice, there are many variations on the above, mostly involving short cuts. Caramel is used for red vermouth. Optional ingredients are in square brackets*

whereas sweet versions (red, rosé or white) have around 130 g/l or more of sugar. Similarly, the ethanol content of vermouth depends on the ethanol contents of the base wine and the mistelle or grape spirit, as well as on the ratio of mixing. Usually, dry vermouths possess ∼18% ABV, whilst sweet vermouths have ∼16% ABV.

The botanical ingredients in vermouth vary from company to company, and the recipes are closely guarded secrets. The Martini museum neat Turin lists over 200 herbs that have been used to produce vermouth throughout the years. Most modern vermouths are made with fewer than 50 botanical ingredients and sometimes as few as 30 (Lichine, 1982b). There is no doubt that, according to organoleptic evidence, botanical recipes have changed over the years, probably in response to changes in fashion and taste, and maybe also in response to concerns over the safety of certain ingredients. It is also evident (again from organoleptic evaluation) that some vermouth manufacturers use different botanical recipes for different products. A good example of this is the firm of Carpano (now part of Fernet Branca): it produces Antico Formula, Classico and Punt e Mes. The first named claims to be made by using the original botanical recipe; it is certainly very different from the other products.

The basis of the herbal contribution to the flavor of vermouth was originally the flower head of the wormwood plant (Wermouth in German), giving vermouth its name. Wormwood is a name used for many species of the genus *Artemisia* (the daisy family), but unfortunately many of these species are botanically quite similar and are not easily identified by amateurs. Furthermore, they have nonbotanical pseudonyms, and the same name from different literature sources may not necessarily refer to the same species. The most important wormwood species in vermouth is *Artemisia pontica*, also known as Roman wormwood, a native of southeastern Europe. Other species include *A. absinthium* (central Europe), *A. annua* (eastern Europe), *A. cinia*, *A. maritime* and *A. vulgaris* (mugwort). The different species of *Artemisia* probably have many flavor compounds in common, although the relative quantities probably differ considerably, and the flavor profile will also depend on which part of the plant is used. Examples of components commonly found in *Artemisia* species are artemisinin (active against malaria), 1,8-cineole, santonin and thujone (see Table 2.12.1

Table 2.12.1 *A short list of herbs used to make Vermouth and their typical aroma compounds and bitter agents (*)*

Common name (part of plant used)	Latin name	Major or typical aroma ompounds	Common name (part of plant used)	Latin name	Major or typical aroma compounds
Aniseed pericarp)	*Pimpinella anisum*	Anethole	Juniper (berry)	*Juniperus communis*	α, β-pinene, limonene, sabinene
Basil (flower, leaf)	*Ocimum basilicum*	Estragole, eugenol	Hyssop (flower)	*Hyssopus officinalis*	1,8-Cineole, linalool, pinocamphone
Camomile (flower)	*Chamomilla recutita*	α-Bisabolol, chamazulen	Mugwort (flower)	*Artemisia vulgaris*	1,8-Cineole, thujone
Cinnamon (bark)	*Cinnamomum verum*	Estragole, ethyl cinnamate, eugenol	Oregano (flower, leaf)	*Oreganum vulgare*	*p*-Cymene, γ-terpinene, *p*-thymol
Citrus (peel)		Citronellol, limonene, α,β-pinenes	Quinine* (bark)	*Cinchona spp.*	Quinine
Clove (pericarp)	*Syzygium aromaticum*	Acetyl eugenol, β-caryophilline, ugenol	Rose (flower)	*Rosa* spp.	Citrinellol, geraniol, nerol, 2-phenylethanol
Coriander (seed)	*Coriandrum sativum*	Camphene, camphor, linalool, sabinene	Sage (flower, leaf)	*Salvia officinalis*	Camphor, β-pinene, thujone
Gentian* (root or rhizome)	*Gentiana* spp.	Amarogentin, gentiopicroside, sweroside	Star anise (pericarp)	*Illicium verum*	Anethole
Ginger (rhizome)	*Zingiber* spp. *tesp. officinale)*	Zingiberene	Thyme (flower, leaf)	*Thymus* spp.	*p*-Thymol
Hop (flower)	*Humulus lupulus*	Humulene, myrcene	Wormwood (flower)	*Artemisia pontica*	Thujone

Source: Information from Williamson and Evans (1989); Santos-Gomes and Fernandes-Ferreira (2003) and Faleiro *et al.* (2005).

and Figure 2.12.3). *Artemisia absinthium* is famous as a major flavor ingredient (via its leaves) of the spirit known as absinthe (Section 3.5.6).

Details of some commonly used botanicals are given in Table 2.12.1 and the structures of selected components are shown in Figure 2.12.3, with indications of likely sources. It should be noted that each botanical ingredient has the potential to contribute hundreds of flavor and taste (especially bitter taste) components to the vermouth. Many components are common to several botanical ingredients. It should also be noted that botanical recipes vary from company to company and some of the ingredients in Table 2.12.1 may only be present in very minor amounts in a particular company's botanical recipe. So, some of the flavor compounds illustrated in Figure 2.12.3 may be present in concentrations below their odor threshold values (OTVs). Additionally, several different species of a botanical genus (e.g. *Artemisia*, gentian, ginger, sage

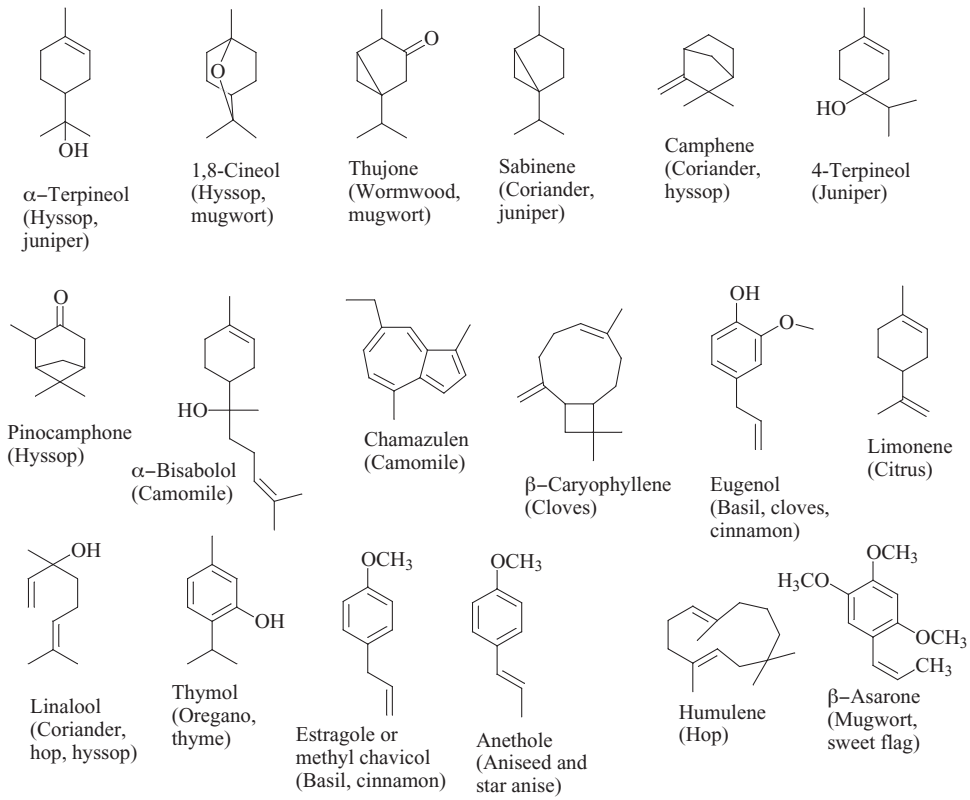

Figure 2.12.3 *Some flavour compounds in vermouth. Major botanical sources in parentheses. Many of these compounds are common to several herbs or spices*

and thyme) may be used in vermouths made in different parts of the world, and it is quite possible that a particular company may include more than one species of a particular botanical genus in its botanical recipe for a particular vermouth. Many (maybe most) of the flavor compounds can be found in most of the botanical ingredients, but it is usual for a handful of components to be present in much greater concentrations than other components, though this does not necessarily mean that these compounds contribute most to the herb flavor; this depends on their OTVs. For example, γ-terpinene and *p*-thymol are important components of the essential oils of oregano (Faleiro *et al.*, 2005) and thyme, estragole (methyl chavicol) is prominent in basil and cinnamon, anethole in aniseed and star anise, and thujone in *Artemisia* species.

The most important flavor compounds are monoterpenoids, as hydrocarbons (e.g. α- and β-pinenes in juniper and many others, camphene in coriander, sabinene in juniper and coriander), alcohols (e.g. α-bisabolol in chamomile, linalool in hyssop and many others), cyclic ethers (e.g. 1,8-cineol in hyssop and mugwort) and carbonyl compounds (e.g. camphor in sage; pinocamphene in hyssop, thujone in sage and wormwood). Aromatic terpene derivatives are also important vermouth flavor compounds. These include estragole (in basil, cinnamon and others), eugenol (in basil, cinnamon and cloves), acetyleugenol (in cloves), *p*-thymol (in oregano and thyme) and β-asarone (in mugwort and sweet flag). Anethole, another aromatic terpene derivative, is a major flavor component of aniseed and star anis. These two spices are the basis for the flavoring of many spirits, such as anis, ouzo, pastis and pernod (Section 3.5.6).

Some of these natural products are known to be toxic if ingested in large quantities – in far greater quantities, however, than is possible even for the most dedicated vermouth drinker. Of particular interest here are β-asarone, estragole, safrole and thujone. The first named has been shown to cause intestinal tumors in laboratory mice if present in their diet in concentrations of up to 250 ppm (Wojtowicz, 1976). The main sources of β-asarone are mugwort and (especially) oil of calamus, distilled from the dried rhizome of *Acarus calamus* (sweet flag). There are many varieties of this aquatic plant, with the European diploid varieties having as little as 5% β-asarone in their essential oils. This compares with Asian tetraploid varieties, whose essential oils can contain more than ten times that quantity of β-asarone (Amerine and Ough, 1980). Nowadays, addition to wine of flavorings that contain this compound is banned in many countries (e.g. the USA), but one of the European varieties of sweet flag may still be used as a minor flavoring agent in vermouth, whence concentrations of β-asarone are likely to be much less than 0.1 ppm (Wojtowicz, 1976). See Section 5.11.2 for a more detailed discussion on toxicity and regulations.

Thujone is a major component of *Artemisia absinthium* leaves and a relatively minor component of *A. pontica*, *A. vulgaris* and other herbs. If ingested in large quantities it can cause hallucinations. It was thought that this compound played a major part in the deterioration of psychological health shown by many heavy drinkers of absinthe, a spirit flavored with *A. absinthium*, which was popular in the latter half of the nineteenth century. Recent work has cast considerable doubt on this hypothesis (Lachenmeier *et al.*, 2008), but for a more detailed discussion, see Section 5.11.2. The most widely used species of wormwood in vermouth, *A. pontica* (as flower heads) has a much lower content of thujone than *A. absinthium* leaves. In all probability, all of the flavor compounds in Table 2.12.1 may prove to be detrimental to health in some way or other if ingested in large enough amounts. Some of the flavor components in vermouth derived from botanicals will be present in concentrations of a few ppm and many others will be present at lower levels, some at ppb or ppt levels. Thus, the health risk to the normal vermouth drinker due to the presence of herb flavor compounds can be discounted, and indeed, ingestion of small quantities could lead to health benefits (Section 5.11.2). The possible health risk due to the presence of ethanol is far more significant (Section 5.6.2).

Apart from the flavor components mentioned above, the botanicals in vermouth are also the source of bittering agents – (mostly nonvolatile) compounds that give a bitter taste. Principal amongst these is cinchona bark (from *Cinchona officinalis* L. or *C. pubescens* Vahl), the source of quinoline alkaloids, including quinine, quinidine and their dihydro derivatives, as well as cinchonine and cinchonidine. Cinchona bark is also an important ingredient in a number of vermouth-like wine based aperitifs, such as Campari (Italy) and Lillet (France) (Section 2.12.3), as well as various spirits (Section 3.4.3). Collectively, these beverages are sometimes called quinquina.

Interestingly, a medicine for malaria given to Louis XIV of France in the late seventeenth century was made from wine, cinchona bark, rose petals and lemon juice – predating bitter aperitifs by 100 years or so. Other bittering agents from herbs in vermouth are flavonoid phenols, such as rhamnetin and isorhamnetin, proanthocyanidins, gallic acid and catechol tannins and iridoids (Figure 2.12.4). Bitter constituents are commonly found in bark, rhizomes and roots, but are also present in flower heads, leaves and stalks. Apart from quinine and related alkaloids, some of the most bitter substances are the iridoids, such as those from gentian roots (usually wild gentian, *Gentiana lutea* L.). These include amarogentin, gentiopicroside (Figure 2.12.4), loganic acid, sweroside and swertiamarin (Carnat *et al.*, 2005).

Many of the botanicals used in the making of vermouth possess a host of other, mainly nonvolatile compounds. These include the sesquiterpenoid santonin, the chromones (1,4-benzopyrones) eugenin and eugenitin, lignans such as deoxyphyllotoxin, and tetracyclic triterpenoids, such as oleanolic acid derivatives, stigmasterol and ursolic acid derivatives. Some of these compounds are illustrated in Figure 2.12.4. Although many of these compounds are insoluble in water, they are soluble in ethanol or ethanol–water mixtures to a certain extent, so it is not unreasonable to suppose that low concentrations of these compounds can be found

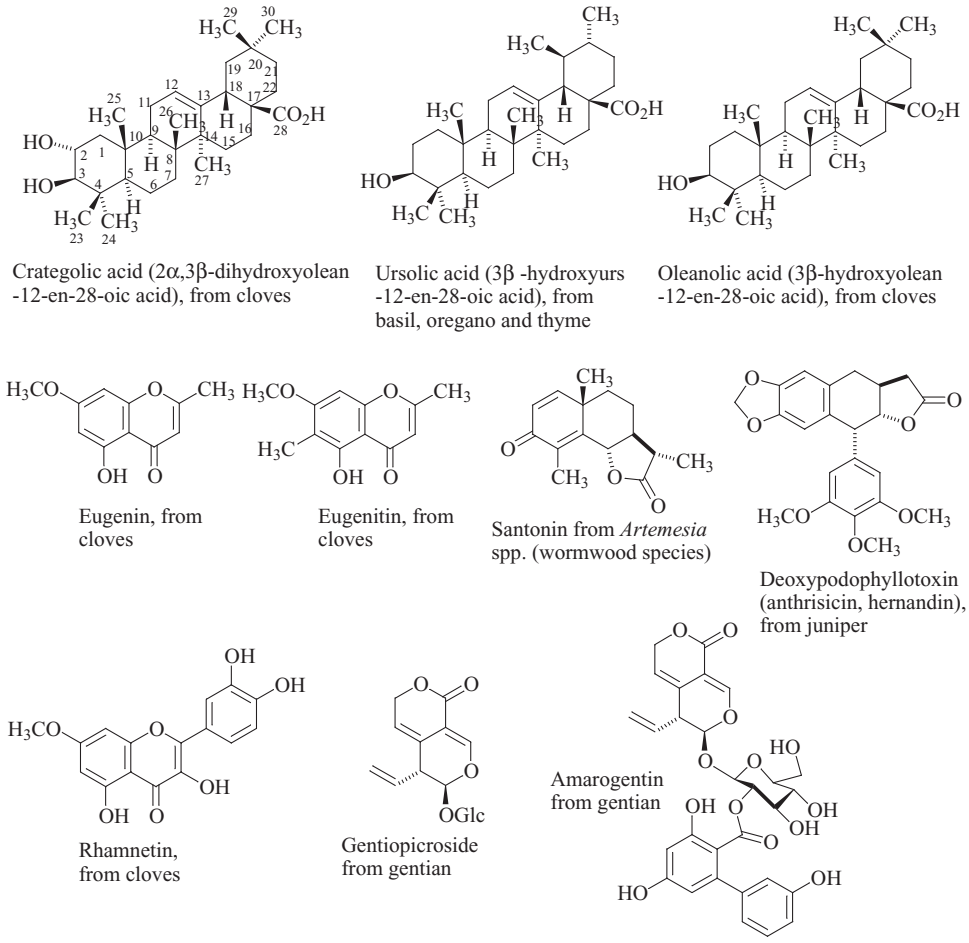

Figure 2.12.4 *Lignans, pentacyclic triterpenoids and phenolic compounds from botanicals used in the manufacture of vermouth*

in vermouth. Some, such as santonin and the triterpenoids are known to have bitter tastes. The latter may also have pronounced health benefits – see Section 5.11.2.

Apart from flavor and other components that arise from the added botanical ingredients, the rather limited literature on the composition of vermouths not surprisingly suggests that they are similar to standard white wines; sometimes more similar to oxidized white wines. Ethyl 1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylate (MTCA-EE) is a β-carboline found in a range of alcoholic beverages (Herraiz, 1999). It is of interest because it is a structural analog of ethyl β-carboline-3-carboxylate, a potent benzodiazepine receptor inverse agonist and a compound that may play a role in alcohol addiction. Vermouths were found to have lower levels of MTCA-EE than almost any other kind of alcoholic beverage. On the other hand, the biogenic amines histamine and tyramine (Section 5.11.3) were found to be present in higher concentrations in vermouths than in sparkling wines and ciders (Vidal-Caron *et al.*, 1989). In a study to determine the levels of γ-hydroxybutyric acid (GHB) and γ-butyrolactone (GBL) in alcoholic beverages, vermouths were found to have concentrations

similar to ordinary white wines (Elliot and Burgess, 2005). GHB and GBL are drugs that are sometimes added to alcoholic drinks ('spiked drinks') (often surreptitiously) and so for forensic analysis, it is important to know the natural background levels of these substances in alcoholic beverages. Analysis of diethyl ether extracts of red vermouth demonstrated the presence of 5-hydroxymethyl-2-furaldehyde (5-HMF), a Maillard product (see Section 2.6.2) (Cartoni *et al.*, 1997). Its probable origin is caramel, which is a frequently used colorant of red vermouths.

2.12.3 Other Aromatized Wines and Apéritifs

Other aromatized wines fall into two major groups: the quinquinas or bitters (popular aperitif wines) and Retsina, pine resin flavored white wine, popular in Greece. The bitter group, like vermouth, are used in cocktails: Americano, Negroni (both with Campari) and Vesper (with Lillet) being prime examples. Like vermouth, the bitter aperitifs are fortified wines (white, sometimes red) infused with herbs (flowers and leaves), spices (dried bark, pericarp and seeds), bark (for bittering agents) and peel, or their essences. The botanical mixture has a different emphasis to those of vermouths, with more of an emphasis on bitterness, and with cinchona playing a more prominent role. There are other differences which will be highlighted in the next paragraphs. Probably the first of the bitter aperitifs (and probably the one that is most vermouth-like) is Dubonnet (founded in 1846) named after Joseph Dubonnet, the Parisian chemist and winemaker who developed it. This beverage was originally intended as a palatable source of quinine (from Cinchona bark) for troops and civilians living in French colonial Africa and other tropical or subtropical colonies, where malaria was rife.

Campari, a well known bitter aperitif was started by Gaspare Campari in 1860, as a rival of vermouth. The botanicals in Campari are quite different to those in vermouth, with cinchona and cascarilla bark being the main ingredients. Also included in the botanical recipe are ginseng (*Panax* spp.) roots, bergamot (*Monarda* spp.) essential oil and rhubarb (*Rheum rhabarbarum*) stalks. Close to 60 other herbs and spices are used in addition to these. Campari is made from a fortified white wine base, the bright red color coming from natural carmine cochineal (E20).

St. Raphael, like most bitter aperitif wines, has its origins in the latter half the nineteenth century, when such drinks were highly popular. It was dedicated to the Archangel Raphael by its originator, Dr Juppet, who is said to have regained his former eyesight upon formulation and testing of the recipe. Unlike the other aperitifs in this section, St. Raphael is really an aromatized vin de liqueur, since its alcohol base is not a fortified wine, but mistelle, a blend of grape must and grape spirit. The botanicals, which include cinchona bark, bitter orange peel, vanilla beans and cocoa beans, are macerated in grape spirit over a period of several weeks. The extract is then blended with the mistelle, cold stabilized, filtered and bottled. The aperitif is now (2008) marketed by Boisset, after a period of time under the Bacardi Martini group. It has 20.5% ethanol (v:v).

Lillet was first formulated in 1882 by the Lillet brothers (wine and spirits merchants in Bordeaux), using a fortified wine base and flavored with cinchona bark. Nowadays, since 1986, the bitter component has been decreased in favor of a citrus and vanilla flavor. The former flavor comes from an orange liqueur made by cold maceration of Haitian, Moroccan and Seville orange peel in brandy for several months, whereas the latter flavor comes mostly from cask ageing. The aperitif is made by blending wine made from Sauvignon Blanc and Semillon (white) or Carbernet Sauvignon and Merlot (red) with orange liqueur in the approximate ratio 85:15, giving a final ethanol content of 17% (v:v). The wines are from around the Podensac area of the Graves region, southeast of Bordeaux. The blend is matured in oak casks for up to 12 months, whence it is filtered and bottled. The original Lillet aperitif was white, the red version originating as recently as 1962. Both drinks are unlike other aperitifs, being lighter, more vinous, and without dominating herb flavors and bitter taste. Instead, they have a delicate citrus-spicy edge, but are still useful in cocktails (such as Vesper).

Retsina is the most famous and longest established member of a family of drinks known as resinated wines. It is the major survivor of the widespread practice of preserving and flavoring wine with pine resin, carried out by the great early civilizations in the countries bordering the eastern Mediterranean Sea. Today, the practice is more or less confined to Greece and the Greek speaking southern areas of Cyprus. The name 'Retsina' is an EU protected designation of origin for Greece and Cyprus: similar wines from elsewhere must be called resinated wine and not Retsina.

Although Retsina is produced in many parts of Greece, the major areas are in center of the country, at Attica (near Athens), Boeotia and Euboea. Local grape varieties are used for Retsina, with the most prominent being Assyrtiko, Athiri (on Rhodes), Rhoditis and Savatiano. The base wine is either white or (less commonly) rosé, but not red, and the winemaking techniques are similar to those used for making standard white or rosé wines (Sections 2.9.1 and 2.9.2). The pine flavor comes from small pieces of pine resin (usually from Aleppo pine) that are added to the fermenting must. After a settling period that follows the termination of fermentation, the wine is racked off the resin pieces and is treated as for ordinary white or rosé wine. Most Retsina wines possess alcohol contents in the region 12–12.5% (v:v).

Relatively few analytical studies have been carried out recently on Retsina. As expected, Retsina has higher levels of phenolic substances compared with nonresinated white wines, because of the additional contribution of the resin pitch (Proteos *et al.*, 2005). At especially elevated levels were (+)-catechin, *p*-coumaric acid, (–)-epicatechin, gallic acid and tyrosol. Biogenic amines, such as histamine and tyramine, although beneficial to humans at low concentrations in the diet, can be damaging to health if ingested at higher concentrations, especially in the presence of ethanol (Section 5.11.3). Their presence in wines at higher concentrations is thought to be largely the result of microbiological contamination arising from poor sanitation in the winemaking process. In a study of biogenic amines in Greek wines and beers, using HPLC of dansyl derivatives with fluorometric detection and atmospheric pressure chemical ionization mass spectrometry (APCI-MS; see Section 4.3.3), Loukou and Zotou (2003) showed that Retsina wines had generally less than average levels of biogenic amines, especially regarding histamine.

The most obvious feature of Retsina is its pine based aroma and flavor. The most usual pine resin used for making Retsina is that of the Aleppo pine (*Pinus halepensis* Miller), which is widespread in Greece. This resin contains and α- and β-pinenes, caryophyllene, cembrene, myrcene, limonene and terpinolene, as well as other terpene hydrocarbons, terpenols, terpene esters and nonterpene esters, similar compounds to the pine needles, but in different relative concentrations (Roussis *et al.*, 1995).

2.13

Low Alcohol and Non-Alcoholic Beers, Ciders and Wines

2.13.1 Overview

Anyone who has tasted grape juice, apple juice and hopped malt wort against their fermented equivalents (wine, cider and beer, respectively) can hardly fail to notice the greater complexity of pleasing flavors of the fermented drinks. So, why has considerable effort been expended on producing a range of low alcohol beverages? Part of the answer is health related: some people need to avoid ethanol intake, either because of some metabolic malfunction or because of some medical condition that requires minimal ethanol content in the diet, either directly or indirectly, due to the prescription of ethanol incompatible drugs. Additionally, health conscious people who like to exercise, or athletes, are able to drink low alcohol beers of the high carbohydrate type for a boost of energy. Other reasons are more social or religious in character: stricter drink-driving legislation and greater awareness of the social implications and greater risks associated with driving after excessive alcohol intake, and religious avoidance of alcoholic drinks, for example. Hence, there is a considerable market for low alcohol or nonalcoholic beer, cider and wine that look and taste like their alcoholic equivalents. Prior to the last two decades, low alcohol beers existed at various times in different countries. During prohibition (*ca.* 1919–1933), breweries were allowed to produce 'near beer' of ∼0.5% ABV. In the Scandinavian countries of Finland, Norway and Sweden, commercial brewing is more or less closely regulated by government and has been influenced by temperance movements at various times. Low alcohol beers (∼2% ABV) form a significant part of beer production in these countries and are generally known as class I beers.

The definition of the terms 'low alcohol' and 'nonalcoholic' vary throughout the world. Nonalcoholic or alcohol free may be used to describe only drinks with no detectable ethanol content in the USA, and in the UK to denote drinks with no more than 0.05% detectable ethanol content. Thus, in these two countries, virtually all of these beverages are described as low alcohol drinks. In Germany and other European countries, drinks can be described as nonalcoholic if they have a maximum of 0.5% ABV. Interestingly, fruit juices and various other foodstuffs, especially bakery products, possess natural ethanol contents from 0.1% to over 0.5% (v:v). Also, in the USA, malt based drinks containing less than 0.5% ethanol (v:v) cannot be called beer; instead they are known as malt or cereal beverages.

2.13.2 Production of Low Alcohol Beverages by Limited or Checked Alcohol Methods

There are two basic ways of producing low alcohol beverages:

- Limited or checked alcohol methods
- Dealcoholization methods.

For low alcohol ciders and wines, only the second of the above techniques may be used, because the first technique would give too sweet a product, with too great a resemblance to apple juice or grape juice. The production of low alcohol beers presents one of the biggest challenges to the brewer because of the inherent balanced nature of the product. Use of limited or checked fermentation methods can lead to beverages that are unacceptably sweet and malty to many people. Also, use of dealcoholized methods can lead to loss of flavor compounds that will need to be replenished before the beer is packaged. On top of this, the production of low alcohol beers requires rigorous filtration and pasteurization regimes, because of the inherent biological instability caused by lack of ethanol and, in some cases, by the presence of fermentable sugars. A great deal of research has gone into improving the methods of low alcohol beer production, so that beers with better color, flavor/aroma balance and head retention can now be brewed (Hornsey, 1999). The first low alcohol beers were brewed using limited or checked fermentation methods (Figure 2.13.1) and some of these methods use conventional worts (with normal balance of maltose and α-glucans and normal hop bitterness). These methods will be discussed first, even though they are no longer widely used.

The checked fermentation method (Figure 2.13.1) involves arresting a normal fermentation (usually of a lager style beer fermenting at ~10 °C) by rapid cooling to 0 °C. Such beer has fermentable maltose and some fermentable α-glucans, and so rather than risk incomplete removal of yeast (by centrifugation and filtration regimes) it is usually heavily pasteurized before chilling, carbonation and packaging. Beers brewed by this method can have a rather harsh, cooked flavor.

The blended beer or Barrell process was also an early method. It uses two fermented worts of the same color, pH and hop bitterness. One batch of wort is of normal OG (typically 1040°), whilst the other is a low OG wort (usually around 1010°). During fermentation, the evolved CO_2 and flavor compounds from the normal wort are transferred to the weaker wort. The final ethanol content can be varied according to the ratio of blending, but lower ethanol products (say 1% ABV) tend to be rather thin and lacking in body.

The cold contact method (Murray and van der Meer, 1994) uses conventional boiled wort of 12–20 °Plato (48-80 °OG), whose acidity has been adjusted to pH 4.0–4.6 by the addition of food grade acid. To this is added a slurry of yeast, freshly harvested from the barm beer (Section 2.6.4) of a regular brew, so that the cell concentration in the wort/slurry is 40–80 × 10^6 yeast cells/ml. This is held at 0–7 °C for up to 30 h. The resulting beer is then separated from all but 0.5–2.0 × 10^6 yeast cells/ml. It may be supplemented with beer esters. After dilution with water, it is cold stabilized, filtered and carbonated.

The other methods of producing low alcohol beers by limiting production of ethanol involve either modified worts, high gravity mashing or by the use of mutant strains of *S. cerevisiae* that are deficient in certain enzymes of the tricarboxylic acid cycle, or by the use of other fermentative organisms. The modified wort method involves mashing at higher than normal temperatures (75–80 °C, as opposed to ~65 °C), so that α-glucans are formed, but are not hydrolyzed to maltose because, at that temperature, β-amylase is disabled (Section 2.6.2). Depending on the mash temperature, this method can produce a wort that yields around 0.5% ethanol (v:v) when fermented with a normal brewery yeast. The unfermented α-glucans are not as sweet as unfermented mono- or disaccharides, so the result is a sweetish, but full tasting beer. This is the original way by which the malt beers of England and Germany (Malzbier) were brewed (Section 2.6.13 and Chapter 5.8) and some beers are still produced by this method today. Methods that involve high gravity mashing are sometimes known as spent grain methods. The high gravity wort is filtered off the grains and then hot water is added to the spent

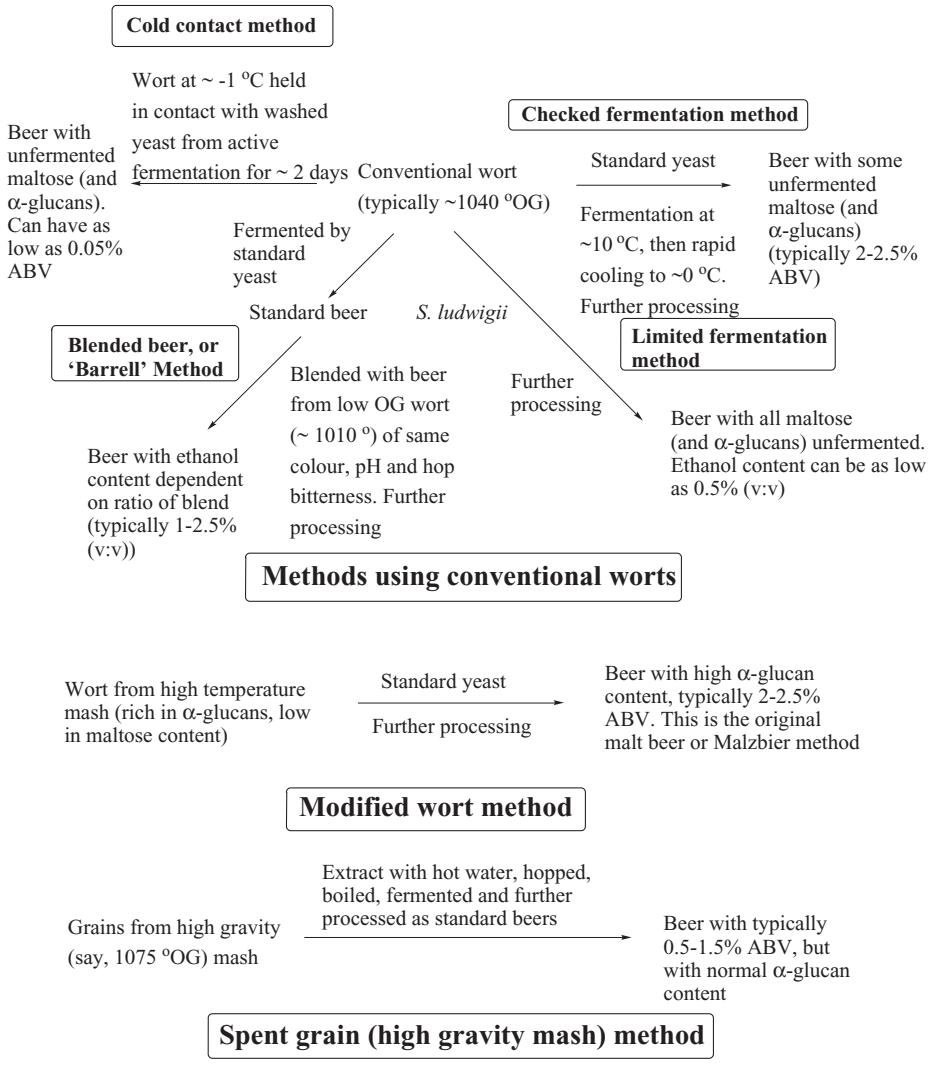

Figure 2.13.1 *Low alcohol beers from checked or limited fermentation methods. Standard yeast is* S. cerevisiae or S. uvarum. *Further processing is described in the text*

grains to extract residual sugars. This second, weak wort is then processed using standard techniques to give beers with ethanol contents of 0.5–1.5% by volume. This is an extreme case of the once common brewery practice of obtaining two beers from a single mash.

Strains of *S. cerevisiae* deficient in one or more enzymes of the tricarboxylic acid cycle have been used recently for the small-scale production of nonalcoholic beers (Selecký *et al.*, 2008). In particular, strains lacking in fumarase (fumarate hydratase) and α-ketoglutarate dehydrogenase produced beers with less than 0.5% ABV. These yeasts had disrupted *FUMI*, *KGD1*and *KDG2* genes and were notated by the symbols Δ *FUMI*, Δ *KGD* and *KGD1*, respectively. The beers had increased levels of carboxylic acids compared with that brewed by a standard brewing yeast strain (W96); for example, the beer brewed with Δ *KDG21* or

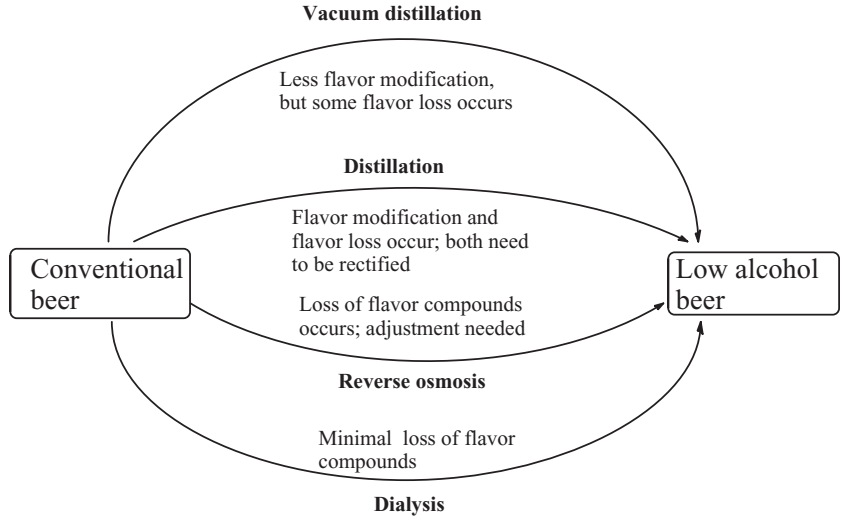

Figure 2.13.2 *Summary of methods for the dealcoholization of beer*

Δ *KDG2* had concentrations of lactic acid contents of ∼550 mg/l, as opposed to ∼50 mg/l for the beer brewed with W96. Far from being an organoleptic problem, the presence of lactic acid was considered to help protect the sugar rich beer from microbiological attack and to mask the unacceptable worty flavor often associated with nonalcoholic beers. Additionally, the nonalcoholic beers produced by the mutants had slightly increased color, hop bitterness, total nitrogen contents and total phenolic contents. However, high levels of diacetyl and low levels of esters negatively affected the beers brewed using the mutant yeast strains, so it was suggested it would be beneficial to produce a hybrid between brewing yeast and a laboratory strain (mutant), carrying the genetic properties needed for well flavored beer, yet lacking TCA enzyme genes (Selecký *et al.*, 2008).

Limited fermentation can be achieved by use of *Saccharomyces ludwigii* on conventional worts, in place of *S. cerevisiae* or *S. uvarum*. This organism will only ferment the monosaccharides fructose and glucose and the disaccharide sucrose; the major wort disaccharide, maltose, is not metabolized. Thus, beers brewed by this method have sweet, rich palates that are unacceptable to some people.

2.13.3 Dealcoholization Methods

Nowadays, most low alcohol beers are produced by dealcoholization methods. In most cases, flavor compounds are removed with the ethanol and this necessitates the addition of a flavor mixture to the dealcoholized product in order to regain the balance of flavor. Figure 2.13.2 outlines the major dealcoholization methods used to make low alcohol beer. Distillation methods are not much used these days, probably because of the effect of elevated temperatures on the flavor profile, as well as loss of volatile flavor components from the beer. The atmospheric pressure distillation method, in particular, causes isomerizations and degradations of flavor compounds, even though it can produce beers with 0.5% ABV (Hornsey, 1999). The vacuum distillation and film evaporation methods operate at lower temperatures because of the reduced pressure; the latter is often operated at 30 °C and 30 mm Hg (0.04 atm) pressure. Straight vacuum distillation is often used to remove flavor compounds that are more volatile than ethanol. These are kept aside and added back to the beer once the ethanol has been removed. The beer is then cold stabilized, carbonated and processed as for standard beers.

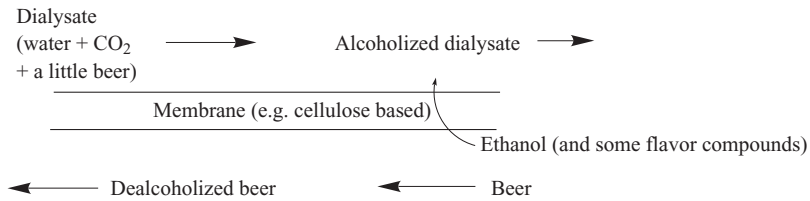

Figure 2.13.3 *Simplified scheme for dealcoholization of beer by dialysis*

The film evaporation method operates rather differently, leading to loss of CO_2, some water and some flavor compounds, as well as ethanol, because of the large surface area of evaporation. The resulting dealcoholized beer is then diluted with carbonated water and a mixture of flavor compounds is added to restore the original flavor characteristics of the beer. Beers with ethanol contents as low as 0.01% (v:v) can be made by this method.

The reverse osmosis method is basically a high pressure filtration of a normal, filtered (or clear) beer through a semi-permeable membrane. Ethanol, other small molecules (including flavor components) and some water is lost from the bulk beer as a result of reverse osmosis. The beer is diluted with deoxygenated water before reverse osmosis to make up for that lost during reverse osmosis and to avoid clogging of the membrane filter. This method can produce beers with ethanol contents of 0.5% by volume (but not usually much lower than this), with little modification of the flavor profile. On the negative side, it can be costly to operate (especially for beers with less than 0.5% ABV) and loss of flavor compounds to the permeate needs to be compensated.

Currently, some of the most commonly used methods for producing low alcohol beers are based on dialysis (Figures 2.13.3 and 2.13.4), sometimes known as isothermal membrane perstration. The beer flows through a module whose walls are constructed of a cellulose or poly(tetrafluoroethylene) membrane (Bowser and Dennison, 1995). At the same time, the outer walls are exposed to a flow of the dialysate or strip solution, pure water containing a small amount of the beer that is undergoing dialysis and CO_2 in order to prevent excessive loss of this gas from the beer during the process. Like reverse osmosis, there is no thermal stress on

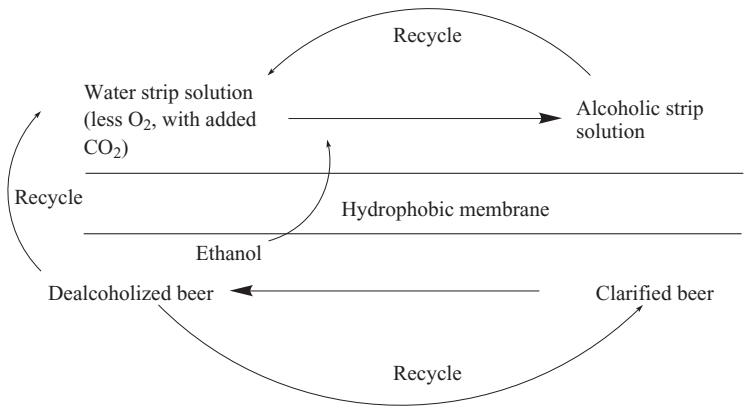

Figure 2.13.4 *Recycling in dialysis dealcoholization of beer to minimize loss of flavor compounds. Based on Michaels* et al. *(1998)*

the beer because the operation runs at ambient temperatures (typically ~12 °C) and near ambient pressure, the pressure difference across the membrane being only 0.1 bar. During dialysis, overall diffusion of ethanol (along with low molecular weight flavor compounds) is from beer to dialysate. The flavor compounds can be recovered from the dialysate and by vacuum distillation and added back to the dealcoholized beer before further processing.

A modified version of the dialysis method, which can be applied to cider and wine as well as beer, uses a polypropylene (or other synthetic polymer), as a hollow fiber membrane, and an initial strip solution consisting of deoxygenated and carbonated water (Michaels *et al.*, 1998). The beer to be dialyzed has been clarified by either cross flow membrane filtration or vortex flow membrane microfiltration. Dialysis is carried out as above, but application of chosen recycling regimes for some of the dealcoholized beer and/or the alcoholized strip solution (Figure 2.13.3) are used to determine the final ethanol content of the beer and to minimize loss of flavor components. Biomass removed from the beer by filtration can be returned to the dealcoholized beer, which is then aged and processed by standard methods. This process can be operated in either batch or continuous modes; it can be used to dealcoholize beers of 3–4% ABV to <1% ABV or to reduce the alcohol content of a 'hot' wine from say 15% to 12% by volume.

In addition to these methods, there is at least one continuous method (Section 2.6.8) for brewing low alcohol beers, using immobilized modified yeast. The Dutch brewery Bavaria (Lieshout) passes modified filtered wort through bioreactors containing a Cultor Spezyme GDC support medium with immobilized yeast colonies. Beers of 0.05–1% ABV can be produced by this method, according to the mode of operation. After fermentation, the beers are diluted, cold stabilized, carbonated, bottled and then pasteurized.

Low alcohol wines can be made by the reverse osmosis and dialysis methods described for beer in the previous paragraphs. The greater reduction of alcohol needed for wine (say 8–12% → 1% ABV) compared with beer (say 3–5% → 0.5% ABV) necessitates a more vigorous process, which means that more flavor compounds will be lost from the wine to the strip solution, if steps are not taken to prevent or minimize this. To this end, the strip solution used in the dialysis process is deoxygenated and sulfited to reduce loss of free (unbound) SO_2 from the wine. Either recycling of the strip solution and/or the dealcoholized beverage can be carried out as previously described (Figure 2.13.4), or a separate reverse osmosis or dialysis step can be used to remove flavor compounds from the wine, which are then added back to the dealcoholized wine (Michaels *et al.*, 1998).

On the other hand, reverse osmosis methods can be used to reduce the ethanol content of wine by, say, one third, without significant loss of many key flavor substances. Reverse osmosis and nanofiltration were used to reduce the ethanol content of a model white wine (containing flavor compounds diethyl succinate, 2-phenylethanol, *cis*-3-hexenol and isovaleric acid (the last being regarded as undesirable) from 12% to 8% ABV (Labanda *et al.*, 2009). Permeation was performed in batch retentate recycling mode with one nanofiltration and two reverse osmosis flat sheet polymeric membranes at 15 °C. Interestingly, of the four flavor compounds chosen for the model wine, isovaleric acid (with undesirable cheesy/rancid notes) was the one that suffered highest loss, an average of ~14%, compared with ~3% for the loss of 2-phenylethanol.

A more recent technique for the dealcoholization of wine is the spinning cone column (SCC) method; it can also be used on beer and cider. The apparatus is essentially a multistage mass transfer device that uses gas–liquid contact. Wine is entered at the top of the column, the interior of which contains a series of alternating stationary (fixed to the interior wall of the column) and rotating truncated cones (attached to the central spindle) (Figure 2.13.5). Wine flows down the surface of the stationary cones, but spreads itself into a thin film on the rotating cones because of the applied centrifugal forces. The stripping gas (e.g. deoxygenated N_2) enters the column from the bottom and flows counter current to the flow of wine, thereby stripping ethanol and the more volatile flavor compounds from the large surface area of wine on the rotating cones. In practice, the wine is run through the SCC to strip the more volatile flavor components first, which are then condensed, collected and are added back to the dealcoholized wine produced by subsequent runs through

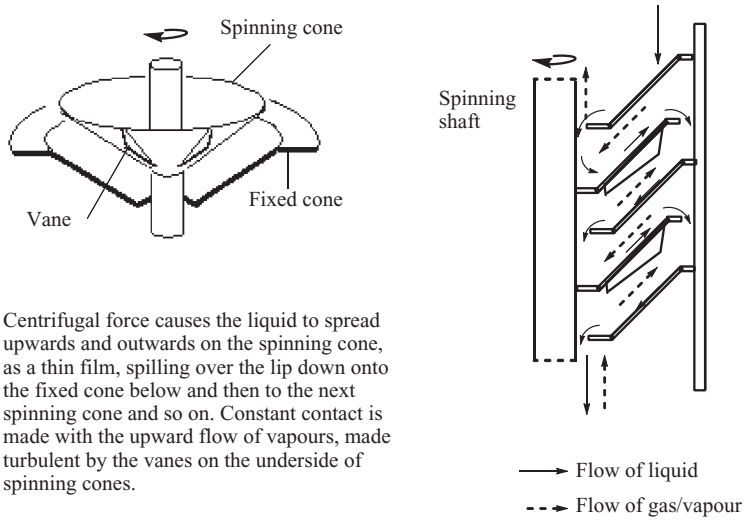

Figure 2.13.5 *Perspective section and horizontal half-section through part of a spinning cone column device*

the SCC. The method can be used to remove off flavors, such as acetic acid, ethyl acetate and hydrogen sulfide. It can also be used for obtaining industrial ethanol from crude yeast fermented mixtures (Wright and Pyle, 1996) and it can be used for essence and essential oil extraction from botanicals, as in the preparation of flavored wines (Section 2.12.2), flavored spirits (Section 3.4.2) and liqueurs (Section 3.9.6). Spinning cone columns are obtainable in sizes that process from1000 l to 10 000 l of wine or other liquid per hour. The smallest is ~2 m high and ~30 cm in diameter, whereas the largest is ~5 m in height and ~1 m in diameter.

In the production of a low alcohol wine, it is important that the product has an aroma profile that is as similar as possible to the original wine, or that at least it is well balanced and acceptable to consumers. As already discussed, present methods for the production of low alcohol wines lead to the loss of some volatile aroma components, thus altering the aroma profile. The lost components can be added back to the dealcoholized product, sometimes having been removed in a separate process prior to ethanol removal. An alternative is to add a particular cocktail of aroma compounds to dealcoholized wine, to give the product a particular well recognized and acceptable character (e.g. a Muscat character). Rather than use a mixture of synthetic food quality chemicals (which then must appear on the label as 'synthetic'), it is preferable to use a mixture of natural aroma compounds, separated from a fermenting wine as described by Schäfer *et al.* (1999). Here, aroma compounds were removed from fermenting Muscatel wine by organophilic pervaporation, using a polyoctylmethylsiloxane on polyetherimide membrane. The best and most faithful Muscatel wine aroma (as judged by a sensory panel) was recovered from fermenting musts of densities 1075–1055 g/l. Higher must densities gave too few aroma compounds, whereas lower density musts (with higher ethanol contents) gave unbalanced aroma profiles, with 'solvent-like' notes.

3.1
Introduction: Distillation Methods and Stills

The Online Encyclopaedia Brittanica describes a distilled beverage, liquor or spirit as 'a drinkable liquid containing ethanol that is produced by means of distilling fermented grain, fruit, or vegetables.' For the purposes of this book, the process of distillation involves the application of heat for the separation of ethanol from water and other constituents in alcoholic beverages by virtue of their different boiling points.

Other methods, that don't involve direct heating, can be used for this separation, but are not dealt with in any detail here. Freeze distillation was used by the Mongols and other Asians to produce various distilled drinks, and also by the early American colonialists (to make apple brandy or 'applejack' from cider). It is still used today in certain breweries for the production of high alcohol beers (Section 2.6.13). Likewise, pervaporation using hydrophobic membranes is used in the dealcoholization of alcoholic drinks (Section 2.13.3).

Distillation of alcoholic beverages was originally performed by apocetheries, ecclesiaticals and scientists (alchemists) mainly for medicinal or research purposes. Later, distillation was also conducted on a small scale by farmers and merchants, who recognized it as a profitable way of dealing with surplus cereal, fruit or root crops, or of preserving wine for export. It is only since the latter part of the nineteenth century that large-scale commercial distillation became commonplace.

This chapter deals with the major distilled beverages of the world, their methods of production and their organoleptic and sensory characteristics, related to combinations of flavor components (known as congeners). Chapters 3.2–3.4 deal with cereal based spirits, although some, like akvavit and vodka can be derived from roots, and some Indian whiskies are partially derived from sugar cane. Chapter 3.5 discusses distilled beverages derived from sugar cane and other vegetable sources, as well as aniseed flavored spirits. Fruit based distilled beverages are discussed in Chapters 3.6–3.8, with liqueurs, often composed of spirit from various sources, covered in Chapter 3.9.

3.1.1 A Brief History and Theory of Distillation

For an account of the early history of distillation, the reader is referred to Section 1.2.1. Distillation of alcoholic beverages to make a potable drink, albeit one to be used for medicinal purposes, was first carried out in Europe during the twelfth century, mainly by apothecaries and medical practitioners. These distilled spirits were given the name *aqua ardens* (burning water) in the *Compendium Salerni* from the medical school at Salerno. They were concoctions of spirit and herbs (botanicals) and were used to treat certain human ailments;

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass

their production method was kept secret by the use of a code system. Later, they were flavored with honey or sugar, in order to make them more palatable, thus developing them into the type of alcoholic beverages now known as liqueurs (Section 3.9.1). Soon enough, they were consumed for enjoyment, as well as for remedial purposes, and their manufacture was taken up by ecclesiastical establishments (and later by secular companies) throughout Europe. At about the same time (the thirteenth to the fifteenth centuries), distillation of alcoholic beverages was becoming widespread throughout Europe and Asia; Irish whiskey, Scotch whisky, vodka and the rice and sorghum spirits of China, Japan, Korea and other Asian countries probably originated in these times.

The earliest stills of the Arabs and eastern Asians were relatively small glass or earthenware pot stills of the alembic type, but did not use flowing water as a coolant. An example of a Korean traditional soju still can be seen in Section 3.4.4. They were originally heated directly by wood or charcoal fires and latterly (in medieval times) by boiling water or steam. Later, copper (and to a lesser extent bronze) became the traditional still material, copper having been produced and used for many centuries and having many advantages over other materials, particularly regarding malleability, durability and heat conductivity. Copper stills could be made to a wide range of shapes and sizes, they could endure several years of use, did not crack when heated directly and caused a more uniform rate of distillation, with minimal charring. It was also known in the nineteenth century that a copper pot still system generally gave a spirit of superior organoleptic properties (as opposed to spirits from say stainless steel stills); this was later attributed to the ability of copper to remove certain malodorous volatile organosulfur compounds from the distillate during distillation (see Sections 3.2.4, 3.3.4, 3.5.3 and 3.8.3). However, on the negative side, under certain unfavorable distillation conditions (Section 3.1.3), the copper material of the still has been implicated in the formation of ethyl carbamate (EC), a noted carcinogen (Section 5.11.5).

The basic alembic (Section 1.2.1) evolved gradually over the centuries into versions of the pot still that are now associated with particular kinds of distilled spirit, such as Cognac (Section 3.6.2), some rum (Section 3.5.3) and Scotch malt whisky (Section 3.2.4), for example. Various refinements and modifications were added, mainly in the nineteenth century and later, in order to give the distiller greater control over the character of the distillate. These refinements included fractionators, dephlegmators and catalytic converters (Section 3.1.2), giving rise to a number of hybrid pot stills and batch column stills that are used in the production of some Armagnac and other grape spirits (Sections 3.6.3 and 3.6.4), some pomace spirits (Section 3.7.2) and some fruit spirits (Sections 3.8.2 and 3.8.3), for example. Other refinements include ethanol (density) or temperature sensors, for tracking distillation progress and, with reagard to batch distillation, for determining the cut off point for distillate fractions.

It is probable that the use of a simple condensing system originated in medieval times. Thaddeus Alderotti, an eminent physician in Bologna during the thirteenth and early fourteenth centuries, in describing cures and medicinal preparations, made reference to a *serpente*, which is believed to have been the coiled tube condenser part of a still. If so, this may be the first reference to this type of cold water condenser system – the worm condenser (a coiled copper tube immersed in a tub of cold water), which can still be seen in a few Scotch malt whisky distilleries (Section 3.2.4), some brandy distilleries (Section 3.6.1) and some rum distilleries (Section 3.5.3). During the twentieth century, in the production of many distilled beverages (e.g. Scotch malt whisky, see Section 3.2.4), the simple worm tub type condenser largely gave way to vertical shell and tube counter flow condensers, which can now be temperature controlled, thus giving the distiller even more control over the nature of his distillate.

The biggest development in distillation equipment came in the early part of the nineteenth century, with the invention of continuous stills (column stills), particularly the Coffey still (Section 3.1.3). Although batch pot still systems were already producing spirit on an industrial scale, the introduction of continuous stills revolutionized distilling by greatly increasing the throughput and minimizing the number of manipulations and amount of manpower needed during the distillation process. Continuous stills rapidly became popular,

so much so that by the end of the nineteenth century, they held top place in the manufacture of most distilled alcoholic beverages, a position that is still held today. There are, however, notable exceptions where pot or batch column stills are prevalent, such as in the production of all Scotch malt whiskies, some other whiskies and grain spirits, some rum, most brandy and some fruit spirits.

The need for distillation in general was originally scientific or commercial; initially in the production of perfumes and medicines from natural (mostly plant) materials and in the alchemist's attempts to turn base metals into gold. Gradually, it became apparent that the process of distillation could be used as a purification technique, the first sample of reasonably pure ethanol probably being recorded by the Arab alchemist Al-Kindi (Alkindus) in the ninth century (al-Hassan, 2009).

In Europe, as distilled alcoholic beverages became more palatable and the focus shifted from purely medicinal purposes to pleasure, so began the gradual increasing commercialization of distilled spirits production. In the sixteenth and later centuries, it was realized that the production of distilled alcoholic beverages was a cost effective way of using surplus perishable crops (e.g. barley, maize (corn), grapes, rice and sugar cane) by making a valuable by-product (e.g. malt whisky, corn whiskey, brandy, rice wine spirit and rum/cachaça respectively). It provided a very desirable extra income for the farmer, by trading it at market, where it was considerably easier to transport then the bulkier fruit or grain crops. Distilled spirits were more durable than the fermented beverages from which they were produced and sometimes, after suitable aging, they were actually an improvement on the original beverage, as in the case of Cognac and Armagnac. Additionally in the eighteenth century, the practice of adding grape spirit to either wine (e.g. Madeira and Sherry) or fermenting must (e.g. Port and vins doux naturels) (see Chapter 2.10) was emerging as an important alcoholic beverage production method.

However, manufacture of distilled spirits has always been in competition with food production from the same crops and there have been numerous occasions in all spirit producing regions when distillation had to give way to the use of crops as food. Also, during the twentieth century, the production of pure (96.5% v:v) ethanol for fuel and industrial uses became an important competitor. Bioethanol, produced from maize, sugar beet, sugar cane and wheat crops, for example, has become an important product in a number of countries, particularly those in North and South America.

To begin a simplified discussion on the theory of distillation, let's consider a near ideal solution of hexane (boiling point 68 °C) in heptane (boiling point 98 °C) at atmospheric pressure (Oxtoby *et al.*, 2002). It is called near ideal, because the forces of attraction between the molecules are relatively weak London dispersion forces. For a given component, the relationship between vapor pressure and composition is expressed by Raoult's Law (Equation 3.1.1), where X is the mole fraction of the component and p_o is the vapor pressure of the pure component. The latter is higher for a more volatile (lower boiling point) component.

$$p(1) = X(1)p_o(1) \tag{3.1.1}$$

The mole fraction is a measure of concentration; for a two component solution, $X(1)$ is given by Equation 3.1.2.

$$X(1) = \frac{n(1)}{n(1) + n(2)} \tag{3.1.2}$$

The vapor pressures of the pure components that make up a solution differ, which means that the vapor phase in equilibrium with the solution will have a different composition: it will be richer in the more volatile (lower boiling point) component.

Consider, at 25 °C, pure hexane, $p_o(\text{hex}) = 0.198$ atm, and pure heptane, $p_o(\text{hep}) = 0.060$ atm, in a solution of mole fraction of hexane $X(\text{hex}) = 0.400$ and mole fraction of heptane $X(\text{hep}) = 0.600$.

$$p(\text{hex}) = X(\text{hex})p_o(\text{hex}) = 0.400 \times 0.198 = 0.0792 \text{ atm}$$

Similarly,

$$p(\text{hep}) = X(\text{hep})p_o(\text{hep}) = 0.600 \times 0.060 = 0.0360 \text{ atm}$$
$$\therefore \text{ total vapor pressure, } p(\text{total}) = 0.0792 + 0.0360 = 0.1152 \text{ atm}$$

If $X(\text{hex})'$ and $X(\text{hep})'$ are the mole fraction of hexane and heptane in the vapor, then

$$p(\text{hex})' = X(\text{hex})'p(\text{total})$$

Hence

$$X(\text{hex})' = 0.0792/0.1152 = 0.688$$

and

$$X(\text{hep})' = 0.312$$

Therefore, the vapor is richer in the more volatile component (the solute, here). Suppose some of the mixture's first vapor were removed by heating and then condensed, on a cold surface to a liquid. The vapor in equilibrium with this new solution would be even richer in the more volatile component: the new solution will boil at a lower temperature than the original one. Continuation of this evaporation/condensation cycle eventually leads to a situation where the vapor is composed entirely of the more volatile component. This is the basic principle of distillation and is best summarized in a temperature/composition diagram (rather than a pressure/composition diagram), since real distillations are carried out at constant pressure (Figure 3.1.1). The diagram is an example of a phase diagram. The curves represent phase boundaries: above the curves only

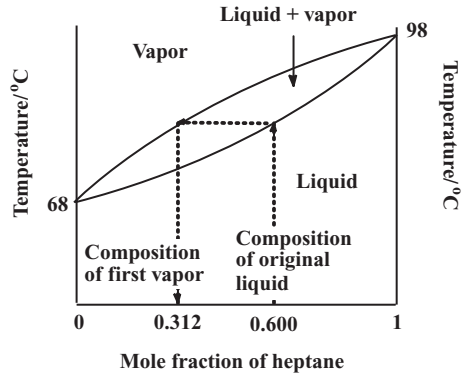

Figure 3.1.1 *Phase diagram for a hexane/heptane solution*

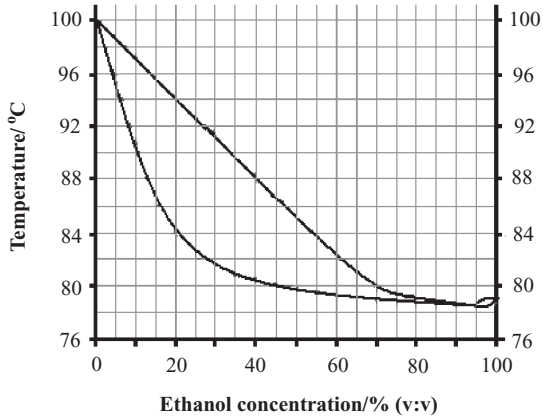

Figure 3.1.2 *Temperature- composition diagram for ethanol–water*

vapor exists (single phase), below only liquid exists, but at the curves liquid and vapor exist in equilibrium, in a two phase system.

Ethanol and water are miscible in all proportions, but do not form an ideal solution because of the relatively strong hydrogen bonding forces that exist between the molecules. Upon distillation, this leads to a more complex phase diagram (Figure 3.1.2), which is characterized by a minimum boiling point at 78.2 °C, corresponding to the ultimate formation a constant boiling mixture (an azeotropic mixture composed of 95.6% ethanol and 4.4% water by volume) when an aqueous ethanolic solution is distilled many times. For convenience, rather than mole fraction, Figure 3.1.2 plots percentage ethanol composition (v:v) (i.e. %ABV) on the *x* axis, because this is the most widely used expression of ethanol content in the alcoholic beverage industry.

If an ethanol–water solution of initial ethanol content of about 8% (v:v) is distilled once, the vapors that condense will possess an ethanol content of about 30%, whereas an initial solution of about 12.5% ABV will yield a first distillate of about 40% (Figure 3.1.2). These correspond to the first distillation (low wines) of whisky and brandy, respectively, ignoring the head and tail 'cuts' (fractions), which are discussed later. If these distillates are redistilled, the result will be distillates of *ca.* 65% ABV and *ca.* 70%, respectively. This corresponds to a double distillation procedure (again ignoring the head and tail fraction management for the time being), used to produce many distilled beverages, such as most malt Scotch whisky, some rum, most brandy and some fruit spirits.

Triple distillation produces distillates of about 80% ABV and over 85% ABV, respectively (Figure 3.1.2) and is used to produce Irish whiskey, a little malt Scotch whisky, some rum and other spirits.

Clearly, if redistillation is carried out many times, the ultimate result will be the azeotropic mixture, containing 95.6% ABV. If this is redistilled, it retains the same composition in the vapor state as in the liquid state and hence no further increase in ethanol concentration can be achieved by simple distillation; this is the upper limit.

3.1.2 Batch Distillation

The multiple distillations described above could be all carried out in batches, by returning the distillate to the (clean and dry) boiler of the same still, or to a fresh still, and redistilling. This is indeed done in the production

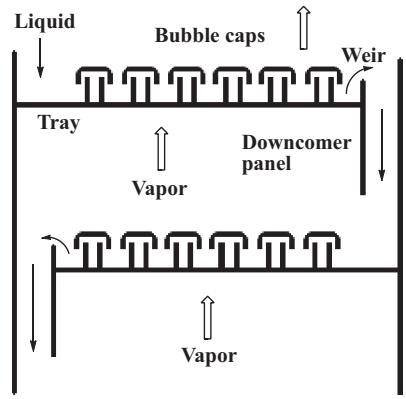

Figure 3.1.3 *Tray and bubble cap system of reflux. Not drawn to scale. [⇑]: vapor flow; [↓]: condensed liquid flow*

of many distilled spirits, as mentioned above, the stills used in this way being known as pot stills. In practice, a certain, but very limited, amount of reflux occurs in simple pot still distillations, depending mainly on the dimensions of the still neck and length of the lyne arm – the length of (usually copper or stainless steel) tubing between the still head and the condenser. A taller neck allows more reflux, thus generally resulting in a somewhat more pure, but rather lighter spirit with somewhat lower levels of congeners.

Greater control of reflux can be provided by the installation of condenser trays into the widest part of the neck, just above the top of the boiler. Reflux is maximized when the trays are in the horizontal position, whereas minimum reflux occurs when the trays are in the vertical position. This version of a pot still is known as a Lomond still. There were once several examples of operating Lomond stills in Scotch malt whisky distilleries, but today, they have all been replaced with conventional stills, although Scapa distillery uses the only surviving example, but only in the capacity of a normal pot still (Section 3.2.4). However, some of the batch column stills described below, used in the production of many fruit and pomace spirits, perform in a similar way to Lomond stills, while being rather more efficient. Examples of pot stills can be seen in Section 3.2.4 (Figure 3.2.8), Section 3.5.3 (Figure 3.5.4), Section 3.6.1 (Figure 3.6.2) and Chapter 3.8 (Figure 3.8.2), whereas simplified diagrams of various stills are given in Sections 3.2.4 (Figure 3.2.9), 3.5.3 (Figure 3.5.3) and 3.6.1 (Figure 3.6.1), as well in Figures 3.1.3 and 3.1.4.

A batch column still has a reflux column fitted somewhere between the head of the boiler and the condenser, so that multiple distillations can be carried out using the same still, in a single run or pass. The reflux column allows a cycle of condensations and vaporizations and in effect acts as a fractionator or rectifier, the efficiency of the column influencing the number of condensations/vaporization cycles, which in turn influences the purity and strength of the spirit emerging from the still.

Various types of reflux columns exist, the most common probably being the bubble cap tray type (Figure 3.1.3). Bubble cap trays are flat and perforated and are fixed to alternative sides of the column internal surface. They have fixed risers above the holes, over which fit the bell-shaped bubble caps. The vapors rise through the risers and bubble caps, and condensation takes place on the column surfaces. Much of the condensed vapors collect in the tray, where eventually sufficient volume will accumulate to cause overflow down the downcomer panel into the tray below. This process continues down the condenser until reaching the boiling liquor. On the way down, much of the condensed vapors will be revaporized, as there is an increasing temperature gradient from column top to column bottom. The cyclical vaporization/condensation processes occurring throughout the length of the column will favor vaporization and collection of lower boiling point components (such as ethanol, esters and sulfur compounds) toward the cooler top part of the column and

significant vaporization of less volatile components (such as acids, fusel alcohols and water) will occur in the hotter lower parts of the column.

Simple sieve trays (without risers and bubble caps) make the most robust tray condensers, but are less efficient compared to bubble cap trays for mass transfer operations and are used when distillations require a smaller number of theoretical stages for separation. Valve tray condensers have perforated tray decks, which are fitted with movable discs or valves to vary the tray open area with changing vapor load.

The reflux column part of a batch column still divides the condensate into fresh distillate, which is collected, and the remainder, which is returned down the column for further reflux. The reflux ratio (returned liquid:fresh distillate) should be high for efficient fractionation. In practice, this means the column still performs best with a lower throughput and a steep temperature gradient in the reflux column. Under these conditions, the residence time of liquid and vapor in the column is long, allowing attainment of equilibrium and lower temperatures at the top of the column, where some of the ethanol/water vapor will run down the condenser as distillate.

Batch column stills, such as those sketched in Figure 3.1.4, are used to make many different types of distilled spirit, including some brandy, much cachaça and rum (Section 3.5.3), most fruit spirit (Section 3.8.3), much North American whiskey (Section 3.3.4) and much pomace spirit (Section 3.7.2).

Even greater control of reflux can be achieved if a cold water condenser is attached to the top of the reflux column or to the still head, or both. This piece of apparatus is known as a dephlegmator; it normally consists of a cylindrical bank of vertical tubes with cold water running through them. A schematic diagram of a batch column still with two dephlegmators can be seen in Figure 3.1.4; one dephlegmator is attached to the top of the boiler, whereas the second is more conventionally situated at the top of the fractionator. Another type of still head condenser, the bowl jacket condenser, is simpler and less expensive than the vertical tube type condensers, but has less control of reflux and sometimes leads to distillations that are both too rapid and too hot (sometimes $> 90\ ^{\circ}C$) (Bruno *et al.*, 2007).

All batch distillations, whether or not reflux columns and dephlegmators are used, need head and tail management, so that high concentrations of potentially harmful or malodorous constituents are removed from the distillate. An account of a typical Scotch malt whisky double distillation using pot stills without either reflux columns or dephlegmators is described in Section 3.2.4, so the account here will focus mainly on batch column distillations.

Fruit and other spirits are frequently produced via a single pass through a column still, as described by Claus and Berglund (2005) for the production of cherry and plum spirits. The 165 l boiler was charged with 150 l of fermented fruit mash and distilled using a temperature probe at the head of the condenser to regulate cooling water flow rate in order to maintain a condenser temperature of 72 °C. The head fraction was discarded and the yield of heart cut (distillate) was up to 7 l when all three trays in the reflux column and a catalytic converter (between the reflux column and condenser) were engaged. The heart cut started at 95% ABV and finished at 58% ABV, giving the distillate an average ethanol content of 77% (v:v). The tail fraction was redistilled with a later batch of mash. The trays were of the sieve type and the catalytic converter was a high surface area copper packing designed to catalyze formation of ethyl carbamate in the converter (rather than elsewhere in the still), where it is separated from the heart cut. The catalytic converter also acted as a fourth tray and so improved rectification, but it also catalyzed the formation of small amounts of acetaldehyde in the distillate by dehydrogenation of ethanol on the catalyst surface.

As expected, congeners with lower boiling points than ethanol (acetaldehyde and ethyl acetate) were more prevalent in the head fraction and early heart cuts, whereas those with higher boiling points (isoamyl acetate and 1-propanol) were more in evidence in the late heart cuts and tails. Methanol, on the other hand, was present in higher concentrations in both the early and late heart cut and at significant levels in the middle hearts. However, careful collection of distillate ensured the methanol content in the product spirit (40% ABV) was below the US regulatory limit of 0.35% v:v ethanol.

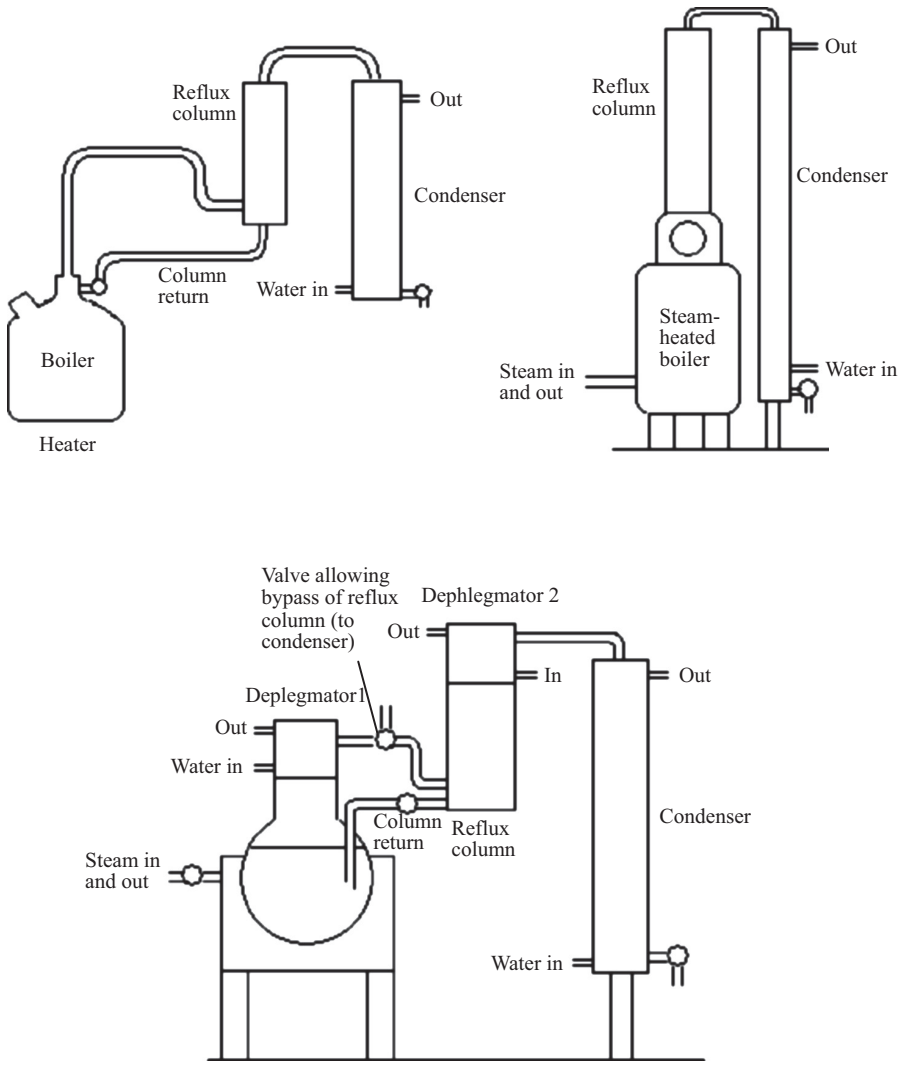

Figure 3.1.4 *Schematic diagrams of batch column still assemblies. Some systems have in line temperature sensors and/or in line catalytic converters (e.g. between reflux column and condenser) for minimizing ethyl carbamate formation. Not drawn to scale*

The distillation of a typical fruit wine to yield a fruit spirit (melon spirit) using a traditional 130 l batch column still (an 'alquitara') for the first distillation and a small (30 l) traditional pot still for the second, has been described by Hernández-Gómez *et al.* (2005). The first distillation was carried out at a rate of 170 ml/min, with the condenser temperature at 21 °C throughout, collecting the distillate until the ethanol content had dropped to 9.2–11.8% (v:v). This gave a distillate of about 18.5–25% ABV and the head fraction was about 200 ml. The second distillation (of 15 l of first distillate) was performed at a rate of 35–40 ml/min. The head fraction (~0.8% of the distillate) was discarded and collection of the heart fraction (second distillate) was stopped at 40% ABV, so giving a final distillate of 58–69% ABV. The fractions from 40–5% ABV were

the tail fractions. The yield of first distillate from 110 l of melon wine (~3% ABV) was 12 l. Analysis of the fractions of the second distillation showed methanol to be distributed throughout the fractions, but most concentrated in the tails, higher alcohols to be fairly evenly distributed between head and heart fractions, and esters to be concentrated in the head fraction, but with significant levels in the heart fraction.

Typical Cognac (Charentais) stills (Section 3.6.2) have boilers of the alembic type, but include a characteristic onion shaped wine warmer that heats the wine before it enters the boiler, as shown in Figure 3.1.5(a). The vapors issuing from the boiler on their way to the condenser heat the wine. Cognac is double distilled, like Scotch malt whisky, the heart cut of the second distillation having about 70% ethanol by volume. Armagnac stills (Section 3.6.3), on the other hand have a pot alembic type boiler, like Cognac stills, but also have a columnar wine warmer and rectifier, and so are intermediate in nature between a pot still and a column still, as can be seen in Figure 3.1.5(b). As there is only one distillation (yielding a spirit of *ca.* 53% ABV), the still can take a continuous supply of wine and hence act as a continuous alembic still. Rectification, however, is

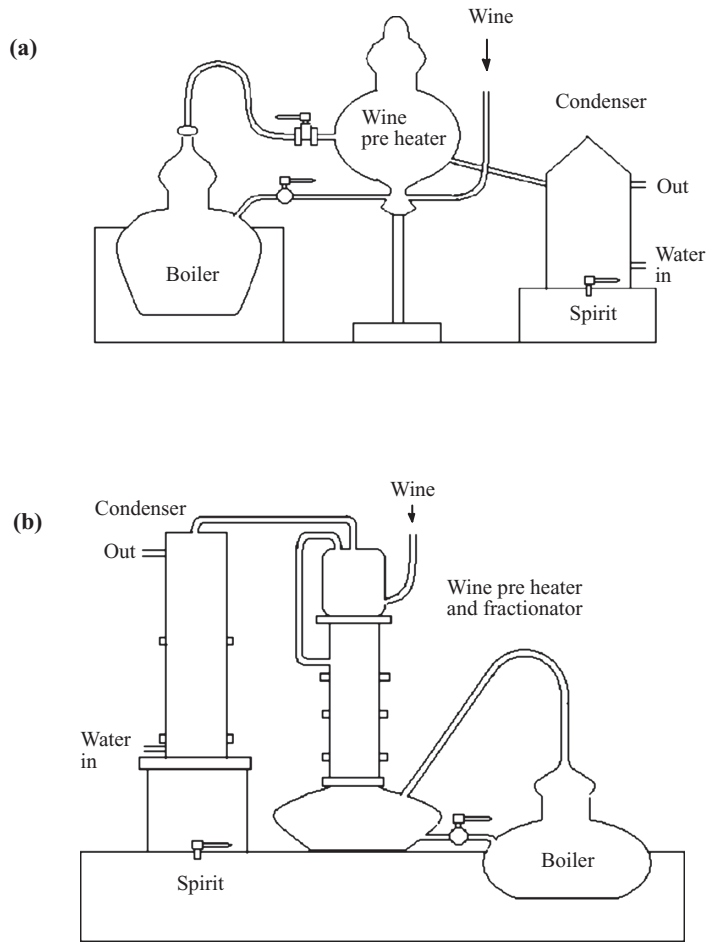

Figure 3.1.5 *Simplified schematic diagrams of (a) Cognac (Charentais) alembic and (b) Armagnac alembic column still. Not drawn to scale*

very limited compared with the continuous column stills discussed in the next section, so that the resulting spirit contains plenty of congeners and has a considerably lower alcohol content than the second spirit from a Cognac still.

Operation of batch stills requires fraction management, so that the desired distillate contains sufficient ethanol, sufficient flavor congeners, but without high levels of undesirable components. For simple pot stills, this means effective separation of the head and tail fractions from the middle fraction, whereas for column stills it means setting the operating conditions to give the optimum spirit. Either way, the distillation needs to be monitored in some way, not only to ensure spirit quality, but also for consistency of quality from batch to batch.

Many distillers monitor distillation progress by manual measurement of distillate density using hydrometers; yet others use in line ultrasonic transmitter/receiver type density detectors (Section 4.6.3) for the same purpose. The former method is the simpler and cheaper of the two, but is open to error if temperature adjustments are not made (see Appendix 2), say in busy periods when a still operator may have to attend to many stills simultaneously. Recently, a 'soft sensor' has been developed for monitoring batch pisco (Section 3.6.4) brandy distillations in Chile (Osorio *et al.*, 2008). The sensor is essentially a computer software programme based on artificial neural networks, involving simple data preprocessing procedures and calibration with laboratory and industrial experimental data. It deduces ethanol concentration from temperature measurements made at four locations within the distillation set up with an accuracy of $\pm 0.6\%$ for small stills and $\pm 1.6\%$ for larger, industrial stills.

3.1.3 Continuous Column Distillation

Continuous column stills, of which patent or Coffey stills are the most common, are designed specifically to distill a pure spirit continuously from a continuous supply of wine or beer. An early version invented by Robert Stein was used at the Cameronbridge grain distillery in Scotland (see Section 3.2.1) in the 1820s. The design was enhanced and patented in 1831 by an Irish excise man, Aeneas Coffey, and it was his version that became popular wherever distilled drinks were produced during the nineteenth century. It is a two column still, the first column (analyzer) has steam rising and wash descending through several levels of perforated fractionating plates. The second column (called the rectifier), carries the alcohol separated in the analyzer from the wash where it circulates until it can condense at the required strength (Figure 3.1.6). Originally, the columns of Coffey stills were of cylindrical design, but modern continuous stills often have rectangular columns, like the ones shown in Figure 3.1.6.

The wash (beer or wine) is fed firstly from a vat or tank through pipes at the top of the rectifier, where it is preheated by steam before being carried from the bottom of the rectifier to the top of the analyzer. There the almost boiling wash cascades through the fractionating plates and meets the rising steam. As the two meet on the surface of the plates, the wash boils and a mixture of vapors of ethanol and other volatile components, as well as uncondensed steam rise to the top of the column. The spent wash (containing less volatile constituents, principally water) runs down the analyzer column and is discharged from the base. The hot vapors now enter the rectifier at the base and as they rise through the column they partially condense on sections of a long coil through which wash is flowing, according to their volatilities (boiling points). The ethanol vapor condenses at the cooler top of the column and is run off through a water cooled condenser to the spirit safe and then on to the spirit receiver. Once the spirit is flowing, it runs continuously until the end of distillation (i.e. until the supply of wash is stopped).

The continuous and rapid nature of the distillation, coupled with the higher concentration of alcohol in the final distillate, are the main advantages over a pot still, or a batch column still, which can only work in batches. Essentially, this means that a pure spirit can be produced more cheaply than with batch columns. The main disadvantage of continuous alcohol stills is that the alcohol produced by them is not entirely free

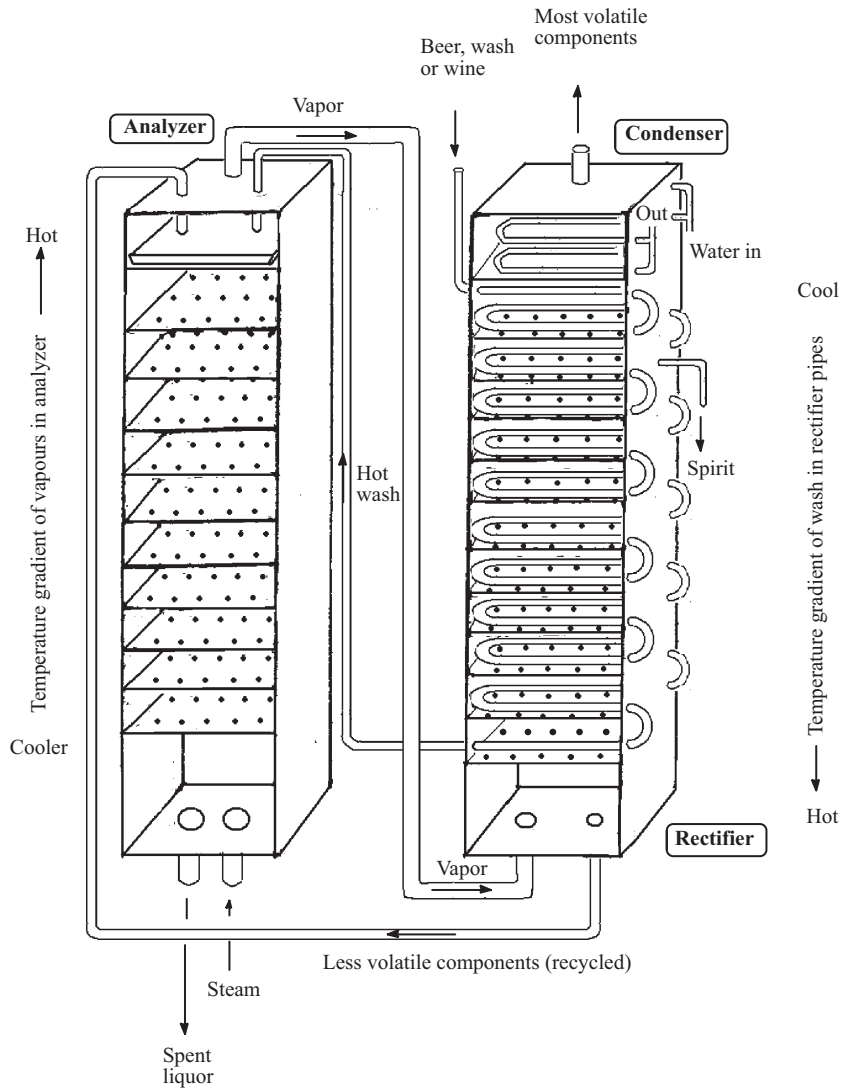

Figure 3.1.6 *Schematic diagram of a continuous still*

of more volatile and potentially harmful components, such as methanol and acetaldehyde, although this situation can be improved by taking the ethanol from just below the top of the rectifier. In this case, most of the acetaldehyde and methanol is taken from the top of the column.

Like batch column stills, continuous column stills yield a relatively pure spirit of high ethanolic strength (up to 95.6% ABV, the strength of the azeotropic mixture), which is low in flavor compounds (congeners: acids, higher alcohols and esters, for example). This is particularly the case with tall column continuous stills, which are able to supply the highest degree of rectification. Grain neutral spirit (GNS) and fuel alcohol ('bioethanol') (produced from any weakly alcoholic wine or wash) are the ultimate examples of pure, almost flavorless spirit. GNS is very important in the production of many spirits, notably gin (Section 3.4.2) and

vodka (where it is further purified by charcoal filtration) (Section 3.4.3), and many liqueurs (Chapter 3.9), where it is frequently used as at least part of the spirit base. The production of bioethanol, although outside the scope of this book, is a booming business in North and South America and is becoming more important in many other countries.

However, in the production of many distilled beverages, regulations require the spirit to be of considerably lower ethanolic strength than that of the azeotropic mixture. For example, the EU stipulates that the distillation of fruit spirits must occur at less than 86% ABV, so that the spirit retains some character of the fruit from which it is derived (Council Regulation (EEC) No. 1576/89 of 29 May 1989, EEC, 1989). Similar regulations pertain to other distilled spirits that are produced using less efficient fractionating systems (Armagnac and some Calvados) or continuous stills (Armagnac).

There has been much discussion in the literature on the relative merits of batch pot still, batch column and continuous column distillation, but as described above, each type has its own character and can produce superlative spirits if operated under proper conditions. Much of the perceived organoleptic differences in pomace spirit (Section 3.7.2) produced by different stills (pot versus column stills) have been ultimately traced to differences in process or operating conditions rather than to fundamental differences in the distillation apparatus (Corich *et al.*, 2005; Cortés *et al.*, 2005). Likewise, differences in the levels of harmful or undesirable components (such as butanoic acid, 2-butanol and methanol) in pomace spirit have been attributed more to process conditions than type of still.

Ethyl carbamate (EC) (Section 5.11.5) formation during distillation is always of concern, because of its potential carcinogenic activity. Bruno *et al.* (2007)in a study of the EC levels in cachaça, produced using a wide variety of still types, concluded that differences in levels were largely due to differences in distillation conditions. The data showed generally higher EC levels for continuous column cachaça, than for alembic (pot still and batch column still) versions, but within each group there were exceptions that could be related to the distillation operating conditions. In particular, low distillation temperatures and high reflux rates gave spirits with minimal EC content, indicating that many of the continuous distillations were either carried out in unsuitable equipment or were performed too rapidly at too high temperatures. Also, insufficient cooling of column still dephlegmators led to high levels of EC in batch column still cachaça.

3.2
Scotch Whisky

Inspiring bold John Barleycorn!
What dangers thou canst make us scorn!
Wi' tipenny, we fear nae evil;
Wi'usquebae, we'll face the devil!
—Robert Burns, Tam O'Shanter

3.2.1 Introduction and Brief History

Whisky (or whiskey) is produced in many parts of the world by distillation of the beer (called 'wash' in the industry) formed by fermentation of cereal wort (Section 2.6.2). The two words used for these spirits, whisky and whiskey, are both corruptions of the Gaelic name for the spirit, *uisge beatha*, meaning water of life. Thus the derivation of names of this distilled beverage is, like akvavit (Scandanavia) and eau-de-vie (France), from the Latin *aqua vitae*. Whisky is the specific name for spirits produced in Scotland or in countries that have been largely influenced by Scotland, such as Canada, India and Japan (Section 3.3.6). The much less well known products of England, the Isle of Man and Wales also use the word whisky, whereas whiskey is used for the cereal spirits of Ireland and generally for those of the USA (Sections 3.3.2 and 3.3.3).

Scotch whisky refers solely to whisky that has been distilled and matured in Scotland. The bulk of the Scotch whisky today is, as it has been for many decades, a blend of malt whiskies and grain whiskies. Scotch malt whiskies are made from malted barley, using pot stills (Section 3.1.2), whereas grain whiskies come from other malted or cooked cereal grains, such as maize or wheat via Coffey (continuous) stills (Section 3.1.3). A single malt Scotch whisky is the product of only one distillery, although the majority, for the sake of consistency, are blends of malt whiskies from different distillation batches (= different casks) over a period of time. The chief blender, or blending panel, decides on the contributing casks of spirit required for a bottling of a particular malt whisky. The whiskies from these casks are then vatted together for a few weeks before any further processing and bottling. Single malt Scotch whiskies became popular from the 1960s, prior to that time they were often difficult to obtain outside Scotland and most malt whiskies were (and still are) destined for blends. Single grain Scotch whiskies are comparatively rare. Vatted malt Scotch whiskies, produced by vatting (blending) malt whiskies from several distilleries are also available, these usually being the products

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

of whisky blending companies and independent bottlers. The general characteristics of all these whisky types are discussed more fully in Section 3.2.6.

It is not known for certain when the first whiskies were distilled in Scotland, but there is a general consensus of opinion that distillation was well established by the fifteenth century. Like brewing of beer, whisky distillation was essentially a cottage industry until the late eighteenth or early nineteenth centuries. It is probable that the first spirits were produced from local grains, most likely oats and barley. The barley (called bigg or bere) would often be the four rowed type that was indigenous to the west coast, although this was gradually replaced by higher yielding two rowed types (Wilson, 1985a). Even so, the yields (in volume of spirit per mass of grain) would have been low by modern standards (Section 3.2.2) and very much at the mercy of inclement weather. Until well into the eighteenth century in the Western Isles and the Highlands, distillation was a sporadic activity carried out largely by farmers according to yield and in competition with food crops. Nevertheless, whisky became a valuable commodity and production grew, so that by the mid eighteenth century, the highlands and islands had acquired a reputation for their malt whiskies, some of which were exported to the Lowlands. The latter areas, especially around Glasgow and Edinburgh, by this time had comparatively large distilleries producing whisky from grains, especially wheat, maize and barley.

A succession of restrictive laws and taxes caused illicit production of whisky in remote highland and island locations, where their discovery by excise men was difficult. The barley for these early whiskies would have been malted by soaking in burn water and leaving exposed to the sun until germination occurred. Drying of the germinated grains would be over a peat fire and indeed all operations involving heat, including distillation per se, would most likely involve peat, this being the most widely available fuel. Distillation was carried out using a small copper pot still inside a well camouflaged temporary structure (a 'bothy'). By modern standards, these whiskies would have been smoky, fiery and generally rough. Maturation in large oak casks was not widely practiced at that time, the whisky being kept or bottled and consumed according to the circumstances.

The growth of large-scale or industrial and hence legal distilleries began in the eighteenth century, especially after the passing of the Wash Act (1784), which eased certain restrictions on the legal trade and at the same time encouraged illicit distillers to obtain a licence. An amendment to this Act in 1785 allowed two stills of up to 180 l in each parish to be operated by respectable tenants, appointed by local lairds. Many licenses were taken out and the growth of the Scotch whisky industry as we know it can be considered as starting around that time. Growth accelerated and consolidated with the Illicit Distillation Action (1822) and the Excise Act (1824); many distilleries were (legally) founded at this time. The illicit croft based distilling industry began a slow course into decline.

Figure 3.2.1 shows the approximate locations of all the presently (2009) active distilleries, both malt and grain distilleries. Also indicated in Figure 3.2.1 are 'silent' distilleries – those that have been inactive for a number of years – and a brief list of some notable defunct distilleries. Various distilleries claim to be the first legal Scotch whisky distillery, although it is difficult to confirm or refute claims because of a lack of precise records. Also, many famous distilleries were built on or close to sites of former illicit distilleries. Certainly, some of the Glenturret distillery buildings date from 1775 and Bowmore distillery (Islay) was well established at the time of the Wash Act (1784). Other distilleries claiming establishment in the eighteenth century include Balblair (1749), Deanston (1785), Glen Garioch (1798), Highland Park (1798), Littlemill (1772), Oban (1794), Strathisla (1786) and Tobermory (1798) (Jackson, 1989).

Like all alcoholic beverage industries, the Scotch whisky industry has undergone (and is still undergoing) many changes: periods of growth, recessions, rationalization, consolidation, increasing automation, modernization of methods and the effects of legislation (Section 1.2.4). The industry is now a mature industry, generally keeping an open mind on innovation and change, but at the same time respecting past achievements and the pictures of tradition that have been gradually (and successfully) developed since the early twentieth

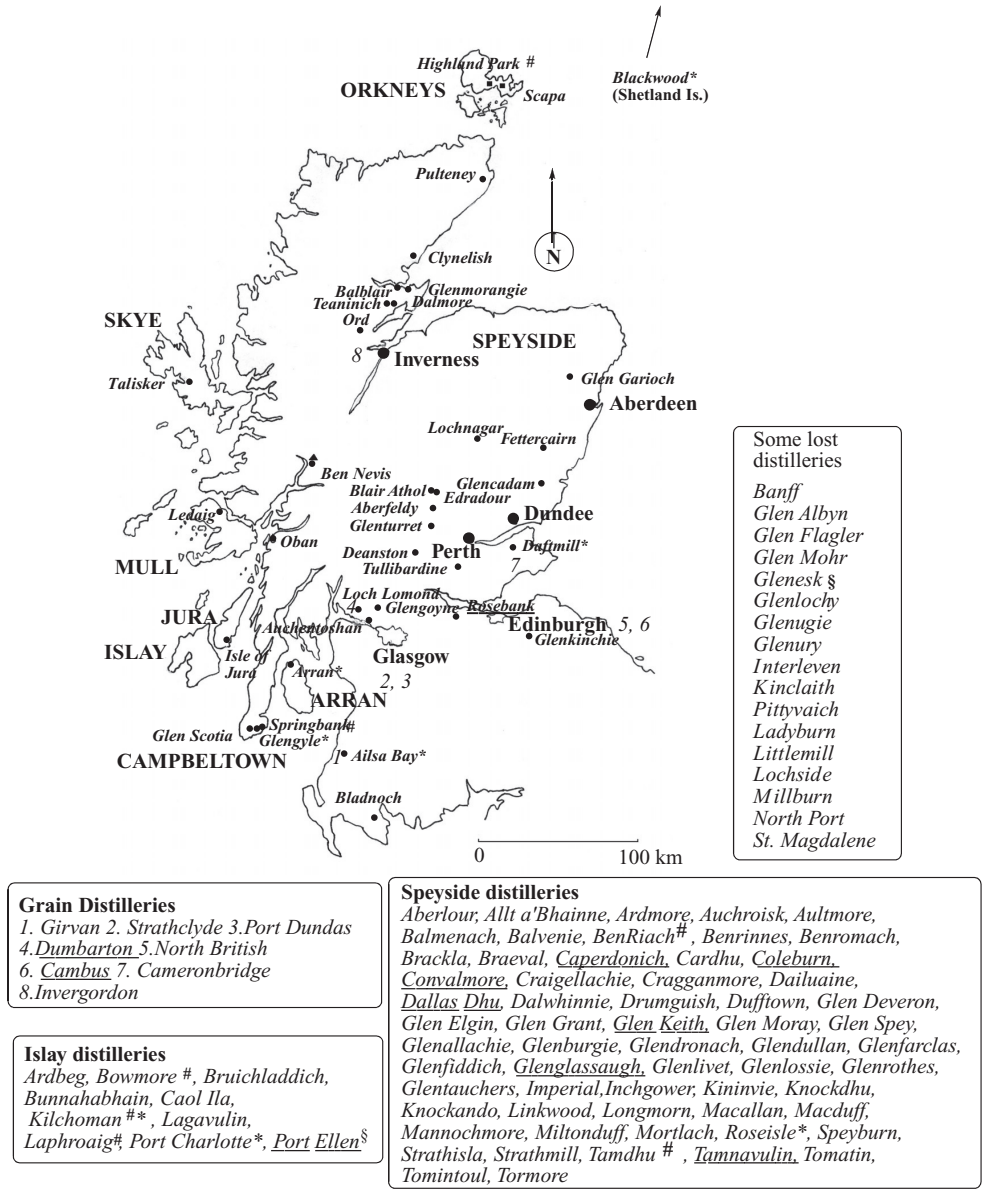

Figure 3.2.1 *The Distilleries of Scotland. Underlined istilleries are silent at the time of writing (2008). Note: some distilleries have alternative names, or produce brands with alternative names - e.g. Longrow, Hazelburn (Springbank), Tobermory (Ledaig), Kilkerran (Glengyle). Lost distilleries are closed down or demolished, but some of their products can be found still. The list of lost distilleries is not exhaustive. Dallas Dhu is a whisky museum. *Relatively new, in some cases single malts not yet available (2008). §Now maltings. #Use own maltings*

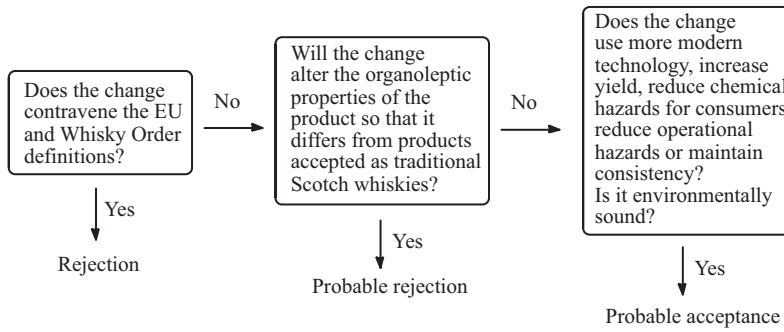

Figure 3.2.2 *General criteria for change within the Scotch whisky industry*

century (Halliday, 2004). Like other alcoholic beverages within the EU, Scotch whisky and whisky in general are protected from counterfeit and fraud by definitions and statements within the EU Spirits Drinks Regulation (1989). This regulation defines the materials from which, and processes by which, whisky must be made (albeit in a rather general way) and also refers broadly to 'traditional practises,' without actually defining them. In particular, the Regulation stipulates that whisky must be matured in casks of less than 700 l capacity for a minimum of three years and the only additive allowed (not counting demineralized water for dilution) is caramel. Additionally, 'tradition practises' must be followed. The Scotch Whisky Order (1990) gives a similar, but more detailed set of definitions and statements, and adds the necessity that Scotch whisky not only must be produced in a distillery in Scotland, but also must be matured in casks in an excise (bonded) warehouse in Scotland.

These protective (and restrictive) legislations leave plenty of room for change and innovations that respect the general picture of tradition (Morison, 2004), as illustrated in Figure 3.2.2. Note that Figure 3.2.2 could be used as a general guide to acceptable and unacceptable change for any protected beverage – inside and outside the EU.

An example of an acceptable innovation is the relatively recent activity of deliberately ageing single malt Scotch whiskies in ex-beer or (more commonly) in ex-wine casks (such as those that had contained Chardonnay, Madeira, Shiraz or Port, for example). This complies with both the law and tradition even though the tradition goes back only to the end of the nineteenth century, ex-Bourbon or ex-Sherry casks being used for this purpose. Ageing in, say, an ex-Port cask will give a different aroma and flavor profile to the spirit, but which is still instantly recognizable as Scotch whisky. In any case, in the early days of cask ageing, some distillers probably used whatever casks were available.

On the other hand, an example of an innovation that would not be acceptable at present is the use of toasted oak chips in the maturation process. Even though aroma and flavor enhancement might well be achieved by this process, it would not be permitted because it is not a traditional process; the spirit could not be called Scotch whisky.

In due course, it is possible that processes like the one described above may become accepted and after a further time become traditional, like cask ageing. Casks were originally used as a convenient storage unit for Scotch whisky, as for most other liquids. In time, it became apparent that longer time in cask certainly benefited the character of the spirit, and so cask ageing became an accepted (traditional) practice, with legislation eventually stipulating a minimum of three years in cask.

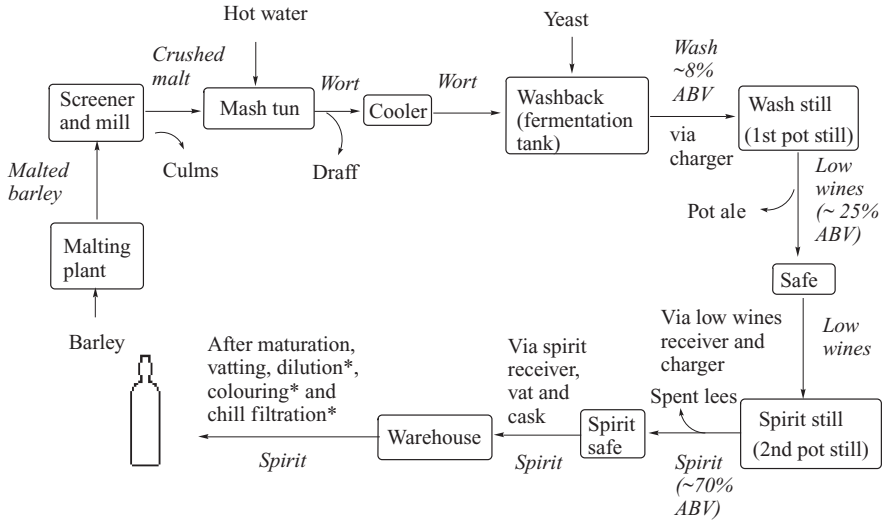
Tradition, then, refers to the accepted ways of doing things at the time; it is forever changing, if only at any one time in subtle details.

Table 3.2.1 *Some twentieth century changes in Scotch whisky production, distillery and allied operations*

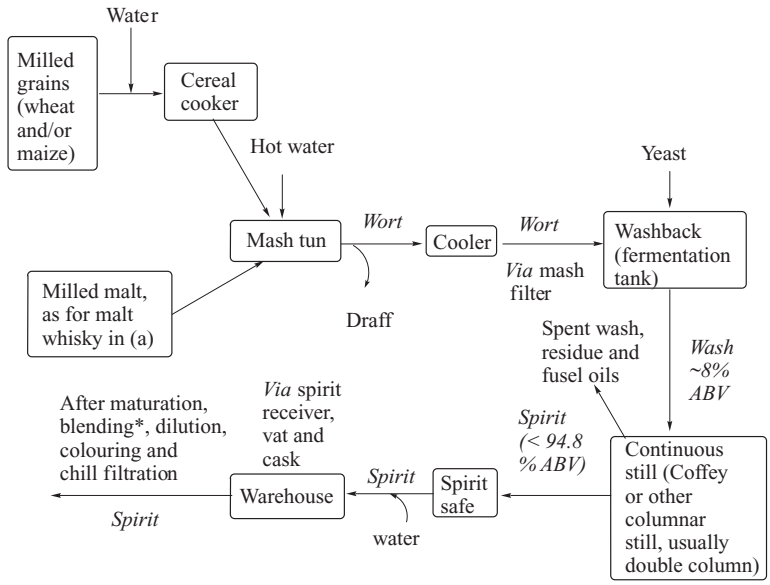
Aspect of production or operation	Major changes and comments
Automation	Extent of automation varies considerably between distilleries and allied industries (e.g. malting), but automation is generally increasing, with fewer personnel involved and much computer control
Barley and other cereals	Breeding and research has produced many improved varieties (with respect to yield, malting quality, spirit yield, disease resistance, etc.) (Section 3.2.2)
Malting	Few distilleries now have their own malting; most malting is done using large drum, saladin box or GKV systems (Section 3.2.3), to distillery specifications, by large malting companies
Fermentation	Improved yeast strains and fermentation control has led to better control of product flavor profile and greater consistency (Section 3.2.3). Some yeasts can produce higher alcohol washes (Section 3.2.3)
Distillation	Steam heating of pot stills has replaced direct heating in some malt whisky distilleries (Sections 3.1.2 and 3.2.4). Vertical shell and tube condensers have replaced worm tubs in many malt whisky distilleries (Section 3.2.4). Alko stills are replacing Coffey stills in some grain distilleries (Sections 3.1.3 and 3.2.4)
Yield of spirit	Yields (in liters of spirit per ton of barley) have increased from ~320 to ~420 over the last 20 years (Sections 3.2.2 and 3.2.4)
Environmental	Water and energy saving operations are in place in many maltings and distilleries, as a result of research and legislation – research is underway to find better and safer use of waste
Maturation	Much Scotch whisky is matured in multistorey palletized warehouses distant from the distillery, as opposed to dunnage warehouses (with earth floors) next to the distillery (Section 3.2.5)
Public relations/tourism	Many distilleries now have visitor centers, with shops selling distillery named goods and related goods, as well as whisky

Scotch whisky production and the ways in which distilleries operate have changed drastically over the last 50 years; some (but by no means all) of these changes are summarized in Table 3.2.1. Also included in Table 3.2.1 are summaries of changes in allied industries, such as malting and agriculture.

The basic processes involved in the production of Scotch malt whisky and Scotch grain whisky are summarized in Figure 3.2.3 ((a) and (b), respectively). The various parts of the overall process depicted in Figure 3.2.3 are discussed in the next sections. The traditional use of pot stills for malt whisky and Coffey or columnar stills for grain whisky is implied in Figure 3.2.3, although in principle these uses can be reversed. There have been experiments using column or hybrid stills (e.g. Lomond stills for the production of malt whisky, and both kinds of stills can be used for Bourbon whiskey (Section 3.3.4), produced from mixed grain (mostly maize) washes. The production of grain whisky, based on wheat (and perhaps some maize), with malted barley up to ~20%, requires a cereal cooking step. Here, the starches of wheat or maize are gelatinized by spending time in the cereal cooker. The resulting soluble starches are then hydrolyzed to fermentable sugars in the hot water mash by α- and β-amylase and limit dextrinase enzymes, released from the malted barley in the mash (Section 3.2.3).



(a) Malt whisky. This scheme is for double distillation. Some malt whiskies are triple distilled. * Not all Scotch malt whiskies undergo these processes. A few single malts are not vatted before bottling (single single malts). Blended spirits from the same distillery give single malt whiskies and from different distilleries give vatted malt whiskies. Many malt whiskies are blended with grain whiskies to give Scotch whisky.



(b) Grain whisky. The vast majority of grain whisky is blended with malt whiskies to give Scotch whisky, but a few single grain whiskies exist. Wheat has been the most important grain for the past three or four decades, prior to that it was maize.

Figure 3.2.3 *Schemes showing production processes of (a) Scotch malt and (b) Scotch grain whisky*

3.2.2 The Raw Materials

The raw materials for making Scotch whisky are cereals (barley alone for malt whisky) and water; yeast is discussed in Section 3.2.3.

Barley is the most important cereal crop regarding Scotch whisky; it the sole cereal for malt whiskies and is used in the production of grain whiskies too. It is the dominant arable crop in Scotland, where the annual yield for 2005–2007 was around 1.7 million tonnes. Almost 50% of this is used in the brewing and distilling industries. The second most important arable crop in Scotland is winter wheat, with an annual production of around 800 000 tonnes for 2005–2007. Again, the Scotch whisky industry is a major consumer of the crop, requiring some 500 000 tonnes annually for the production of grain whisky.

UK barley breeding programmes have tended to develop around certain core varieties, resulting in an elite gene pool and giving rise to cohorts essentially derived from Vada (a nonmalting feedstock variety), and Proctor and Triumph (malting varieties). Selection is according to phenotype, and is based on the following malting, brewing and distilling characteristics:

- High friability (∼90%) (see Section 2.6.2)
- Hot water extractability (∼78%) (amount of soluble starches formed on malting)
- High diastase activity (high levels of starch hydrolytic enzymes)
- High fermentability of wort (for high ethanol yield)
- High β-amylase thermal stability
- Low *epi*-heterodendrin levels
- Low β-glucan and pentosan levels
- Low nitrogen levels.

In addition to these parameters, selection is based on a number of agricultural characteristics, as follows:

- High yield (>72 kg/ha)
- High disease resistance
- Strong, short stems (for use of mechanical harvesting).

The distiller would expect a spirit yield of about 420 l from a tonne of malted barley. Similarly, low nitrogen, low moisture (<14%) and soft endosperm grains are prime characteristics of wheat preferred by distillers.

Cereal plant breeding is carried out by the commercial sector, by companies such as Nickerson, Rothwell, Syngenta, Saaten Union and Twyford. Breeding new barley or wheat varieties is geared toward the needs of both farmers and industries that use these crops: baking, brewing, distilling and animal feed. Practitioners within these industries will generally only accept grain from certain varieties – those that have a maximum number of beneficial attributes for those industries. For distillers, this means high grain yield, good resistance to fungus diseases (minimal fungicide spraying, with minimal crop loss when unsprayed), low nitrogen content, soft endosperm (for wheat), friable grain structure, low β-glucan content (thin cell walls) and low cyanogenic glycoside content.

Under the auspices of HGCA (the cereals and oilseeds sector of the Agricultural and Horticultural Development Board – AHDB), field trials are conducted at various sites and by various companies and institutes. Depending on performance after three years of trials, a new variety can be provisionally recommended, or can be designated for special use by the Scottish Agricultural Colleges (SAC) and the National Institute for Agricultural Botany (NIAB), for example. The HGCA crop evaluation committees are aided by the

Malting Barley Committee, the Scotch Whisky Association and others. Good performance under commercial production leads to recommended status and any new traits (good or bad) are noted for established varieties. Various research institutes, particularly the Scottish Crop Research Institute (SCRI) and NIAB, conduct research that identifies key regions of the barley and wheat genomes that affect desirable and undesirable characteristics and hence determine suitability for brewing and distilling. Knowledge of these genome regions allows development of markers that breeders can use in genotype selection (known as marker assisted selection or MAS). More generally, a better understanding of the genetic factors that determine malting (and hence brewing and distilling) quality and how these are inherited can help scientists and cereal crop breeders alike (Rae *et al.*, 2007). Scientists are seeking molecular markers for major genes or quantitative trait loci (QTL) that control key traits in barley and other cereals, mostly by using doubled haploid (DH) populations specifically targeted to one or more of these traits. Gene markers are available for traits such as resistance to yellow mosaic virus, β-amylase thermostability, hot water extractability, fermentability and nonproduction of *epi*-heterodendrin (Section 5.11.5).

The last named trait is important for distillers, since whisky produced from *epi*-heterodendrin nonproducer barley varieties will have minimal amounts of the carcinogenic ethyl carbamate (urethane) (Section 5.11.5). *Epi*-heterodendrin is a plant defence pheromone – it is toxic to small animals (e.g. rabbits) that attempt to feed on the plant. On disruption of plant tissues, *epi*-heterodendrin is hydrolyzed to 2-hydroxy-3-methylpropanonitrile, a cyanohydrin that decomposes to the toxic hydrogen cyanide (HCN) and 2-methylpropanal (valeraldehyde) (see Section 5.11.5, Figure 5.11.4). In whisky production, HCN reacts with ethanol in the presence of copper during distillation to give ethyl carbamate. The last named compound can also be produced from urea, a byproduct of alcoholic fermentation performed by certain yeast strains. So, careful choice of barley strain for malt and yeast strain for fermentation should give whiskies with levels of ethyl carbamate below limits of detection.

Recommended cereal varieties for brewing and distilling meet with varying success and spend varying lifetimes as recommended varieties. In recent years, Optic (spring) and Pearl (winter) have dominated the production of certified seeds for growing malting barley for whisky production. Previously, Triumph and Golden Promise (both spring types) were favorites, and before them, Tyne and Proctor (1950s). Good winter wheats for distilling are reckoned to be Alchemy, Consort, Glasgow, Istabraq, Riband, Robigans and Zebedee. Some examples of spring and winter barley cultivars and winter wheat varieties that are considered to be best suited to distilling are listed in Table 3.2.2, along with specific weights, crop yield and other data. It can be seen from Table 3.2.2 that yields have generally increased over the years and loss of crop due to lack of fungicide spraying appears to diminish. This latter characteristic is more difficult to assess, as experience has shown that resistance to fungal diseases may not be maintained with time, so such figures may be misleading. Table 3.2.3 lists some of the more successful cultivars of barley, from 1983–2004, for brewing and distilling. Only varieties that have constituted more than 4% of total seed production are included in Table 3.2.3, so that successful varieties like Pipkin (3.4%) and Maris Otter (2.6%) are omitted (Rae *et al.*, 2007).

Before the widespread implementation of intensive arable crop farming, with its use of lime and fertilizers (i.e. prior to the nineteenth century), Scots Bere, a Scottish landrace barley, gave the most important crop for whisky production. In even earlier times, it is possible that oat and wheat crops were also used for the same purpose. Since the nineteenth century, successive cultivars have outperformed Scots Bere in terms of yield and other factors, such as lower nitrogen content. Also, the weak straw of Scots Bere renders it less than ideal for harvesting by combined harvester machines. Nevertheless, interest is growing in Scots Bere, as its malt has a high level of diastatic power (Section 4.6.3), arising from a high level of β-amylase (not α-amylase) (Ellis, 2004). Experimental generation of random inbred lines of plants from a cross between Scots Bere and a modern barley variety is currently underway. Also, one newly proposed malt whisky distillery (Blackwood in the Shetland Isles, whose company already produces gin and vodka) intends to use locally grown Scots Bere for at least part of its source of malt.

Scotch grain whisky distilleries relied more heavily on maize than wheat up to the 1980s, but for economic reasons (maize had to be imported), wheat has dominated the industry since that time. As stated previously, wheat is now Scotland's second cereal crop – in 1960, the major cereal was oats, followed by barley and wheat.

Grain whisky distilleries generally use processes originally designed when maize was the major cereal; under such conditions wheat gives an inferior ethanol yield per tonne of grain than maize. Ethanol yield

has been shown to be inversely related to grain nitrogen content and hard wheat can cause some processing problems, so distillers prefer low nitrogen samples from soft wheat varieties. Similarly, wheat varieties whose grains have a mealy endosperm (e.g. Consort), rather than a steely endosperm, release starch easily, but it seems that many genetic factors influence the ethanol yielding potential of wheat (Swanston *et al.*, 2007).

Although there has been very little breeding of wheat varieties specifically for distilling, the possibility exists of combining factors such as high yield, high starch content, low nitrogen content and low cyanogenic glycoside content by choosing complementary parents and selecting progeny with all these desirable characteristics (Swanston *et al.*, 2007).

Recently there has been considerable interest in the assessment of alternative cereals, such as millet and sorghum, for the production of grain whisky (and industrial ethanol). In a comparison of maize, millet, sorghum and wheat for this purpose, Agu *et al.* (2006) showed that, except for high nitrogen wheat, all four cereals gave similar performances with regard to alcohol production and processing. Wheat with high nitrogen content is not generally used by distillers because of its lower alcohol yield and also because of the difficulties caused by its higher viscosity and consequent processing problems (particularly in the recovery of spent wash/spent grains). Agu *et al.* (2006) confirmed these notions and suggested that the higher viscosities of high nitrogen wheat distillation residues were due to higher levels of pentosans in these grains. Levels in maize, millet, sorghum and low nitrogen wheat are known to be similar. Whereas the nitrogen content of wheat greatly influenced the alcoholic yield, this factor appeared to have little influence on the alcohol yield of the other cereals. Greater ethanol yields were achieved with maize and sorghum starches, whereas maize, millet, sorghum and wheat (low N) grains gave similar yields. This suggested that the starches extracted from maize and sorghum can better withstand distillery processing effects (heat and steam stresses) than those of millet and wheat. Millet and sorghum would thus appear to be good alternative cereals for distillation, should unfavorable market conditions overtake maize and wheat in Scotland.

Not counting cleaning, water is used in three ways with regard to Scotch whisky production:

- Steeping of barley grains during malting (Sections 2.6.2 and 3.2.3)
- Mashing – extraction of soluble starches and hydrolytic enzymes from malted barley (and for grain whisky, gelatinized starches from cooked grains) and their conversion to fermentable sugars (Section 3.2.3; see also Section 2.6.2)
- Dilution of spirit to desired strengths prior to bottling (Section 3.2.5).

It can be said that water is the single most important element of Scotch whisky and influences the character of the final spirit, but not in easily defined ways, as there are many other influences (Sections 3.2.3–3.2.5). Most distilleries have their own (jealously guarded) water supply, usually a burn (stream) or loch (lake) and often assisted by a dam or reservoir. Water for distilling is usually untreated, although it must meet standards of purity laid down for potable water (Section 5.10.4). Water that rises from hard rock, such as granite, and has little or no contact with peat is thought to convey a clean softness to the whisky, if no peated malt (Section 3.2.3) is used in its production. Such water is used at Glengoyne distillery in Dumgoyne, a village at the southern foot of the Campsie Hills on the northwestern outskirts of Glasgow (Figure 3.2.1). The water runs off Dumgoyne Hill (427 m, 1404 ft) via Distillery Burn into a dam just behind the distillery. Another example of such water can be found at the Isle of Jura distillery (Figure 3.2.1), which uses water from the dammed Loch a'Bhaile Mhargaidh (Market Loch) to the west of the distillery. However, at Jura, unlike Glengoyne, some peated malt is used. In contrast, water which rises from peat and flows over peat contains much more organic matter and is thought to impart a certain smoky character to the whisky, even if no peated malt is used in its production. However, distilleries located in peat water areas almost invariably use peated malt in producing their whiskies, which are typically smoky. The reasons for this are partly economical and partly traditional. Classic examples of this style can be found in the Islay whiskies (Figures 3.2.1 and 3.2.16), which

draw their water from burns and lochans in the peaty interior of the island, water from the Solan Lochs being used by Lagavulin distillery, for example. Unusually, Laphroaig takes its water directly from the bog to the north.

The water used by many malt distilleries rises from rock and flows partly over rock and partly over peat. This is especially the case with Speyside distilleries (Figure 3.2.1). For example, Glenfarclas and Benrinnes distilleries (Dufftown) draw their water from burns issuing from Ben Rinnes (841 m, 2,759 ft), the highest mountain in Speyside.

Nowadays relatively few breweries and distilleries draw their water from artesian wells, probably because of increasing agricultural pollution and the possibility of insufficient supply for large-scale operations. Nevertheless, Daftmill distillery, a new enterprise near Cupar (Figure 3.2.1) uses artesian well water. Other distilleries that use water from wells or bore holes include Braeval, Glenlivet and Macallan (all Speyside).

Peat contains humic substances such as humic acid and fulvic acid, discussed more fully in Section 3.2.3. Humic acid is a supramolecular aggregation of lignin and tannin-like molecules with carbohydrate and peptide side chains. The hundreds of individual molecules ($<$ 1000 amu) contain many functional groups that can form chelation complexes with heavy metal ions (such as Pb^{2+}) and ions such as Ca^{2+} and Mg^{2+} that contribute toward water hardness. Thus, water that has had prolonged contact with peat is softened to a certain extent and has a lower pH. On the other hand, water that rises from and flows over calcareous rocks contains much higher concentrations of mineral salts and is of higher pH. It is called hard water, the type (permanent or temporary) and extent of hardness being governed largely by the local geology and the extent of water/rock contact (see Section 2.6.2).

The geology of the whisky producing regions of Scotland is such that the majority of distilleries use soft or slightly hard water. This is considered by some to contribute to the unique character of Scotch whisky, but at least two highly respected distilleries, Cragganmore (Speyside) and Highland Park (Orkney) use water that possesses a considerable degree of hardness.

3.2.3 Malting, Mashing, Cooking and Fermentation

The great majority of malting is now carried out in large dedicated malting complexes, some of which belong to the same company as the distilleries. For example, the Diageo Scotland Maltings supply malted barley to distilleries of the former United Distillers, bought by Guinness (now part of Diageo) in 1986. Figure 3.2.4 shows malting sites in Scotland. They are typically located in major barley producing areas: Black Isle (north of Inverness), Grampian (Aberdeen to Inverness), Tayside (around Dundee), Fife and Edinburgh and Ayrshire. The majority use germination and kilning vessels (GKVs) (malting vessels that are used to steep, germinate, dry and kiln the barley) or automated horizontal steeps and Saladin type germinating boxes, with rotating drum dryers and separate kilns. The largest maltings (Burghead) (Figure 3.2.4) produces over 80 000 tonnes of malted barley per year, but all the dedicated maltings shown in Figure 3.2.4 produce over 10 000 tonnes per annum.

At the time of writing (2009), only those distilleries indicated in Figure 3.2.4 malt their own barley: Benriach (Speyside), Bowmore (Islay), Highland Park (Orkney), Kilchoman (new – Islay), Laphroaig (Islay), Springbank (Campeltown) and Tamdhu (Speyside). All but the last named use traditional malting floors; a picture of the Kilchoman Distillery malting floor can be seen in Figure 3.2.5. It is generally agreed that a single large-scale malting complex can produce the same quantity of malt in a more efficient, cost effective way than a large number of smaller traditional floor maltings at distilleries. In the early part of the last century, most Scotch malt whisky distilleries had their own maltings on site; mostly floor maltings, but some, like Benrinnes and Tamdhu, had saladin box maltings. Others, such as Glen Grant and Speyburn (Speyside) had drum maltings. Some distilleries, such as Glengoyne (Western Highlands) converted their malting buildings

Figure 3.2.4 *Malting sites in Scotland. □ Dedicated malting plants; ○ Maltings as part of active distillery*

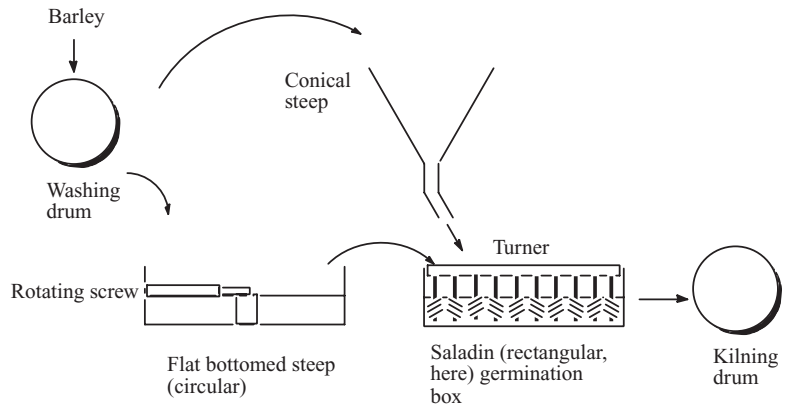

Figure 3.2.6 *Schematic diagram of possible modules in a modern box malting plant*

to perform other functions at an early date, because of lack of space. Some distilleries, such as Ledaig (Tobermory, Isle of Mull) never had a malting house, for the same reason. However, many distilleries gave up malting their own barley only in relatively recent years; these include Ardbeg, Benrinnes, Glen Grant and Glen Garioch.

The malting of barley for distilleries is a similar process to malting for breweries (Section 2.6.2), although there are two major differences. Firstly, the distiller needs only lightly kilned malts; colored and roasted malts are of interest only to the brewer. Secondly, some distillers require peat fire dried malt, to give a smoky flavor to some or all of their products. A few brewers also use some smoked malts for specialist beers (Section 2.6.13), but the vast majority of malts destined for beer production are hot air dried.

The biological and chemical changes that occur during malting of barley are described in Section 2.6.2, so the following paragraphs are limited to a discussion of modern malting plants and the role of peat.

The traditional floor malting process is outlined in Section 2.6.2. The majority of modern malting plants use highly automated processes that can give annual outputs of over 100 000 tonnes of malt, with more economical use of labor and space, and with reduced water and energy consumption. Modern plants are either of the box or tower types, with the malting processes of washing, steeping, germination and kiln drying being essentially horizontal in the former and vertical in the latter. Figure 3.2.6 depicts possible arrangements of modules in a box malting plant. One version of a tower malting plant is described in Section 2.6.2. In Figure 3.2.6, the rotating drum washer allows barley to absorb *ca.* 25% of its own weight of water (in 30 min) ready for the steeping phase. Washing removes fungal spores and although intensive, uses only 0.8 m^3/tonne of water. The barley is then transferred to a flat bottomed steep or a series of conical steeps. The former typically hold around 500 tonnes of barley, with the rotating screw supplying the steeping water, discharging the spent steeping water, giving forced aeration during the wet phase and extracting CO_2 during the dry phase. Conical steeps hold around 50 tonnes of barley each and several are arranged in parallel for dealing with large batches. Again, there is forced aeration during wet steeping and CO_2 extraction during the dry phase.

Some malting plants carry out the entire malting process in large automated containers known as germinating and kilning vessels (GKVs), thus washing/steeping, germination and kilning all occur in an accurately controlled single vessel. This, and the procedures mentioned in the previous paragraph are expensive to install, but increased malt output together with reduced water, energy and labor costs leads to greater cost effectiveness compared with traditional floor maltings.

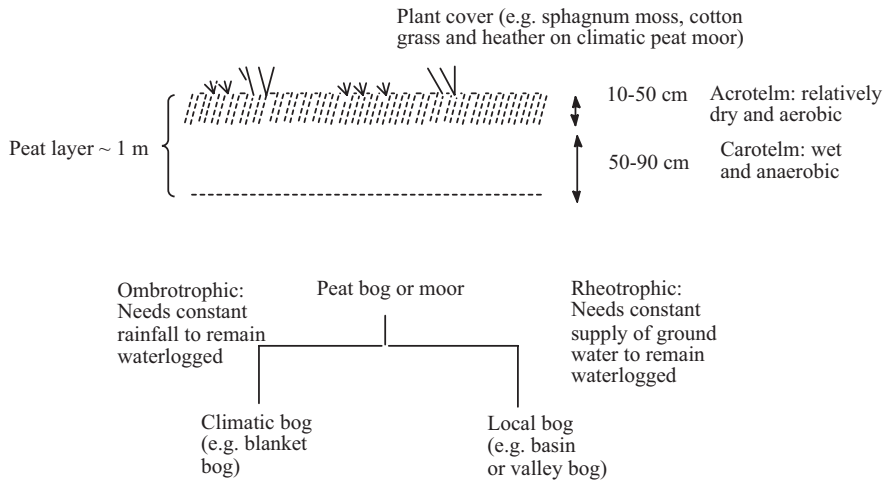

Figure 3.2.7 *Simplified anatomy of a peat moor and classification of peat bogs that supply peat for the smoking of malted barley in the production of Scotch malt whisky*

Scotch malt whiskies vary greatly in smoke character, from the highly smoky products of Islay (and the islands in general) to certain nonsmoky, cleaner malts of the Highlands (e.g. Glengoyne) and the Lowlands (e.g. Auchentoshan). Some distilleries produce malt whiskies of both types: Springbank distillery, for example, produces a smoky malt known as Longrow, besides its normal products.

Smokiness is derived from the smoke emanating from peat fires used to dry or kiln the malt after germination has proceeded far enough. For that reason, malt whiskies made using smoked malt are often known as peated malts. Up to the instalment of hot air kilns, all malted barley was dried over peat or wood fires, so that all malt whiskies prior to the late nineteenth century were smoky in character.

Peat moors and bogs cover a substantial area of Scotland, especially western and northern regions, including islands such as Islay and mainland Orkney. Peat is defined as the sediment formed by the decomposition of dead plant material under waterlogged conditions. It takes about 1000 years to form a 1 m thick layer of peat, which can be formed from almost any plant source – mosses and other bryophytes, grasses, shrubs (like heather and bilberry) and trees. Peat moors and bogs can be classified broadly as climatic bogs (such as blanket bog of the western isles) or local bogs, as outlined in Figure 3.2.7. Thus the plant species that have produced peat over two centuries vary widely. The humic substances (derived from specific plant materials by decomposition under specific geological, climatic and microbiological conditions) will differ from area to area. Their pyrolysis products (in the smoke of burning peat) will likewise vary, although there will be many common products, irrespective of the origin of the peat. Indeed, it has been possible to differentiate peats from various locations using infrared spectroscopy and analyzing the data using principal component discriminant function analysis (Harrison *et al*., 2006).

The humic substances of peat include the water insoluble humic acid and the water soluble fulvic acid; although written in the singular, they both contain a very large number of chemical compounds. They are formed by the oxidative degradation of biomacromolecules derived from plant tissues, such as carbohydrates, lignins, lipids and proteins. Humic material is a large supramolecular structure of relatively small molecules ($<$1000 Da molecular mass) held together by weak dispersive forces (hydrogen bonding, dipole–dipole forces, π–π forces, CH–π forces and van der Waals forces) (Fiorentino *et al.*, 2006; Piccolo, 2002). Humic acid is composed of large supramolecules, whose individual molecules contain phenol-like, lignin-like, quinoline

core units, with short carbohydrate, fatty acid and peptide chains. The core units are highly oxidized, the oxygen being present in carboxylic acid groups, phenolic OH functions, ether linkages and ketone (and quinone) functions (Peña-Mendez *et al.*, 2006). The fulvic acid fraction appears to be a supramolecular mixture of smaller polyphenol, carbohydrate and peptide molecules (Gonzalez *et al.*, 2003).

The burning of peat leads to the formation of pyrolysis products (thermal degradation products when there is inadequate supply of oxygen for combustion) that are typical of the humic fractions; humic acid, fulvic acid and humin. Typical pyrolysis products of humic acid include phenolic compounds, such as 2,4-dimethylphenol, guaiacol, 4-methylcatechol and 4-vinylphenol, benzoic acid derivatives, such as benzoic acid itself, syringic acid and vanillic acid, reflecting the polyphenol/lignin character humic acid acid molecules (Gonzalez *et al.*, 2003). Other pyrolysis products, such as 2-acetylfuran and pentanedione can be considered as being derived from carbohydrate units in humic acid. Typical carbohydrate pyrolysis products, such as furfuraldehyde, furanone, hydroxydihydropyranones and levoglucosenone were more prevalent in the pyrolysis of fulvic acid. Products indicating the presence of polyphenol/lignin moeities and peptide moeities in fulvic acid were also observed (González *et al.*, 2003). See Section 3.2.6 for further discussion of pyrolysis compounds in relation to the organoleptic character of Scotch malt whiskies.

The peat for use in kilning is dug in narrow strips and the briquettes are stacked in small pyramid formations indoors to dry. Increasing production of Scotch whisky over the years has led to some peat moor sites being exhausted, so that some distilleries, such as Springbank (Campbeltown) have to import peat from Islay or other areas. Like many other industries, the Scotch whisky industry pays attention to environmental issues, so there are in operation several methods that either increase the efficiency of the smoking of malted barley process and/or cut down the quantity of peat used in the smoking process.

Three distilleries on Islay have malted their own barley using somewhat different smoking techniques to this effect. In the 1980s, Laphroaig used peat smoke for drying malt over rather more than half the kilning time; the rest of the time the malt is dried with hot air (Wilson, 1985b). At around the same period, Bowmore distillery, on the other hand, used dried peat that was ground to a coarse powder and exposed to a smokeless fire used to dry the malt. The small particle size of the peat increases its smoke yield (Wilson, 1985b). In both uses, however, much of the smoke escapes through the pagoda roof and contact time with the barley will be relatively short.

The more traditional approach to smoking the malt is exemplified by the new Kilchoman distillery, which at the time of writing (uniquely) actually grows and malts its own barley, which makes up about one third of the grain bill, the remainder coming from the Port Ellen malting plant. At Kilchoman, the germinated barley, containing 30–35% moisture, is transferred from the malting floor (Figure 3.2.5) to the kiln, where it is exposed to a peat fire that was started 8 h previously. The malt lies on a perforated floor above the fire and the smoke is drawn through the bed of malt by a fan. This continues for 8 h, after which time the peat fire is extinguished and the malt is dried for a further 30 h by warm air. The malt now has 4–5% moisture content with 18–23 ppm phenolic content from the peat smoke; it is normally used for production within six weeks.

Probably the most efficient smoking of malt can be achieved using rotating drum kilns at larger malting plants, such as Port Ellen (Islay). Here contact time between malt and smoke is much longer, the drum kilns providing a relatively closed environment.

The next stage in Scotch whisky production is mashing, and for grain whiskies this includes cereal cooking. Mashing is the process whereby amylase and limit dextrinase enzymes hydrolyze most of the soluble starch molecules (which are extracted from the crushed grains by the hot water) to fermentable sugars. Other reactions occur during mashing. These, and details of other aspects of mashing are described in Section 2.6.2, so discussion here is limited to details that are more specific to Scotch whisky production.

In the case of malt whisky, crushed malt and water are the only ingredients of the mash, which in some distilleries is still carried out in cast iron vessels with perforated false bottoms and turning rakes. Some malt whisky distilleries now use water jacketed stainless steel mashing vessels (e.g. Balmenach, Speyside). In the

production of grain whisky, the mash is a slurry of milled malt (10–20%) and a cooked slurry of milled grains of wheat and/or maize. Traditional cereal cookers are large horizontal, cylindrical pressure cookers, operating with continuous batches of cereals. The malt grist supplies some of the soluble starch and all of the diastase enzymes, whereas most of the soluble starch comes from the cooked cereals. Cooking consists of heating a slurry of milled grains and water (approximately 3:8 w:w) slowly to 85° C and then at *ca*. 140 °C under pressure for about 15 minutes. This process gelatinizes the starch cells in the grain flour via disruption of the cell walls, making the starch molecules more amenable to hydrolysis by diastase enzymes. The cooking slurry is then transferred to the mash tun, where at a predetermined initial mashing temperature (see Section 2.6.2), the grist of high diastase malt is added and mashing begins.

The cooking conditions in grain whisky distilleries are essentially those designed for maize, even though wheat is now the major cereal. Under these conditions, wheat delivers less alcohol per tonne of grains than maize. It has been found that on a laboratory scale, a lower cooking temperature (85 °C, as opposed to142 °C) of wheat led to a large increase in potential ethanol yield, irrespective of whether high or low nitrogen wheat was used (Agu *et al*., 2008).

In many malt whisky distilleries, the mashing program involves firstly a residence at 65 °C, followed by draining of the wort and subjecting the grist to two further residences, with fresh water at 75 °C and 85 °C. The worts from the first two residences are mixed, cooled and fermented, whereas the wort from the last stage is used to start the next mashing programme, being too low in fermentable sugars. Other malt whisky distilleries and grain whisky distilleries mash at a single temperature (∼65 °C) for about 90 minutes and then sparge with water at ∼75°C.

Unlike in the brewing of modern beers (Section 2.6.2), the wort for whisky production is not boiled prior to fermentation and so is nonsterile. It contains diastase and other enzymes, many of which may be active well into fermentation. Also, the wort contains a range of thermophilic microflora whose activity lowers the mash pH toward the end of the mashing period and into the fermentation period. In a Japanese malt whisky distillery, it was found that the lactic acid concentration at the beginning of wort transport (to the wash back or fermentation vessel) was only half of that at the beginning of sparging (520 μg/l) (Takatani and Ikemoto, 2004). Likewise, the level of acetic acid was much higher at the start of sparging (185 μg/l, as opposed to 15 μg/l at the start of wort transport).

The presence of microorganisms in the wort, lower wort pH and the presence of starch hydrolytic enzymes (especially limit dextrinase) in the wort all have important influences on the organoleptic character of the new make spirit (Takatani and Ikemoto, 2004) and on the fermentability (ethanol yield) of the wort (Takatani and Ikemoto, 2004; Bryce *et al*., 2004). Laboratory-scale malt whisky mashes acidified with either lactic acid or acetic acid (reducing the pH from ∼5.9 to ∼5.5) showed slightly improved sugar yield and a higher amino acid content. The resulting worts fermented more rapidly than conventional worts (Takatani and Ikemoto, 2004).

Fermentability of the wort is of prime importance in the production of Scotch whisky and indeed more generally in the production of spirits from cereals. Even a slight increase in fermentability, leading to increased spirit yield, is of high economic importance to a distillery. Oligosaccharides that have α-(1→6)-glycosidic branches (see Figure 2.6.4, Section 2.6.2) are not easily metabolized by yeasts and hence are essentially nonfermentable. These sugars are known as branched α-glucans or branched (limit) dextrins and are formed during mashing by the action of α- and β-amylases on the branched starch amylopectin (Section 2.6.2). Of the diastatic enzymes, only limit dextrinase can hydrolyze α-(1→6)-glycosidic linkages and hence full activity of this enzyme is vital for maximum fermentability of the wort and consequently for maximum spirit production.

Bryce and coworkers (2004) have shown that limit dextrinase activity in laboratory-scale mashes was higher at pH 4.4 than at the normal mash pH of 5.5. Furthermore, limit dextrinase activity of wort at pH 5.5 increased as fermentation proceeded with a drop in pH from 5.5 to 4.0. A comparable fermentation of

wort buffered at pH 5.5 also showed increased limit dextrinase activity, but not to the same extent as the unbuffered fermentation. Limit dextrinase in malt is mostly protein bound and inactive. Furthermore, the purified enzyme is inhibited by two natural barley proteins at pH 5.0–7.0, but not at pH 4.5 (MacGregor *et al.*, 1994). It thus appears that reduced mash or fermentation pH activates 'free' limit dextrinase from its bound form and prevents protein derived inhibition.

Support for the above findings comes from the common practice in grain distilleries of adding 'backset' (stillage or spent wash) in place of 40% of the water used to cook the wheat during mashing. Some distilleries also add 'backset' to the wash back. The reasons for this are to reduce water consumption and energy expenditure. Stillage is basically the wash stripped of ethanol and most other volatiles. It has considerable acidity. Experiments with laboratory-scale grain mashing (wheat:barley = 9:1) and subsequent fermentation showed that addition of 40% backset generally enhanced the mash activity of limit dextrinase (Cooper *et al.*, 2004). α-Amylase activity was adversely affected in the 40% backset wash, whose pH was *ca.* 4.5. Limit dextrinase peak activity was lower during fermentations of wort with 40% added backset (pH 4.5–4.0) compared with fermentations of control wort at (pH 6.0–4.0). However, in the latter case, significant enzyme activity occurred during only about half the fermentation period, reaching maximum values when the pH had dropped to 4.0–4.5. With added backset, enzyme activity was present over the entire fermentation period.

After the mashing period (up to 1.5 h), most malt whisky distilleries transfer the wort and sparges to the wash back (fermentation vessel) by filtration through the spent husks and grains of the coarsely crushed malt. Nearly all distilleries now use a heat exchanger (cooler in Figure 3.2.3) to cool the wort and sparges to suitable fermentation temperatures. Edradour distillery still uses an open cooling vessel (a coolship – see Section 2.6.3). Grain distilleries mill their grains for cooking and mashing to powder using hammer mills. This gives maximum conversion and extraction during mashing, but requires the use of a mash filter to remove the majority of suspended solids before addition of the yeast for fermentation.

Like breweries, distilleries possess their own strains of yeast, grown from pure strains in sterile conditions. Distiller's, brewer's and baker's yeast are all used, with some distillers using several strains for the fermentation in order to balance yield of spirit against flavor. Most fermentations begin at temperatures around 20 °C, increasing to over 30 °C in some malt whisky distilleries where no temperature control is exercised.

Brewer's yeast is thought to influence the organoleptic qualities of malt whisky both directly, by producing a range of flavor active metabolic end products and indirectly, by its influence on other microorganisms, especially lactic acid bacteria (LAB). Distillates of brewer's yeast fermented malt worts have been reported to have higher concentrations of fruity esters, fatty methional and sweet (2*H*)-furanones than distillates from distiller's yeast fermentations (Wanikawa *et al.*, 2004). These were considered to be direct flavor contributions from yeast metabolism. Fermentations of malt wort with brewer's yeast were shown to give washes richer in certain esters (e.g. ethyl 9-decanoate and ethyl 2-methyl butyrate) than those fermented with distiller's yeast. The same authors (Wanikawa *et al.*, 2004) have reported that brewer's yeast fermentations, in the presence of LAB, give higher concentrations of 10-hydroxypalmitic acid and 10-hydroxystearic acid in the wash than corresponding fermentations with distiller's yeast and LAB. These hydroxy acids, derived from fatty acids such as oleic acid, are thought to be precursors of γ-lactones, such as γ-dodecalactone, that are responsible for sweet, fatty notes in malt whiskies.

Because whisky production involves the fermentation of unboiled (nonsterile) wort, microorganisms that survive the mashing regime will be transferred in the wort to the wash back and will be present during fermentation, upon which they may have considerable influence. Although thermophilic bacteria, such as *Streptococcus thermophilus* are present, the most important from the point of view of fermentation are LAB, particularly those of the genus *Lactobaccillus*. Lactic acid bacteria (discussed more fully in Chapter 2.3) are either of the homofermentative (they convert sugars to lactate) or heterofermentative type (they convert sugars to lactate, acetate and CO_2). The former can metabolize only hexose sugars, whereas the latter can metabolize both hexoses and pentoses. *Saccharomyces cerevisiae* cannot utilize pentoses, hence these sugars,

though in a minority in malt wort, provide a ready source of carbon for the growth of heterofermentative LAB in the early and middle stages of fermentation (Priest *et al.,* 2004). The principal LAB at these stages are *Lactobacillus brevis*, *Lb. fermentum* and *Lb. ferintoshensis*, but populations of these will normally be low, so *S. cerevisiae* dominates. As fermentation proceeds, the *S. cerevisiae* cells die off, pH drops, temperature increases and then drops, and populations of LAB change. Toward the end of fermentation, homofermentative LAB, particularly, *Lb. paracasei*, *Lb. acidophilus* and *Lb. delbruckii*, actually dominate. For example, after 120 h of fermentation, the population of *S. cerevisiae* are $\sim 10^4$ cells/ml (especially if a brewers' yeast, rather than distiller's yeast strain is used), whilst LAB populations may be above $\sim 10^8$ cells/ml (Wanikawa *et al.*, 2004). This means that any influence of LAB on the organoliptic character of the spirit is likely to be more pronounced when lengthy fermentation periods are used.

Priest *et al.* (2004) identified lactic acid bacteria in late fermentation samples of 23 Scotch malt whisky distilleries by partial sequencing of the CRNA gene. They were strains of *Lb. brevis*, *Lb. fermentum* and *Lb. paracasei* mostly, but strains of *Lb. pentosus* and *Lb. plantarum* were also found, along with a new species, named *Lb. ferintoshensis* (after Ferintosh, an early brand of whisky). The more detailed fingerprinting technique of random amplified polymorphic DNA fingerprinting (RAPD) showed the strains of specific species (say *Lb. paracasei*) from different distilleries to be generally different – each distillery has its own distinct bacterial flora. The same group also found that the floral spectrum isolated from samples of Glenkinchie (Figure 3.2.1) wash remained the same over 11 months of sampling. It also appears that changes in raw materials (e.g. change in malt) have little impact on the strains present in the distillery (Simpson, 2004).

Lactic acid bacteria may influence the sensory properties of scotch malt whisky in several ways, by production of specific metabolites that survive distillation and maturation, production of metabolites that are precursors for flavor active compounds in the mature spirit, alteration of the chemical processes occurring during distillation, as a result of lower wash pH and the presence of enhanced levels of acetate and lactate in the wash.

Examples of the first kind include the production of higher levels of certain esters and phenolic compounds, such as vinylguaiacol and 4-vinlyphenol (by decarboxylation of ferulic acid and coumaric acid, respectively), in new make spirit (Priest *et al.*, 2004). Likewise, enhanced levels of β-damascenone were found in the new make spirit from LAB-containing fermentations (van Beek and Priest, 2000). All the above components are also found in mature whiskies, where β-damascenone in particular is considered to be important (floral, herbal notes, sometimes tobacco-like). Also hydroxyalkanoic acids produced in the wash of fermentations in the presence of LAB are thought to be precursors of γ-lactones (sweet, fatty or waxy notes) (Wanikawa *et al.*, 2004).

In traditional Scotch whisky production, spirit yield, savings in energy and materials, and dispersal of waste have long been items of interest. Yield of spirit is related to both yeast activity and effective conversion of starch to fermentable sugars during the cooking and mashing stages. Energy savings have been achieved to a limited degree by using heat exchange systems (Section 3.2.4), but the most energetically costly processes of cereal cooking, mashing and distillation are essentially unaltered since the middle of the twentieth century. Consequently, there has been interest in developing yeast strains that are able to secrete diastase enzymes to hydrolyze grain starch and ferment the resulting sugars to produce a wash for grain whisky in a single low temperature step. This process would cut out the mashing step at least, the cooking step still being needed to produce gelatinized starch. *S. cerevisiae* does not, except for *S. cerevisiae* var. *diastaticus*, secrete diastases and the addition of exogenous enzymes is not permitted in the production of Scotch whisky.

Early attempts at achieving starch hydrolysis and fermentation in a single step using a whisky yeast *S. cerevisiae* var. *diastaticus* cross (or hybrid) had only limited success, because of the low levels of diastatic enzymes released by this hybrid (Pretorius, 1997). *Lipomyces kononenkoae* is a fungus that efficiently degrades raw starch, so four whisky yeast strains (and a commercial wine yeast strain, as control) were transformed

with integration plasmids containing the LKA1 and LKA2 α-amylase genes from *L. kononenkoae* and tested on starch containing media (La Grange-Nel *et al.*, 2004). These fermentation trials indicated that the GMOs produced up to 66% of the theoretical ethanol yield, but those based on wine yeasts (such as VIN13) may be better candidates for the development of starch degrading whisky yeasts than contemporary whisky yeasts.

Although there are obvious economic advantages that could be achieved by the development and use of starch degrading SMO yeasts, quite aside from the general resistance toward the use of GMOs, it would need to be shown that the resulting spirit is organoleptically indistinguishable from traditional Scotch whisky before such yeasts could be accepted by the industry.

3.2.4 Distillation

The copper pot still is central to Scotch malt whisky production. It is also central to the traditional images of malt whisky distilleries and their products, along with the pagoda roof of the maltings, although this is now merely a decoration in all but a handful of Scotch malt whisky distilleries.

As with brewery kettles (Section 2.6.3), pot stills were originally constructed of copper because of the malleability, ductility and superior heat conduction of that metal. Unlike breweries, however, copper is still very much in evidence in Scotch malt whisky distilleries, despite some disadvantages such as erosion (pitting) and difficulties of maintenance. In most distilleries, working at less than a seven day per week production, most stills will last 10–20 years before needing replacement. The bottom half of a wash still will normally last twice as long as the top half (∼20 and 10 years respectively) and the reverse is true for a spirit still. Naturally, a more intensive production year after year would shorten the useful lifetime of both wash and spirit stills. In the nineteenth and early twentieth centuries, engineering works manufactured pot stills in a wide range of dimensions and many distilleries have taken pains in the past to add or replace stills with the same dimensions as the old. However, Scotch malt whisky distilleries nowadays have a much more uniform range of modern pot stills, although there is still plenty of diversity, especially in capacity, as can be seen in Figure 3.2.8. Small capacity stills can be seen at the Edradour, Macallan and Oban distilleries, whereas the Imperial and Glenmorangie distilleries possess some of the largest pot stills in Scotland. The simplified anatomy of a pot still is shown in Figure 3.2.9. Most Scotch malt whisky is double distilled, distillation firstly being carried out in the wash stills and then continued in the spirits stills (Figure 3.2.8), so that in many distilleries the stills are arranged in pairs. Wash stills are generally of rather greater capacity than spirits stills, those at Glengoyne distillery (16 780 l or 3729 gallons; 5000 l or 1111 gallons, respectively) being typical. Imperial distillery (Speyside) had 36 000 l wash stills, while in contrast, Macallan distillery (also Speyside) has 11 000 l wash stills and 3600 l spirit stills) (Figure 3.2.8). The height of the still (the distance of the still head from the boiler bottom) influences the nature of the spirit. A tall still allows a greater number of condensation/evaporation (reflux) cycles to occur during distillation, giving a somewhat more pure spirit, with fewer fusel alcohol and ester congeners. A short still, on the other hand, tends to produce a more heavily flavored spirit. A few distilleries once possessed Lomond stills, which had rectifying plates in the wide still neck. These could either be filled with cold water or left empty. When the plates were rotated into the horizontal position, refluxing action was maximized and a cleaner spirit resulted. The opposite situation applied when the plates were in the vertical position, whence a heavier spirit was produced. Such distilleries made varying styles of whisky, some of which are still available (see Section 3.2.6).

Some pot stills have a cooling system on the lyne arm (or lye pipe) (Figure 3.2.9), but all have cooled condensers. Most distilleries now have vertical shell and tube counter flow condensers attached to the lyne arm, where the vapors and liquids are cooled by cold water flow in the inner tubes – rather like a multiple Liebig condenser in reverse. Shell and tube condensers can be seen in Figure 3.2.8. Some distilleries employ automated temperature control of the condensers, for consistent distillate character.

Many distillers are of the opinion that the geometry of the lyne arm and the type of condenser strongly influence the nature of the spirit, and is likely that a particular distillery's stills are the result of much trial and error. In some cases, configurations are partly decided by circumstances – e.g. short lyne arms in cramped distilleries, such as Oban and Ledaig.

The original type of condenser is known as a worm tub condenser. Here the tube from the lyne arm is formed into a coil (the worm), which is immersed in a vat (the tub) of cold water, often standing against the distillery's outside wall (Figure 3.2.9). Distilleries where worm tub condensers are in operation (2009) include Balmenach (Speyside), Benrinnes (Speyside), Edradour (central Highlands), Mortlach (Speyside), Oban (western Highlands), Pulteney (northern Highlands) and Talisker (Skye) (see Figure 3.2.1). Worm tub condensers can also be seen in some rum and cachaça distilleries (Section 3.5.3).

Originally, pot stills were heated by peat or wood fires, which gave way to coal in many distilleries in the nineteenth century. Coal firing in turn gave way to heavy oil or gas firing in the twentieth century. Nowadays,

the majority of pot stills are heated indirectly with steam generated by the heating of water in external oil or gas fired boilers. The steam most likely heats the still via internal coils, such as those illustrated in Figure 3.2.8.

Because of the large amount of heat required for distillation, some distilleries operate heat exchange or recycling systems. In the 1980s, Bowmore distillery (Islay), operated a system whereby some of the hot water from the condensers (produced by condensation of the hot vapor) was led to a water/air heat exchanger, where it supplied the hot air for kilning the malt (Wilson, 1985b). Bowmore is one of the few distilleries that still has its own malting house, in this case a traditional floor maltings. Some of the hot condenser water was also used to produce steam (at reduced pressure) to heat the still and mashing water. Processes like these, although they require considerable capital investment, are claimed to reduce fuel costs by 50% with payback on investment in around three years (Wilson, 1985b).

The Glen Garioch distillery at Old Meldrum, near Aberdeen, in the 1970s employed a waste heat recovery system that provided heat for growing tomatoes and other plants in greenhouses built adjacent to the distillery. The produce was sold locally, and although the scheme was reasonably successful, it was terminated in the 1980s. Schemes such as the ones outlined above are useful in lowering the temperature of the water when it is ultimately discharged into streams and rivers.

Environmental regulations governing factory (including distillery) discharge water temperatures are likely to tighten, so that distilleries with no heat exchange schemes may need to lower the temperature of the condenser water by refrigeration, which expends more energy and creates CO_2 emissions. On a more positive note, refrigeration of the input condenser water will maximize the spirit yield and with controlled flow rate and temperature should assure distillate consistency (Halliday, 2004).

Sets of two pot stills are used in the big majority of malt whisky distilleries to give double distilled spirit, but a few, such as Auchentoshan (Lowlands) produced triple distilled spirit from sets of three pot stills. With reference to Figure 3.2.3(a), the first distillation in a double distillation process occurs in the 'wash still,' whereas the second distillation occurs in the 'spirit' or 'low wines still.'

The wash still is charged with wash (~8% ABV) and slowly brought to the boil. The vapor, containing about 25–30% ethanol (v:v), condenses to liquid in the condenser, whence this first distillate is run into the low wines safe. Here, it is monitored for strength and quality and is then run into a vessel known as the low wines and feints receiver.

This first distillate, called low wines, is first mixed with feints and foreshots from a previous running of the spirit still. Then this mixture is transferred to the spirit still and brought to the boil for the second distillation. The second distillate is monitored carefully at the spirit safe, as follows. The first spirits to arrive at the spirit safe (the first 15% or so of the run) are known as foreshots or leads; this fraction is not considered fit for consumption, so it is diverted via the spirit safe to the low wines and feints receiver to be redistilled with the next batch of low wines.

The next fraction to arrive at the spirits safe, after about 20 minutes of distillation and composing around 15% of the total distillate, is the spirit or middle cut. This fraction is collected in the spirits receiver while it has an ethanol concentration of 68–73% (v:v), as monitored by the still operator at the spirit safe.

When the ethanol content of the middle cut suddenly drops to about 60% (v:v), the next (final) fraction, known as feints, is diverted (about 40% of the total distillate) to the low wines and feints receiver to join the foreshots and low wines already there. This mixture will be redistilled later in one of the spirit stills. After this, the distillation is stopped and the residual liquid (spent lees) is allowed to cool and then discharged to waste.

The spirit still is charged with a new batch of low wines, foreshots and feints, which are distilled to give a fresh middle cut fraction to the spirits receiver. The middle cut fractions from several batches of distillations are combined in a vat before being transferred to casks to be matured in a warehouse (Section 3.2.5).

Scotch grain whisky is traditionally made by continuous distillation in a Coffey or similar still. These stills normally consist of two columns, the 'analyzer' and the 'rectifier,' although a third column can be added for the production of neutral spirits, but not for Scotch whisky. The Coffey still is described in Section 3.1.3

(Figure 3.1.6), where it can be seen that the analyzer and rectifier correspond very broadly to the wash still and spirit still of a pot still system. The continuous still is a multiple distillation system capable of producing a much purer (and higher strength) spirit than double distillation using pot stills.

The wash, after being preheated in the rectifier column, is introduced at the top of the analyzer column, while at the same time, steam enters the bottom of the column. As the wash proceeds downs the column, via the perforated plates, it is heated by the rising steam. The aqueous ethanolic vapor, called low wines, rises to the top of the column and is fed into the rectifier. The residual liquid reaching the bottom of the analyzer (spent wash or stillage) consists of water and dissolved solids mainly, and is discharged to waste.

The low wines are redistilled many times in the rectifier column, where the less volatile fractions reach the bottom and are pumped back to the analyzer for recycling. The spirit fraction is run off from the top of the rectifier through the spirit safe to the spirit receiver. It is frequently monitored for alcoholic strength, which is much higher than the ∼70% (v:v) strength of spirit from standard twin pot stills. Nevertheless, according to Council Regulation (EEC) No. 1576/89, the alcoholic strength must be less than 94.8% (v:v). New make grain whisky is diluted with pure water to ∼68% (v:v) before being transferred to cask for maturation in the warehouse (Section 3.2.5).

3.2.5 Maturation, Blending and Other Postdistillation Processes

All Scotch whisky by law must be aged for a minimum of three years in wooden casks. In practice, the benefits of long (but not too long!) cask maturation are well recognized and most Scotch whiskies spend more than five years in cask; 15–21 years are often considered optimum cask maturation times for many malt whiskies. Depending on the character of the whisky and the quality of the cask, much longer than 21 years in cask can be detrimental, leading to a wood dominated palate. Some distillers maintain that cask maturation and blending make the biggest contribution to the whisky's final character. Certainly, the importance of these two processes should not be under-rated.

In the days before 1824, when much of the malt whisky in the highlands was produced from illicit stills, large casks may not have been widely used, being too expensive and too conspicuous for an illegal product. Widespread use of casks probably started at the lowlands grain distilleries and in the highlands after 1824, when legal distillation became a more financially attractive business. Initially, a wide variety of casks would have been used – refill Burgundy, claret, Sherry and Port casks, since in those days much wine from Europe was shipped to the British Isles in cask. The improvement in quality arising from time in wood soon became apparent and Sherry, especially ex-oloroso casks gradually became popular with some malt whisky distilleries, during the twentieth century. Indeed, distilleries like the Macallan have rows of oloroso casks in Jerez bodegas (Section 2.10.2) earmarked for shipping to Scotland once their contents have been bottled. Additionally, since US law requires Bourbon whiskey to be matured in new charred oak casks (which must not be reused for ageing Bourbon) and there are many connections between Scotch whisky Bourbon whiskey distillers, there is a steady supply of ex-Bourbon casks for the maturation of Scotch whisky.

Nowadays casks used for Scotch whisky ageing are of either (first fill or refill) American oak (Bourbon casks), (first fill or refill) European oak (usually Sherry casks) or rejuvenated oak (Halliday, 2004). Casks of rejuvenated oak are made from selected staves of used casks. It is common practice to ship once used Bourbon cask staves to Scotland, where they are built into casks with larger (non-Bourbon) heads, thus increasing their capacity from 180 l to 250 l (a 'hogshead') (Delevante, 2005). Sherry butts are of 500 l capacity. It will be discussed later that whisky ages more rapidly in smaller casks. By law, Bourbon casks must be charred, just enough to singe the internal surface of the staves and cause tiny cracks to appear. Both these factors influence the character of Scotch whisky aged in ex-Bourbon casks. Many Scotch whisky distillers prefer ex-Bourbon

casks to ex-Sherry casks, because they feel the former allow more of the distillate's own character to shine through. Many malt whiskies are vatted (blended) from components out of both kinds of casks.

The changes that occur to Scotch whisky during its long sojourn in oak casks are summarized below:

- Oxidation and subsequent reactions
- Leaching of substances from the cask material
- Adsorption of substances onto the cask material
- Loss of ethanol.

The first two can be considered as contributing to mature flavor and masking of immature flavor, whilst the first and third may contribute to loss of immature or undesirable flavors.

These processes, including their rates, are dependent on a number of factors, the most important of which are listed next:

- Temperature of storage
- Humidity of storage
- Size (capacity) of the cask
- Configuration of stored casks (on their sides or on end)
- Nature of the wood – American or European oak
- Cask history – Bourbon (charred) or Sherry (etc.) (first fill or refill)
- Alcoholic strength of the new make whisky.

An important part of the ageing process is oxidation. Ingress of oxygen through the pores of the wood promotes slow oxidation of new make spirit components such as fusel alcohols, ethanol and aldehydes to carboxylic acids in some cases, which react slowly with alcohols to produce fruity esters. The flavor contribution of these esters in the mature spirit may not be high, however, depending on the other components of the whisky matrix (Steele *et al*., 2004). As ageing proceeds, wood lignins are hydrolyzed to phenolic adlehydes, which are released into the whisky. Also, oak tannins, such as those of ellagic and gallic acids, and lignins are leached from the wood during maturation. The tannins and lignins are strongly antioxidant and probably prevent excessive oxidation of alcohols and aldehydes, including phenolic aldehydes (Conner *et al*., 2004). However, some of the latter are oxidized to flavor active compounds like syringaldehyde and vanillin during ageing.

Another important factor in the whisky maturation process is the leaching of hydrolyzable tannins (Section 5.8.6), lignin hydrolysis products and pyrolysis products from the wood. The last named include the whisky lactones (*cis*- and *trans*-β-methyl-γ-octalactone), formed during the charring of Bourbon casks or the toasting of wine casks. Also included here are colored compounds, which give the finished whisky a mature appearance; a deep or dark golden color is expected in a mature whisky. As Bourbon casks are used and reused, the overall quantity of substances leached from the wood diminishes and the depth at which leaching occurs increases. In some experiments with cask staves prepared from American White oak (*Querous alba*), it was found that repeated exposure to whisky led to less leaching. New charred (unused) Bourbon staves had more extractable lignin hydrolysis products, whisky lactones and colored substances than either used Bourbon or first fill Scotch staves, and 'exhausted' Scotch staves had the least (Conner *et al*., 1992). It has been suggested that the concentrations of lignin derived guaiacyl and syringyl compounds could be used as an indicator of cask exhaustion (Conner *et al*., 1993).

Apart from aroma and flavor changes, ageing is responsible for improved 'mouthfeel' – a smooth and harmonious texture, with no rough edges. Tannins are believed to contribute to mouthfeel (as in red wines – see Section 2.9.2), but if their concentrations are too high, the whisky may have bitter, harsh overtones

(Delevante 2005). Smoothness or mellowness of palate in malt whiskies is thought to be characterized by clusters or aggregates of ethanol and water molecules (e.g. $16C_2H_5OH{:}12H_2O$ (Nose *et al*., 2004). Tanaka *et al*. (2002) showed that total polyphenol concentration increased with increasing maturation time in oak. Results of titrations at pH 7 and pH 12 suggested that extracted polyphenols were oxidized during extended maturation and these oxidation products were better able to stabilize the ethanol–water clusters. More recently, Koga *et al*. (2007) have shown that reactive oxygen scavenging activity (free radical scavenging activity, H_2O_2 reduction activity under peroxidase coculture and peroxidase-like activity) of Japanese and Scotch malt whiskies increased with increased ageing in oak. About 20% of this activity was attributed to ellagic and tannic acids (derived from tannins) and lyoniresinol (derived from lignins). Koga *et al*. (2007) proposed that the reactive oxygen scavenging activity of mature whisky components prevent excessive stimulation of taste receptor cells in the mouth and the epidermal mucous membrane in the oral cavity. This excessive stimulation by reactive oxygen species (including hypothiocyanite ($OSCN^-$) ion produced by peroxidase oxidation of saliva thiocyanate) is thought to give harsh residual sensations associated with new make or young whisky.

As the whisky impregnates the wood, via the pores and the cracks caused by charring, certain aroma active compounds are adsorbed, especially if the cask is a new or first fill Bourbon cask. This can have beneficial and detrimental values. For example many organosulfur compounds have objectionable odors (e.g. bad egg or rotten cabbage notes) at high concentrations, but at levels close to their odor threshold values (OTV) (see Section 4.7.3) they can provide pleasant background aromas. Some, like certain thiophene derivatives, have plant-like or nutty aromas; others give rise to fruity, floral or solvent notes, more typical of carboxylate esters (Steele *et al*., 2004). Methyl 2-methyl 3-furyl disulfide (MMFDS), with an OTV of 0.015 μg/l (or ppb), is responsible for meaty notes, which can be very attractive in certain full bodied whiskies (Steele *et al*., 2004). A happy medium would be adsorption of sufficient quantities of organosulfur compounds, leaving residual levels that can contribute to the complexity of flavor. Although new make malt whisky has comparatively high copper ion content, this tends to decrease during ageing, as Cu^{2+} ions are bound strongly to ligands (probably lignins and tannins) in the wood (Adam *et al*., 2002).

Most Scotch malt whiskies are casked for ageing at about 68% ABV, but some, such as those at Glengoyne distillery start their maturation period at just under 64% ABV. Scotch grain whiskies are generally casked at around 68% ABV. At these alcoholic strengths, casks have a greater porosity for ethanol than for water, meaning that evaporation of ethanol is more rapid than evaporation of water and consequently the whiskies decline in alcoholic strength as ageing progresses. This loss of ethanol is known as the 'angels' share' and it has been calculated to amount to 11 million l per annum in the 1970s (Lichine, 1982).

Bourbon whiskeys and some other spirits start their aging at alcoholic strengths close to 55% (v:v) (Delevante, 2005). These, like the fortified wines Madeira, Port and Sherry (and others) (Chapter 2.10) of 17–20% ABV actually gain in alcoholic strength as maturation proceeds; at these alcoholic contents the cask wood is more porous toward water than ethanol.

The four factors contributing to Scotch whisky ageing (described above) are influenced by many storage parameters, other than cask origin or history (also described above). European oak is less dense than American oak, so that the whisky penetrates the former more quickly, leaches lignin hydrolysis products and tannins more rapidly and is exposed to rather more oxygen during ageing. Hence maturation in European oak casks tends to be more rapid and color development is faster, especially if ex-oloroso Sherry casks are used. Ex-Bourbon single fill casks also give good color development, because of the specific charring that is required by US law (Section 3.3.4).

Ageing rates also depend on cask capacity: the smaller the cask, the more rapid the ageing process. Bourbon is aged in 180 l casks (Section 3.3.4), but the standard cask sizes for Scotch whisky maturation are ∼250 l ('hogshead') and ∼500 l ('butt'). Ex-Bourbon casks are sometimes broken up into separate staves in the USA and are then shipped to Scotland, where they are used to construct larger casks. Other cask sizes are used to

mature Scotch whisky, but are comparatively rare. Maturation in general is known to proceed more rapidly in hot climates – especially when there are distinct variations in day and night temperatures. Scotch whisky must be matured in Scotland, which has a moist, temperate oceanic climate. Under these conditions, the oxidation, condensation, esterification and other reactions, and the leaching and hydrolysis of wood materials are slow – even necessitating warehouse heating in winter. Hence malt whiskies normally have a minimum of 10 years ageing, with 15–21 years often being regarded as optimum, whereas for rum matured in hot climates, 10 years is often considered to be more than sufficient.

The optimum temperature for whisky ageing has never been established. In experiments involving the maturation of Scotch whisky in 1.2 l mini casks (to aid rapid ageing – see next paragraph) at different temperatures, it was found that the lignin extractive profile of the whisky after eight weeks of ageing did not vary significantly with temperature (5–45 °C) (Steele *et al*., 2004). Only the synapaldehyde concentrations of warm matured whisky (45 °C) were significantly higher than those of cooler matured whisky (5 °C, 35 °C).

Warehouse humidity, as well as temperature, has an influence on the way Scotch whisky matures. In traditional dunnage warehouses, with earth or cinder floors, casks stacked on their sides three high on wooden runners mature their contents reasonably evenly. The humidity in such warehouses is usually high because of the permeable nature of the floor, especially if the warehouse is close to the sea, as in some highland distilleries, or adjacent to the sea, as in most of the Islay distilleries. Figure 3.2.10 shows casks of malt whisky in the traditional warehouse at Kilchoman distillery, Islay. In a humid atmosphere, evaporation from the casks is less, so that at the end of the maturation period there is less ullage (smaller air pockets) in the casks. Many distillers believe that malt whiskies aged in humid surroundings are softer and more rounded than those stored in drier warehouses, although they may need slightly longer maturation times. Much Scotch whisky is now transported in tankers to warehouses in central southern Scotland where they are transferred to oak casks. The casks are either stacked on their sides in high steel racks 12 or so high or on their ends on pallets six or so high. Although this is more efficient in space and manpower usage, it does raise some questions regarding maturation. In such warehouses, with concrete floors and high roofs, the casks experience

Figure 3.2.10 *Casks of malt whisky in the maturation warehouse at Kilchoman distillery, Islay.* Photo courtesy of Kilchoman Distillery, Scotland

different air circulation, humidity and temperature conditions according to their positions in the stack. Those at the top will experience the warmest and least humid conditions; the opposite to those at the bottom. Casks in the centre of a stack will experience less circulation of air. Ingress of oxygen, reaction rates and evaporation rates – in other words maturation rates – will vary somewhat according to the location of casks in the stack. Furthermore, modern warehouses are generally less well insulated than traditional stone walled and slate roofed dunnage warehouses, and are less humid. Both these factors favor more rapid ageing, but many distillers and blenders (who can sense subtle differences) claim that a malt whisky aged in a modern warehouse in the ways described above will be rather harsher and less rounded than the same whisky aged in a traditional warehouse, despite the practice of cask rotation in the former.

The production of just about all Scotch whisky, like most other spirits, involves blending as an important step. In most cases, even a single malt whisky will be a blend of malt spirits from the same distillery – a vatting of several casks of different distillation batches. These contributors can come from different seasons, but the label on the bottle must specify the age of the youngest spirit in the blend. Thus Springbank 10 year old indicates that the youngest whisky in the bottle has had 10 years in oak casks; this will be the major component, but there could well be 11 or 12 year old (or even older) components present.

Some Scotch malt whiskies are made up entirely of components distilled in the same season; this fact is sometimes indicated on the bottle label (e.g. Bowmore, distilled in 1966). At the other extreme, some distilleries offer limited quantities of malt whiskies bottled from single casks (i.e. unblended). These are known as 'single single malts,' and they too display a distillation date on the label – Glengoyne distillery produces an unusually wide range of these specialized items, which are named 'single cask.'

A blend of malt whiskies from several distilleries is known as a 'vatted malt.' These are not so common, but the independent bottlers (see Section 3.2.6) produce pleasant examples that are meant to typify the region of origin of their components. For this reason, they are often given names like 'Pride of Orkney.' Others have less descriptive names, such as Glenleven and Strathconon, but whatever the name, a vatted malt will be indicated on the label as (Highland) malt Scotch whisky, the word 'single' will be missing.

Scotch whisky per se (without words 'single' or 'malt' on the label) is a blend of grain whiskies and malt whiskies. Usually it will be a complex blend of spirits of varying ages, but as ever, the age of the youngest component must be quoted on the bottle label. Cheaper Scotch whiskies will include younger spirits (e.g. five year old) and a greater proportion (up to ~60%) of grain whiskies. More expensive versions (usually called 'de luxe' blends or given special names like 'Blue Label') are composed of more aged spirits (e.g. 12–27 year old) and have a higher proportion of malt whiskies (sometimes exceeding 70%).

In all the above examples, except single cask malt whiskies, success depends upon the skill of the blender. Indeed, the enormous growth in the export of Scotch whisky during the last century was as much a result of skilled blending as skilled marketing. The blenders are much prized individuals in distilleries and each company has its own closely guarded styles and methods of blending. The blenders' main job is to ensure high quality and uniformity (consistency) of the distillery's regular products. In a malt whisky distillery, he or she will advise on which casks are to be vatted for producing say, the 15 year old version, from year to year. For Scotch whiskies, the blender will decide on the various proportions of the various casks of malt whiskies that will be blended with the grain whiskies. In either case the blenders base their decisions on fine sensory evaluation skills and experience of what the company and its customers expect of the products.

Sensory evaluation of Scotch whisky is carried out via aroma only – by sniffing or 'nosing' the sample, usually after it has been diluted by pure water to 20% ABV. The dilution reduces the pungency due to the presence of ethanol and also helps release aroma compounds. Medium and long chain esters have more limited solubility at 20% ABV, so that volatile esters originally held in agglomerates are released into solution and/or into the headspace (Conner *et al.*, 1994). Evaluation can be performed by a single person, the head blender, or more likely these days, by a team of trained panellists, in which case standard procedures for sensory evaluation are used (Jack, 2003). In these procedures, special attention is paid to general preparation

Figure 3.2.11 *Bill McDowall nosing a sample at Glengoyne Distillery.* Photograph by courtesy of Glengoyne Distillery

and presentation of the sample, control of temperature and sample sharing, as well as experimental design, training of panelists and sensory room design. The panelists give scores for predetermined aroma descriptors and the results are collected and processed using sensory evaluation software, often being presented as spider diagrams (Section 4.7.4).

Nosing is carried out in the distiller sample room at around 21 °C, with the sample held in a tulip glass no more than 25% full, and equilibrated to room temperature (Figure 3.2.11). The chief blender will nose the whisky at different stages: as new make spirit, as aged spirit, prior to vatting and just prior to bottling. New make and many other spirit samples, as well as aroma evaluation standards, are stored in the sample room for comparison and reference purposes.

In most recent years, there have been attempts to correlate sensory and analytical data, the objective being to use analytical data to predict and control aroma/flavor character, thus enabling greater consistency. This is especially important, as new make malt spirits destined to be components of blended Scotch whiskies are often sold prior to maturation, with sensory character being the major quality criterion. Experiments focusing on the 'sulfury' character of a large number of examples of new make malt spirits from several distilleries showed a good correlation between predicted sulfury character (from GC analytical data) and sensory panel scores for sulfury character (Jack and Fotheringham, 2004). Partial least squares regression (PLS) analysis was used to compare the levels of all 36 identified organosulfur components ('routine sulfur data') and sensory scores, but the better correlation was obtained by including the levels of 20 unknown sulfur compounds in the analysis.

Most Scotch whisky is diluted, color standardized (by addition of caramel) and chill filtered prior to bottling. The first two processes are used for the sake of consistency and customer expectation, whereas the third is used to prevent the formation of chill haze and is traditionally carried out after the first two. New

make malt spirit enters the cask at *ca*. 68% ABV. After ageing 12 years, this will have dropped to around 59%, depending on the cask and conditions of maturation; the ethanol contents of spirits of the same age from two different casks are never exactly the same. Hence vatting and addition of pure water (which must conform to potable water standards) is carried out for most whiskies to a final ethanol content of 40%, 43% and 46% (v:v).

Likewise, the color development of ageing whisky proceeds at different rates in different casks, so vatting of the matured spirits with addition of caramel (as well as dilution) ensures consistency of color. Some distilleries bottle some of their malt whiskies without vatting, dilution or addition of caramel (Section 3.2.6). Filtration of Scotch whisky is permitted by regulation only to remove physical impurities and components that may lead to the formation chill haze (chill floc) (Halliday, 2004). Most Scotch whisky is chill filtered after vatting, dilution and coloring, prior to bottling. Some malt whiskies are bottled unfiltered, in which case they are likely to develop a haze at low temperatures (Section 3.2.6).

The processes of dilution, coloration and filtration outlined above are carried out in various ways, depending on the distillery. In some, they are largely manually controlled, in others, especially larger distilleries, there is considerable or full automation. Consistency of alcoholic strength of the final product, after blending and dilution, is important for both payment of excise duty and expected organoleptic character. The ethanol content of whisky is monitored at all stages in its production, by a variety of in line and off line techniques, including gas chromatography (Section 4.3.2), ultrasound sensors (Section 4.6.3), hydrometry (Section 4.6.3) and ebulliometry (Section 4.6.3).

Packaging of whisky is still very much biased toward glass bottles. The traditional bottle is ~70 cl capacity, made of colorless glass, cylindrical with a bulge in the neck (Figure 3.2.12) and often enclosed by a metal screw cap. Some of the lower capacity bottles are of the squat, flat type. Other sizes (e.g. 1 l, 50 cl, 350 ml down to 5 cl for miniatures) are available and many malt whiskies can be found in bottles enclosed with a flanged cork stopper and finished with an attractive foil cap (Figure 3.2.12). A few whiskies, such as Glenfiddich malt whisky are offered in green glass bottles and some whiskies are offered in bottles with plastic screw caps. Bottling lines at central warehouses or bigger distilleries are often fully automated, coping with up to

Figure 3.2.12 *Standard range of single malt whiskies from Glengoyne distillery. Many malt whisky distilleries produce whiskies of different ages, as well as speciality products - see Section 3.2.6.* Photograph by courtesy of Glengoyne Distillery

600 bottles per minute, including depalletization of empty bottles, loading onto conveyors, filling, enclosing, labeling, capping and palletization of filled bottles. Sophisticated computer control on some bottling lines allows fast bottle format and size change with parallel label and capper change.

Scotch whisky is seen by many consumers as a more traditional drink than, say, gin or vodka, so the glass bottle continues in use for the great majority of whiskies. Although the traditionally minded consumer will always be important, there is a growing need for greater consumer accessibility for Scotch whisky. Greater breadth of format (e.g. premix in kegs, tetrapaks and sachets) should help the industry to target nontraditional consumers, as has already happened in other spirit industries (Halliday, 2004).

Waste in the Scotch whisky production process, although not entirely a postdistillation phenomenon, is discussed as the last topic of this section.

Figures 3.2.3(a) and 3.2.3(b) indicate the points in the production process where waste occurs. The two major wastes are spent grains from the mash and spent wash from the distillation (also the pot ale from the wash still in malt whisky distilleries). In the USA, traditionally, the spent grains (draff) are dried and sold as distillers dried grains (DDG) and distillers dried grains with soluble (DDG-S) to farmers for use as livestock feed. As they are low in starch, but high in protein and fiber, DDG and DDG-S are valuable in this respect. Recently, there has been interest in developing alternative uses for DDG and DDG-S derived from maize (corn) (Saunders *et al.*, 2008). A possibility is their use in the diets of people suffering from diabetes or Coeliac's disease. Processes making flour from these grains and the possibilities of modifying their color, odor and baking functionality are being investigated. In the USA corn ethanol plants now produce over 3.5×10^9 l of ethanol via fermentation/distillation, so alternative uses for waste are worthy of investigation. In Scotland, however, the majority of spirits are distilled from malted barley or wheat wash rather than maize wash and so spent grains would not be suitable for Coeliac's disease sufferers, because of the presence of allergenic proteins (prolamins) (Section 5.11.3).

Spent lees, and in malt whisky distilleries pot ales, are wastes that can only be discharged to the environment, although some is used as 'backset' (Section 3.2.3) in mashing/cereal cooking and fermentation in grain whisky distilleries. However, spent lees from malt whisky distilleries contain high levels of copper compounds (including soluble organic copper complexes) - up to 20 μg/l - and pot ales contain up to 0.7 μg/l (Adam *et al*., 2002). Although a little of this copper (∼3%) comes from the barley, the majority is derived from the copper pot stills, as indicated by the generally very much higher copper content of malt whiskies over grain whiskies (Adam *et al*., 2002). It is estimated that during distillation, about 1 kg of copper is released daily to waste with the pot ale and spent lees from a distillery such as Talisker (Adam *et al*., 2002). This can be taken as a representative value and illustrates why distilleries ensure adequate dilution of pot ale and spent lees is carried out before the waste is discharged into the environment.

Also a problem is the discharge of hot water from the condenser coils (cooling waste water). Some continuously working distilleries have or have had heat exchanger or recycling schemes, whereby hot cooling water is used for mashing or for heating the next batch for distillation or (as at Bowmore distillery, Islay) is used in a water/air exchanger, the hot air being used to dry malt in the kiln. Thus recycling saves fuel, although optimum benefits are only felt during continuous distillery operations. A less busy distillery, as Imperial (Speyside), used a canal system for cooling the water prior to discharge into a local burn.

3.2.6 The Flavor and Styles of Scotch Malt Whiskies

Some aspects of Scotch whisky flavor have been discussed briefly in Sections 3.2.3 and 3.2.5, with regard to the contributions arising from peated malt and maturation in oak, respectively. The purpose of this subsection is to examine more closely certain aspects of flavor, particularly those relating to molecular origin and influences of distillery practices or conditions.

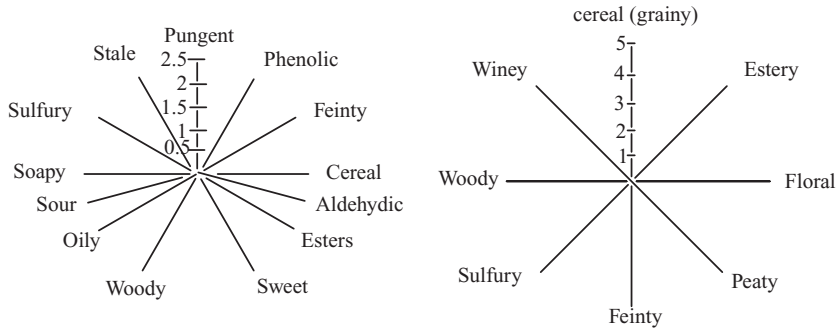

Figure 3.2.13 *Scaled flavor profile templates used to describe Scotch malt whisky. The arbitrary scale applies to all spokes of the wheel. The panel gives a mean score for each flavor descriptor, then the scores are joined by lines to give a spider web pattern describing the flavor profile*

There are several flavor vocabularies that have been proposed for the description of whisky flavor (Simpson *et al*., 2004). The terms in these vocabularies range from 13 to 43, and although flavor descriptors used by the Scotch whisky industry have not been universally agreed, there is a general consensus of opinion favoring the use of 13 terms to describe various whiskies, such as malt, blended or new make. Flavor profiles for Scotch whiskies can be built using these terms in flavor wheel or spider web diagrams (Jack, 2003) (Figure 3.2.13) – these are discussed more fully in Section 4.7.3. Thus, the basic flavor descriptors commonly used for Scotch malt whiskies are aldehydric (sometimes grassy or green is used here), cereal, estery (fruity can be used here), feinty, oily, phenolic, pungent, soapy, sour, stale, sulfury, sweet and woody.

In reality, there are over 250 known flavor compounds in Scotch whisky, which may contribute to one or other of the flavor attributes mentioned above. The vast majority of these flavor components are common to many distilled beverages and it is their relative concentrations that allow differentiation of a malt whisky from, say, a dark rum. Nevertheless, there are some components that are probably unique to Scotch whisky or are more strongly associated with that product. These include some phenolic compounds, characteristic of peated malts, whisky lactone, common to all whiskies, and certain organosulfur compounds, with various flavor impacts.

Many of the flavor descriptors mentioned above can be subdivided into related terms: phenolic, for example, can be described as burnt, medicinal or smoky. Likewise, the term estery, can be given the qualifying descriptors fruity or solvent – particular fruit may even be invoked, such as apples or bananas. Olfactometric-GC ('sniff GC' or GC-O) analysis usually leads to a wider range of descriptors, now relating to individual components as they are eluted from the gas chromatograph (Section 4.7.3). Terms such as mushroom, spicy or curry can be used to describe certain individual elements (Steele *et al*., 2004). Thus individual odorous components, often with quite specific aroma descriptors, mingle in the bulk sample of Scotch whisky and combine to give a more general aroma/flavor profile that is characteristic of Scotch whisky, despite the fact not one of the individual component's odors can be described as whisky.

The contribution each component makes to the overall flavor depends on its odor activity, which in turn depends on its odor threshold value (OTV) and concentration, or more specifically its activity coefficient. The latter parameter for a specific component depends on the identity and quantity of cosolutes, which influence aroma intensity by affecting the headspace spirit partition coefficient (Conner *et al*., 1999) for that component (matrix interactions). For example, the leeching of phenolic compounds from oak during maturation was found to reduce the headspace spirit partition coefficient of long chain ethyl esters (such as ethyl decanoate), which are generally believed to confer soapy or waxy, immature notes to Scotch whisky. This result was

used to explain the decreased impact of immature aromas in matured whiskies and was linked to the greater formation of ethanol–water aggregates in oak-aged spirits (Conner *et al*., 1999) (Section 3.2.5). Thus some components are not flavor active, but contribute nonetheless to the overall odor background or by affecting the spirit headspace partition of flavor active compound.

As with other alcoholic beverages, it is possible to relate flavor descriptors for, say, malt whisky, to the presence of certain types of aroma compounds. Thus the terms grassy, green or aldehydic can be attributed to aldehydes, estery to esters, phenolic to phenols, sulfury to organosulfur compounds and so on. Although this is useful, it is by no means universally correct, because the aromas of a set of structurally diverse molecules can be described by the same flavor descriptor (or similar flavor descriptors). Thus estery aromas can also arise from certain organosulfur compounds, some phenols have aromas best described as spicy, rather than phenolic, and some esters do not have typical estery aromas (Steele *et al*., 2004).

Many esters have been found in Scotch whisky, as in other spirits (Demyttenaere *et al.*, 2003; Câmara *et al*., 2007; Campo *et al*., 2007). These are formed during fermentation (e.g. see Sections 2.2.11 and 2.6.4) and are subsequently concentrated by distillation. Some esters may be formed in slow reactions between ethanol and carboxylic acids, during maturation. Short chain esters such as ethyl acetate, 2-methylpropyl acetate, ethyl 3-methylbutanoate, *iso*-amyl acetate and medium chain ethyl esters (such as ethyl hexanoate) possess aromas that can be described as estery, fruity or solvent-like. Longer chain esters, such as ethyl hexadecanoate have aromas more reminiscent of soap or wax and some mixed aliphatic/aromatic esters, such as 2-phenylethyl acetate, have floral odors. Although many of the short and medium chain esters have low OTVs, their presence may not contribute greatly to the overall whisky aroma. This could be because of low concentrations in the spirit (and hence in the headspace) or possibly because of low headspace levels caused by the presence of long chain esters trapping them in the liquid phase (an example of matrix effects, described previously). Certainly, there appears to be no correlation between concentrations of esters in the liquid and in the headspace; increased ester levels in a whisky will not necessarily be perceived as increase in estery or fruity character (Steele *et al*., 2004). At least two studies have shown that long chain fatty acid ethyl esters, such as decanoate, dodecanoate, tetradecanoate and hexadecanoate, are amongst the most abundant esters in both the liquid and headspace of Scotch whisky, judging by relative peak areas in GC chromatograms (Demyttenaere *et al*., 2003; Câmara *et al.*, 2007).

A recent multidimensional GC/MS study has focused on the presence of esters with particularly low OTVs in alcoholic beverages, including wine, Port, Sherry, brandy and two Speyside malt whiskies - Cardhu and Knockando. The esters, ethyl cyclohexanoate, ethyl 2-methylpentanoate, ethyl 3-methylpentanoate and ethyl 4-methylpentanoate, were found in many of the beverages, but their odor activity values (OAVs) (= concentrations/OTVs) were generally higher in fortified wines and spirits, including the two malt whiskies (Campo *et al*., 2007). It was concluded that these powerfully odorous esters made a major contribution to the fruity notes of the beverages, especially certain fortified wines, brandies and the two malt whiskies. Similarly, in an analysis of volatile components in blended Scotch whiskies, on the basis of OAVs (Section 4.7.2), ethyl decanaoate, ethyl dodecanoate, ethyl hexanoate, ethyl octanoate, isoamyl acetate, 3-methylbutan-1-ol, 2-methylpropanol, decanoic acid, hexanoic acid and octanoic acid were considered to contribute most to aroma (Caldeira *et al.*, 2007). The most odor active component was ethyl octanoate (fruity, sweet), followed by isoamyl acetate (banana, fruity), 2-methylpropan-1ol (winey, solvent), ethyl decanoate (floral, soap) and decanoic acid (fatty).

Phenolic compounds make important contributions to Scotch whisky flavor, either directly, as in the case of volatile phenols, or indirectly, as in the case of nonvolatile phenols. Volatile phenols are derived from:

- Barley (via hydrolysis of lignins during mashing (fermentation)
- Peat smoke (via pyrolysis of lignins and polyphenols)
- Oak (via hydrolysis of wood lignins).

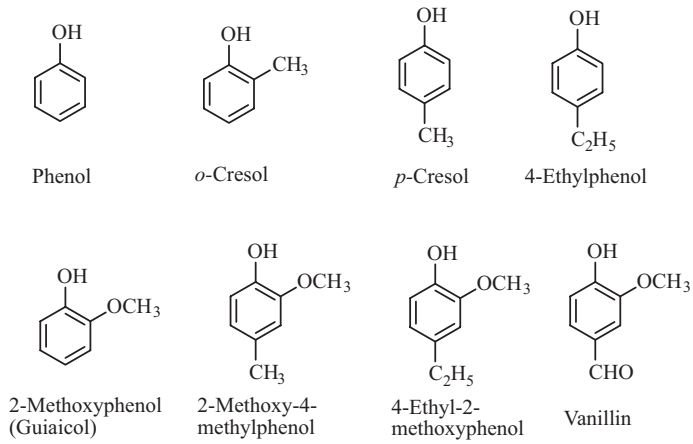

Figure 3.2.14 *Some volatile phenols found in Scotch malt whisky*

Several, mainly simple substituted phenols, have been found in malt whiskies (Steele *et al*., 2004; Câmara *et al*., 2007). These include the compounds shown in Figure 3.2.14. Phenolic notes (burnt, medicinal, smoky) are most noticeable in peated malt whiskies, where some or all of the malted barley has been kilned using the hot air derived from burning peat. The smoke, containing pyrolysis products of lignins and polyphenols (Section 3.2.3) permeates the malt, and the compounds deposited there tend to survive the whisky production process into the mature whisky. Most of the volatile phenols of peated malt whiskies have been found as pyrolysis products of the humic acid and fulvic acid fractions of peat (González *et al*., 2003) (Section 3.2.3).

The more highly peated malt whiskies, such as those of Islay and the islands, show flavor characteristics that can be related to the concentration of phenols. However, GC-olfactometry shows that relatively few of the phenols are present at high enough concentrations to provide a distinctive aroma (Steele *et al*., 2004). Many are present at levels below their OTVs and will not themselves be of sensory significance. Even so, these may synergistically contribute to the overall phenolic notes of a malt whisky, and this, combined with the differing levels of flavor active phenols, may account for the differences in peaty/phenolic aroma perceived in malt whiskies such as Highland Park, Lagavulin, Laphroaig, Ledaig, Longrow and Talisker.

Matured nonpeated malt whiskies and new make spirit from nonpeated malt also possess a portfolio of phenolic compounds, although generally their direct influence on flavor is much less profound than in the case of peated malt whiskies. This suggests that some volatile phenols are derived from the cask and raw materials (barley) in all malt whiskies, with peated spirits also having phenols derived from the peat smoke.

As with all spirits and wines aged in new or almost new oak casks, phenols such as 4-ethylphenol, guaiacol, 4-ethylguaiacol and 4-methylguaiacol, hydrolysis or pyrolysis products of wood lignins, are leeched into the malt whisky during maturation. This is true whether the malt whisky is aged in charred ex-Bourbon casks or in toasted ex-Sherry casks, although different levels of essentially the same phenols lead to differences in flavor profiles (Steele *et al*., 2004). Malt whiskies aged in ex-Bourbon casks tend to have more pronounced floral and sweet toffee notes, whilst those aged in ex-Sherry casks tend to possess nutty, burnt sweet and vinegar notes.

Low concentrations of phenols have been found in new make spirits. For example, vanillin (Figure 3.2.14) was present in 53 out of 59 new make malt spirits at levels ranging from 20–170 μg/l (Steele *et al*., 2004). The most likely origin of vanillin in new make spirit is via hydrolysis of barley endosperm lignins during

mashing. Although levels are low, it is possible that these phenols make some contribution toward mature character during aging.

Apart from the direct contributions to flavor profile outlined above, the presence of phenols in general in malt whisky is thought to influence the partition coefficients of volatile constituents, thus affecting the flavor profile in an indirect way. For example the volatilities of ethyl esters of long chain fatty acids (responsible for soapy immature notes) are subdued by the presence of phenolic compounds, such as those derived from oak aging (Conner *et al*., 1999). Also, as discussed previously, other contributions from phenols toward mature character, may include stabilization of ethanol–water clusters and reactive oxygen scavenging ability (Koga *et al*., 2007) (see Section 3.2.5).

Organosulfur compounds are present in malt whiskies and many are considered to be important flavor components. They are generally present at low levels and at such levels their flavor contributions are positive, having a range of descriptors (using GC-O analysis) from burnt match, through vegetal, nutty, floral, fruity to meaty (Figure 3.1.15) (Steele *et al*., 2004). At higher concentrations, however, their flavor impact may be less beneficial, although this is uncommon in copper pot still spirits in general (see Section 3.5.3) because of some decomposition caused by reaction with Cu at distillation temperatures.

The origins of organosulfur compounds can be traced back to fermentation (Sections 2.2.11 and 2.6.4). Methional (3-thiomethyl propanal) is produced from the α-amino acid methionine (Section 2.10.6) by yeast metabolism during fermentation. Methional concentrations in cereal wash have been shown to correlate with dimethyl disulfide (DMDS) and dimethyl trisulfide (DMTS) levels in spirit from Coffey stills (Prentice *et al*., 1998). Thus DMDS and DMTS appear to be distillation products of methional and hence in the production of grain whisky, the methional concentration of the wash needs to be regulated, so that extraneous DMDS and DMTS concentrations are not formed. Fermentation of the wort with low sulfur compound producing yeasts is beneficial here, and also particular operation of the Coffey stills can modulate final DMTS levels. Such considerations are not usually necessary in the production of malt whisky, because of the role played by the copper still material in preventing high levels of organosulfur compounds from entering the distilled spirit. In grain whisky production, it may be possible to incorporate a portion of copper into the otherwise stainless steel Coffey stills, as has been suggested for cachaça (Faria *et al.*, 2004).

The ‘aldehydic’ flavor descriptor (Figure 3.2.13) can be given the alternative name of ‘green’ and can be subdivided into secondary descriptors ‘leafy’ and ‘floral.’ Green notes can be important in unpeated lowland and highland malt whiskies, such as Auchentoshan and Glengoyne, respectively. Multidimensional GC-MS-olfactometry of Japanese malt whiskies has demonstrated two aldehydes and three alcohols (mostly unsaturated) as contributing significantly to the green notes of those whiskies (Figure 3.2.15) (Wanikawa *et al*., 2002). Malt whisky samples with high green note organoleptic scores contained higher levels of some of these compounds than whiskies with low scores. These compounds, (2*E*),(6*Z*)-nonadienal, (2*E*)-nonenal, 1-octen-3-ol, 4-hepten-1-ol and nonan-2-ol are thought to be formed during fermentation by the action of yeast lipoxygenases on barley lipids. At the time of writing (2009), the configurations of the double bond in 4-hepten-1-ol and of the chiral centres in 1-octen-3-ol and 2-nonanol are not known, nor is it known the identities of several other compounds that gave a green note in olfactometric analysis.

The great wines of the world are generally classified according to their region of origin. So it is with Scotch single malt whiskies. The regions were originally devised for the regulation of licenses and excise duties, but in general they do each give certain broad characteristics of flavor and style to their whiskies. Naturally, within each region, there are variations in style, just as in, say, Haut Medoc, the wines of St Estéphe differ in detail from those of Margaux, even though they have a family resemblance that sets them apart from red wines of a different region, say the Northern Rhône.

The Scotch single malt whisky regions are generally reckoned to be the Lowlands, Campbeltown, the Highlands (which includes Speyside) and Islay, as summarized in Figure 3.2.16.

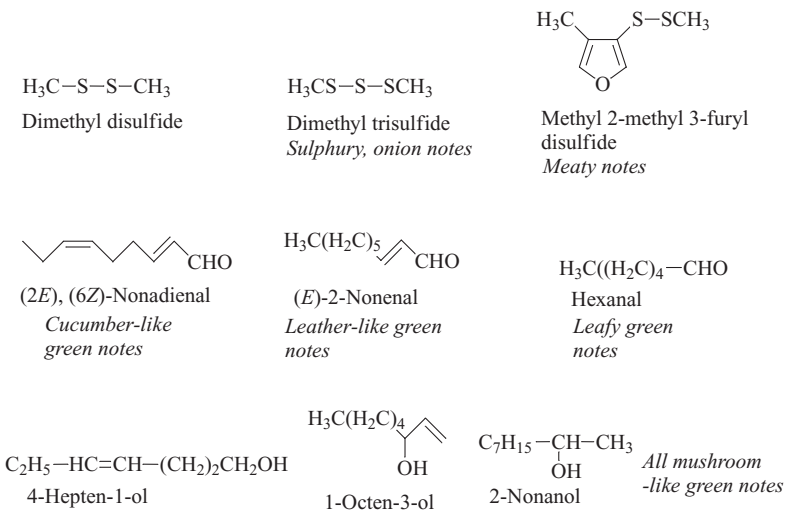

Figure 3.2.15 *Organosulfur compounds of wide sensory character and some compounds responsible for 'green' or 'aldehydic' notes in malt whiskies*

Campbeltown is sometimes considered as a district of the Lowlands region, but its whiskies are so distinctive as to deserve their own Appellation. In Figure 3.2.16, it can be seen that the very diverse Highland region possesses the big majority of working distilleries, with Speyside being the most important (in terms of output of single malt whiskies) of all districts.

The demarcation line between the Lowland and Highland regions follows the old county boundaries between the Clyde and Tay estuaries. Except for Speyside, both regions are geographically very diverse, matching the diversity of their single malt styles, particularly with respect to the Highlands. Rather less variation is observed for the single malts of the geographically more restricted regions of Campbeltown and Islay, along with the Speyside district of the Highland region. The next paragraphs discuss the general characteristics of style and flavor of the single malt whiskies from the four regions in terms of methods and practices of production. Where appropriate, characteristics of the products of individual distilleries are discussed in terms of specific aspects of their own production.

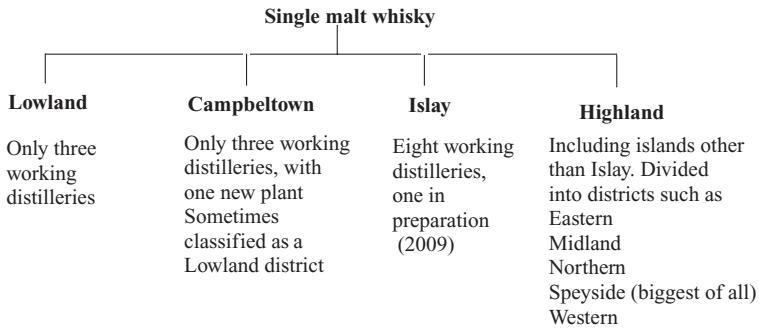

Figure 3.2.16 *Scotch single malt whiskies classified according to region*

The Lowlands region is geographically large, stretching from a line joining the Clyde and Tay estuaries to the border with England. Unfortunately, the number of Lowland malt distilleries presently stands at just four: Ailsa Bay, Auchentoshan, Bladnoch and Glenkinchie. These are well separated, in the west, south and east of the region, respectively, but all produce light bodied, mellow (even subtle) malt whiskies with a fresh grassy or citrus character. Lightness of body and freshness arise from the use of unpeated malt or lightly peated malt and (sometimes) triple distillation, the traditional mode of pot still distillation in the Lowlands. Triple distillation produces a new make spirit of around 76% ABV (as opposed to ~68% ABV for double distillation), with rather lower concentrations of flavor compounds (congeners), especially if a narrow 'middle cut' is taken from the final still. The use of refill ex-Bourbon casks rather than ex-Sherry casks for aging ensures that the whisky does not take up too much vanilla or Sherry character, allowing the malt character to shine through.

The Lowlands region has witnessed the demise of several malt distilleries since 1983: Interleven, Kinclaith, Littlemill, Rosebank and Saint Magdalene. Just before that time, in the 1970s, the region lost Ladyburn distillery, adjacent to the Girvan grain distillery (Figure 3.2.1). The owners of the Girvan grain distillery (W. Grant of Glenfiddich fame) built Ailsa Bay malt distillery, on the site of the Girvan complex. It started production in September 2007 and it is expected that the first malts will be available for blending in 2012.

Campbeltown, rather isolated at the southern end of the Mull of Kintyre peninsular, once had 30 distilleries. Nowadays (2009) there are only three, with the youngest (Glengyle) being owned by an existing local distillery company that owns Springbank distillery (J. and A. Mitchell). Glen Scotia is the other working Campbeltown distillery and its eight year old product, along with partially triple distilled Springbank 10 year old can be regarded as the epitome of Campbeltown single malts. The latter whisky is produced using one wash still and two low wines (spirits) stills, but the second low wines still receives charges (~20–25% ABV) directly from the wash still, as well as the feints (heads and tails ~30–35% ABV) in about a 1:4 ratio, the middle cut from the final still being collected at *ca.* 71% ABV. These whiskies have the lightness of body typical of Lowland malt whiskies, but at the same time a fresh, briny character is evident on the nose and palate that is rarely found so clearly in other whiskies. These characteristics, along with a remarkable smoothness and depth of flavor for such young malt whiskies is considered to be the result of aging in warehouses that are close to the sea, so that a damp, salty atmosphere prevails.

Although the eight and 10 year old products mentioned above have subdued or no discernable smoky character (due to the use of lightly peated or unpeated malt), Springbank distillery also produces a smoky style of malt whisky. This is known as Longrow, and as it is double distilled using entirely heavily peated malt, it has a pronounced smoky/phenolic character on the nose and palate, although the characteristic saltiness is still there in the aftertaste. Springbank distillery has its own traditional floor malting house, but the peat for smoking the malt comes mostly from Islay. The same distillery also produces (since 1999) a triple distilled single malt called Hazelburn, after a now defunct nearby distillery. Also, the distillery company has renovated the Glengyle distillery next door to Springbank to produce a malt whisky known as Kilkerran. The first distillation was in 2004, with the limited release of a five year-old spirit in 2009, with subsequent limited releases until the 12 year old is ready for bottling in 2016.

The Arran distillery at Lochranza on the Isle of Arran started producing single malt whiskies in 1995. In style, its products are somewhere between a typical Campbeltown malt, such as Glen Scotia, and Western Highland malt, such as Oban.

The Highland region possesses the huge majority of distilleries (Figure 3.2.1), with the greatest diversity of styles and flavors in its single malt whiskies. There are only four distilleries in the western districts – Ben Nevis in Fort William, Oban on the coast, Glengoyne, northwest of Glasgow, and Loch Lomond at Alexandria, north of Dumbarton. The latter two produce light/medium bodied, fragrant whiskies, whilst Oban makes a peaty, smoky malt whisky, somewhat akin to the island whiskies.

Glengoyne is situated in Dumgoyne, a hamlet just over the Highland line; in fact the whiskies are distilled in the Highlands and are matured in the warehouses across the road, in the Lowlands. Glengoyne distillery produces an unusually broad range of malt whiskies, apart from the 10, 12, 17, and 21 year olds (Figure 3.2.12), there are single cask malts of a wide range of ages, as well as vintage malts. Some single cask malts are aged in special sherry hogsheads that previously held amontillado or palo cortado Sherry. All the Glengoyne malt whiskies are produced from unpeated malt.

The Lomond distillery has both pot stills and stills incorporating a rectifying column, which can be adjusted to produce whiskies of varying heaviness. A range of malt whiskies has been produced by their distillery, as well as vatted malts and various blends. The best known malt whisky is probably Inchmurrin.

Further north, the Oban distillery produces a 14 year old malt whisky that has some of the peaty/smokiness of some of the island whiskies. The stills are small (the distillery is rather cramped), with small lyne arms leading to worm tub condensers (Section 3.2.4). The island distilleries of the Highland region: Isle of Jura, Ledaig (Tobermory, Mull), Talisker (Skye), Highland Park and Scapa (both mainland Orkney) are all well established producers of malt whiskies of varying peatiness. Scapa distillery uses unpeated malt, but peaty water. Its malt whiskies are aged in ex-Bourbon casks and are characterized by a salty grassiness, with attractive bitter chocolate and caramel notes. Scapa's neighbor, Highland Park uses peated malt from its own floor maltings (Figures 3.2.1 and 3.2.3). Consequently, its malts have a smoky character, but also heathery notes that are a characteristic of other northern Highland malt whiskies. It may be that the local shallow beds of peat, with a plant cover largely of heather, make some contribution to those aroma and flavor notes. At the time of writing, there are intentions of setting up a malt distillery called Blackwood in the Shetland Islands. Blackwood is a company already producing a range of spirits, and although plans are not well advanced (2009), the establishment of a malt distillery on Shetland would make it the most northerly.

Of the three west coast island distilleries (ignoring Islay for the moment), Isle of Jura, in Craighouse, on the southeastern coast of the island, makes the mostly lightly peated malt whisky. It uses water from Loch a' Bhaile Mhargaidh that flows mostly over rock. The stills at Jura have tall necks and thus produce a relatively clean spirit, with only a hint of peatiness, but with a characteristic dry island saltiness.

Ledaig and Talisker, the other two west coast island distilleries, produce intensely pungent smoky malts, more in the style of certain of the Islay malt whiskies. The former distillery, situated on a very cramped site by the harbor in Tobermory, has had a chequered history of production and there were many silent periods up to the 1990s. Talisker, on the other hand is owned by Diageo and its distinctive malt whiskies are included in that company's Johnnie Walker and other Scotch whisky brands. Talisker malt is also a component of the vatted malt whisky Poit Dubh (Black Bottle), produced on Skye. The distillery, situated at Carbost, on the west coast of the island, is one of the few with worm tub condensers, the worm tubs being kept full of cool water from Carbost Burn.

The Highland region contains clusters of distilleries (16) in the east (three), the midlands (six) and the north (seven, not counting Orkney) (Figure 3.2.1). Although generalization inevitably leads to oversimplification, common characteristics, apart from some peatiness, of the northern malt whiskies are heatheriness, salt and spice, whereas the midland and eastern malts can often be described as fruity and nutty, and often have a creamy palate.

The most northerly mainland distillery, Pulteney (near Wick and not far from John O'Groats) produces its malt whiskies from unpeated malt and these are thus the least peaty of the northern Highland whiskies. All the distilleries of this group are close to the sea, but Pulteney is on the coast and the fresh, salt-like character typical of coastal whiskies is more pronounced in Old Pulteney malts than in any of the other products of this group of distilleries. Pulteney is also interesting in that at the time of writing (2009), production of its malts is entirely nonautomated and worm tubs are still used for condensation of the spirit.

Clynelish distillery at Brora is the next along the coast from Pulteney. Its malts also have a salty 'coastal' or 'island' character, but are less delicate and more robust than Pulteney, with some spicy notes on the finish. Stills with shorter necks than some of those at Pulteney may account for some of the differences.

At the southern end of the northern Highland group of distilleries can be found Balblair, Dalmore, Glenmorangie and Teaninich, quite close together around the Dornoch Firth (Balblair and Glenmorangie) and Cromarty Firth (Dalmore and Teaninich). The first two generally produce the lighter spirits. Glenmorangie distillery possesses the tallest necked stills in Scotland (over 5 m high). This, the use of lightly peated malt, ex-Bourbon casks and the distillery's estuary location all contribute to the light, spicy character of the 10 year old product, with its faint, but distinct whiff of the sea. Older malt whiskies are often given some time in ex-oloroso casks to finish their maturation time. Glenmorangie, along with Glenfiddich and Glen Grant (both Speyside), was one of the first distilleries to promote its malt whisky aggressively in and outside Scotland; it is now the market leader of single malt whiskies in Scotland. Balblair has a claim to be Scotland's oldest distillery (1749), although the present buildings date from the 1870s only.

Dalmore and Teaninich further south, on the Cromarty Firth, produce rather heavier spirits, with spicy, Sherry and earthy, spicy, smoky notes, respectively. Single malts of the former distillery possess components aged in ex-Sherry casks, whereas most of the malt whiskies from the Teaninich distillery are components of a number of blended Scotch whiskies.

The midland and eastern Highland distilleries (Aberfeldy, Blair Athol, Deanston, Edradour Fettercairn, Glencadam, Glengarioch, Glenturret, Lochnagar and Tullibardine) tend to produce malt whiskies with citrus or fruity notes overlaying the malt character, provided ageing in ex-Sherry casks has not been too extensive. Many of these malts are also characterized by a smooth, creamy palate. Edradour distillery (owned by Pernod Ricard) is the smallest in Scotland. Situated close to Pitlochry, it takes some pride in its 'farm distillery' status and traditional equipment, including mainland Scotland's smallest stills, with worm tub condensers. Some ageing in ex-oloroso casks is practiced for its 10 year old malt, which can be detected on the nose, along with spice, smoke and mushroom. Despite the small stills, the spirit is relatively light, but after 10 years maturation, develops a remarkably smooth, creamy palate.

Glenturret distillery, on the banks of the river Turret near Crieff, is also very small and has a good claim to be Scotland's oldest, with some of its buildings dating from 1775. The distillery was revived in 1959 (after closing in the 1920s) by James Fairlie as a craft malt distillery showpiece – a venture that was very much against the grain at that time. The result has been a remarkable range of malt whiskies, in age, style and alcoholic strength. The over-riding character seems to be malt, toffee, toasted oak and nuttiness, but some versions have pronounced Sherry notes and most are characterized by a smooth, creamy finish, like Edradour. Deanston distillery is interesting in that it is partly housed (the warehouse) in a former cotton mill designed by Richard Arkwright and built in 1785. The original mill was water powered and the present distillery uses water powered turbines; a major reason for the distillery's location is the abundant water supply. Deanston's spirit stills are characterized by sloping lyne arms, which promote reflux during distillation thereby producing a lighter, cleaner spirit.

The biggest concentration of malt whisky distilleries in Scotland is to be found in the area known as Speyside, a hilly region with a network of rivers and burns, stretching from Tomatin distillery in the west to Glenglassaugh in the north, Glendronach in the east and Balmenach in the south (Figure 3.2.17). Many burns rising in granite hills and flowing over granite and peat to the many river valleys (glens) in which the distilleries are located, provide the water for a wide range of whisky styles. The major rivers are (west–east) the Findhorn, Lossie, Spey, Avon, Livet, Fiddich, Dullan, Isla, Deveron and Bogie, with the greatest number of distilleries being in the Spey valley (Figure 3.2.17).

Differences in methods of production (e.g. malt peatiness, types of stills, distillation procedure, types of casks used for ageing, etc.) probably contribute more to the variation in style than geographical location of the distillery (and its water). Having said that, the distilleries close to the Avon or Livet (several include

Glenlivet in their names) – Braeval, Cragganmore, Glenlivet, Tamnavulin, Tomintoul and Tormore – are noted for their delicate, light, but complex malt whiskies. Such is the reputation of Glenlivet, several distilleries (e.g. Dufftown and Longmorn) situated a long way from the valley of the Livet sometimes use Glenlivet as a subscript to their own names on bottles of their products. The glen itself is deeply set in the hills and its burns of very cold water travel good distances underground from their sources on the hillsides.

Glenlivet distillery rather unusually obtains its water, which has a degree of hardness, from an artesian well. About one third of Glenlivet distillery's whisky is aged in ex-Sherry casks, which is evident on the nose and palate of some of its wide range of products. Likewise, smokiness is evident from the use of some peated malt, but like the Sherry character, this does not overwhelm the complex, delicate combination of fruity, flowery and spicy notes. Of the Livet valley malts, those of Glenlivet distillery are the most assertive, whilst those of Tamnavulin are the lightest and most delicate. Tomintoul and Tormore malt whiskies are of the same mold, but perhaps a little fuller in body than Tamnavulin. The highly automated Braeval (Braes of Glenlivet), some 355 m above sea level now (2009) markets a single malt as an official bottling.

At the other extreme, the full bodied, high Sherry character Speyside style of malt whisky is typified by the products of Aberlour, Balvenie, Glenfarclas, Linkwood, Longmorn, the Macallan and Mortlach. Although

most of these distilleries are along either the river Spey or Fiddich/Dullan, it is probably the production methods rather than geographical location that accounts for their full bodied character, as many neighboring distilleries (e.g. Dufftown, Glenallachie, Glenfiddich, Glen Spey and Tamdhu) produce lighter malts. The Macallan distillery in Craigellachie produces some of the most respected of all single malt whiskies, the emphasis being on sherry character - indeed, the distillery owns casks holding oloroso wines (2.10.2) in Jerez bodegas. Once the casks have been emptied they are shipped whole (i.e. not dismantled) to Scotland for ageing Macallan whisky.

The smallest stills on Speyside can be found in the Macallan distillery (Figure 3.2.8), which must (at least in part) account for the heaviness of the spirit, although Glenfarclas distillery (further up the Spey valley - see Figure 3.2.17) produces malts of similar style and reputation, but slightly lighter, using the biggest stills on Speyside (Figure 3.2.8). This distillery uses new (unsherried) casks, as well as ex-Sherry (first fill and refill) casks, which could account for the somewhat muted Sherry character of its malts, compared with those of the Macallan distillery.

Both the Macallan and Glenfarclas were early in marketing their single malt whiskies, but they were not the pioneers – that accolade goes to Glenfiddich distillery, near Dufftown in the valley of the Fiddich. Glenfiddich Special Old Reserve was vigorously promoted outside Scotland in the early 1960s, the characteristic black, gold, red and white label showing the company emblem (a stag's head) on its distinctive dark bottle soon became a familiar sight in bars and wine shops. Glenfiddich distillery is the only Speyside distillery to have a bottling line on site; indeed, the only other malt distillery having on site bottling facilities in Scotland is Springbank distillery, Campbeltown. Next door, the Balvenie distillery is also owned by William Grant and Sons, but produces malts with much more Sherry character – particularly the 'Classic' version.

Elsewhere in Speyside, the malt whiskies from the distilleries around Keith (Auchroisk, Aultmore, Glen Keith, Glentauchers and Strathisla) are noted for their firm, robust constitutions. Strathisla distillery probably has the best claim as Speyside's oldest – indeed, it has a good claim to be Scotland's oldest malt distillery. Its wide range of malts is characterized by firm body, maltiness, Sherry notes and a long, smooth aftertaste. These whiskies are produced in small stills using local semi-hard spring water and lightly peated malt.

All of the distilleries on the periphery of Speyside (Tomatin, Brackla, Benomach, Glenburgie, Glen Moray, Miltonduff, Knockdhu, Glendronach, Ardmore and Balmenach), as well as those on the coast (Inchgower, Glenglassaugh and Macduff/Glen Deveron) produce characterful malts, many of which are highly regarded by blenders. Glendronach, once belong to Teachers, is now owned by the same management as Benriach, the only Speyside distillery to have its own floor maltings (Tamdhu distillery on the River Spey has saladin box maltings). The distillery was bought from Chivas Brothers (who closed it in 2002) by the present management in 2004. The malts from the coastal distilleries possess some fresh, grassy, salty character that sets them aside from most other Speyside malts. This character is more pronounced in the Inchgower and Glenglassaugh products than in Glen Deveron's (Macduff's) malts. However, Glenglassaugh is closed at the time of writing, but was bought by the Scaent group in 2008.

A majority of Speyside distilleries are owned by Diageo, who inherited United Distillers when the company was formed from the merger of Grand Metropolitan and Guinness (1997), the latter company having bought United Distillers in 1986. Like most malt distilleries, much of their production goes into blended Scotch whiskies, in this case brands such as Bell's, Haig, Johnnie Walker and White Horse, and deluxe blends such as the Antiquary, Dimple and Old Parr. The single malt whiskies of many of these distilleries are more easily found as independent bottlings (notably those of Gordon and Macphail) than as official bottlings. Indeed the products of Allt a'Bhainne (Dufftown, Chivers/Pernod Ricard), Kininvie (Dufftown, W. Grant & Sons) and Mannochmore (Lossie, Diageo) have been available as official bottlings only recently – Kininvie in 2006.

A surprising number of Speyside distilleries were either built or extensively reconstructed (not counting extensions) in relatively recent times: Allt a'Bhainne, Aultmore, Benromach, Brackla, Caperdonich, Cardhu, Craigellachie, Drumguish, Glenallachie, Glen Deveron, Glendullan, Glen Elgin, Glenglassaugh, Glen Keith,

Glen Spey, Glentauchers, Glenury, Kininvie, Linkwood, Mannochmore, Tamdhu, Tamnavulin, Tomintoul and Tormore. Many were built or reconstructed during the 'boom years': 1950s–1970s. Many closed during the recession years of the 1980s, including Brackla, Dallas Dhu, Glenglassaugh, Glentauchers, Imperial and Knockdhu. Several closed for good – Dallas Dhu became a whisky museum, whilst others, such as Banff, Glen Albyn, Glen Mohr and Millburn have been demolished. Caperdonich, Coleburn and Convalmore are still mothballed, but the others were gradually brought back into circulation in the 1990s. Mannochmore works only in alternate years at the time of writing (2009) and shares it workforce with the nearby Glenlossie distillery. Nevertheless, it has produced a single malt called Loch Dhu. At the time of writing, Diageo is building a malt distillery at Roseisle next to the Burghead/Roseisle malting plants. It is anticipated that the new distillery's output will go largely into the company's many Scotch brands. It is a large distillery, with an intended output of 10 million liters of malt whisky per annum.

The malt whisky production processes used by the Speyside distilleries vary enormously in their degree of automation and extent of modernization. The majority of distilleries have experienced some degree of modernization and the newer ones, such as Allt a'Bhainne and Braeval (Braes of Glenlivet) are fully automated, employing very few staff. However, it was another Speyside distillery, Glen Keith (Isla – see Figure 3.2.17) that was the first to use gas fired stills and it was also the first to computerize part of its production process. In other distilleries where modernization has been extensive, it is still possible to see the occasional piece of traditional equipment still in use – worm tubs, for example, are still used to condense the distillate at the Benrinnes and Mortlach distilleries. At the other extreme, Balmenach distillery (Cromdale – see Figure 3.2.17) still uses a cast iron mash tun and Douglas fir wash backs, as well as worm tubs. It is owned by Inver House Distillers (who also own Pulteney Distillery), a company that prides itself on tradition.

Traditional appearance of the distillery is usually considered to be something of importance, as witnessed by the presence of malting house ventilation pagodas in even the most modern of distilleries, such as Braeval. All Speyside distilleries apart from two, Benriach (Ben Riach) and Tamdhu, receive all their malt either from big nearby malting complexes (often owned by the parent companies of the distilleries) or from suppliers outside the region, so the pagodas are entirely decorative. Ben Riach uses traditional floor maltings (unique on Speyside) for some of its malt and Tamdhu distillery uses Saladin box maltings for all its malt.

Islay is an important producer of highly distinctive malt whiskies; it has been said that there are very few Scotch whisky blends that do not have at least a small Islay malt whisky component. The production area is naturally compact (Figure 3.2.18), and although there is a wide range of styles (particularly in degree of smokiness or peatiness), all the malts share the 'island character' of saltiness (or brine) found in other island or coastal malt whiskies.

The smoky character comes from the use of peated malt (Section 3.2.3) and is most pronounced in the products of the distilleries on the south coast, close to Port Ellen – Laphroaig, Lagavulin and Ardberg. Port Ellen (Diageo) ceased distilling in 1983 (although its malts can still be found as independent bottlings), but malting is still carried out in the large drum malting house next door. Malt is supplied to Diageo's two Islay distilleries, Lagavulin (mentioned above) and Caol Isla, on the northeastern coast of the island and to other independent distilleries. Those two distillery's floor maltings ceased production when the Port Ellen malting complex was built in 1973. Floor malting, however, is still carried out at Bowmore, Kilchoman and Laphroaig distilleries, satisfying around 50% of their malt requirements, the remainder coming from the Port Ellen maltings, mainland Scotland or further afield. The kilning of malt (Section 3.2.3) for Ardberg, Lagavulin and Laphroaig distilleries involves the greatest use of smoke from peat furnaces. Consequently, the malt whiskies from these three distilleries are the most powerfully smoky of all the Islay products. This, coupled with their salty island character, makes for some of the most pungent of Scotch malt whiskies, along with Ledaig, Longrow and Talisker. Terms like 'iodine,' 'medicinal,' 'disinfectant,' 'tar' and 'seaweed' have been used by tasters to describe the aroma and flavor of some of these malt whiskies. Using the flavor wheel shown in Figure 3.2.13, these malts would have high scores on the pungent and phenolic spokes of the wheel.

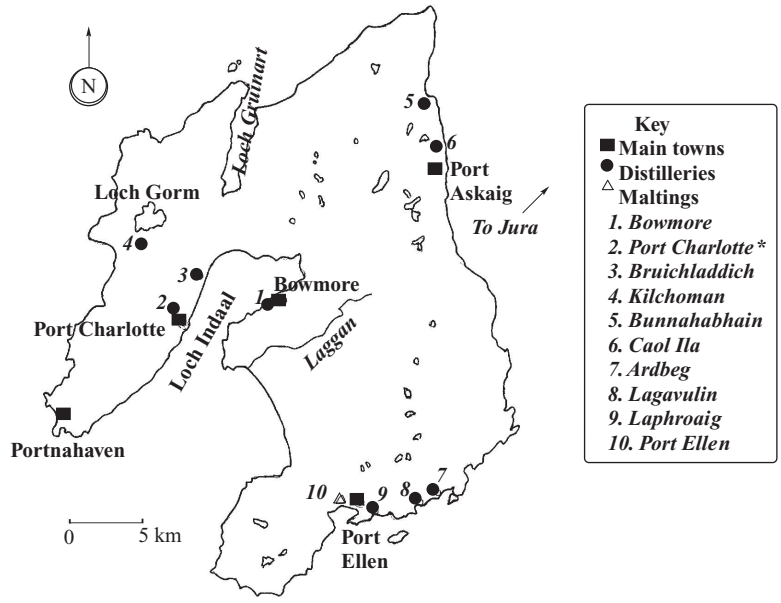

Figure 3.2.18 *Islay malt distilleries. *In preparation (2009)*

The lightest of the Islay malt whiskies are those of the Bunnahabhain and Bruichladdich distilleries - which is no criticism, as they are both well rounded and elegant products with lots of island character. The latter distillery uses stills with long necks, which probably accounts for some of the distillate's relative lightness. Intermediate between these two extremes are the malt whiskies of Bowmore and Caol Isla. The former distillery uses both ex-Bourbon and ex-Sherry casks, so a Sherry character is often discernable in some of its many versions of malt whisky. The products of both distilleries are characterized by a good balance between maltiness, saltiness, smokiness and Sherry character.

The distillery at Kilmochan, just south of Loch Gorm (Figure 3.2.18) distilled its first whisky in November 2005, some of which will be bottled and ready for sale in 2009. It is aiming at an annual production of 90 000 l (see Table 3.2.4 for selected malt whisky production figures), fashioning its distillate in part from home grown and home malted barley (using traditional floor maltings). Kilchoman is now the most westerly distillery in Scotland. At the time of writing (2009), Bruichladdich distillery is helping to prepare a new distillery in Port Charlotte, using equipment from the now demolished Interleven distillery. The new distillery is on the site of the former Lochindaal distillery.

The lowland grain distilleries were amongst the first licensed (and therefore legal) distilleries and for a long time were much more industrialized and technically advanced than their (mostly highland) malt distillery counterparts. Originally producing their distillates using pot stills, they rapidly switched to Coffey stills in earlyto mid nineteenth century. Until the 1980s, maize was the major grain, the switch to wheat being economically driven.

The usual cycles of economic growth and recession with their concomitant rationalization programmes have left just a few (see Figure 3.2.1) large grain distilleries, which are in the hands of the larger companies, such as Diageo and Pernod Ricard. They are mostly in the industrial belt around Glasgow and Edinburgh, with one (Invergordon) to the north and another (Girvan) to the south. Almost all of their whiskies are blended with malt whiskies to produce the large number of brands of Scotch whisky that are available worldwide. Larger

Table 3.2.4 *Approximate annual production figures for selected malt whisky distilleries and grain whisky distilleries**

Distillery	Production of spirit ($\times 10^6$ l per annum)	Distillery	Production of spirit ($\times 10^6$ l per annum)
Balmenach (Speyside)	1.8	Glenmorangie (N. Highlands)	4.0
Benromach (Speyside)	0.25	Bowmore (Islay)	2.0
Clynelish (N. Highlands)	3.4	Kilchoman (Islay)	0.1
Cragganmore (Speyside)	1.6	Knockdhu (Speyside)	0.9
Glengoyne (W. Highlands)	1.2	Macallan (Speyside)	6.0
Glen Grant (Speyside)	5.9	Cameronbridge* (Diageo)	30
Glenlivet (Speyside)	5.9	Girvan (W. Grant)*	15

companies have their own grain and malt distilleries, with malt whiskies from particular distilleries featuring in particular brands, the grain whisky acting as a base for blending. For example Glen Elgin, Linkwood and Lagavulin malts are important components of the White Horse brand (Diageo); Dufftown and Inchgower of Bell's whisky (Diageo); Highland Park and Tamdhu of the Famous Grouse blend; Dalmore and Fettercairn of Whyte and Mackay blends.

Grain whiskies are subject to the same regulations as malt whiskies and the age statement on a bottle of blended Scotch whisky must refer to the youngest whisky in the blend, be it malt or grain whisky. Most blended Scotch whiskies have around 60% grain whisky in their composition, but this can drop to 40% or less for deluxe brands. As with other alcoholic beverages (see for example, Sherry Section 2.10.2) blending is an art, but the grain whisky is normally meant as a backdrop to the more pronounced character of the malt whisky components. Rather few single grain whiskies have been released over the years, the best known probably being Cameronbrigg, from Diageo's Cameronbridge distillery in Fife.

For many years now, various malt distilleries have sold bulk new make spirit to a number of companies (usually via brokers or distributors), ranging from grocers, department stores, supermarkets to wine and spirit merchants and independent bottlers/blenders. Over the years these have included (and many are still in business) Adolphi, Berry Brothers and Rudd, Cadenhead, Gordon and MacPhail, Harrods, Reid Wines (Bristol), The Scotch Whisky Society, Signatory, Duncan Taylor, J.G. Thomson (Glasgow), the Wine Society (Stevenage) and various supermarket chains.

Some of these companies, such as Gordon and MacPhail, mature the whiskies in their own warehouses and bottle them when they are considered to be at their best. This can be done by the vatting of several casks of the same distillate to ensure continuity of style (this is the tendency of Gordon and MacPhail) or from individual casks (which is the tendency of Cadenhead). Amongst these independent bottlers, there is also a variation in prebottling dilution, as well as in bottling techniques. Thus Cadenhead tends to dilute its products to 46% ABV, whereas Gordon and MacPhail tend to bottle at 40% ABV and J.G. Thomson specialize in cask strength (~58% ABV) malts (the 'As We Get It' series). Bottling is sometimes performed without chill filtration, as at Cadenhead.

All the variations mentioned above, plus the variety of casks in use, has naturally led to wide variations in the character of single malt whiskies from particular distilleries that have been matured and bottled by independent bottlers. This has sometimes resulted in considerable controversy, as some distilleries are unhappy about their products appearing for sale in a form over which they have had no control. For example, for many years the distillers William Grant and Sons have not released whisky to independent bottlers for

blending under the Glenfiddich name. However, there can be no doubt that the independent bottlers perform a valuable service to the malt whisky enthusiast, especially in the following respects.

They provide an extended range of malts from distilleries that bottle only one or two versions of their own whiskies. For example, for a time Strathisla distillery released only a 12 year old 40% ABV version of its malt, but 8, 15 and up to 35 year old versions were available from Gordon and MacPhail, whereas Cadenhead provided a 20 year old 46% ABV version.

They provide malts from distilleries that have either never or rarely bottled their own. Examples here include Ardmore, Benrinnes, Glencadam and Teaninich.

They provide malts from mothballed or demolished distilleries, such as Banff, Coleburn, Convalmore, Glen Mohr, Glenugie, Interleven, Kinclaith, Ladyburn, Littlemill, Lochside, North Port, St Magdalene and Tamnavulin.

They provide special bottlings of malts produced in certain distilleries from stills that are no longer in operation. Thus, Gordon and MacPhail have provided malts from now defunct Lomond stills in Glenburgie and Miltonduff distilleries. These versions were named 'Glencraig' and 'Mosstowie,' respectively. They provide a range of 'regional' and other vatted malts and blends.

Many independent bottlings have acquired a high reputation and have become well known, examples being the Scotch Malt Whisky Society bottlings, the Signatory range, the 'As We Get It' range, Gordon and MacPhail's Connoiseur's Choice range and Duncan Taylor's Peerless range. Two independent bottlers have direct links with the industry (other than as customers for some of its whiskies): Gordon and MacPhail own the small Benromach distillery near Forres (Speyside) and Cadenhead are owned by the Springbank distillery owners (J. and A. Mitchell).

3.3
Whiskeys

Too much of anything is bad, but too much of good whiskey is barely enough.
—Mark Twain

3.3.1 Scope

The main purpose of this chapter is to review distilled beverages that are distilled from fermented cereal mash and take the name whisky (apart from Scotch whisky, see Chapter 3.2) or whiskey. Also discussed here are similar drinks, known as Korn or Kornbrand, popular in German speaking countries. The Council Regulation (EEC) No. 1576/89 of 29 May 1989 of the (now) European Union (EU) defines whisky or whiskey in the following way:

- A spirit drink produced by the distillation of a mash of cereals saccharified by the diastase of the malt contained therein, with or without other natural enzymes
- Fermented by the action of yeast
- Distilled at less than 94.8% (v:v), so that the distillate has an aroma and taste derived from the raw materials used
- Matured for at least three years in wooden casks not exceeding 700 l capacity.

Hence for a distilled beverage to be sold as whisky or whiskey, its manufacture must comply with the above details. Korn or Kornbrand has a similar definition, except that the cereals are actually specified (wheat, barley, oats, rye or buckwheat), the regions are broadly specified ('Germany and in regions of the Community where German is one of the official languages provided that this drink is traditionally produced in these regions and if the grain spirit is obtained there without any additive') and there is no mention of maturation.

Within and outside the EU, the governments of individual countries superimpose additional or impose their own specific regulations governing the production of specific distilled beverages. This is necessary to protect the product from fraud and counterfeit and to ensure consistently high quality. Thus, Irish whiskey must be produced and matured in Ireland according to specified regulations (Section 3.3.2), Bourbon must

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

be produced and matured in the USA according to its own set of regulations (Section 3.3.4), and so on. Most whiskies produced in different parts of the world are grain spirits and can be exported to countries (e.g. to the EU or the USA) where this definition is in place. However, certain inexpensive Indian whiskies are produced from molasses spirit or from a mixture of molasses and grain spirit, and so cannot be exported to such countries under the name of whisky or whiskey (Section 3.3.6).

3.3.2 Irish Whiskey

The debate on whether it was the Irish or Scots who first distilled whisky is probably as old as the spirit itself. Although there is a distinct lack of written evidence, it is probable that regular distilling of whisky was established at about the same time in Ireland and Scotland. However, in the early part of the nineteenth century (and indeed, up to the end of that century), it was Irish whiskey that had the greater reputation abroad. Scotch malt whiskies at that time were largely consumed in Scotland, being thought too strongly flavored for the English and other foreign palates. This view was still widely held in the 1950s/1960s when distillers like W. Grant made the first serious drives to market single malt whiskies, such as Glenfiddich in England and elsewhere. Grain whisky from the lowlands (in the early nineteenth century, a pot still spirit) was the main Scotch for export and Irish whiskey was considered by many to be generally superior to this.

Later in the nineteenth century, especially following the advent of the Coffey still, blended Scotch whisky was the main competition for Irish whiskey abroad. Different economic circumstances, rather than differences in quality or character caused the eclipse of Irish whiskey in favor of (blended) Scotch whisky. General difficulties under British rule, the struggle for independence, economic depression and two World Wars (the Republic of Ireland was neutral in the latter) led to mergers, closures and general rationalization of the industry, so that the number of distillers diminished alarmingly in the twentieth century.

In 1966, John Power and Son (Dublin), John Jameson and Son (Dublin) and Cork Distillers (Midleton) merged to form the Irish Distillers Group. The Dublin distilleries were closed and a new facility was built adjacent to the old distillery at Midleton (which is now a visitors' center). The new distillery houses no less than thirteen 75 000 l pot and column stills (the pot stills are the largest in the world) and uses a combination of stills to produce all the old brands, as well as some new ones. The whole process is highly automated and highly computerized, with sensor devices on the column stills to control distillation. The production capacity is 19 000 000 l per annum. For a comparison with the annual output of Scotch distilleries (see Table 3.2.4, Section 3.2.6). In 1972, Bushmills Distillery (County Antrim, Northern Ireland) joined the group, keeping its distillery. However, weakened by an unsolicited takeover bid by Allied-Lyons, Grand Metropolitan and Guinness, (rather in the style of the acquisition of United Distillers by Guinness in 1986), Irish Distillers was bought by Pernod Ricard in 1988. Bushmills was sold to Diageo in 2005.

From 1972 until the early 1990s, all Irish whiskey was produced by the Irish Distillers Group (later Pernod Ricard), but Cooley Distillery was set up 1987 in a former vodka plant in County Louth on the Cooley Peninsular and now provides some much needed competition.

In many ways, Irish whiskey is similar to Scotch whisky: barley and other cereals (maize and wheat) are used, both pot stills and continuous stills are used, and both spirits are aged in small oak casks. However, there are three major differences: Scotch malt whisky is mostly double distilled from all malted barley, usually at least part of which (peated malt) has been exposed to peat smoke. Irish whiskey, on the other hand can be made with unmalted barley as well as malted barley, traditionally all unpeated and triple distillation (as for some Lowland and a handful of Highland Scotch malts) is the traditional method. Nowadays there are exceptions to the Irish tradition of unpeated malt and triple distillation, the first examples, significantly, being provided by Cooley Distillery, the only independent distillers in Ireland.

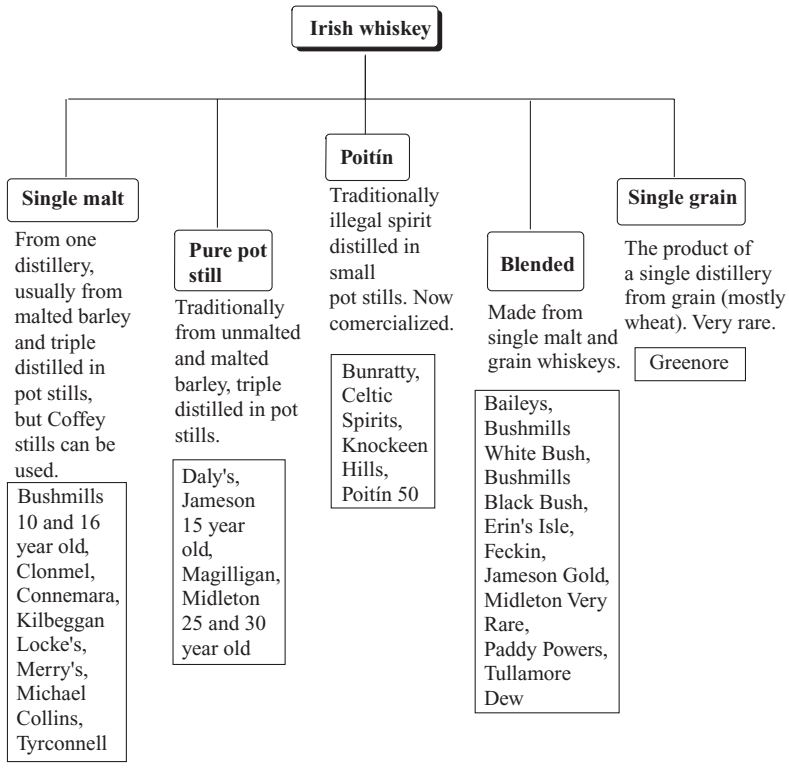

Figure 3.3.1 *Five basic categories of Irish whiskey*

Irish whiskey can be subdivided into five categories as shown in Figure 3.3.1. Of these, the blended types have the biggest share of the Irish whiskey market, with the greatest number of brands. The blend names often allude to now defunct, but once famous distilleries or their brands. The single malt and single grain categories have essentially the same meaning as for Scotch whisky (Section 3.2.1). Poitín (Potcheen) is the name for an originally artisanal and, for a long time, illegal spirit, the Irish 'moonshine.' Poitín was once widely produced in many small private pot stills in farmsteads and villages dotted about the countryside. Increased taxation and attempts by various British governments to suppress private distillation forced the production of poitín underground, as in Scotland. It was recently legalized for consumption in Ireland and there are now several commercial versions, some of which have 80% alcohol by volume. Single grain whiskey (like its Scots equivalent) is very rare, the huge majority of grain whiskeys being used in blends. At present, there is only one brand, Greenore, produced by the Cooley Distillery.

The pure pot still whiskey category is unique to Ireland, the 'green' or unmalted barley giving the spirit a distinct grainy/spicy character. The ratio of unmalted to malted barley varies between brands, but the Jameson 15 year old has an unmalted:malted barley ratio of 60:40. According to Irish law, any whiskey distilled using pot stills can be called 'pot still whiskey,' hence it is not a legal requirement for the Irish whiskey distiller to include unmalted barley in the grain bill. In a sense this is a pity, because a purely Irish characteristic remains unprotected at a time when virtually every indigenous style of alcoholic beverage in the European Union has been protected by a recognized geographic name of origin.

The next paragraphs give a brief account if the Irish Whiskey distilleries and their products.

Irish Distillers Group

Now owned by Pernod Ricard, the IDG runs the big distillery at Midleton, near Cork, producing a wide range of whiskeys, of which the Jameson brands are the biggest selling worldwide and the Powers brands are Ireland's best sellers. Other blends produced are Midleton Very Rare, Redbreast and Tullamore Dew. Pure pot still whiskey is also made here, Jameson's 12 year old, Midleton 25 year old and Midleton 30 year old being some of the oldest Irish pot still whiskeys available. Production at the new distillery began in 1975, but the old distillery was established in the early seventeenth century.

Grain whiskey, distilled at the Midleton site goes into the many IDG blends and some is sold to the Bushmills Distillery in Northern Ireland. Additionally, highly rectified spirits from Coffey stills are used to make Cork Dry Gin (Ireland's best selling gin) and Huzzar Vodka (the second best selling vodka brand).

Old Bushmills

Now owned by Diageo, the Bushmills Distillery, in the village of that name in County Antrim, is the oldest licensed whiskey distillery. The license was obtained in 1608 from King James I and in 1784 Old Bushmills Distillery became an officially registered company, in this respect predating Scotch malt whisky distilleries by several decades. The distillery produces two blends: Original ('White Bush' or 'White Label') and Black Bush. The latter contains a high proportion of oloroso cask-matured single malt whiskey in its blend. The Bushmills Distillery was the first (1980s) to introduce an Irish single malt whiskey, the 10 year old, matured in ex-Bourbon casks, but nowadays several single malts are available at varying ages – 12, 16 and 21 year old. These malt whiskeys generally undergo mixed cask maturation, for example the 21 year old spends time in firstly ex-Bourbon casks, then ex-oloroso sherry casks and is finished in ex-Madeira casks before bottling. All are triple distilled using pot stills.

Cooley

This is the only independent all Irish owned distillery company. It has two distilleries, the original one on the Cooley Peninsular near Drogheda, set up in 1987, and the recently (2007) renovated Locke's distillery/museum at Kilbeggan in County Westmeath. The Kilbeggan distillery has its origins in the eighteenth century and so is one the oldest in the world. In 2007, a nineteenth century pot still at the distillery was rejuvenated and put into operation after 50 years of silence, making it the oldest operating pot still in the world. A limited number of miniatures of spirit from this still of varying degrees of maturity were released in 2009 in advance of the release of the first (three year old) spirit. The first releases from the Kilbeggan distillery are expected to be in 2010, but at present Locke's Single Malt Whiskey, Locke's Blended and Kilbeggan brands are distilled at Cooley, but the malt whiskey is matured at Kilbeggan. The Cooley distillery has modern automated, computer controlled facilities for making both malt and grain whiskeys. Included are pot stills with long, wide necks that allow for some reflux during distillation, thus producing a lighter, cleaner spirit. A number of Cooley's products break away from Irish whiskey tradition; double rather than triple distillation is carried out in pot stills for the single malt brands and Connemara Peated Single Malt is the only Irish whiskey produced using wholly peated malt. Also, Greenore (15 year old) is the only single grain whiskey commercially available. Cooley Distillery has progressed remarkably since its birth and has accumulated numerous international awards, most recently (2010) being named 'Distillery of the Year' by the US whisky magazine, 'Malt Advocate.'

All of the above distillery companies produce whiskeys for international drinks companies, supermarkets and food companies (for use in confectionery and baked products for example).

The Cooley and Midleton distilleries are two of the most modern in the world. The former, originally much smaller, is expanding as demand grows, but its production monitoring system allows for expanding facilities, as well as enabling tuning of the manufacturing processes, quality assurance/control, preventative maintenance and early warning of process failure. At the present time (2009), there are no artisanal or craft distillers of Irish whiskey.

3.3.3 The Whiskeys of America

The alcoholic drinks of the early American and Canadian settlers and postrevolutionary Americans did not include that much whiskey; cider and beer (and later, fruit wines) were the main fermented drinks, whilst rum, fruit spirits and applejack were the major distilled drinks. The last mentioned drink was often made by pouring off the alcohol enriched liquid from frozen cider. Whiskey became the staple spirit of the pioneers who, from the closing years of the eighteenth century pushed west from the original American states through to the fertile lands in Kentucky, Illinois, Indiana, western Pennsylvania, Maryland and Tennessee. Here, the land was ideal for growing cereals – barley, maize, rye and wheat in particular – and the water was clear, with little organic matter, but contained dissolved salts (hardness), since it ran over chalk or limestone in many of these areas. High yielding native corn (maize) and barley predominated in Kentucky, Tennessee and Virginia, whereas rye was the main crop in Pennsylvania. Given that many of the new settlers were of Scots-Irish or German descent, the remoteness of these areas with respect to the richer eastern states and the poor road system (often impassable after heavy rain), it is understandable that most farmers chose to distil part of their cereals crop into a valuable, less bulky, more easily transported product, whiskey, just like their ancestors in Ireland and Scotland.

Whiskey had ousted rum as the major distilled spirit in the USA in the latter half of the nineteenth century, by which time production was running at around 374 000 000 l per annum. Up to that time, the big majority of American whiskey distillers had been using copper pot stills, like their malt whisk(e)y producing ancestors in Ireland and Scotland, but column stills (made of copper and wood) began replacing many of these in the 1890s, until today, the big majority of American whiskeys are produced using column stills. Also, definite styles were well established by that time: corn whiskey, rye whiskey, sweet mash, sour mash, charcoal filtration, aging in charred casks were all in progress and Kentucky Bourbon County whiskey had taken a high profile since about the time of the Civil War. In the twentieth century, the fortunes of American whiskey took a roller coaster ride between the lows of two World Wars, the Depression and Prohibition (1920–1933) and the boom period a few years after the Second World War, when in 1951, production peaked at ~767 000 000 l (Lichine, 1982). Since then, production of American whiskey more or less stabilized at ~400 000 000 l – about the level of production just before World War I – for many years.

Nowadays, consumption of American whiskey of all types makes up about 13% of spirits consumption in the USA, with Canadian whisky close behind on 10%. In 2001, the total whisk(e)y consumption in the USA was 29% of all distilled spirits; about half of the 1975 figure (Corrigan, 2004), but still a substantial portion. The ground has been lost principally to gin, rum, tequila and vodka, which are used mainly in cocktails, 'long' alcoholic drinks and latterly, 'ready to drink' beverages. The prohibition period damaged the American whiskey industry, not only by diminishing the number of distilleries (many of those in Kentucky and Tennessee, the heart of American distilling, never reopened after Prohibition ended), but also by influencing public taste. During Prohibition, people acquired a taste for blended Scotch whisky and Canadian whisky smuggled into the country, both of which generally had milder characters than pre-Prohibition Kentucky, Tennessee or rye whiskeys. Canadian whisky is still consumed more than American 'straight' whiskeys (see next paragraphs), although consumption of Scotch whisky has dropped, except for Deluxe blends and single malts (Section 3.2.6), whose consumption has increased markedly (Corrigan, 2004).

Table 3.3.1 *Categories of American whiskey*

Whiskey	Cereal-base	Comments
Bourbon	≥51% corn (maize), the rest usually rye and barley.	Other restrictions are given and discussed in 3.3.4. Most Bourbon is of the "straight" category.
Corn	≥80% corn	No cask-aging requirement, but in practice, often aged in used or uncharred casks.
Rye	≥51% rye	Much is blended, but there are examples of straight rye and blended straight rye whiskeys.
Straight	As above	Must be distilled at no more than 80% ABV and aged at least 2 years in charred oak casks (except straight corn whiskey).
Blended Straight	As above	A blend of two or more straight whiskeys. Used to make blended whiskeys.
Blended	As above	A blend of at least 20% straight whiskey (50% ABV) and either other whiskey or, more likely, grain neutral spirit.
Bonded (or Bottled in Bond)	As above	Refers to straight whiskey (usually Bourbon) (50% ABV) from a single distillery, from a single season and aged in government-supervised "bonded" warehouses for at least 4 years.

The production of modern American whiskeys is governed by legislation overseen by the US Food and Drugs Administration (USFDA or simply FDA) and supported by such commercial bodies as the American Distillers Association and the Kentucky Distillers' Association. However, labeling, like that of wines and beers, is regulated by the Treasury Department's Alcohol and Tobacco Tax Bureau.

American Whiskey can be made using any grain (but with certain restrictions for specific whiskeys, like Bourbon), distilled to less than 95% ABV (above which it becomes grain neutral spirit), aged in oak casks at not more than 62.5% ABV and bottled at no less than 40% ABV. These requirements govern the production of all whiskeys, with additional requirements for some, such as Bourbon and rye whiskey and modifications for others, such as corn whiskey (which is not required to be aged in casks). Further details are given under the appropriate whiskey heading, in Sections 3.3.4 and 3.3.5.

By law, American whiskey is classified into several categories, according to production history, although one of these categories (Blended Straight Whiskey) is of little importance to the consumer as it serves as the base from which other categories are constituted. They are summarized in Table 3.3.1.

Nowadays, the big majority of American whiskey distilleries are located in Indiana, Illinois, Kentucky, Ohio, Tennessee and Virginia, with many others dotted about in various states, such as California, Colorado and New York. Some of these are microdistillers (craft or artisanal distillers) producing a range of spirits, rather than just whiskey. Tuthilltown Distillery in New York makes corn and Bourbon whiskey, Peach Street Distillers in Colorado produce Bourbon whiskey, Templeton Spirits (Iowa) makes Bourbon, two Californian companies, St. George Spirits and St. James Spirits produce malt whiskey and whisky, respectively. A full list can be found in the Directory of Craft Distillers (2009).

3.3.4 Bourbon and Tennessee Whiskey

Bourbon whiskey (sometimes the Scottish variant whisky is used) takes its name from the old Bourbon County of Kentucky, to the west of Virginia, itself named after the French Bourbon dynasty that did much

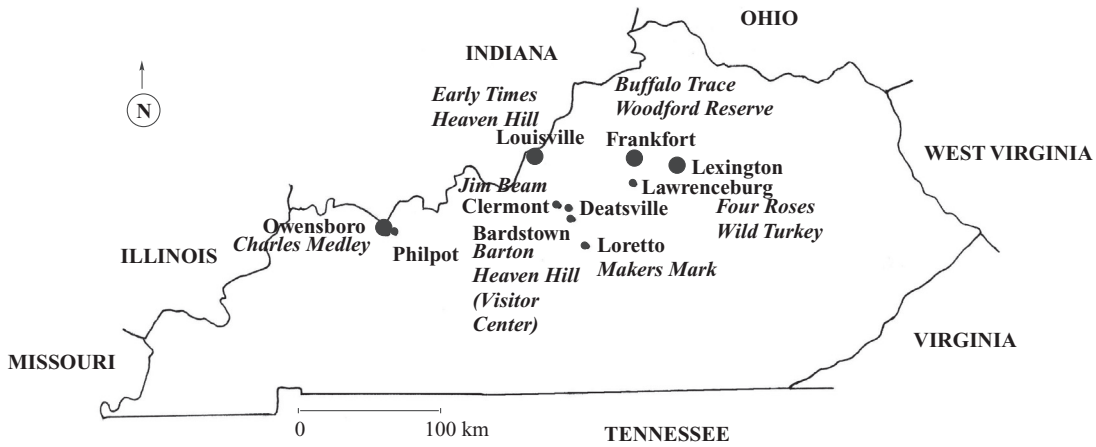

Figure 3.3.2 *Kentucky Bourbon distilleries*

to aid the colonialists in the Revolutionary War. Amongst the first settlers were (largely Protestant) Scots and Scots-Irish immigrants, who established small distilleries in the early 1800s, during the first colonization pushes into native American territories west of the original 13 states. Elijah Craig, a Baptist minister, set up one of the first stills in Georgetown, near Frankfort (Figure 3.3.2), in what was then Bourbon County, Kentucky. There were several small distilleries in Kentucky and surrounding states in the early 1800s, to which many farmers sent their corn crops for turning into whiskey at each harvest time. The whiskeys from this area soon acquired a good reputation and became known as Bourbon County Whiskey, but sometime before the Civil War, two processes that led to Bourbon whiskey having special distinction were developed and adopted: these were sour mash fermentation and the use of charred oak casks for maturation. In time, these two procedures were adopted by some distillers located outside Bourbon County and even in neighboring states, and so the general style eventually became known as Bourbon. Also in the then Lincoln County in the neighboring state of Tennessee, a process of trickling the new make whiskey through charcoal made from sugar maple wood was developed in the 1820s. This process became known as the Lincoln County process.

The origins of these special processes are uncertain, but it is known that the sour mash process was developed by James Crow, probably from the experience of producing a distinctive whiskey by using a portion of beer lees, rather than fresh yeast, from a previous fermentation to start a new fermentation. The starter contained lactic acid bacteria as well as yeast, thus giving a beer, and hence whiskey, with a special aroma/flavor profile.

The charring of oak casks was probably taken from the experience of importers of West Indian rum in the eighteenth century (or possibly from the rum distillers themselves); they found that rum matured in some accidentally charred casks tasted better than that aged in ordinary or toasted casks. Nowadays, once used charred Bourbon casks or their staves are used to mature many Scotch malt whiskies (Section 3.2.5) and rums, such as Puerto Rican rums (Section 3.5.4).

The use of charcoal filtration was probably developed by a distiller called Alfred Eaton, at the Cave Spring Distillery (now the Jack Daniel Distillery) in Lynchburg, Tennessee; at least he put his name to the process and helped to publicize it, if not actually inventing it. The idea probably came from the well known ability of charcoal to remove impurities and off flavors from liquids such as drinking water.

Bourbon whiskey, after a long period of consolidation up to the late 1990s, has experienced a boom during the first decade of the twenty-first century; production has doubled since 1999 (Kosar, 2008). The boom is

fueled by increased sales, especially export sales, of high-end and super premium Bourbons; in 2006–2007, export sales increased by 14.4%, with one particular super premium product, Woodford Reserve (Labrot and Graham/Brown-Forman), increasing its sales by 24%. Export sales of Bourbon whiskey totaled $713,000,000 in 2007 (Kosar, 2008). Increased sales began in the 1990s, with increased production of super/ultra premium brands, the gross revenue growth of this type growing by 20.1%, as opposed to 0.1% for the ordinary Bourbon category in the period 1996–2000 (Lioutas, 2004). A similar boom has been enjoyed in recent years by premium Scotch whisky, Scotch malt whisky and premium rum producers.

Present day Bourbon can be made anywhere in the USA, provided specific regulations (discussed next) are followed. In reality, all but one of the 11 large Bourbon distilleries are located in Kentucky, the odd man out being the A. Smith Bowman Distillery at Fredericksburg, Virginia. These are nearly all owned by large international corporations, such as Brown-Forman, Constellation Brands and Pernod Ricard. Additionally, several small 'specialty' or craft Bourbon distilleries have sprung up in the past few years. The latest craft distillery (2009) is the Corsair Artisanal Distillery at Bowling Green, Kentucky; it plans to produce Bourbon and rye whiskeys, as well as other spirits (Dowd, 2009). Tennessee has just two large distilleries, Dickel (at Tullahoma) and Jack Daniel (at Lynchburg), the latter being the largest producer of American whiskey.

Bourbon whiskey must be produced and matured in the USA, according to the following restrictions (see also Table 3.3.1).

- The grain bill must contain at least 51% (but not more than 79%) corn (maize)
- Maximum distillation strength must be not more than 80% (ABV) (160 American proof)
- New make whiskey must enter the casks at no more than 62.5% ABV (125 American proof)
- Maturation must be carried out in newly charred American white oak casks for a minimum of two years.

In practice, corn usually makes up well over 51% of the grain bill, with barley in second place, followed by rye, and much Bourbon is distilled at 70% ABV and is casked at below 60% ABV, for a maturation period of more than two years – often 10 years or more.

The corn is milled to a specified particle size, mixed with local limestone water and then steamed in a large cereal cooker. After cooling to ~65 °C, milled malted barley and rye are added to provide enzymes for hydrolysis of the starch to fermentable sugars. Most of the larger distilleries use an amylase enzyme mixture in place of some malt. Spent mash from a previous distillation (like the backset used in Scotch grain whisky production, but including the grains – see Section 3.2.3) is added at this stage or just before the pitching of yeast. The spent mash is of high acidity and hence lowers the pH of the new mash when mixed; this is now 'sour mash,' a medium that allows lactic acid bacteria as well as yeasts to flourish during fermentation. The sour mash method is used by the majority of American whiskey distillers. The remainder of the spent mash, a protein rich slurry, provides a valuable food for cattle and pigs.

The mash is then cooled to ~21 °C, and either a fresh yeast slurry or a slurry of yeast deposit (draff) from a previous fermentation is added. Fermentation proceeds for several days, after which the beer (grains and all) is transferred to the still, usually a pair of continuous columns, where distillation occurs and the new make whiskey is collected at 70% ABV, diluted to 60% ABV and is eventually transferred to new charred American white oak (*Quercus alba*) casks for maturation. Super premium Bourbons, such as Woodford Reserve are triple distilled in copper pot stills, just like the original Bourbon whiskeys in the early 1800s, and like Irish whiskey (Section 3.3.2) and a few Scotch malt whiskies (most are double distilled – see Section 3.2.4). In this case, distillation heads and tails management must be conducted, via a spirit safe (Section 3.2.4), during the second (high wines) and third (spirit) distillation, as for Scotch malt whisky distillation (Section 3.2.4) (Lioutas, 2004). The heart fraction is collected at ~80% ABV, vatted with fractions from previous distillations, diluted to ~60% ABV and eventually casked.

Compared with Scotch malt whisky wash, Bourbon beer derived largely from maize and having undergone a sour mash fermentation, has much higher concentrations of fusel alcohols and various carbonyl compounds, as a result of extensive lactic acid bacteria activity. Also, because of the much higher solids, protein and lipid content of maize, care needs to be taken during pot still distillation to ensure that no extraneous lipid oxidation products (such as unsaturated aldehydes) occur in the heart fraction going to the spirits receiver. This can be done by heating the still with steam, so that distillation occurs around 90 °C, and also by careful heads and tails management.

It is interesting to note that an 8750 l (2500 US gallons) charge of mash in a pot still will leave about 2000 kg of proteins, lipids and solids behind in the still after distillation, some of which forms a black deposit in the still and lyne arm. The black color is derived from copper (II) sulfide, which is formed by reaction of copper metal on the surface of the still with organosulfur compounds derived from both the cereals and the fermentation process. This has the important effect of removing the more objectionable aromas due to high levels of certain highly odor active organosulfur compounds, such as ethanethiol, dimethyl sulfide, dimethyl disulfide and others. After distillation, some of these organosulfur compounds will either be present below their odor threshold values or will be present at levels that make positive contributions to the whiskey aroma. See Section 3.2.5 for more detail about distillation and organosulfur compounds. This, of course is common to distilled spirits in general; distillates from purely stainless steel stills can have cooked vegetable and cabbage notes that are too pronounced. The column stills used to distil most Bourbon and Tennessee whiskeys are either hybrid stills (with stainless steel exterior shells, but the with copper internal structures, such as boiler plates and condenser tubes) or are made of stainless steel, in which case, it is common practice to include pieces of cut up copper tubing into the still.

The congener profile for new make Bourbon is quite different for pot still and column still processes. Pot still whiskey has higher levels of certain of the more volatile (lower boiling point) constituents, such as acetal, acetaldehyde, ethyl acetate and 1-hexanol, as well as higher ethyl esters such as ethyl butanoate, caprate, lactate, laurate, myristate and palmitate. Column still whiskey, on the other hand has higher concentrations of some fusel alcohols, *iso*amyl acetate, 2-phenylethanol and 2-phenylethyl acetate. Apart from these differences, pot still and column still Bourbons have many common congeners, with over 300 compounds being identified, if other whisky types are included. Of these, only a few (known as odor active compounds) possess odor activity values (OAV $>$ 1) (Section 4.7.3) that allow them an individual contribution the overall spirit aroma, with the most active of these being known as key odorants. However, many of the other congeners with lower OAVs ($<$1; background volatiles) are now thought to modify the aroma of key odorants and consequently it is believed that they make a valuable joint contribution.

Techniques such as GC-olfactometry ('sniff GC') (Section 4.3.2) and dilution to odor theshold methods such as aroma extract dilution analysis (AEDA) have been used to distinguish odor active volatile compounds from the background volatiles in the matrix (Connor *et al.*, 2001; Poisson and Schieberle, 2008a; 2008b). Connor *et al.* (2001) used GC-O on SPME extracts of Scotch whisky and found *cis*-whisky lactone and vanillin to be important contributors to whisky aroma. Previous to that, it had been proposed, on the basis of odor activity values (OAV = concentration/odor threshold value (OTV) in aqueous-ethanol; see Section 4.7.3) on components of model whisky, that butanal, 2,3-butanedione, 3-methylbutanal, methylpropanal and certain esters, such as ethyl acetate and ethyl hexanoate were important whisky aroma compounds (Salo *et al.*, 1972).

More recently, the application of aroma extract dilution analysis (AEDA) has been applied to the identification of key aroma compounds from fractionated solvent extracts of Bourbon (Poisson and Schieberle, 2008a). On the basis of the highest flavor dilution factors (FD), the key odorants (from 45 odor active compounds) were found to be (in order of decreasing FD values and not including an unknown flowery compound) (*E*)-β-damascenone; γ-nonalactone; 4-allyl-2-methoxyphenol (eugenol), γ-decalactone, 4-hydroxy-3-methoxybenzaldehyde (vanillin) and *cis*-whiskylactone (Figure 3.3.3). Overall, these compounds make an

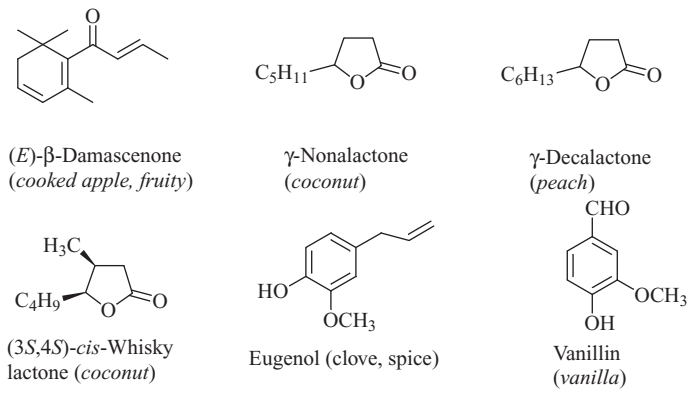

Figure 3.3.3 *The six most aroma active compounds of Bourbon whiskey. From Poisson and Schieberle (2008a)*

important contribution to the perceived overall fruity, smoky vanilla note of the Bourbon sample. Additionally, 3-methylbutan-1-ol (malty note), β-ionone (violet note), 2-phenylethanol (flowery), *trans*-whiskylactone (coconut note) and ethyl (*S*)-2-methylbutanoate (fruity) make important contributions. Furthermore, several unsaturated aldehydes ((*E*)-2-decenal, (*E*)-2-heptenal and (*E*,*E*)-2,4-nonadienal) contributing green or fatty notes were identified for the first time in Bourbon.

Thirty-one of the 45 odor active components of Bourbon whiskey were quantified by stable isotope dilution assays, their odor threshold values (Section 4.7.3) were determined in ethanol:water (4:6) and hence their odor activity values (Section 4.7.3) could be calculated (Poisson and Schieberle, 2008b). Twenty-six of these components had OAVs >1 and hence can be considered to make a direct contribution to Bourbon aroma. The compounds with the highest OAVs included (in order of decreasing values) ethanol, (*S*)-ethyl (2)-methyl butanoate, 3-methylbutanal, vanillin, (*E*)-β-damascenone, ethyl hexanoate, ethyl butanoate, ethyl octanoate, 2-methylpropanal, (3*S*,4*S*)-*cis*-whiskylactone, (*E*,*E*)-2,4-decadienal, 4-allyl-2-methoxyphenol (eugenol), ethyl 3-methylbutanoate and ethyl 2-methylpropanoate. Aroma recombination experiments using the 26 key aroma compounds dissolved in ethanol:water (4:6) allowed the aroma of Bourbon whiskey to be mimicked and omission studies supported the importance of all the esters, ethanol, *cis*-whiskylactone and vanillin for the overall aroma of Bourbon.

GC-O analysis of the headspace volume above the whisky indicated 23 compounds with the greatest odor activity, of which 3-methylbutanal (malty) had the highest RDF factor (smallest headspace volume in which the aroma compound is detectable), followed by ethanol, ethyl methylpropanoate (fruity), 2-methylbutanal (malty), 1,1-diethoxyethane (fruity), 3-methylbutanol (malty) and an unknown sulfury compound (Poisson and Schieberle, 2008a).

The norisoprenoids (*E*)-β-damascenone, α-damascenone and β-ionone are believed to be derived from carotenoids and have been found in a range of distilled spirits and wines. The immediate precursor of (*E*)-β-damascenone is thought to be 3-hydroxy-7,8-dihydro-β-ionol (Roberts and Acree, 1995).

The whisky lactones and the other odorous lactones are derived from the wood of American white oak during maturation; they are generally found at higher levels in whiskies aged for long periods in heat treated oak casks (Connor *et al.*, 2001). The unsaturated aldehydes (*E*)-2-nonenal and (*E*,*Z*)-2,6-nonadienal (already found in other whisky samples) and the new ones described above are probably formed by degradation of cereal lipids, which are abundant in maize. However, linoleic acid is also formed during fermentation and lipids can be released from oak wood during aging, so there are three possible sources for these aldehydes. See Figure 3.3.3 for the six most odor-active components of Bourbon whiskey.

A key feature of American whiskeys in general (and of course many Scotch whiskies and premium rums) is the use of charred casks made from the American white oak. Some companies, such as Brown-Forman have their own cooperages, but each year over half a million casks are supplied to the Bourbon industry by the Independent Stave Company of Lebanon, Missouri. Casks are made preferably from 80 year old trees, since at that age there is much tylose present to block the vascular channels in the heartwood, thus increasing the waterproofing ability and decreasing the permeability. American white oak casks are known to cause slower maturation than French oak casks of similar size, because of the coarser grain of French oak wood. Also, American white oak wood contains less tannin than French oak, so it is considered by many to be more suitable for the maturation of whiskies, where excessive tannin is not required.

Oak wood for making casks is treated in different ways according to the cooperage and according to the type or brand of whiskey it is destined to contain, but a general scheme is outlined next. Wood for casks is usually left in the open for four weeks or so, during which time its water content falls from ~40% to ~30%. It is then taken to a pre-dry shed for about four weeks where it is subjected to steam derived humidity at ~30 °C, starting at 60% humidity and dropping to 40% at the end. Following this, the wood, now containing ~20% water is moved to the kiln where it rests for about a week at ~60 °C in the presence of mildly turbulent hot air. After this, the water content is down to 10–14% and the wood is ready for fashioning into casks.

The wood for cask heads is planed and cut into circles. On the other hand to make staves, logs must be hand split to preserve the wood grain and endow. The logs are quartered and then cut to the appropriate length, tapered at each end, beveled, planed on the outside and given a second planing to induce a slight cupping on the inside. Sufficient staves for a cask are assembled together and a temporary steel hoop is placed over them. The whole is steamed for ~15 minutes to make the staves more pliable. Next, a cone device bends the staves into shape and a hoop is placed near the top. This is followed by dry heating to maintain pliability of the wooden staves, allowing them to be pressed together and leveled, so that later the cask heads can be fixed on securely. Next, two temporary bilge hoops are added to the middle, the staves are pressed tightly into place by a 'roll out' machine and a 'trusser' machine fixes the hoops tightly. The trussed staves are now ready for charring.

Charring of trussed staves is carried out using rotating blow flames so that an even char is obtained. There are five levels of charring, on a scale of 1–5, depending on the time of exposure to the flame. Each distillery has its own requirements for charring, but the most common is grade 4, which requires 1 min exposure to the flames. The heads are treated in a similar way, moving on a conveyer belt over the flame.

The whole cask is then assembled by fitting the heads onto the staves. The ends of the joined staves are trimmed and a 'croze' or groove is cut into the staves, near to each end, to receive the barrel heads (Figure 3.3.4). Barrel heads are custom cut to fit the croze, and are assembled using dowels and reed to make a perfect seal. The heads are fitted into the croze and the head hoops are place in position. The cask is tested for leakage and if passed, it receives a final planing and some sandpapering to give a pleasing finish.

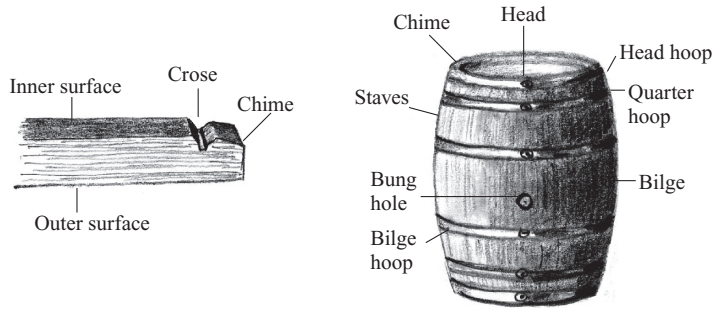

Figure 3.3.4 *Anatomy of a whiskey cask and close-up sketch of a stave top, showing where the cask head fits*

Some cooperages, such as the Bluegrass cooperage of Brown-Forman subject their cask interiors to toasting by a small flame as well as charring. Toasting results in:

- Decomposition of some of the wood lignins to vanillin and phenols (such as eugenol)
- Decomposition and oxidation of lipids to give lactones, such as *cis*- and *trans*-whiskylactones
- Caramelization of wood carbohydrates to furan and other derivatives
- Formation of brown coloring compounds via caramelization and Maillard reactions
- Decomposition of some polyphenolic compounds into simpler units, such as gallic acid.

The charring process results in a layer of black material over a thin layer of red toasted wood, rich in the products of toasting mentioned above. Processes occurring during maturation in oak casks are discussed for wine in Section 2.9.5 and for Scotch whisky in Section 3.2.5), so the discussion here will be limited to the influence of charring and toasting. During the aging of whiskey in charred oak casks, the charred layer, which contains many tiny fissures, acts as a filter, allowing some evaporation and some ingress of oxygen. It also acts as an adsorbent material for some unwanted compounds that when present in whiskey at higher concentrations give it an immature or rough character. At the same time, compounds from the red toasted layer are slowly leached into the whiskey, where they contribute certain aroma/flavor characteristics: vanillin and phenols give vanilla and spicy notes, lactones give coconut notes and furans give caramel notes. Additionally Maillard compounds contribute to the golden color of Bourbon and the phenolic compounds contribute to 'mouthfeel.'

Much Bourbon is matured in thermostatted warehouses, so that at higher temperatures whiskey expands into the wood material, but on cooling it contracts, bringing into solution flavoring and coloring compounds out of the red toasted layer.

A process that has some affinity with the charred cask method is the Lincoln County process of subjecting new make Tennessee whiskey to contact with charcoal immediately before transferring the whiskey to casks for aging. The charcoal is produced by burning sugar maple wood; it has a low surface area ($\sim$300 m^2/g) and so adsorbs a certain amount, but by no means all of the congeners that give new make whiskey its harshness. The purpose of charcoal treatment is to mellow the spirit before its long sojourn in cask. Hence the charcoal vats are sometimes known as mellowing vats. Treating spirits with charcoal is not unique to American whiskey, as it is used in much vodka production (Section 3.4.3), and sochu and soju production (Section 3.4.4). The main difference is that the use of activated charcoal with a surface area up to $\sim$1500 m^2/g to treat vodka strips away all flavor compounds and leaves an almost odorless and tasteless spirit.

The wood for charcoal is cut from shaded sugar maple trees in the autumn. After drying in air, the wood is cut into $\sim$10 cm $\times$ 10 cm $\times$ 1.5 m billets, which are stacked on open ground (not in a pit like charcoal is often made) six at a time, criss-crossed in layers forming 'ricks' about 2–2.5 m high. The ricks are set in squares of four, with a definite lean toward the center, so that the structures collapse inward when burning. The ricks are doused in alcohol and set alight, the fire being controlled by spraying with water. This prevents too much oxygen access to the burning wood, keeps down the temperature and hence prevents the formation of ash; too much water, however, leaves unburned wood with the charcoal. Burning takes about three hours, after which time the charcoal is allowed to cool before being broken up into pea sized pieces.

The vats at the Jack Daniel distillery are about 1.5 m in diameter and 3 m deep. They are filled to a depth of 2.5 m with charcoal pieces, with a white wool blanket at the bottom and new make whisky is sprinkled on to the surface from two crossed perforated tubes at a rate sufficient to give a flow of 30 l/min at the bottom of the vat. The charcoal bed is replaced every six months or so and in total there is about a 1% loss of spirit penalty to pay for the mellowing process.

At the Dickel distillery, the mellowing process is performed in refrigerated vats. A wool blanket is placed at the bottom of the closed off vat, followed by the charcoal pieces and another wool blanket at the top. New make whiskey (or whisky as it is called at Dickel) is trickled onto the top blanket whence it fills the vat,

permeating the whole of the charcoal bed. When filled, the valves at the bottom of the vat are opened and the mellowed whisky is transferred to a spirit vat for casking. The refrigeration is used because it was noticed many years ago at Dickel Distillery that the whisky mellowed in the cold winter months was superior. Soaking the charcoal bed with whisky is reckoned to give more efficient contact and to prevent inefficiencies caused by channeling. In this way, a charcoal bed at Dickel lasts about a year, but at either distillery, the time to replace a charcoal bed is judged by nosing and tasting the outcoming whiskey. A new charcoal bed takes out rather too much of the whiskey flavor components as well as less desirable elements, whereas toward the end of its life it is perhaps just beginning to lose its effectiveness at adsorbing all the less desirable components. Once again, taking into consideration the variations mentioned above as well as other variations (e.g. due to different cask characteristics), the blenders play their important role by assembling which casks are to be vatted (blended) before bottling, thus providing a uniform product.

3.3.5 American Rye and Corn Whiskies

Rye is an important cereal for the production of Korn (sometimes more generally termed Schnaps) and Vodka in northern Europe and so it was natural for the German immigrants of Maryland and western Pennsylvania to grow rye and produce rye whiskey from it.

American rye whiskey must be made from a minimum of 51% rye, distilled at less than 80% ABV and aged for a minimum of two years in new charred casks. Unless the distillation process includes extensive rectification, rye distillate has a characteristically pungent aroma and hard edged spicy, grain-like flavor. According to American law, a highly rectified spirit (say, distilled at 95% ABV) produced from rye beer could not be called rye whiskey. It is probably this rather uncompromising nature of rye whiskey that led to its decline during the second half of the twentieth century. National Prohibition played even greater havoc with rye whiskey than other with American whiskey types, since during that time and during World War II, peoples' palates became better attuned to more neutral and more delicate spirits; bootleg and smuggled liquor at first, imported and legally home produced liquor later. The market for rye whiskey diminished so considerably that nowadays the major brands of straight rye are produced by the Bourbon distillers of Kentucky and Indiana, as well by Jack Daniel's Distillery in Tennessee.

More recently, there has been a surge of interest in American rye whiskey, with several Bourbon distilleries producing premium straight rye whiskeys, often with old Pennsylvania or Maryland brand names or original distillery names (Regan, 2007). These include Rittenhouse Rye 100 Proof, Pikesville (both Heaven Hill Distillery), Sazerac 18 year old, Van Winkle Family Reserve Rye 13 year old (both Buffalo Trace Distillery), Red Hook Rye 23 year old and Mitcher's 10 year old Straight Rye Whiskey (Kentucky Bourbon Distillers), Old Overholt four year old (Jim Beam Distillery) and Russell's Reserve Rye (Wild Turkey Distillery). Other straight rye whiskeys produced at Bourbon or Tennessee distilleries include Jim Beam Rye, Wild Turkey Straight Rye Whiskey and Jack Daniel's Rye.

Apart from the products of the Bourbon distilleries, two premium rye whiskeys have recently emerged from new distilleries. The first is Old Potrero distilled at the Anchor Distillery (under the same ownership as Anchor Brewery) in San Fransisco. It is a single malt distilled in pot stills from beer made with 100% malted rye and is matured in toasted (rather than charred) oak casks. There are currently three versions: Eighteenth Century Style and Nineteenth Century Style (neither with an age statement) and Hotaling's, a 13 year old whiskey. The second is from the Mount Vernon Distillery in Washington, close to George Washington's home; the whiskey is allegedly based on the rye whiskey produced by George Washington. Although the number of straight rye whiskeys is increasing steadily and even includes a number of premium and single malt brands, the majority is used for blending with grain neutral spirit and other straight whiskeys (to produce blended whiskeys) or with other straight whiskeys (to produce blended straight whiskeys).

Canadian whisky was once referred to as 'rye whisky,' because at one time rye was high in the grain bill of such whiskies. However, for many years now rye has been a minor component of the grain bill of most Canadian whiskies (the major cereals being maize and wheat, but see Section 3.3.6 for some exceptions), which are characterized by sweeter, less spicy, perfumed and pungent characters than American rye whiskeys. Furthermore, Canadian law makes no distinction between (Canadian) whisky or rye whisky, provided it possesses the aroma, taste and character associated with Canadian whisky (Section 3.3.6). This has inevitably led to some confusion and there are still those who believe that Canadian whisky is essentially rye whisky. All this is especially ironic considering that American rye whiskey was displaced largely by Canadian whisky when prohibition ended in 1933.

According to US law, corn whiskey must be distilled from beer made from a mash containing at least 80% corn (maize); Bourbon must contain less than 79% corn. Like other American whiskeys, it must be distilled at less than 80% ABV, but unlike the others, there is no obligation to age it in oak casks. However, if it is matured in oak, then the law specifies two years in new or used uncharred casks. This type of whiskey, when made in pot stills, is probably the closest to the first grain whiskeys produced by the early colonial settlers in Virginia and neighboring states. It was produced openly by most farmers in these areas for home consumption and for trading until permanent excise taxes were imposed after the Civil War. Production of corn whiskey by small farmer-distillers then went 'undergound' and became known as 'moonshine.'

Today, most corn whiskey is produced using column stills and is used for blending after storage in cask for at least two years, but at Belmont Farm Distillery in Virginia a fresh (unaged) clear spirit 'Virginia Lightning' is made from almost 100% corn mash using pot stills. The home grown corn is ground and cooked in a stainless steel cooker. On cooling, crushed barley malt is added to achieve saccharification and the mash is fermented with added yeast. After fermentation (about four days), the mash is transferred to the 2000 US gallon (7000 l) copper pot still, where the first distillation takes place. A second distillation in a doubler is carried out to purify the spirit and to increase its alcoholic strength.

3.3.6 Whiskies from Other Countries

Canada

Canada, India and Japan figure prominently amongst a large number of other countries that produce grain spirits called whisky. Canadian whisky is consumed worldwide and constitutes a significant proportion of distilled spirits consumption in many countries, particularly the USA (Corrigan, 2004). Domestic Canadian whisky is often described as 'rye whisky,' despite the fact that rye malt is only a minor part of the grain bill for the big majority of products. According to Canadian law, Canadian whisky or Canadian rye whisky or rye whisky must be made according to the following criteria (CRC, 2009):

- It must be a potable alcoholic distillate, or a mixture of potable alcoholic distillates, obtained from a mash of cereal grain or cereal grain products saccharified by the diastase of malt or other enzymes and fermented by the action of yeast or a mixture of yeast and other organisms
- It must be aged in small wood for not less than three years
- It should possess the aroma, taste and character generally attributed to Canadian whisky
- It must be manufactured in accordance with the requirements of the Excise act and the regulations made thereunder
- It must be mashed, distilled and aged in Canada
- It should contain not less than 40% alcohol by volume
- It may contain caramel and flavoring.

In practice, the big majority of Canadian whisky is produced mainly from maize and wheat, with malted barley and rye generally playing a minor role from a quantitative sense, but the last two are important for supply of diastase enzymes for saccharification of gelatinized starch derived from maize (mostly) or wheat. Although barley and wheat are grown in nearly all the provinces, maize is grown extensively only in southern Ontario and Quebec, and indeed, Canada is a net importer of corn, most of the imports coming from the USA.

The production of most Canadian whisky in some ways resembles that of Scotch grain whisky (Section 3.2.3), based on maize or wheat, it is distilled in continuous Coffey stills and matured in oak casks for 4–12 years (although the law requires a minimum of three years). The main difference is in the blending: Canadian blends are composed of different grain whiskies, Scotch blends contain both grain and malt whiskies. The multiple continuous stills allow fine temperature control and, by increasing or decreasing the number of plates, at one extreme, grain neutral spirit (∼96% ABV) can be produced, or at the other extreme, more flavorsome distillates (at ∼60–70% ABV) can be made. The blander and more strongly flavored distillates are blended to give a product that is representative of the particular brand, according to the style of the company (nearly all Canadian whisky distilleries are owned by international companies). In general though, the emphasis is on lightness and delicacy, features that render Canadian whisky good for making mixes and cocktails.

Growth in Canadian whisky consumption was just 1.6% in the USA between 2002 and 2006. Value brand consumption dropped, but as in other distilled drinks sectors, sales of premium and super premium brands increased (Peck, 2008). Crown Royal (Diageo) was the sales leader in the USA (∼25% of Canadian whisky sales) in 2008, kept there by growth of two ultrapremium whiskies: Canadian Royal XR and Canadian Royal Cask No. 16. Wiser's was the leading Canadian whisky in Canada in 2008 (Peck, 2008), but Canadian Club (Beam Global/Fortune Brands) and Canadian Mist are better known outside Canada.

At the time of writing (2009), there is only one single malt whiskey produced in Canada, the 10 year old Glen Breton Rare Single Malt Whiskey, distilled and matured at the Glenora Inn and Distillery on Cape Breton, Nova Scotia. This whiskey, produced in the Scottish style was threatened a few years ago by an objection from the Scotch Whisky Association (Olver, 2007). The objection was related to the use of the word 'Glen' in the name – the product could be mistaken for being of Scottish origin. Canada's Trade-Marks Board over-ruled the objection, so the production of Glen Breton continues. Also at the time of writing, the construction of Pemberton Distillery (British Columbia) is underway. It is intended to produce a malt whisky, as well as vodka, using organic produce.

The Canadian distiller is probably subjected to more government control than any other distiller. Excise officers are allocated specific distilleries, where they exert supervision of the whole process, from arrival of the grains through fermentation, distillation, maturation to filtration and bottling. However, the excise office does not interfere with actual techniques; each distillery has complete control over the quality and character of its products.

Japan

Japan is the world's fourth largest producer of malt whisky (after the USA, Scotland and Canada) and the second producer of single malt whisky (after Scotland). The first Japanese distillery (Yamazaki) was set up by Shinjiro Torii (founder of Suntory) in 1924, in collaboration with Masataka Taketsuru, who in 1919–1920 had undergone some training in Scotland (Bunting, 2009). In 1934, the latter went on to found Nikka, Suntory's main modern rival in Japanese malt whisky. The military were the first major customers, whisky being an important beverage of the Imperial Japanese Navy. After World War II, the industry expanded enormously, under a protectionist regime that imposed high taxes on imported whisky, but the main product was blended whisky, sometimes made using neutral spirit in place of grain whisky in those days. In the 1990s the protectionist rules were removed, young upwardly mobile Japanese shifted their interests to the indigenous

Figure 3.3.5 *Sketch map of Japan, showing whisky distillery locations*

shochu (Sections 1.3.5 and 3.4.4), rich, more elderly men looked for imported whiskies, so the domestic market for mass whisky more or less collapsed. The surviving whisky distillers were forced to concentrate on premium products, particularly single malt whiskies for both domestic consumption and export. Blends are still produced, and have won international prizes (Bunting 2009; MacDonald and Ushio, 2008), but it is in the single malt category that Japan has excelled in the first decade of the twenty-first century. Several prizes have been won by Japanese malts from 2001, culminating in the capture of the gold award at the International Spirits Challenge by a Yoichi (1987) 20 year old malt whisky (Nikka) in 2008).

There are currently eight malt whisky distilleries in operation (Figure 3.3.5) and, like Scotland, several have been demolished or mothballed or diverted to other uses in recent years (Bunting, 2009). All but two of the working distilleries now producing malt whisky belong to the large conglomerates Nikka, Kirin and Suntory (Figure 3.3.5). The last mentioned company is the original and biggest whisky distiller in Japan. Its Yamazaki Distillery, built in 1923 was Japan's first, producing the Suntory Shirafuda blended whisky (released in 1929) initially. The distillery has 12 copper pot stills: six low wine and six spirit stills, most of the former being direct flame-heated (gas fired), whilst all the latter are steam heated. Good, iron free water is obtained from wells. This distillery produces single malts of various ages, from 10 to 50 year old, as well as Sherry wood aged malts, mostly at 43% ABV.

Suntory's Hakushu Distillery site has two buildings, the original one was built in 1973 and was for a few years the world's largest distillery. It housed no less than 24 copper pot stills (Jackson, 1989), producing malt whiskies for blends, but appears to be silent nowadays. The second building, known as Hakushu Higashi was built in 1981 and houses 12 pot stills with rectifying columns that produce 10, 12 and 18 year old malt whiskies at 40 or 43% (ABV). Suntory also has a grain distillery, known as Sungrain.

Japan's second largest whisky distiller is Nikka, with one distillery at Yoichi (Hokkaido) and the other near Sendai in northern Honshu (the Miyagikyo Distillery). The former was the original distillery, built in 1934 and housing at that time just one pot still that doubled as a low wine and spirit still. Now there are six coal fired stills. Hokkaido's climate is much more temperate than that of the Japanese islands further south, and although it is warmer than Scotland, it does have peat moors – peat was once used by the distillery. The

Yoichi Distillery is close to the sea and its water comes from underground aquifers. The single malts from Yoichi are some of Japan's most distinctive, ranging from cask strength versions to 10, 12 and 15 year old products of 43% or 45% ABV. The Miyagikyo Distillery was built in 1969 with eight stills. It produces a similar range of malt whiskies.

The Scots tradition has been largely upheld over the years and most of the distilleries are in maritime locations, so that Japanese and Scotch malt whiskies tend to have similar characteristics, with a similar range of congeners. Many of the production aspects of Japanese whisky have been studied over the years, especially during the present decade. This includes the influence of brewers' and distillers' yeasts (Wanikawa *et al.*, 2004) and the influence of lactic acid bacteria on spirit quality (Takatani and Ikemoto, 2004). Brewers' yeast was found to give higher concentrations of γ-lactones, unsaturated fatty acid ethyl esters (especially ethyl 9-decenoate) and other esters (such as ethyl 2-methylbutanoate) in the wash and also in the distillate (Wanikawa *et al.*, 2004). These components were shown by sensory analysis to be responsible for sweet, fatty notes and fruity notes (respectively) in whisky, especially new make spirit. It was shown that they are produced in greater quantities by lactic acid bacteria, which thrive in the wash fermented by brewers' yeast (but not distillers' yeast) as a result of the early death of the yeast cells. *Lactobacillus casei*, *L. plantarum* and *L. brevis* were found to thrive at lower temperatures, early in the fermentation, whereas *L. acidophilus* and *L. fermentum* were dominant at the higher temperatures of the mid to late fermentation period (Takatani and Ikemoto, 2004). The individual species of *Lactobacillus* gave specific estery, fatty, grassy sweet and other characteristics to the new make spirit, with *L. casei* giving, citrus, creamy and spicy notes of some complexity. If thermophilic bacteria such as *Streptococcus thermophilus* act upon the wort during mashing to reduce its pH from ∼5.9 to ∼5.5, both fermentation and the lactic acid bacteria activity were enhanced, leading to greater alcohol content of the wash and greater complexity of the resulting spirit, especially with regard to estery and fruity notes. Thus, although the basic flavor framework of the whisky is derived from alcoholic fermentation by *Saccharomyces cerevisiae*, beneficial supplementary flavors can be supplied by controlled (i.e. not dominant) bacterial activity. Lessons learnt from studies of these kinds by the Japanese and other whisky industries may well contribute to improved malt whisky quality.

At the other end of the production process, longer aging gives a higher concentration of phenols in the finished whisky, especially ellagic and tannic acids (derived from tannins) and lyoniresinol (derived from lignins) (Koga *et al*., 2007). It is thought that these compounds in the whisky contribute to the mature, smooth mouthfeel in two ways: firstly by enhancing the clustering effect of ethanol (Tanaka *et al.*, 2002; Nose *et al.*, 2004) and water molecules, and secondly by acting as reactive oxygen scavengers. Nonhydrated ethanol molecules are thought to give a rough mouthfeel through generating reactive oxygen species. Since many studies of the production methods and sensory characteristics have included Scotch and Japanese malt whiskies together, these have been discussed in greater detail in Sections 3.2.4 and 3.2.5.

India

Alcoholic beverages of various kinds were produced in India as far back as Vedic times and it is possible that the first distillations of fermented drinks were carried out in India or China. Nowadays, many traditional fermented beverages are still produced and large volumes of molasses based spirit are consumed by the countryside population. These are known as arrack and tharra (Section 3.5.2) and it is estimated that 250 million cases of arrack are consumed each year in India (Maitin and Stephen, 2004). At present, brandy, gin, rum, vodka and whisky produced in India are known as 'Indian-Made Foreign Liquors' (IMFL), of which *ca.* 80 million cases are produced, with *ca.* 60% of that being labeled whisky. Unlike the whisky of other countries, most Indian whiskies are based on grain neutral spirits distilled from fermented molasses. This is largely because molasses is a by-product of sugar refining (and cane sugar grows and yields well in much of India), so there is little competition for it as a food or other source, whereas the competition for barley, maize, rye and wheat as food means that very little of these crops are used to produce distilled spirits.

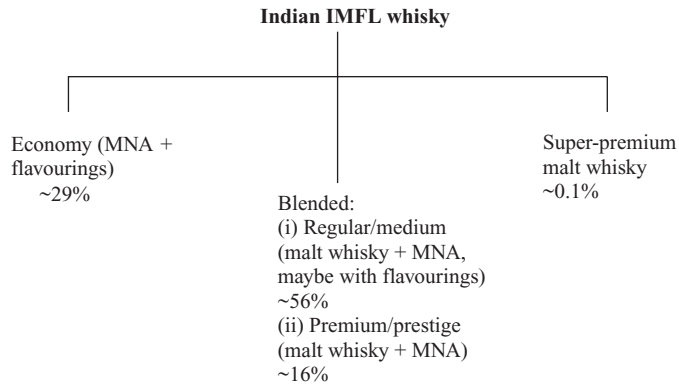

Figure 3.3.6 *Classification of Indian-made whisky. Approximate market share for early 2000s shown. Data from Maitin and Stephen (2004)*

The classification of present day Indian IMFL whisky is shown in Figure 3.3.6, where it can be seen that blends of malt whisky and molasses neutral alcohol (MNA) and flavored MNA type whiskies together form the overwhelming bulk of indigenous Indian whisky. Neutral spirits are produced from molasses in continuous column stills, as in other countries, and likewise the potable portion is only a fraction (in India about one third) of this, the rest being used for industrial and other purposes. Malt whiskies are produced in pot stills and matured in small oak casks, like their Scots counterparts.

A comparison of the flavor profiles of super premium Indian whiskies and the blended categories generally reflects the different materials and methods. Single malt or super premium whiskies have greater malt, oak and peat (smoke) character, along with a better mouthfeel, but some economy whiskies, whilst being low in these flavor attributes, can match the single malt whiskies on fruity, spicy and sweet characteristics, as a result of the flavorings used. The other blended whiskies tend to have intermediate flavor profiles, although some premium blends can match the single malts on floral and peat character (Maitin and Stephen, 2004). Correspondingly, Indian single malt whiskies are higher in congeners associated with pot still malt whisky: ethyl acetate, ethyl caprylate, ethyl laurate, *iso*amyl acetate, *iso*amyl alcohol, 2-methylpropan-1-ol and 1-propanol, for example.

Naturally, the blended whiskies and economy style are the lightest and were preferred by the majority of Indian whisky drinkers in 2004 (Maitin and Stephen, 2004). However, as more Indian people travel and taste foreign liquor, tastes may change and a growing middle class is already acquiring a taste for more flavorsome whisky of the premium or super premium type. Moreover, taxes on spirits imported into India have dropped, leading to greater competition from imports, and reciprocally, India is producing more malt whisky, including single malts, to improve its international standing and to challenge internationally renowned spirits such as Scotch whisky and rum (Battacharjee, 2004).

Europe

Whisky is produced in several European countries, apart from Ireland and Scotland. In the British Isles, there is a distillery in England (St. George's Distillery at Roudham in Norfolk), the Isle of Man (ManX) and Wales (Penderyn Distillery). The oldest of these distilleries is ManX, originally producing a whisky known as Glen Kella. Nowadays, the Manx distillery makes a unique spirit by taking a previously matured Scotch malt whisky and redistilling it in such a way as to preserve the major aroma and flavor profile. The result is a colorless, but flavorsome spirit that the company claims is ideally suited to making cocktails, but is also good to sip neat.

Much more recent is Penderyn Distillery, which opened in 2004 in the village of that name, near the Brecon Beacons. It produces a malt whisky using a hybrid pot still with a rectifying column above the pot, rather like stills that are used for some forms of pomace spirit (Section 3.7.2) and fruit spirit (Chapter 3.8). The column has seven perforated plates and so in theory can be used to produce a range of distillates, from light to heavy, by adjusting the amount of reflux. In practice, a highly rectified distillate (~92% ABV) is collected. It is diluted to 63.4% ABV before maturation in ex-Bourbon casks (many coming from the Buffalo Trace Distillery, see Section 3.3.4). Before bottling, it spends some time in ex-Madeira casks and it is probably this finishing touch that gives the whisky its distinction (it has been rated very highly by professional tasters). The Welsh Whisky Company, who owns the distillery, has succeeded in making the first Welsh whisky for about 100 years. The company also makes gin, vodka and a cream liqueur and is located in an area famed for the quality of its mineral water. Penderyn Distillery water flows through limestone into underground aquifers where it is retrieved and used for all distillery operations requiring water (except cleaning).

St. George's, which started distilling in 2006, is the youngest of these new distilleries. It produces unpeated and peated single malt whiskies that, at the time of writing (2009) are lying in casks in a bonded warehouse, with some of 2006 distillations being offered for sale.

There are several whisky distilleries in continental Europe, the best known being the Glann ar Mor Distillery on the northern coast of Brittany (Côtes d'Armor). This distillery, owned by the Celtic Whisky Compagnie, uses small flame heated copper pot stills with worm tub condensers, like a few Scotch malt whisky distilleries. Unpeated and peated malt whiskies are produced, all of which are aged in ex-Bourbon casks and some of which subsequently spend time in ex-Sauternes casks. The first distillation was in 1999, with the first bottles (Taol Esa) being offered for sale in 2005. The company also produces an impressive range of whiskies known as 'Celtic Connection,' which are matured Scotch malt whiskies rematured in ex-brandy or more exotic ex-wine casks, such as Jurançon, Monbazillac and Quartes de Chaume. Additionally, the company provides a good range of independently bottled Scotch malt whiskies (Section 3.2.6).

Sweden now has five malt whisky distillery companies (Box Destilleri, Gotland Whisky, Grythyttan Whisky, Mackmyra Svensk Whisky and Spirit of Hven), but only Mackmyra Svensk Whisky is distilling on a larger scale. This distillery started small-scale production in 1999, which was upgraded in size in 2002. So far, official bottlings are 'Den första utgåvan,' 'Preludium: 01 to 06' and 'Privus: 01 to 06.'

Korn is a German spirit that can be made from barley, buckwheat, rye and/or wheat. In practice, the most prestigious versions are distilled from wheat wash using column stills to give a highly rectified spirit, but one that retains some flavor of the original ingredients. It is lightly filtered and often spends a year in oak casks before dilution with deionized water and bottling, so it often has a pale golden color and has much more flavor than the more highly rectified and heavily filtered vodka, with which it is often compared. Korn is usually sold at ~32% ABV, versions with at least 38% ABV being known as 'Doppelkorn.' Korn is made in many areas of Germany, but is more popular in the north. One of the biggest producers is the Berentzen Gruppe; its output includes Berentzen Traditionskorn (from wheat), Dornkaat Korn and Strothmann Weizen (wheat) Korn and Doppelkorn. Other Korn manufacturers include Dieckmann (Helmstedt), Hegemann (Sprockhövel), Hoffe Alt (Rüssath-Hoffnungstaal), Kilian (Hünfelder-Dauborn), Mackenstedt (Bremen), Schmittmann (Düsseldorf) and Wöltingrode Kloster Kornbrennerei (Vienenburg, Braunschweig). The latter produces St. George Edelkorn, which is aged in ex-whisky casks. Many Korn distilleries produce other spirits, such as fruit spirits or aquavit; for example, the Berentzen Gruppe makes Bommerlunder Aquavit (Section 3.4.3).

3.4
Other Cereal Based Spirits

When the clergyman's daughter
Drinks nothing but water
She's likely to finish on gin.
—Rudyard Kipling

3.4.1 Introduction and Scope

This section discusses a number of distilled spirits, other than whiskies, derived from cereals. Two of these, gin and vodka, have large world markets and together account for well over 30% of the distilled spirits consumed in the USA, presently the world's biggest consumer of spirits (Corrigan, 2004) and around 33% of the UK spirits sales by volume (Atkinson, 2004). The remainder, Akvavit (or Aquavit) and rice wine spirits, such as soju (Korea) and shochu (Japan) all have big markets in more restricted areas: northern Europe for the first two and Asia for the last named.

In many cases, versions of these spirits may be of noncereal origin. For example, some vodka is made from potatoes and either gin or vodka may be produced from molasses. Highly rectified spirit produced in three column continuous stills from any of the above sources has minimal flavor and so is ideal for use as a base spirit for cocktails and other mixes or for combining with natural or nature identical flavorings to give flavored spirits. The European Union merely stipulates that juniper flavored spirits (which includes gin) may be produced from 'ethyl alcohol of agricultural origin and/or grain spirit and/or grain distillate' (EEC, 1989). However, it is widely held that gin and vodka in particular are superior if originating from cereals (Lichine, 1982). That is why the following discussions on gin (Section 3.4.2) and vodka (Section 3.4.3) will be limited to their production from cereal grains; by the distillation of fermented cereal mash.

3.4.2 Gin and Similar Juniper Flavored Spirits

Gin is essentially a juniper flavored spirit, although several other flavoring agents (called 'botanicals') are also used in the many versions produced all over the world (Aylott, 2003). The name gin, now in universal use, is a corruption of the French word genièvre, meaning juniper. Other corruptions of genièvre, including geneva,

Handbook of Alcoholic Beverages: Technical, Analytical and Nutritional Aspects Edited by Alan J. Buglass
© 2011 John Wiley & Sons, Ltd. ISBN: 978-0-470-51202-9

genever, genebra, ginebra and jenever, are used for specific kinds of gin. In the EU, all the above names may be used, depending on the circumstances, for what are classed as 'juniper flavored spirit drinks'; other, more local names such as peket and Wacholder may also be used where appropriate. Gin is normally produced from grain spirit to which juniper distillate and/or raw distillate of fermented juniper has been added. In many cases, this mixture is redistilled.

Although many botanical ingredients are used to flavor most gin, the major contribution comes from juniper berries. The juniper plant *Juniperus communis* grows in many areas of the world, where it produces an abundance of strongly flavored blueish berries. Juniper spirit per se is made in several central European countries by distilling a macerate of juniper berries in raw juniper distillate, itself produced by the distillation of a wine made by fermenting a juniper berry–water infusion. In Germany and Switzerland this 'juniper brandy' is known as Steinhäger. Juniper spirit is really a fruit spirit (Chapter 3.8), but is mentioned here as it is a close relative of gin distillates that are used to flavor many kinds of gin.

The first gin was produced in Holland during the seventeenth century at a time when spirits were still partly regarded as medicines. Fransiscus de la Boe, a physician and professor at the University of Leiden, while seeking a medicine for treating kidney disorders, found that the diuretic juniper oil could be introduced into the body more effectively by mixing it with either fruit or grain spirit. In the latter case, the juniper oil was found to greatly improve the taste, and hence his medicine, 'Genever' became popular in Holland and surrounding countries.

Its fame soon spread to England, where in the early eighteenth century (the early years of the Industrial Revolution) it was made essentially by distilling a juniper berry infused, hopped beer in small pot stills by a large number of artisanal distillers, particularly in London. Generally, it was not matured and the spirit probably contained high levels of undesirable and/or unhealthy components, such as methanol and fusel alcohols. Its rough, raw character was partially masked by the juniper and hop flavors and so its popularity grew alarmingly rapidly, causing great concern amongst governments, brewers and abstentionists alike. In an attempt to control the level of gin drinking, especially by the working classes, the government introduced the second Gin Act (1736), which required distillers to acquire an expensive licence and which imposed a duty on all the gin sold by the distillers, and further duties were payable by retailers, such as the owners of inns and taverns. Even though there was a heavy penalty for any person found selling gin without a licence, some 12 000 persons were prosecuted during the first two years following the passing of the Act (Young, 1979). Evasion was rife and so the Gin Act was repealed in 1743, the duty was removed and the distilling licence vastly reduced.

The discovery of redistillation and later of rectification allowed the production of a much more pure spirit that did not need aging in wooden casks.

Nowadays, gin can be found in three basic styles, as outlined in Figures 3.4.1–3.4.3. The Hollands, Geneva or Jenever style can be considered the original style, although there are several variations on this, as can be seen from Figure 3.4.1. Firstly, a beer (or wash) is made by fermenting the mash (Section 2.6.2) made from malted barley, rye and sometimes maize. Some distillers add juniper berries to the mash. After two or three days, the wash is distilled in pot stills and the middle distillate of which is redistilled with the added botanicals. The botanicals can be in the form of raw materials, but are more likely to be a distilled maceration of raw materials known as a gin distillate. The resulting spirit is usually aged in bulk, chill filtered and diluted with pure water to ~40% ABV before bottling (37.5% ABV is the minimum allowed by EU law). The process of a further redistillation in the presence of flavoring agents gives rise to double gin. Some Hollands gin is aged for several years in oak casks to give a more mellow character and golden color; this is virtually the only gin to be aged in this way. All Hollands gin has some grain flavor resulting from the congeners in the double or triple distilled spirit.

Nowadays, the London dry style of gin is the most prominent type, being produced in the USA and many countries other than the UK. An outline of its manufacture is shown in Figure 3.4.2, where it can be seen that

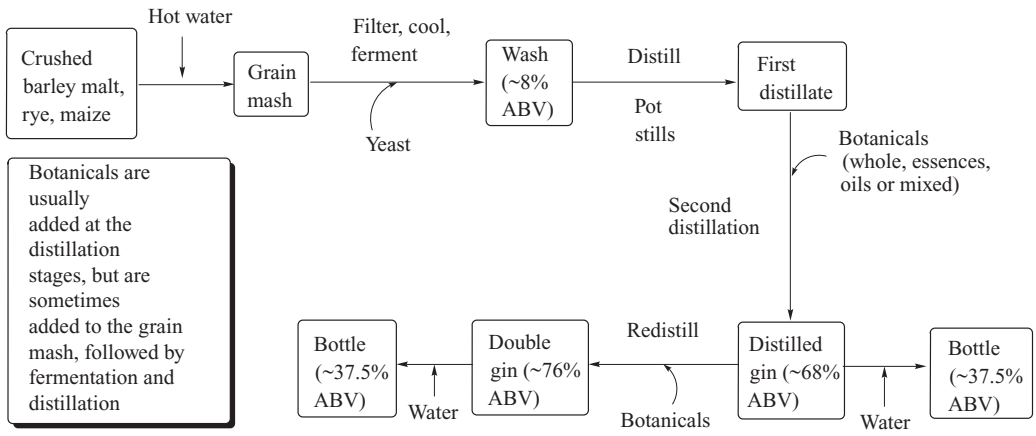

Figure 3.4.1 *Simplified scheme for production of distilled gin, such as Hollands or Geneva*

rectified or neutral grain spirit (usually produced from barley, maize and wheat) is the alcohol base, rather than the (essentially) more flavorful whiskey base used for Hollands gin. The neutral spirit will contain close to 96% (v:v) of ethanol concentration (EU law forbids use of spirit of greater strength than this), it will be low in congeners, including fusel alcohols and according to EU requirements (EEC, 1989) it must contain less than 50 mg/l of 100% ethanol by volume of methanol and less than 2 mg/l of 100% ethanol by volume of aldehydes (expressed as acetaldehyde). The botanicals are added and the mixture is redistilled. If this process is repeated, a London dry gin is the product. It contains ethanol, water and many flavor compounds from the botanicals, but very few of the compounds that render a new make double distilled spirit such as Scotch whisky harsh and raw. Hence, London dry gin needs no aging and can be bottled soon after distillation.

At the time of writing (2009), Plymouth gin is the only UK gin to have geographical protection; it can be produced only in Plymouth. Traditionally, it has been intermediate in style between London dry gin and Hollands gin, but nowadays it is probably rather closer to the former. Plymouth gin is made from crude spirit that has been distilled from wheat liquor at distilleries in London. The spirit is redistilled over botanicals 11 times in gas fired copper pot stills. It is diluted to ~41.2% ABV with deionized water before bottling.

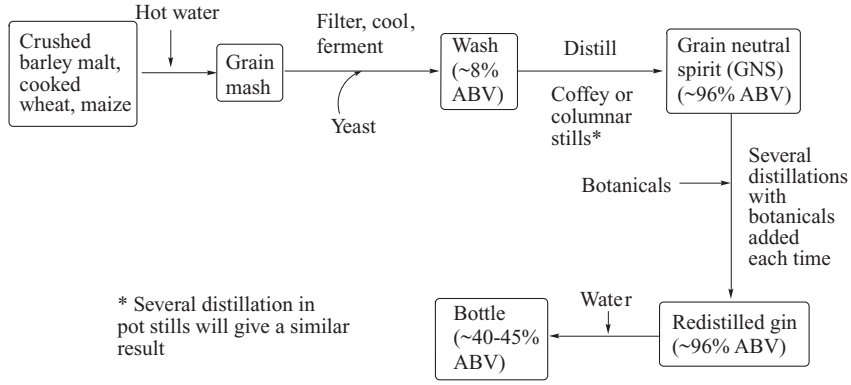

Figure 3.4.2 *Simplified scheme for production of redistilled gin, such as London Dry or Plymouth gin*

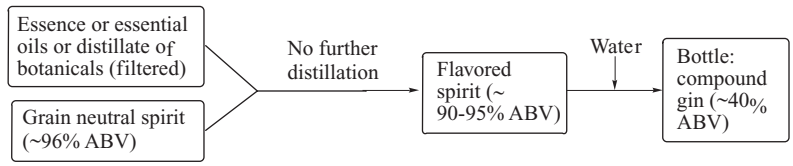

Figure 3.4.3 *Simplified diagram showing the production of compound gin*

In the EU, gin of the London dry or Plymouth type is known as 'distilled gin.'

The final type is an undistilled gin, whose typical manufacture is outlined in Figure 3.4.3. It is sometimes known as compound gin, although the EU allows the simple name of gin, but not distilled gin. It is simply made by mixing gin distillate with highly rectified neutral spirit of agricultural origin and diluting with deionized water to ≥35% ABV before bottling. This kind of gin can be made by amateurs and some less expensive commercial gin is produced this way; it is generally considered to be of inferior quality, but nonetheless is useful in the preparation of cocktails, mixes and 'ready to drink' beverages (alcopops).

The flavoring ingredients or botanicals are a crucial part of gin manufacture. Up to 100 ingredients can be used (Coates, 2000) to give additional complexity and each company has its own closely guarded secret recipe. Juniper berries, of course, are prominent, but many other ingredients are used, including allspice seeds, angelica root, cardamom pods, cinnamon bark, citrus peel, coriander seeds, ginger root, hop flowers, lavender flowers, orange flowers and orris root. Although mixtures of these raw materials can be used directly in the production of gin, most gin is made using mixtures of extracts and oils or most of all by using a distillate of a mixture of botanicals macerated in grain neutral spirit. The latter is known as a gin distillate or essence and an example of a method of preparing such a distillate, based on an example recipe given by Zach (2007), is shown in Figure 3.4.4. After steeping for two days the mixture is distilled slowly under vacuum, presumably not a high vacuum, and with the need to heat up to ~60 °C or so, as in the distillation of some commercial gin (Greer *et al.*, 2008).

The botanicals used to make gin, particularly juniper berries, are rich in monoterpenoids and other terpenoids, especially linalool from coriander seeds (see Table 2.12.1, Section 2.12.2). Although the monoterpenoids are important contributors to gin flavor, if present in high concentrations they can give the gin an overtly pungent aroma and flavor (Greer *et al.*, 2008). Furthermore, it appears that the application of heat during conventional distillation (~80 °C, no vacuum) of a maceration of juniper berries, coriander, dried

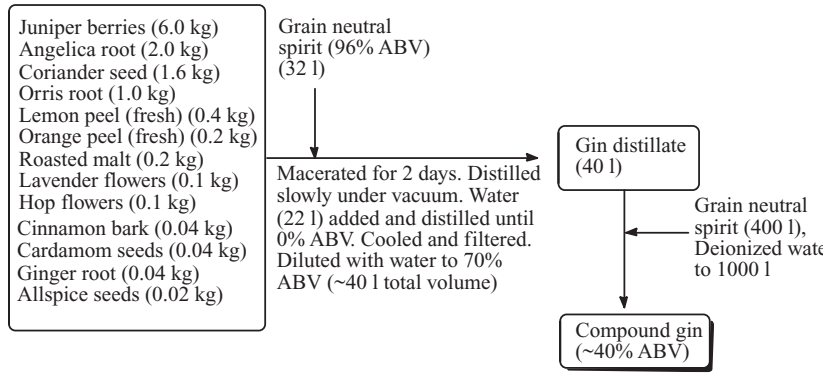

Figure 3.4.4 *Example recipe for compound gin. Based on Zach (2007)*

lemon peel and angelica in grain neutral spirit to make a model gin alters the flavor profile by causing the formation of extraneous monoterpenes (including α-pinene, (*E*)-caryophyllene, α-phellandrene and β-myrcene) compared with the predistilled botanicals (Greer *et al.*, 2008). Distillation of the same maceration at 0 °C under reduced pressure (<0.1 mm Hg) gave a distillate with much lower (fivefold in some cases) levels of monoterpenoids than the conventional distillate. The gin made with vacuum still distillate was judged by a tasting panel to be more flowery and pleasant compared with conventionally produced gin, which had greater pungency and spiciness (Greer *et al.*, 2008). The stainless steel and glass pilot plant consisted of a 20 l still attached via a lyne arm to a glass collecting reservoir containing a stainless steel liquid nitrogen coldfinger and connected to a positive displacement pump at the bottom and a vacuum pump (with 10^{-6} mm Hg capability) at the side. This vacuum distillation system has been scaled up to commercial size to produce trial lots of 'super premium' gin that has a flavor profile similar to the botanicals from which it was made.

Apart from the two mentioned above, there are several recent literature reports on the analysis of distilled gin or gin essential oil mixtures (gin distillates) (Vichi e*t al.*, 2005; MacNamara *et al.*, 2007; El-Ghorab *et al.*, 2008; Vichi *et al.*, 2008). Analysis of essential oils were carried out using gas chromatography, either by direct injection using two dimensional GC with spectral deconvolution (MacNamara *et al.*, 2007) (Section 4.3.2) or by solvent extraction (Greer *et al.*, 2008) or solvent extraction/column chromatography (Section 4.2.2) followed by GC analysis (El-Ghorab *et al.*, 2008).

Dichloromethane extraction of a steam distillate of *Juniperus drupacaea* L. berries, followed by fractionation using column chromatography and analysis by GC/MS/FID, El-Ghorab *et al.* (2008) were able to identify a large number of less volatile, as well as volatile, constituents. Although *J. drupacaea* is a native juniper shrub of the eastern Mediterranean countries, it is a relative of *J. communis* of northern and central Europe, the berries of which are used to make gin. Of the less volatile compounds, 4-*epi*-abietal, β-farnesol, laurenene, (*Z*)-nerolidyl acetate and rimuene (all terpenoids) were present in the highest concentrations. Otherwise *exo*-fenchyl acetate, (*Z*)-β-ocimene, methyl butanoate, α-pinene and thymol methyl ether were the most abundant volatile compounds. The solvent extracts of *J. drupacaea* berries showed high antioxidant activity according to 1,2-diphenyl picrylhydrazyl (Section 4.4.3) and β-carotene assays and were also active against various microbes, such as *A. parasiticus*, *C. albicans* and *S. aureus*. Although the flavor profile of *J. drupacaea* berries is different to that of *J. communis* berries, many compounds are common to both and it is reasonable to suppose that gin inherits some the antioxidant and antimicrobial character of juniper extracts (see also Chapter 5.8 and Section 5.11.2).

The composition of botanicals that are used in the formulation of gin is very complex and hence it is not usually possible to achieve a complete separation of volatile compounds by standard capillary gas chromatography. Even after a lengthy sample preparation (Section 4.2.1), this may still be the case. Hence a minor constituent that makes an important contribution to gin flavor can be masked by coelution with a major component, so that there is some difficulty in identifying all the key flavor constituents. Two dimensional GC (automated sequential heart cutting) has allowed the identification of 101 components of a test sample of a mixture of 10 different proprietary botanical and citrus oils used in making gin (MacNamara *et al.*, 2007). The deconvoluted data from the 2D process can then be routinely used to identify components in the same matrix by conventional (1D) GC/MS.

In this way, low level components are readily identified in the presence of major components and it is possible to include such minor components in routine quality control, aging or shelf life studies and consumer sensory perception studies.

Recent GC/MS analyses of the volatile constituents of commercial gin samples have used solid phase micoextraction (SPME) (Section 4.2.4) in either headspace mode (HS-SPME) (Vichi *et al.*, 2005) or contact mode (Vichi *et al.*, 2008) as an extraction/focusing device. The HS-SPME method allowed the identification of a large number of sequiterpenes and some of their oxygenated derivatives as well as monoterpenoids in a number of different representative gin samples. The sesquiterpenoids are in general less volatile than

monoterpenoids, but nonetheless may make important contributions to gin flavor, either individually or collectively, as background flavor. Gamma- and δ-cadinene, caryophyllene, β-elemene, γ-elemene, α-humulene and germacrene D were the most abundant sequiterpenes in the gin samples, whereas caryophyllene oxide, toreyol and α-cadinol were the most abundant oxygenated sequiterpenes, although the total concentration of former was much greater than the latter.

Gin with geographical denomination (Plymouth gin, UK and Mahon gin, Spain) had higher levels of the main sesquiterpenes than London dry gin. Discriminant analysis of the GC/MS data was able to differentiate between the geographically denominated gin samples and the London dry gin samples on the basis of both sesquiterpene and oxygenated sesquiterpene contents, as well as monoterpenoid and oxygenated monoterpenoid concentrations, but clear differentiation between all the London dry gin samples was not possible (Vichi *et al.*, 2005; 2008). However, on the basis of oxygenated monoterpenoids, it was possible to partially differentiate between London dry gin samples. The main monoterpenes in the gin samples were α-pinene, β-myrcene and limonene, followed by γ-terpinene, *p*-cymene, sabinene and β-pinene. Mahon gin had higher levels of α-pinene, β-myrcene, *p*-cymene, sabinene and β-pinene, suggesting a higher proportion of juniper berries were used during aromatization, whereas Plymouth gin had the highest concentrations of limonene and γ-terpinene, suggesting greater use of citrus peel in the manufacture of this gin. The oxygenated monoterpenoid linalool is a minor component of juniper berry, but a major one of coriander seed. Mahon gin had easily the lowest mean level of linalool (1.93 mg/l), suggesting coriander may be absent from or was a very minor component of the aromatization essence used to make this gin. At the other extreme, two samples of London dry gin had very high concentrations of linalool (23.18 and 36.99 mg/l), suggesting coriander is a major flavoring ingredient for these two. Interestingly, the Mahon gin had high (but not the highest) total contents of monoterpenes and oxygenated monoterpenes, and the highest total contents of sesquiterpenoids and particularly oxygenated sesquiterpenes, with a very high caryophellene oxide mean concentration and also high mean levels of torreyol, α-cadinol, spathulenol and *t*-muurulol. Plymouth gin had the highest mean totals of monoterpenoids (37.14 mg/l), with over half of that coming from limonene and γ-terpinene. One of the samples of London dry gin had the highest mean total of oxygenated monoterpenoids, with a high level of geranyl acetate; Mahon gin had the next highest mean total of oxygenated monoterpenoids, with particularly high mean level of α-terpineol, again indicative of a high juniper content. Thus by analyzing the terpene composition it was only possible to partially distinguish samples from different brands of London dry gin, but it was possible to fully distinguish Plymouth from Mahon gin and the different brands of London dry gin. It was also possible to obtain a qualitative estimate of the proportion of certain botanical ingredients used to aromatize the spirit, particularly, juniper berries, coriander seeds and citrus peel.

There is only one recent report on the analysis of diterpenoids in commercial gin (Vichi *et al.*, 2008), although the diterpenoid content of the bark, berries and leaves of *Juniper communis* have been investigated and reported in several studies (see references in Vichi *et al.*, 2008). The diterpenoids of juniper are of interest because of their known beneficial physiological properties (Barjaktarović *et al.*, 2005); after all gin was first formulated as a medicine for kidney problems. Using contact SPME followed by GC/MS for the analysis of the less volatile diterpenoids in eight commercial brands of gin, Vichi *et al.* (2008) showed, by comparison with a hexane extract of dried juniper berries, that the levels of diterpenoids were dependent upon the brand, which differed according to the proportion of juniper berries used in the aromatization mixture. Statistical analysis of the gin diterpenoid contents allowed differentiation of two geographically denominated gins (Mahon and Plymouth gin) and six London dry gins. The diterpenoids were all oxygenated – the most abundant four are shown in Figure 3.4.5. Interestingly, Mahon gin had easily the highest total diterpenoid content (190 μg/l compared with 10 μg/l for one of the London dry gins). Since all the samples of gin, by definition, had juniper berries as a component of their aromatizing essence (or gin distillate), it is unlikely that this big difference arises solely from the differences in proportion of juniper berries to the other aromatic ingredients (such as coriander and citrus peel). It seems more probable that production methods (e.g. the type

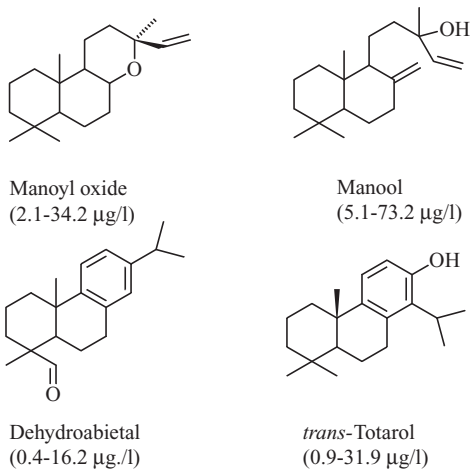

Figure 3.4.5 *Diterpenoids found in commercial gin. Vichi et al. (2008)*

of essence used, the mode of distillation and the degree of rectification) play a big role in determining the diterpenoid content of gin. In any case, this method was able to characterize different types and brands of commercial gin and hence could be used as a criterion of authenticity or quality.

A sensory vocabulary (Section 4.7.4) used to describe gin and distillates of individual botanical gin distillates has been developed along the lines of vocabularies used to describe Scotch whiskies (Phelan *et al.*, 2004). The sensory characteristics of gin could be described by 16 attributes: aniseed, buttery, citrus, floral, fruity, herbal, juniper, oily, pungent, soapy, solventy, sour, spicy, stale, sulfury and sweet. Variation in gin flavor could be quantified using this vocabulary and the contribution of individual botanicals to the overall flavor could be assessed. The major differences among commercial gins could be described in terms of aroma intensity and complexity, probably relating to both the total amount and number of botanicals used and their relative proportions. Juniper berry distillate was characterized by the terms juniper, pungent, but with citrus and floral components. On the other hand coriander seed distillate, usually the next major gin botanical, was described as pungent, citrus, floral and herbal, but with soapy, fruity and sweet components.

3.4.3 Akvavit (Aquavit) and Vodka

These are spirits that originate in northern Europe (especially Scandinavia and the Baltic countries) and Russia. They are treated here together because although their methods of production are quite variable and differ in a number of respects, their overall roles in the indigenous drinking culture of these areas are similar. In this respect, vodka differs from akvavit in being universally popular, as well as enjoying popularity in its regions of origin. Indeed, vodka is the most widely consumed distilled spirit worldwide. In the USA its share of total distilled spirits consumption is more than 25% (Corrigan, 2004) and in the UK, white spirits account for ~40% of spirits consumption, the major share being taken by vodka (Atkinson, 2004). Outside its countries of origin, vodka is the colorless, almost flavorless spirit that is widely used in cocktails (especially of the Bloody Mary, Martini and Screwdriver type) and as a base for the more recently popular 'ready to drink' (RTD) beverages, often known as 'alcopops.' Flavored vodka, for decades popular in northern Europe and Russia, is gradually becoming more popular worldwide.

Akvavit and vodka are distilled from the fermented mash of cereal grains, principally barley and wheat, but sometimes including rye and in a few cases other cereals, such as buckwheat, maize or millet. In principle, they can also be produced from any fermentable sugar source, such as molasses or hydrolyzed potato starch. The common feature of both spirits is their high rectification, so that almost all the flavor of the base materials has disappeared. This is normally accomplished using continuous column stills, but can also be achieved by multiple distillations in pot stills. Additionally, as well as high rectification, a series of filtrations (often triple filtration) through charcoal beds is used in the production of most vodka, thus ensuring that total extractives (components other than water and ethanol) are below 3 g/l (Zach, 2007).

Flavor compounds (congeners) in vodka are of course present at very low levels, often well below 1 mg/l (Simpkins, 1985) although some can be detected by tasters and the majority can be detected (and many quantified) by sorptive preconcentration/focusing techniques, such as solid phase microextraction (SPME) (Section 4.2.4), followed by GC/MS analysis (Ng *et al.*, 1996). The major congeners detected in vodka are ethyl esters, but terpenoids, 5-hydroxymethyl-2- furaldehyde (5-HMF) and triethyl citrate (TEC) have been found in some vodkas and as well as contaminants such as 2,6-di-*tert*-butyl-4-methylphenol (BHT) and bis(2-ethylhexyl)adipate (DEHP) (Ng *et al.*, 1996). Despite the generally low levels of congeners, Ng *et al.* (1996) were able to rationalize differences amongst 18 brands of vodka from different countries according to the base materials and method of production, on the basis of different ethyl ester profiles and the presence of markers, such as 5-HMF and TEC. For example, a Japanese vodka derived from barley and maize was the only one with ethyl decanoate as the most abundant ethyl ester and a German vodka from potatoes was unique regarding the presence of $C_{16:1}$ (ethyl palmitolate) and a high ratio ($\sim$2) C_{18}: $C_{18:1}$ (ethyl stearate to ethyl oleate). On the other hand, the American vodka GC profiles had relative intensities of $C_{18:1}$ and C_{18} to C_{16} ethyl esters of comparable values ($\sim$0.5). Also, the American vodkas were distinguishable by the presence of both 5-HMF and TEC. These were considered to exist as a result of addition of sugar syrup and citric acid, respectively, such additives being allowed by US Federal regulations. The presence of sugar and citric acid was confirmed by HPLC, where sugar concentration ranged from 40 to 2200 mg/l and citric acid was present in the range $<$0.1–357 mg/l. They are added after distillation/rectification/charcoal filtration and prior to bottling.

Akvavit (Akevitt in Norway), unlike most vodka is flavored, the usual dominant flavoring being from caraway seed, but many other botanicals (but not usually including juniper berries) can be used to give some complexity of aroma and flavor. The botanicals are macerated in alcohol/water mixture for several days, after which the mixture is distilled, filtered and diluted to the required alcoholic strength (Zach, 2007) (Figure 3.4.6(a)). Most examples of akvavit are pale gold, reflecting aging in old oak casks or the addition of a little caramel, which is allowed (EEC, 1989). Darker examples most likely indicate considerable aging in new or young oak casks (especially if Norwegian), but could instead be the result of the use of a greater quantity of caramel. Most Akvavit has a pronounced flavor of caraway (not unlike aniseed), but some, especially aged Norwegian versions have strong oak character superimposed on this and others, such as Aalborg (Denmark) have rather more subtle flavors due to the use of a special ingredient, such as amber.

Aquavit is sometimes marketed in clear glass bottles, in which case they should be stored out of sunlight or fluorescent light since, over a period of months, light catalyzes many reactions that lead to undesirable sensory changes (Refsgaard *et al.*, 1995). For example, photo-oxidation of limonene gives hydroperoxides (turpentine-like notes), carvone gives carvonecamphor (camphor notes), and possibly1,5-(*Z*)-octadien-3-one (metallic, geranium notes) is produced, although this was not confirmed. It is, however, responsible for metallic off flavor in caramel.

Denmark and Sweden make the greatest quantities of Akvavit, but Norway produces some of the most distinctive examples; in particular, Norwegian Akevitt is aged in oak casks for at least a year (up to 12 years), where it acquires some color and extra complexity of flavor if the casks are new or young. Well known producers include Aalborg, Den Bornhomske Spritfabrik (Denmark), Symposion International AB, Vin and

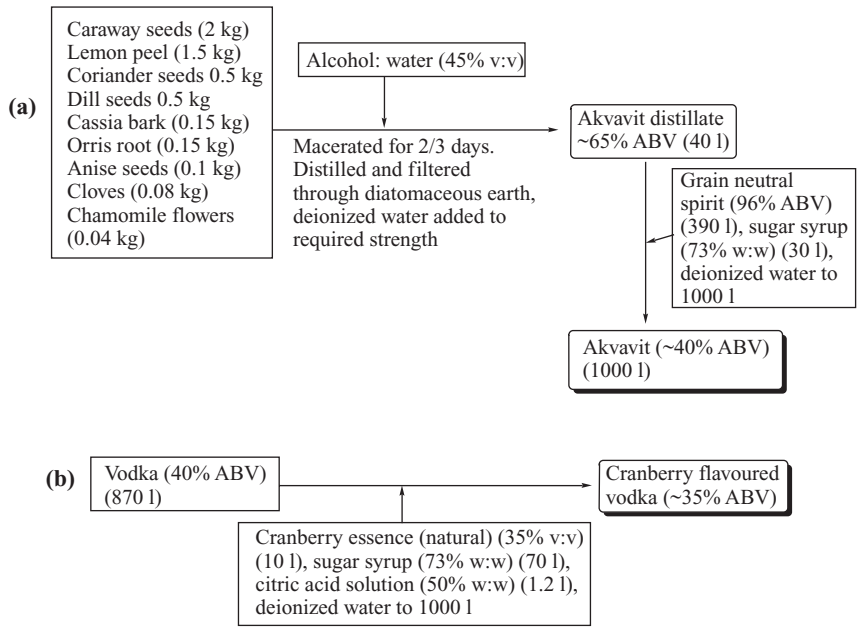

Figure 3.4.6 *Formulations for (a) Akvavit and (b) flavoured vodka. Based on Zach (2007)*

Spirit AB (Sweden) and Arcus (Norway). The Norwegian firm of Arcus make a brand of Akvavit known as Linie, which refers to the tradition of aging the spirit by shipping it around the world for 19 weeks or so in wooden casks, rather like the original Madeira process of estufagem (Section 2.10.6). As for Madeira, the rolling action of the ship during the voyage, coupled with the daily variation in temperature has a beneficial effect upon the maturation, but unlike Madeira, attempts on land to simulate the conditions of the sea voyage failed to give the same maturation benefits. Maybe this is because of the differences in alcoholic strength (~20% ABV for Madeira and ~60% ABV for Akevitt) and differences in humidity (Madeira is much more humid than Norway and hence has conditions closer to those of a sea journey). Traditionally, the ships should cross the equator twice before the casks are brought back to Norway to be sold.

Akvavit is also produced in Finland (akvaviitti), Iceland (ákavíti), Poland (okowita), the Baltic countries of Estonia, Latvia and Lithuania, as well as Northern Germany, (where it is called Aquavit), particularly Schleswig Holstein, which still has a sizeable Danish minority. German Aquavit producers include August Ernst (Sankt Petrus), Alte Mackenstedter (Lloyd Finest), Bartels-Langness (Kieler Sprotte Aquavit), Berentzen Brennereien (Bommerlunder Aquavit), Wilhelm Büchter (Nordkap), Dwersteg (Friedensreiter), A.H. Johannsen (Flensburg) (Aquavit No. 6), Kreuzritter (Dreiling), Schilking (Wikinger Feuer) and V&S Deutschland (Malteserkreuz).

3.4.4 Asian Grain Spirits

Grain spirits are produced all over Asia, but particularly in the far eastern countries of China, Japan, Korea, Thailand and Vietnam. In total, they are probably the most popular distilled beverages in the world, although they are derived from wines or mashes (porridges) made from a very wide range of saccharified cereals,

Table 3.4.1 *Distilled Spirits of China, Korea and Japan.*

Country	Beverage
Korea	Soju – traditionally distilled from rice wine, but commercially most commonly made in combination with other ingredients such as wheat, barley, or sweet potatoes to give a grain neutral spirit, which is then diluted to 20–30% ABV and sweetened. Traditional spirits are stronger, more flavoursome and unsweetened.
Japan	Shōchū – a distilled alcoholic beverage that can be made from rice wine, although it is more commonly made from barley, sweet potato, or sugar cane. Often of ~30% ABV, but traditional versions are stronger. Awamori – a distilled rice spirit from Okinawa.
China	Many liquors distilled from fermented mashes of sorghum or a mixture of grains, often maize, rice, sorghum and wheat (e.g. jiannanchun and yanghe daqu). Chinese liquors often have stronger flavours than their Japanese and Korean equivalents and are sold at 40–55% ABV. Rice baijiu – a potent spirit distilled from mijiu

including barley, buckwheat, maize, millet, rice, sorghum and wheat. Potatoes and sweet potatoes are also used as a carbohydrate source to produce some of the cheaper mass produced spirits. It is possible that the world's first distilled beverages were produced in China and it is possible that the Chinese passed on their knowledge of alcoholic distillation to other Asian nations at all points of the compass via normal trade. However, it is also possible that knowledge of distillation was passed from the Persians (who themselves learnt it from the Arabs further west) via Mongol invasions and wars, as well as by normal trade routes. Even today, traditional methods of producing distilled drinks in Asia tend to be broadly similar, from country to country, but with differences in fermentation and distillation techniques. A summary of the major distilled beverages of China Japan and Korea is given in Table 3.4.1.

Chinese Liquors

Today, Chinese distilled beverages are often known as liquors. Their annual consumption in China exceeds 4 billion (4×10^9) liters and they are produced from sorghum or more likely from whatever is available, but typically a mixture of maize, rice, glutinous rice, sorghum and wheat, with rice hulls being used as a fermentation aid (Fan and Qian, 2006a). Chinese liquors are often classified according to their aroma (Fan and Qian, 2006b):

- Light (milder fruity notes)
- Strong (more pronounced fruity, estery notes)
- Soy sauce (piquant, roasted notes)
- Sweet, honey (honey notes)
- Miscellaneous.

The basic process for the production of Chinese liquor is outlined in Figure 3.4.7, although in practice there are many variations. The fermentation starter is made from fermented/malted wheat or a mixture of barley, pea and wheat, and is available in solid (powder) form (daqu) or semi-liquid form (xiaodaqu). The starters contain a range of bacteria, fungi and yeasts, as well as amylolytic enzymes; they are similar to koji and nuruk used to make Japanese and Korean rice wines (Section 2.7.1). Daqu is added to cooked grains for fermentation in ratios of around 1:4 by weight. One of the most popular liquors, known as yanghe daqu is of the strong aroma type and is produced from barley, pea and wheat daqu, whilst two other popular liquors,

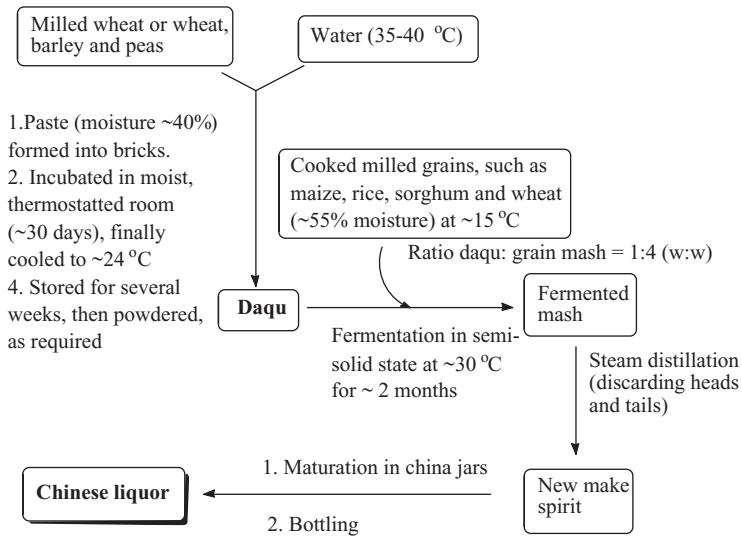

Figure 3.4.7 *Basic outline of Chinese liquor manufacture*

jiannanchun and wuliangye (of the soy sauce, roasted type), are made using wheat only daqu. A list of well known Chinese liquors is given in Table 3.4.2.

Not only does daqu vary according to its ingredient composition, but also according to the incubation temperature: < 45 °C (low temperature daqu), 45–60 °C (moderate temperature daqu) or > 60 °C (high temperature daqu). The spectrum of microorganisms likely depends on the incubation temperature, giving different aroma profiles in the different fermented mashes and hence in the corresponding distilled beverages. Additionally, higher temperatures are likely to produce greater amounts of Maillard products, which include furans with biscuit-like aroma and pyrazines with roasted aromas (Fan and Qian, 2007).

Yanghe daqu liquor is made in the following manner (Fan and Qian, 2006b). Firstly, to prepare the daqu, wheat, barley and peas (ratio 5:4:1 by weight, often to give a total weight of at least 1000 kg) are milled, mixed well and water (35–40 °C) is added until the moisture content is about 40% by weight. The resulting paste is pressed, formed into bricks (about 30 cm × 18.5 cm × 6 cm) and then kept in a fermentation room under controlled temperature and humidity. The temperature of the daqu climbs from ~25 °C to around 58 °C after eight days or so as fermentation gathers momentum, after which a careful ventilation and/or spraying of

Table 3.4.2 *Some well-known Chinese liquors*

Spirit	Typical ethanol content (%ABV)	Spirit	Typical ethanol content (%ABV)
Dongjiu	54	Moutai	53
Fenjiu	45	Shite	52
Gujinggong	55	Wuliangye	52
Jiannanchuan	52	Yanghe daqu	70
Jinshiyun	42	Yanghelansejindian	46
Langjiu	53	Xifengjiu	45

Source: Data from Fan *et al*. (2007); Fan and Qian (2006b).

cool water is used to keep the daqu temperature around 55 °C. It remains at this temperature for about 10 days – the daqu for other Chinese liquors can be held at lower or higher temperatures than this, according to the extent of ventilation/spraying. A further 12 days are required to cool the daqu gradually down to about 24 °C, after which the moisture content of the bricks should be about 17% (w:w). The bricks are finally transferred to another (dry) room where they are stored for three months or so before use.

Grains (maize, rice, sorghum, sticky rice and wheat total weight, say 800 kg) are milled, mixed with rice hulls (∼140 kg) and pressure cooked so that their moisture content is ∼55% by weight. After cooling to 15 °C, the mash is mixed with daqu powder (200 kg) and the fermentation of the semi-solid mixture occurs anaerobically at 28–32 °C for two months. The inner surface of the fermenting vessel is sometimes lined with a slurry of clay, bean cake powder and spent grains, containing populations of bacteria, such as *Clostridium* spp.

At the end of fermentation, the thick liquor is distilled a single time with steam, the head and tail fractions being discarded and the middle fraction being collected as the new make spirit. Chinese liquors are usually aged in sealed 1000 l porcelain jars for a minimum of three years, after which they are bottled in a variety of containers, including finely decorated porcelain bottles. Many distilleries make more then one brand of liquor, and, as with many other spirits, blending is often used to give consistently acceptable products.

The aroma and flavor compounds of Chinese liquors have been investigated by a variety of techniques, including HS-SPME or liquid–liquid extraction/GC-O AEDA (Section 4.7.3) (Fan and Qian, 2005; Fan and Qian 2006a), normal phase chromatographic fractionation/GC (Fan and Qian, 2006b) and liquid–liquid extraction and HS-SPME/GC (Fan and Qian, 2007). Many Chinese liquors possess distinct fruity/estery aromas, so it has been suggested, on the basis of GC-O analysis of column chromatographic fractions, that aliphatic esters, particularly ethyl hexanoate (fruity, floral), ethyl butanoate (pineapple) and possibly ethyl octanoate (fruity), 3-methylbutyl hexanoate (apple) and ethyl pentanoate (apple), make important contributions to the aroma of yanghe daqu liquor (Fan and Qian, 2006b). Acetals (fruity notes), some acids (cheesy, sweaty) some alcohols (fruity, pungent, solvent) and phenols (mostly spicy/smoky notes) were considered to make significant contributions. These findings were in broad agreement with earlier results using HS-SPME/GC-O AEDA on the same liquor (Fan and Qian, 2005), where aged samples had similar aroma profiles to young samples, but with aroma compounds in the former having higher flavor dilution (FD – see Section 4.7.3) factors.

Jiannanchun and wuliangye liquors, belonging to the strong aroma family of Chinese liquors (like yanghe daqu), also have strong fruity aromas and similar compounds (but in different ratios) were found in fractionated liquid–liquid extractions, analysed by GC-O AEDA (Fan and Qian, 2006a). However, these two liquors, especially wuliangye, have more roasted, soy sauce type aroma character than yanghe daqu, which is attributed, in part, to the presence of alkylated pyrazines with nutty, baked and roasted notes, especially in wuliangye liquor. These differences arise from different methods of manufacture, particularly with regard to the preparation of the daqu: jiannanchun and wuliangye liquors are made using wheat daqu, which is incubated at a higher temperature than that of yanghe daqu liquor.

Liquors of the roasted, soy sauce aroma family, jinshiyun, langjiu, moutai and moutaiyingbin were found to have the highest total pyrazine contents, corresponding to the highest temperatures for the incubation of daqu (60–65 °C for 10–12 days) (Fan and Qian, 2007). Jiannanchun and wuliangye had intermediate levels of total pyrazines, corresponding to daqu incubation at 58–60 °C for 10–12 days, whereas fenjiu had the lowest level, corresponding to incubation of daqu at the lowest temperatures (40–45 °C for 10 days). The major pyrazine components were the 2-ethyl-5-methyl-, 2,3,5,6-tetramethyl-, 2,6-dimethyl- and 2-acetyl-6-methyl-derivatives (in moutaiyingbin and moutai), but a total of 27 pyrazines were found amongst 12 different Chinese liquors (Fan and Qian 2007).

The alkylpyrazines in Chinese liquors are thought to arise from nonenzymic Maillard reactions (Section 2.6.2) between acetoin, 1-hydroxypropanone and similar compounds with ammonia, (all known to

be fermentation metabolites in Chinese liquors) although L-threonine was found to be the precursor of 2,5-dimethylpyrazine for *Bacillus subtilis* in the solid state fermentation of soybean (Larroche *et al.*, 1999). Similarly, acetylpyrazines are believed to be formed by the same route as alkylpyrazines, but with the initial pyrazine reacting further with C-methyl triose reductone (another Maillard intermediate) to produce a compound that dehydrates by the loss of two water molecules.

Pyrazines are important aroma/flavor components of many baked or fermented foodstuffs and they have also been found in several alcoholic beverages, including Chinese liquors, tequila, whisky and wine. In red wines, 3-alkyl-2-methoxypyrazines are of special importance, but have not yet been found in Chinese liquors.

Japanese Shochu and Related Spirits

Shochu (sometimes written shōchū) is the generic name for a large group of distilled drinks that are indigenous to and highly popular in Japan, although some Japanese people refer to these beverages, as to all domestic alcoholic drinks, as sake. Shochu is made from a wide range of ingredients by a variety of fermentation and distillation techniques and hence varies considerably in organoleptic character. The different kinds of shochu are broadly outlined in Figure 3.4.8. As in Korea, there are two basic types of spirit that depend mainly on the nature of the ingredients, the fermentation method and the mode of distillation. These factors also decide whether maturation is necessary before bottling and sale.

Traditional sochu (otsu-rui or honkaku), known as Type B Shochu, is generally produced from one ingredient, it is fermented with yeast and koji (Section 2.7.1), which is usually made from the same ingredient, distilled just once in a pot still (with appropriate head and tail management) and matured for about three years. The wine for distilling is usually of at least 15% ABV, because of the high levels of sugars in the mash. Hence the distillate is often in excess of 45% ABV, although it is often reduced to 25% or 30% ABV by the addition of deionized water before filtration and bottling. The original ingredient was probably rice (see awamori, below), but nowadays barley, buckwheat (soba in Japanese), rice, sweet potatoes or other sources of starch, such as chestnuts or sugar cane, are used. The most delicately flavored shochu is probably that made from rice, whereas the most strongly flavored is probably sweet potato or sugar cane shochu. Traditional shochu is usually enjoyed straight, on ice, or with a dash of water. In winter, it can be enjoyed with hot water (‘oyu-wari’).

There are various versions of koji whose use depends on the base material and which differ in the active species of *Aspergillus* present. For example, sake-koji (containing *Aspergillus oryzae*) (Section 2.7.1) is
